Dedication

As with the first four editions, I dedicate this book to Marietta Voge, a truly rare individual who was widely recognized as one of the world's leading parasitologists. During her years as a diagnostic and research parasitologist at the University of California, Los Angeles, she touched the lives of many students and staff in a very special way. She was always more than willing to share her expertise with all who asked and volunteered this help over the years whenever contacted. She was always willing to donate a considerable amount of her personal time as a volunteer for various medical projects throughout the world.

She was a very special individual to work with, always interested in the person as well as the problem at hand. Her areas of teaching extended far beyond science. Whatever subject she was interested in received her total enthusiasm and dedication, and she had an exceptional ability to deal with detailed work. Her sense of fairness and professional integrity were remarkable; these ideals were shared with all who came in contact with her.

Her contributions to the field of diagnostic parasitology were numerous and included many classes, seminars, papers, and textbooks. The importance of working with Dr. Voge is hard to put into words. She was unique in her ability to allow a student to grow, both scientifically and personally. She could guide without constraints, teach without formal lectures, counsel without being judgmental, challenge without being unrealistic, tease without being cruel, and always be supportive regardless of the situation. She expected much from her students and employees and yet always gave considerably more than she received.

Scientific information gained from our association with her was invaluable; however, her impact on our lives was considerably more than scientific. She was always available for consultations and just to talk. She left all of us with a sense of having personally matured as a result of knowing and working with her over the years. She is missed by all of us, and yet her contributions in terms of teaching, consultations, volunteer work, professionalism, and friendship will remain with us forever.

I also dedicate this book to John Lawrence. He was an extraordinary individual, and without his original encouragement and assistance, the first edition of the book would never have been written.

PART I

Clinically Important Human Parasites I

1 Philosophy and Approach to Diagnostic Parasitology 3

2 Intestinal Protozoa: Amebae 6

- Entamoeba histolytica* 6
- Entamoeba dispar* 19
- Entamoeba moshkovskii* 21
- Entamoeba hartmanni* 21
- Entamoeba coli* 22
- Entamoeba polecki* 23
- Entamoeba gingivalis* 24
- Endolimax nana* 25
- Iodamoeba bütschlii* 27
- Blastocystis hominis* 27

3 Intestinal Protozoa: Flagellates and Ciliates 33

- Giardia lamblia* 33
- Dientamoeba fragilis* 47
- Pentatrichomonas hominis* (*Trichomonas hominis*) 49
- Trichomonas tenax* 50
- Chilomastix mesnili* 50
- Enteromonas hominis* 51
- Retortamonas intestinalis* 51
- Balantidium coli* 51

4 Intestinal Protozoa (Coccidia and Microsporidia) and Algae 57

- Coccidia 57
 - Cryptosporidium* spp. 57

- Cyclospora cayetanensis* 73
- Isospora* (*Cystoisospora*) *belli* 80
- Sarcocystis* spp. 83
- Microsporidia 87
- Algae (*Prototheca*) 98

5 Free-Living Amebae 102

- Naegleria fowleri* 104
- Acanthamoeba* spp. 109
- Balamuthia mandrillaris* 118
- Sappinia diploidea* 121

6 Protozoa from Other Body Sites 123

- Trichomonas vaginalis* 123
- Toxoplasma gondii* 130

7 Malaria and Babesiosis 142

- Malaria 142
- Babesiosis 180

8 Leishmaniasis 190

- Old World leishmaniasis: cutaneous leishmaniasis 191
- Old World leishmaniasis: visceral leishmaniasis 198
- New World leishmaniasis: cutaneous leishmaniasis 205
- New World leishmaniasis: visceral leishmaniasis 212

9 Trypanosomiasis 218

- African trypanosomiasis 218
 - Trypanosoma brucei gambiense* 218
 - Trypanosoma brucei rhodesiense* 228
- American trypanosomiasis 232
 - Trypanosoma cruzi* 232
 - Trypanosoma rangeli* 243

10 Intestinal Nematodes 249

- Ascaris lumbricoides* 250
Enterobius vermicularis 258
Trichuris trichiura 261
Capillaria philippinensis 264
Hookworms (*Ancylostoma duodenale* and *Necator americanus*) 266
Trichostrongylus spp. 270
Strongyloides spp. 271

11 Tissue Nematodes 283

- Trichinella* spp. 283
Baylisascaris procyonis 294
Lagochilascaris minor 298
Toxocara canis and *T. cati* (visceral larva migrans and ocular larva migrans) 298
Ancylostoma braziliense and *A. caninum* (cutaneous larva migrans) 302
Human eosinophilic enteritis 303
Dracunculus medinensis 304
Angiostrongylus (Parastrongylus) cantonensis (cerebral angiostrongyliasis) 307
Angiostrongylus (Parastrongylus) costaricensis (abdominal angiostrongyliasis) 309
Gnathostoma spinigerum 310
Gnathostoma doloresi, *G. nipponicum*, *G. hispidum*, and *G. binucleatum* 312
Anisakis simplex, *A. physeteris*, *Pseudoterranova decipiens*, *Contracaecum osculatum*, *Hysterothylacium aduncum*, and *Porrocaecum reticulatum* (larval nematodes acquired from saltwater fish) 312
Capillaria hepatica 315
Thelazia spp. 315

12 Filarial Nematodes 319

- Wuchereria bancrofti* 321
Brugia malayi 332
Brugia timori 333
Zoonotic *Brugia* infections (American brugian filariasis) 334
Tropical pulmonary eosinophilia 335
Loa loa 335
Mansonella ozzardi 338
Mansonella perstans 339
Mansonella streptocerca 340
Onchocerca volvulus 341
Dirofilaria *Dirofilaria* and *Dirofilaria*
Nochtiella spp. 348

13 Intestinal Cestodes 357

- Diphyllobothrium latum* 357
Taenia solium 362
Taenia saginata 371
Taenia saginata asiatica (Asian *Taenia* or *Taenia asiatica*) 373
Hymenolepis nana 374
Hymenolepis diminuta 376
Dipylidium caninum 377

14 Tissue Cestodes: Larval Forms 381

- Echinococcus granulosus* (cystic disease, hydatid disease) 381
Echinococcus multilocularis (alveolar disease, hydatid disease) 393
Echinococcus oligarthrus and *Echinococcus vogeli* (polycystic hydatid disease) 399
Taenia (Multiceps) spp. (*Taenia multiceps*, *Taenia serialis*) (coenurosis) 402
Spirometra mansonioides and *Diphyllobothrium* spp. (sparganosis) 402
NOTE: *Taenia solium* (cysticercosis) is discussed in chapter 13.

15 Intestinal Trematodes 411

- Fasciolopsis buski* 411
Echinostoma ilocanum 416
Heterophyes heterophyes 417
Metagonimus yokogawai 419
Gastrodiscoides hominis 420

16 Liver and Lung Trematodes 423

- Liver flukes 423
Clonorchis sinensis 423
Opisthorchis viverrini 429
Opisthorchis felinus 431
Fasciola hepatica 432
Fasciola gigantica 435
Less common liver flukes 436
Dicrocoelium dendriticum, *Dicrocoelium hospes*, and *Eurytrema pancreaticum* 436
Lung flukes 438
Paragonimus spp. 438

17 Blood Trematodes: Schistosomes 445

- Schistosoma mansoni* 446
Schistosoma japonicum 458
Schistosoma mekongi 463
Schistosoma haematobium 466
Schistosoma intercalatum 472

18 Unusual Parasitic Infections 478

- Aquatic Protist 478
 - Rhinosporidium seeberi* 478
- Protozoa 482
 - Myxozoan parasites 482
- Nematodes 483
 - Oesophagostomum* spp. 483
 - Eustrongylides* spp. 485
 - Mermis nigrescens* 486
 - Micronema deletrix* 487
 - Diocotophyia renale* 487
 - Ternidens deminutus* 488
 - Mammomonogamus laryngeus* (*Syngamus laryngeus*) 488
 - Ascaris suum* 489
 - Gongylonema pulchrum* 489
 - Haycocknema perplexum* 490
- Cestodes 490
 - Diplogonoporus* spp. 490
 - Bertiella studeri* 491
 - Inermicapsifer madagascariensis* 491
 - Raillietina celebensis* 491
 - Mesocestoides* spp. 492
 - Taenia crassiceps* 492
- Trematodes 493
 - Alaria americana* 493
 - Plagiorchis* spp. 493
 - Neodiplostomum seoulense* 494
 - Spelotrema brevicaca* 494
 - Brachylaima* sp. 494
 - Troglotrema salmincola* 494
 - Stellantchasmus falcatus* 494
 - Phaneropsolus bonnei* and *Prosthodendrium molenkempi* 495
 - Phaneropsolus spinicirrus* 495
 - Haplorchis taichui* 496
 - Gymnophalloides seoi* 496
 - Metorchis conjunctus* (North American liver fluke) 497
 - Schistosoma mattheei* 498
 - Philophthalmus lacrimosus* 498
 - Achillurbainia* spp. 499
- Pentastomids 499
 - Armillifer* spp., *Linguatula serrata*, and *Sebekia* spp. 499
- Acanthocephalans 500
 - Macracanthorhynchus hirudinaceus* and *Moniliformis moniliformis* 500

19 Parasitic Infections in the Compromised Host 506

- Entamoeba histolytica* 508
- Free-living amebae 518

- Giardia lamblia* 522
- Toxoplasma gondii* 523
- Cryptosporidium* spp. 524
- Cyclospora cayetanensis* 528
- Isospora* (*Cystoisospora*) *belli* 530
- Sarcocystis* spp. 531
- Microsporidia 532
- Leishmania* spp. 537
- Strongyloides stercoralis* 540
- Crusted (Norwegian) scabies 540

20 Nosocomial and Laboratory-Acquired Infections 549

- Nosocomial infections 549
- Nosocomial gastrointestinal infections 550
 - Cryptosporidium* spp. 550
 - Giardia lamblia* 553
 - Entamoeba histolytica* 554
 - Microsporidia 555
 - Isospora* (*Cystoisospora*) *belli* 555
 - Hymenolepis nana* 555
 - Taenia solium* 555
- Nosocomial blood and tissue infections 556
 - Plasmodium* spp. 556
 - Babesia* spp. 556
 - Trypanosoma brucei gambiense* and *T. brucei rhodesiense* 556
 - Trypanosoma cruzi* 556
 - Leishmania donovani* 557
 - Toxoplasma gondii* 557
- Nosocomial infections with ectoparasites 557
 - Pediculus* spp. and *Phthirus pubis* 557
 - Sarcoptes scabiei* 557
 - Myiasis 557
- Nosocomial infections in the pediatric patient 558
 - Cryptosporidium* spp. 558
 - Giardia lamblia* 558
 - Pediculus humanus capitis* 558
 - Sarcoptes scabiei* 558
- Nosocomial infections in the compromised patient 558
- Laboratory infections 560
 - Intestinal protozoa 560
 - Free-living amebae 560
 - Plasmodium* spp. 560
 - Trypanosoma brucei gambiense* and *T. brucei rhodesiense* 560
 - Trypanosoma cruzi* 562
 - Leishmania* spp. 562
 - Toxoplasma gondii* 562
 - Specimen handling 563
- Summary 563

21 Immunology of Parasitic Infections 567

- Amebiasis 570
- Giardiasis 575
- Toxoplasmosis 577
- African trypanosomiasis 579
- American trypanosomiasis 580
- Malaria 582
- Summary 586

22 Antibody and Antigen Detection in Parasitic Infections 592

- Protozoal infections 594
 - Amebiasis 594
 - Babesiosis 597
 - Chagas' disease 597
 - Cryptosporidiosis 598
 - Cyclosporiasis 598
 - Giardiasis 598
 - Leishmaniasis 598
 - Malaria 600
 - Toxoplasmosis 601
 - Trichomoniasis 603
- Helminth infections 604
 - Cysticercosis 604
 - Hydatid disease 605
 - Fascioliasis 605
 - Filariasis 606
 - Paragonimiasis 607
 - Schistosomiasis 608
 - Strongyloidiasis 609
 - Toxocariasis 610
 - Trichinellosis 610
- Intradermal tests 611
 - Casoni test 611
 - Montenegro test 611

23 Histologic Identification of Parasites 616

24 Medically Important Arthropods 670

- Arthropods and their relationship to disease 670
 - Biological vectors of microorganisms 670
 - Bites and envenomation 671
 - Tissue invasion 676
 - Entomophobia and delusory parasitosis 676
- Class Insecta (insects) 678
 - Order Diptera (flies, mosquitoes, and midges) 679
 - Myiasis 683
 - Order Hemiptera (true bugs) 690
 - Order Coleoptera (beetles) 692
 - Order Siphonaptera (fleas) (*Ctenocephalides* spp., *Xenopsylla cheopis*, *Pulex irritans* [human flea], *Tunga penetrans*, *Nosopsyllus fasciatus*, *Echidnophaga gallinacea*, and "sand fleas") 693

- Order Anoplura (sucking lice) 694
- Order Mallophaga (biting and chewing lice) 696
- Order Hymenoptera (bees, wasps, and ants) 696
- Order Blattaria (cockroaches) 698
- Class Arachnida (ticks, mites, spiders, and scorpions) 699
 - Subclass Acari (ticks, mites, and chiggers) 699
 - Subclass Araneae (spiders) 708
 - Subclass Scorpiones (scorpions) 710
- Other arthropods 711
 - Class Chilopoda (centipedes) 711
 - Class Diplopoda (millipedes) 712
 - Class Crustacea (copepods, crabs, crayfish, etc.) 712
- Control of arthropods of medical importance 712
 - Physical control 712
 - Biological control 712
 - Chemical control 715

25 Treatment of Parasitic Infections 718

**PART II
Diagnostic Procedures 759**

26 Collection, Preservation, and Shipment of Fecal Specimens 761

- Safety 761
- Fresh-specimen collection 762
 - Collection of the specimen 762
 - Number of specimens to be collected (standard recommendation) 762
 - Number of specimens to be collected (pros and cons of various options) 763
 - Collection times 764
 - Specimen type, specimen stability, and need for preservation 764
- Preservation of specimens 768
 - Preservatives 768
 - Formalin 768
 - MIF 769
 - SAF 771
 - Schaudinn's fluid 772
 - PVA 772
 - Modified PVA 773
 - Single-vial collection systems (other than SAF) 773
 - Use of fixatives 774
 - Quality control for stool fixatives 774
 - Procedure notes for use of preservatives 775
 - Procedure limitations for use of preservatives 775
- Shipment of diagnostic specimens, biological products, etiologic agents, or infectious substances 775

27 Macroscopic and Microscopic Examination of Fecal Specimens 782

- Macroscopic examination 782

Microscopic examination (ova and parasite examination) 783

- Direct wet smear 783
- Concentration (sedimentation and flotation) 788
 - Formalin-ethyl acetate sedimentation concentration 789
 - Iodine-trichrome stain for sediment 792
 - Zinc sulfate flotation concentration 794
 - Commercial fecal concentration devices 796
 - Automated workstation for the microscopic analysis of fecal concentrates 797
- Permanent stained smear 797
 - Preparation of material for staining 798
 - Trichrome stain 802
 - Iron hematoxylin stain 807
 - Modified iron hematoxylin stain (incorporating the carbol fuchsin step) 811
 - Polychrome IV stain 812
 - Chlorazol black E stain 813

Specialized stains for coccidia (*Cryptosporidium*, *Isospora*, and *Cyclospora* species) and the microsporidia 813

- Modified Kinyoun's acid-fast stain (cold method) 813
- Modified Ziehl-Neelsen acid-fast stain (hot method) 816
- Carbol fuchsin negative stain for *Cryptosporidium* (from W. L. Current) 819
- Rapid safranin method for *Cryptosporidium* 819
- Rapid safranin method for *Cyclospora*, using a microwave oven 819
- Auramine O stain for coccidia (from Thomas Hänscheid) 819
- Modified trichrome stain for the microsporidia (Weber—green) 821
- Modified trichrome stain for the microsporidia (Ryan—blue) 823
- Modified trichrome stain for the microsporidia (Kokoskin—hot method) 825
- Acid-fast trichrome stain for *Cryptosporidium* and the microsporidia 826

28 Additional Techniques for Stool Examination 831

- Culture of larval-stage nematodes 831
 - Harada-Mori filter paper strip culture 832
 - Filter paper/slant culture technique (petri dish) 833
 - Charcoal culture 834
 - Baermann technique 835
 - Agar plate culture for *Strongyloides stercoralis* 837
- Egg studies 840
 - Estimation of worm burdens 840
 - Hatching of schistosome eggs 842
- Search for tapeworm scolex 844
- Qualitative test for fecal fat 845
- Quantitation of reducing substances (Clinitest) 847

29 Examination of Other Specimens from the Intestinal Tract and the Urogenital System 850

- Examination for pinworm 850
 - Cellulose tape preparations 851
 - Anal swabs 851
- Sigmoidoscopy material 852
 - Direct saline mount 853
 - Permanent stained slide 853
- Duodenal contents 854
 - Duodenal drainage 854
 - Duodenal capsule technique (Entero-Test) 854
- Urogenital specimens 855
 - Trichomoniasis 855
 - Filariasis 856
 - Schistosomiasis 856

30 Sputum, Aspirates, and Biopsy Material 859

- Expectorated sputum 859
- Induced sputum 861
- Aspirates 868
 - Lungs and liver 868
 - Lymph nodes, spleen, liver, bone marrow, spinal fluid, eyes, and nasopharynx 869
 - Cutaneous ulcer 871
- Biopsy material 871
 - Skin 876
 - Lymph nodes 876
 - Muscle 876
 - Rectum and bladder 877

31 Procedures for Detecting Blood Parasites 881

- Preparation of thick and thin blood films 881
 - Thick blood films 882
 - Thin blood films 884
 - Combination thick and thin blood films (on the same slide) 884
 - Combination thick and thin blood films (can be stained as either) 884
 - Buffy coat blood films 886
- Staining blood films 887
 - Giemsa stain 888
 - Wright's stain 889
 - General notes on staining procedures 891
- Proper examination of thin and thick blood films 891
 - Thin blood films 891
 - Thick blood films 893
 - Determination of parasitemia 893
- Diagnosis of malaria: review of alternatives to conventional microscopy 894
 - QBC microhematocrit centrifugation method 895
 - ParaSight F test 896
 - NOW malaria test 900

Flow anti-pLDH <i>Plasmodium</i> monoclonal antibodies 901	
PCR 902	
Automated blood cell analyzers 903	
Diagnosis of leishmaniasis: review of alternatives to conventional microscopy 903	
ICT for detection of anti-rK-39 antibodies 903	
Concentration procedures 903	
Cytocentrifugation technique 903	
Knott concentration procedure 904	
Membrane filtration technique 904	
Gradient centrifugation technique 905	
Triple-centrifugation method for trypanosomes 905	
Special stain for microfilarial sheath 905	
Delafield's hematoxylin 905	
32 Parasite Recovery: Culture Methods, Animal Inoculation, and Xenodiagnosis 910	
Culture methods 910	
Intestinal protozoa 911	
Pathogenic free-living amebae 917	
Pathogenic flagellates 922	
Flagellates of blood and tissue 926	
<i>Toxoplasma gondii</i> 931	
<i>Plasmodium</i> and <i>Babesia</i> spp. 931	
<i>Cryptosporidium</i> spp. 932	
Microsporidia 932	
Animal inoculation 932	
<i>Leishmania</i> spp. 932	
<i>Trypanosoma</i> spp. 933	
<i>Toxoplasma gondii</i> 933	
Xenodiagnosis 933	
33 Fixation and Special Preparation of Fecal Parasite Specimens and Arthropods 936	
Fixation of parasite specimens and arthropods 936	
Protozoa 937	
Solutions to induce relaxation in adult helminths 938	
Nematodes 939	
Trematodes 940	
Cestodes 940	
Helminth eggs and larvae 940	
Arthropods 940	
Mounting and staining of parasite specimens for examination 941	
Nematodes 941	
Trematodes 942	
Cestodes 943	
Mounting of arthropods for examination 944	
Mites 944	
Fleas and lice 944	
Ticks 945	
Miscellaneous arthropods 945	
34 Artifacts That Can Be Confused with Parasitic Organisms 947	
Protozoa 947	
Amebae 947	
Flagellates 949	
Ciliates 949	
Coccidia and microsporidia 949	
<i>Cryptosporidium</i> spp. and <i>Cyclospora cayetanensis</i> 949	
<i>Isospora belli</i> 950	
Microsporidia 951	
Blood and body fluids 951	
Malaria parasites and <i>Babesia</i> spp. 951	
Leishmaniae and trypanosomes 951	
Microfilariae 951	
Body fluids: ciliated epithelial cells 953	
Helminths 953	
Adult worms and larvae 953	
Eggs 954	
Human cells 954	
Polymorphonuclear leukocytes 956	
Eosinophils 956	
Macrophages 956	
Lymphocytes 957	
Red blood cells 957	
Charcot-Leyden crystals 957	
Nonhuman elements seen in feces (yeast cells) 957	
Insect larvae 958	
Spurious infections 958	
Delusory parasitosis 959	
35 Equipment, Supplies, Safety, and Quality System Recommendations for a Diagnostic Parasitology Laboratory: Factors Influencing Future Laboratory Practice 961	
Equipment 961	
Microscope 961	
Centrifuge 965	
Fume hood 965	
Biological safety cabinet 965	
Refrigerator-freezer 966	
Supplies 966	
Glassware 966	
Miscellaneous supplies 967	
ATCC quality control organisms 967	
Safety: personnel and physical facilities 967	
General precautions 967	
Handwashing 968	
Personal protective equipment (OSHA 2001 blood borne) 969	
Handling specimens 970	
Processing specimens 970	
Spills 972	

- Disposal of contaminated materials 973
- Standard precautions 974
- Hepatitis exposure protocol 976

GLOSSARY 1151

INDEX 1165

Preface

During the past few years, the field of diagnostic medical parasitology has seen dramatic changes, including newly recognized parasites, emerging pathogens in new geographic areas, bioterrorism considerations and requirements, alternative techniques required by new regulatory requirements, reevaluation of diagnostic test options and ordering algorithms, continuing changes in the laboratory test menus, implementation of testing based on molecular techniques, reporting formats, coding and billing requirements, managed care relevancy, increased need for consultation and educational initiatives for clients, and an overall increased awareness of parasitic infections from a worldwide perspective. We have seen organisms like the microsporidia change from the status of “unusual parasitic infection” to being widely recognized as causing some of the most important infections in both immunocompetent and compromised patients. More sensitive diagnostic methods for organism detection in stool specimens are now commercially available for *Entamoeba histolytica*, *Entamoeba histolytica/E. dispar*, *Giardia lamblia*, *Cryptosporidium parvum*, and *Trichomonas vaginalis*. Reagents are actively being developed for other organisms such as *Dientamoeba fragilis* and the microsporidia. We have seen *Cyclospora cayotensis* coccidia become well recognized as the cause of diarrhea in immunocompetent and immunocompromised humans. We continue to see new disease presentations in compromised patients; a good example is granulomatous amebic encephalitis caused by *Acanthamoeba* spp., *Sappinia diploidea*, and *Balamuthia mandrillaris*. With the expansion of transplantation options, many parasites are potential threats to patients who are undergoing immunosuppression, and they must be considered within the context of this patient group. Transfusion-associated transmission of potential parasitic pathogens continues to be problematic. Transfusion in general is becoming more widely recognized as a source of infection, and donors are also more likely to come from many areas of the world where parasitic infections are endemic.

With expanding regulatory requirements related to the disposal of chemicals, laboratories are continuing to review the use of mercury compounds as specimen fixatives and learning to become familiar with organism morphology when using substitute compounds. Permanent staining of fecal smears confirms that none of the substitute fixatives provide results of the same quality found with the use of mercuric chloride-based fixatives. However, the key issue is whether the intestinal parasites can be identified using these alternative fixative-

tives, not how “perfect” they look. Many fixative options are now available, including single-vial collection systems, some of which are coupled with their own stains. Requirements also mandate that any laboratory using formalin must have formalin vapor monitored as both an 8 h time weighted average and 15 min readings. Most laboratories are now familiar with the regulations on protection of health care workers from blood and other body fluids and have implemented specific changes that are no longer optional. Although laboratories were already using many of the safety recommendations, these regulations delineate in detail what must be done and documented. Regulatory information based on new shipping requirements is also included.

On the basis of excellent suggestions and comments regarding features of the fourth edition of this book, the following changes have been made in this edition: a new chapter has been added that contains a large number of parasite medical case histories (case history, study questions, correct answer and discussion, and illustrative material); some of the life cycles have been redrawn, and new life cycles have been added; algorithms have been expanded; new tables and figures have been added throughout the book; additional drawings and photographs have been added; extensive updated text information is included, all of which was taken from a comprehensive literature review of all aspects of diagnostic medical parasitology; additional examples of unusual parasitic infections are included; the chapter on arthropods has been expanded and includes additional photographs and drawings and expanded text; the chapter on the immunology of parasitic infections has been enlarged, and updated information on both antigen and antibody detection methods continues to be included in this edition; the chapter on histologic identification of parasites has been greatly expanded with diagrams of various parasites and their visual presentations in tissue sections along with greatly enhanced legends for all images; diagnostic methods using newer immunoassay and “dipstick” technology are described; and the chapter on quality control has been expanded to include information on instrumentation and equipment, safety regulations, quality control and quality systems information, continuous quality improvement, and managed care considerations. The appendixes have been expanded to contain more information on artifacts; expanded lists and photographs of products and commercial suppliers; algorithms for ordering specific tests that complement the ova and parasite examination; flowcharts for processing stool specimens; quality control recording sheets for use in the laboratory; and general references and relevant websites. One of the most important expanded areas of the fifth edition is found in appendix 8. This section contains information that has been published within months prior to the final printing of this edition. This “late breaking” synopsis of very recent publications can assist the reader in having access to the latest information available. I encourage you to review this section as you read various chapters throughout the book.

The approach to the fifth edition of the book is similar to that for the first four editions. My objective is to provide the user with clear, concise, well organized, clinically relevant, cost effective, and practical quality procedures for use in the clinical laboratory setting. To use and fully understand these methods for the parasites discussed, it is imperative that the user also understand information related to life cycle, morphology, clinical disease, pathogenesis, diagnosis, treatment, epidemiology, and prevention. My intent is to provide a comprehensive discussion of both aspects of the field of diagnostic medical parasitology: first, a comprehensive discussion of the individual parasites, and second, relevant diagnostic methods designed to detect and identify the organisms present. I believe that the book fulfills these objectives and provides readers, whether

they are laboratorians, physicians, or other health care professionals, with not only comprehensive but also very practical information.

It is also important for readers to understand that there are many diagnostic test options available to the clinical laboratory; not every laboratory will approach the diagnosis of parasitic infections in the same way. The key to quality and clinically relevant diagnostic work is a thorough understanding of the pros and cons of each option and how various options may or may not be relevant for one's particular geographic area, laboratory size and range of expertise, client base, number and type of patients seen, personnel expertise and availability, equipment availability, educational initiatives, and communication options, just to name a few variables. However, it is also important to understand the regulations and technical recommendations that govern and guide this type of laboratory work; many of these guidelines are related to coding and reimbursement, proficiency testing, and overall clinical relevance.

The use of product names is not intended to endorse specific products or to exclude substitute products. Also, because of possible advances and changes in the therapy of parasitic infections, independent verification of drugs and drug dosages is always recommended. The diagnostic procedures are intended for laboratory use only by qualified and experienced individuals or by the personnel under their direct supervision. Every effort has been made to ensure accuracy; however, ASM Press and I encourage you to submit to us any suggestions, comments, and information on errors found.

Acknowledgments

I would like to express my thanks to the many colleagues and students who have helped shape my perspective regarding the field of medical parasitology over the years, especially Yost Amrein, Bruce Anderson, Michael Arrowood, Lawrence Ash, Gordon Ball, Ralph Barr, Marilyn Bartlett, Kenneth Borchardt, Peter Boreham, Emilio Bouza, Thomas Brewer, Sandra Bullock-Iacullo, Ann Cali, David Casemore, Francis Chan, Ray Chan, John Christie, Frank Cox, William Current, Peter Deplazes, J. P. Dubey, Mark Eberhard, Ronald Fayer, Sydney Finegold, Ana Flisser, Jacob Frenkel, Thomas Fritsche, Hector Garcia, Raj Gill, Robert Goldsmith, Thomas Hanscheid, George Healy, Barbara Herwaldt, Donald Heyneman, George Hillyer, Peter Horen, Peter Hotez, David John, Stephanie Johnston, Irving Kagan, Ray Kaplan, John Kessel, Jay Keystone, Mary Klassen-Fischer, Elmer Koneman, Jaime LaBarca, William Lewis, Andrea Linscott, Earl Long, Alex Macias, Edward Markell, Marilyn Marshall, Mae Melvin, Michael Miller, Anthony Moody, William Murray, Ronald Neafie, Ron Neimeister, Ann Nelson, Susan Novak, Thomas Nutman, Thomas Orihel, Ynes Ortega, Robert Owen, Josephine Palmer, Graeme Paltridge, William Petri, Kathy Powers, Paul Prociw, Gary Procop, Fred Rachford, Sharon Reed, William Rogers, Jon Rosenblatt, Norbert Ryan, Peter Schantz, James Seidel, Nicholas Serafy, Irwin Sherman, Robyn Shimizu, James Smith, Rosemary Soave, Deborah Stenzel, Charles Sterling, Alex Sulzer, Sam Telford, R. C. A. Thompson, Peter Traynor, Jerrold Turner, Govinda Visvesvara, Marietta Voge, Susanne Wahlquist, Kenneth Walls, Rainer Weber, Wilfred Weinstein, John Williams, John Wilson, Marianna Wilson, Martin Wolfe, Lihua Xiao, Charles and Wiladene Zierdt, and many others I may have forgotten to mention specifically. If the information contained in this edition provides help to those in the field of microbiology, I will have succeeded in passing on this composite knowledge to the next generation of students and teachers.

Special thanks go to Graeme Paltridge, who reviewed the third edition and offered suggestions for improvements for subsequent editions, and to Sharon Belkin for her additional illustrations for this edition. I also thank Ronald Neafie from the Armed Forces Institute of Pathology for providing many photographs to illustrate several areas of the book, particularly the information on histological identification of parasites, and Herman Zaiman for providing slides that he has prepared and/or edited from many contributors worldwide.

I would like to acknowledge the excellent contributions of David A. Bruckner, my coauthor for the first three editions. I sincerely hope that the fifth edition will match the high standards that were set for the previous editions.

I also thank members of the editorial staff of ASM Press, including Susan Birch, Jeff Holtmeier, and our copy editor, Yvonne Strong; they are outstanding professionals and made my job not only challenging but fun.

Above all, my very special thanks go to my husband, John, for his love and support for the many projects that I have been involved in over the years. I could never have undertaken these challenges without his help and understanding.

Philosophy and Approach to Diagnostic Parasitology

The basic approach to diagnostic parasitology should be no different from that used in other areas of microbiology. There are guidelines published by the American Society for Microbiology (10, 11), the American Society of Parasitologists (8), the American Society for Medical Technology (16), the College of American Pathologists (7), and the Clinical and Laboratory Standards Institute (formerly NCCLS) (1, 2, 13–15) that contain recommended procedures for this field. If these general guidelines and recommendations are not followed, there is some question as to the qualifications of the laboratory performing the diagnostic work. At the very least, the clinician should be informed about the limitations of the procedures that are being used. These guidelines are also accompanied by specific regulations for a number of laboratory issues and include the Clinical Laboratory Improvement Act of 1988 and requirements related to safety and protection of employees from blood or bloodborne pathogens (standard precautions) (1, 3–6, 12).

Because it is difficult for the medical staff to maintain expertise in every available diagnostic procedure within microbiology, it is mandatory that close communication exist between the laboratory and clinicians. This type of frequent and complete communication, particularly concerning appropriate test orders and the clinical relevance of any diagnostic procedure within the context of total patient care and quality assurance, is very important. Therapeutic intervention often depends on results obtained from these procedures; therefore, the clinician must be aware of the limitations of each test method and the results obtained. This information becomes particularly important when one is discussing the patient's history and the recommended number and types of specimens to be submitted for examination.

During the past few years, there has been an increased awareness of the importance of having trained and qualified personnel perform these diagnostic procedures. There has been a concerted effort among many individuals and institutions in this country to upgrade the level of teaching and to bring to the medical community's attention the need for individuals who are familiar with diagnostic parasitology. With many laboratories decreasing staff size as a cost containment measure, we are also seeing more "generalists" who are rotating throughout many sections of the laboratory, not just microbiology. Although necessary because of managed-care constraints and continued growth

of capitated contracts, this approach contributes to the difficulties in maintaining well-trained staff in some of the specialty areas of microbiology. It becomes even more important to provide well-written laboratory protocols and to standardize test methods for consistency. There has also been increased awareness within the medical community of the need for additional training in the area of infectious diseases for the clinician and laboratory technician alike. This need has been reflected in the number of workshops, seminars, and publications that are available. The integration of information among all members of the health care team has certainly improved in terms of overall patient care.

The field of microbiology has taken on additional relevance and importance for a number of other reasons. Improved means of travel has made the world a smaller place. An individual's chances of exposure to parasites not endemic to his or her homeland and the possibility of acquiring or transmitting certain infections have been increasing. These facts emphasize the need for taking a correct and complete history from a patient. It is important to be aware of the organisms commonly found within certain areas of the world and the makeup of the patient population being serviced at any particular health facility.

The most important step in the diagnosis of parasitic infections is the selection and submission of the appropriate clinical specimen within specified time lines and according to set protocols.

It is also important for the physician to know the efficacy of any diagnostic technique for parasite recovery and eventual diagnosis. Our approach to testing is undergoing continuous review, particularly within the current health care environment and cost containment initiatives. The issue of patient care becomes particularly important when we begin to examine the number and types of compromised patients now being seen in all facilities. The increased publicity concerning patients with AIDS has led to a greater awareness of parasitic infections in the compromised patient, regardless of the original cause of the immune deficiencies. Many of these patients with immune system defects are particularly at risk, whether because of previously acquired infections that have remained latent for many years or because of susceptibility to new infections. Many of these infections may present with unusual symptoms, and some are relatively new disease entities (microsporidiosis, granulomatous amebic encephalitis, and infection with *Cyclospora cayetanensis*).

Often in other areas of microbiology, therapy is begun on the basis of patient history and symptoms. This approach is generally not recommended or used in cases of parasitic infection. Thus, understanding of the characteristics of any parasitic infection (general geographic range, life cycle, clinical disease, diagnostic methods, therapy, epidemiology,

and control) and the use of appropriate diagnostic procedures accompanied by a complete understanding of the limitations of each procedure become very important. Because of this approach to patient care, general consensus among individuals within the field of diagnostic medical parasitology is that the use of certain incomplete procedures may result in incorrect information for the physician and may ultimately compromise patient care.

The main emphasis should be on the importance of understanding and recognizing potential parasitic infections, submitting the appropriate number and type of clinical specimens, knowing what procedures may provide confirmation of the diagnosis, and recognizing the implications and limitations of information provided to the physician. With the current emphasis on the development and use of immunoassay methods, understanding the benefits and limitations of these procedures will be critical to patient care outcomes. If there is an incomplete understanding of the requirements for high-quality diagnostic testing, incomplete information will be transmitted to the clinician (9). It is the responsibility of both the laboratory and the clinician to develop a greater awareness of the importance of these requirements.

Intestinal Protozoa: Amebae

Entamoeba histolytica

Entamoeba dispar

Entamoeba moshkovskii

Entamoeba hartmanni

Entamoeba coli

Entamoeba polecki

Entamoeba gingivalis

Endolimax nana

Iodamoeba bütschlii

Blastocystis hominis

Entamoeba histolytica

Entamoeba histolytica was first described by Losch after being isolated in Russia from a patient with dysenteric stools. Although Losch found the organisms in human colonic ulcers at autopsy and was able to induce dysentery in a dog that was inoculated rectally with the patient's stools, he failed to recognize the causal relationship. This organism was eventually more fully investigated and differentiated from *Entamoeba coli* and *Entamoeba hartmanni* with respect to both morphology and pathogenesis (15). Based on the genome, this organism has a number of metabolic adaptations shared with two other amitochondrial protest pathogens: *Giardia lamblia* and *Trichomonas vaginalis*. These adaptations include the use of oxidative stress enzymes usually associated with anaerobic prokaryotes, as well as reduction or elimination of most mitochondrial metabolic pathways. There is evidence for lateral gene transfer of bacterial genes into the *E. histolytica* genome, a large number of novel receptor kinases, and expansions of a variety of gene families, including those associated with virulence (25).

E. histolytica has been recovered worldwide and is more prevalent in the tropics and subtropics than in cooler climates. However, infection rates in unsanitary conditions in temperate and colder climates have been found to equal those seen in the tropics. The World Health Organization reported that *E. histolytica* causes approximately 50 million cases and 110,000 deaths annually (51). Only malaria and schistosomiasis surpass amebiasis as leading parasitic causes of death (41).

At least 10 amebae are found in the mouth or intestinal lumen (*E. histolytica*, *E. dispar*, *E. moshkovskii*, *E. hartmanni*, *E. coli*, *E. polecki*, *E. gingivalis*, *E. nana*, *Iodamoeba bütschlii*, and *Blastocystis hominis*). However, of these, only *E. histolytica* and *B. hominis* have been considered to be pathogenic.

E. histolytica* versus *E. dispar

Although a large number of people throughout the world are infected, only a small percentage will develop clinical symptoms. Morbidity and mortality due to *E. histolytica* vary, depending on the geographic area, the organism strain, and the patient's immune status. For many years, the issue of pathogenicity has been very controversial, with, essentially, two points of view. Some thought that

what was called *E. histolytica* was really two separate species of *Entamoeba*, one being pathogenic and causing invasive disease and the other being nonpathogenic and causing mild or asymptomatic infections. Others thought that all organisms designated *E. histolytica* were potentially pathogenic, with symptoms depending on the result of host or environmental factors, including the intestinal flora.

In 1961, with the development of successful axenic culture methods requiring no bacterial coculture, sufficient organisms could be obtained for additional studies. Approximately 15 years later, reports indicated that *E. histolytica* clinical isolates could be classified into groups by using starch gel electrophoresis and review of banding patterns related to specific isoenzymes (15). The four isoenzymes are glucophosphate isomerase, phosphoglucomutase, malate dehydrogenase, and hexokinase. Sargeant concluded from this work that there are pathogenic and nonpathogenic strains (zymodemes) of *E. histolytica* that can be differentiated by isoenzyme analysis. On the basis of analysis of thousands of clinical isolates, he also concluded that the zymodeme patterns were probably genetic rather than phenotypic.

Others argued that the bacterial flora present in the gut played a role in the potential pathogenicity of *E. histolytica*. Some of the *in vitro* culture studies indicated that bacteria enhance the virulence of *E. histolytica*. During the 1980s and early 1990s, these issues were discussed with a number of questions still remaining unanswered (30).

According to Diamond and Clark (8), the most logical explanation of their failure to obtain conversion of “nonpathogenic” *E. histolytica* isolates to the “pathogenic” form during axenization of the amebae was culture contamination. In reviewing this possibility, they used a method based on analysis of stable DNA polymorphisms that allows the identification of individual pathogenic isolates. The DNA patterns obtained with the “converted” amebae were identical to those of reference isolates present in the laboratory at the time of conversion (8). Diamond and Clark also found that transfer of very few pathogenic organisms was necessary for the pathogens to become established in a nonpathogenic culture. Within the context of these studies, cross-contamination fully explained the conversion and the designation of specific pathogenic *E. histolytica* and nonpathogenic *E. dispar* was confirmed (8).

Studies confirming the differences between the two organisms include direct sequencing of the PCR-amplified small-subunit rRNA gene of *E. dispar* and the design of primers for rapid differentiation from *E. histolytica*, differences in the *E. histolytica* and *E. dispar* phosphoglucomutases, molecular biology of the differences in the hexokinase isoenzyme, differences in the secretion of acid

phosphatase, and the detection of DNA sequences unique to *E. histolytica* (35, 49, 57).

Genetic differences may not totally explain the overall differences. Among 79 *E. histolytica* isolates obtained from different geographic regions, a total of 53 different genotypes were observed among 63 isolates. The most extensive variations among the four loci were found in the serine-rich *E. histolytica* protein (SREHP) locus. However, no association between clinical presentation and the SREHP genotype was demonstrated (17).

Research has centered on explaining the molecular differences between the pathogenic *E. histolytica* and the nonpathogenic *E. dispar*. However, the molecules considered the most important for host tissue destruction (amebapore, galactose/*N*-acetylgalactosamine inhibitable lectin, and cysteine proteases) can be found in both organisms. Pathogenicity differences may be related to the composition and properties of the surface coat components (or pathogen-associated molecular patterns) and the ability of the innate immune response to recognize these components, thus eliminating the organisms (6). Targets of the host immune system modulation appear to be both neutrophils and macrophages, which are unable to abort the infection even when present at the site of the lesion (10). The total body of evidence supports differentiation of the pathogenic *E. histolytica* from the nonpathogenic *E. dispar* and their classification as two distinct species (15).

Life Cycle and Morphology

The life cycle is shown in Figure 2.1. The cyst form is the infective form for humans.

Morphology of Trophozoites (Table 2.1). Living trophozoites vary in size from about 12 to 60 μm in diameter. Organisms recovered from diarrheic or dysenteric stools are generally larger than those in a formed stool from

Figure 2.1 Life cycle of *Entamoeba histolytica*.

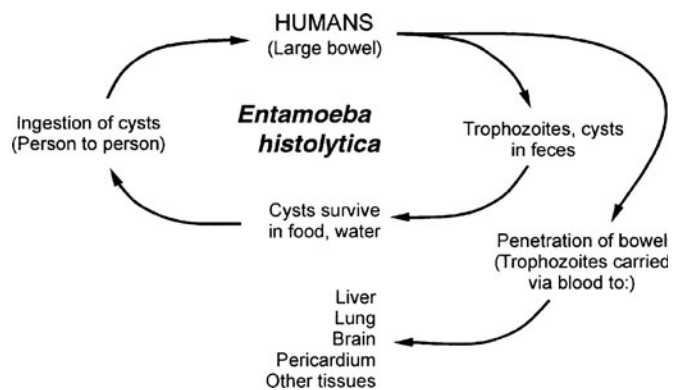

Table 2.1 Intestinal protozoa: trophozoites of common amebae

Characteristic	<i>Entamoeba histolytica</i>	<i>Entamoeba dispar</i> / <i>Entamoeba moshkovskii</i>	<i>Entamoeba hartmanni</i>	<i>Entamoeba coli</i>	<i>Endolimax nana</i>	<i>Iodamoeba bütschlii</i>
Size ^a (diam or length)	12–60 µm (usual range, 15–20 µm); invasive forms may be over 20 µm	Same as <i>E. histolytica</i>	5–12 µm (usual range, 8–10 µm)	15–50 µm (usual range, 20–25 µm)	6–12 µm (usual range, 8–10 µm)	8–20 µm (usual range, 12–15 µm)
Motility	Progressive, with hyaline, fingerlike pseudopodia; motility may be rapid	Same as <i>E. histolytica</i>	Usually nonprogressive	Sluggish nondirectional, with blunt, granular pseudopodia	Sluggish, usually nonprogressive	Sluggish, usually nonprogressive
Nucleus: no. and visibility	Difficult to see in unstained preparations; 1 nucleus	Same as <i>E. histolytica</i>	Usually not seen in unstained preparations; 1 nucleus	Often visible in unstained preparations; 1 nucleus	Occasionally visible in unstained preparations; 1 nucleus	Usually not visible in unstained preparations; 1 nucleus
Peripheral chromatin (stained)	Fine granules, uniform in size and usually evenly distributed; may have beaded appearance	Same as <i>E. histolytica</i>	Nucleus may stain more darkly than in <i>E. histolytica</i> / <i>E. dispar</i> , although morphology is similar; chromatin may appear as solid ring rather than beaded	May be clumped and unevenly arranged on the membrane; may also appear as solid, dark ring with no beads or clumps	Usually no peripheral chromatin; nuclear chromatin may be quite variable	Usually no peripheral chromatin
Karyosome (stained)	Small, usually compact; centrally located but may also be eccentric	Same as <i>E. histolytica</i>	Usually small and compact; may be centrally located or eccentric	Large, not compact; may or may not be eccentric; may be diffuse and darkly stained	Large, irregularly shaped; may appear “blotlike”; many nuclear variations are common; may mimic <i>E. hartmanni</i> or <i>D. fragilis</i>	Large, may be surrounded by refractile granules that are difficult to see (“basket nucleus”)
Cytoplasm appearance (stained)	Finely granular, “ground-glass” appearance; clear differentiation of ectoplasm and endoplasm; if present, vacuoles are usually small	Same as <i>E. histolytica</i>	Finely granular	Granular, with little differentiation into ectoplasm and endoplasm; usually vacuolated	Granular, vacuolated	Granular, may be heavily vacuolated
Inclusions (stained)	Noninvasive organism may contain bacteria; presence of RBCs diagnostic	Organisms usually contain bacteria; RBCs not present in cytoplasm	May contain bacteria; no RBCs	Bacteria, yeasts, other debris	Bacteria	Bacteria

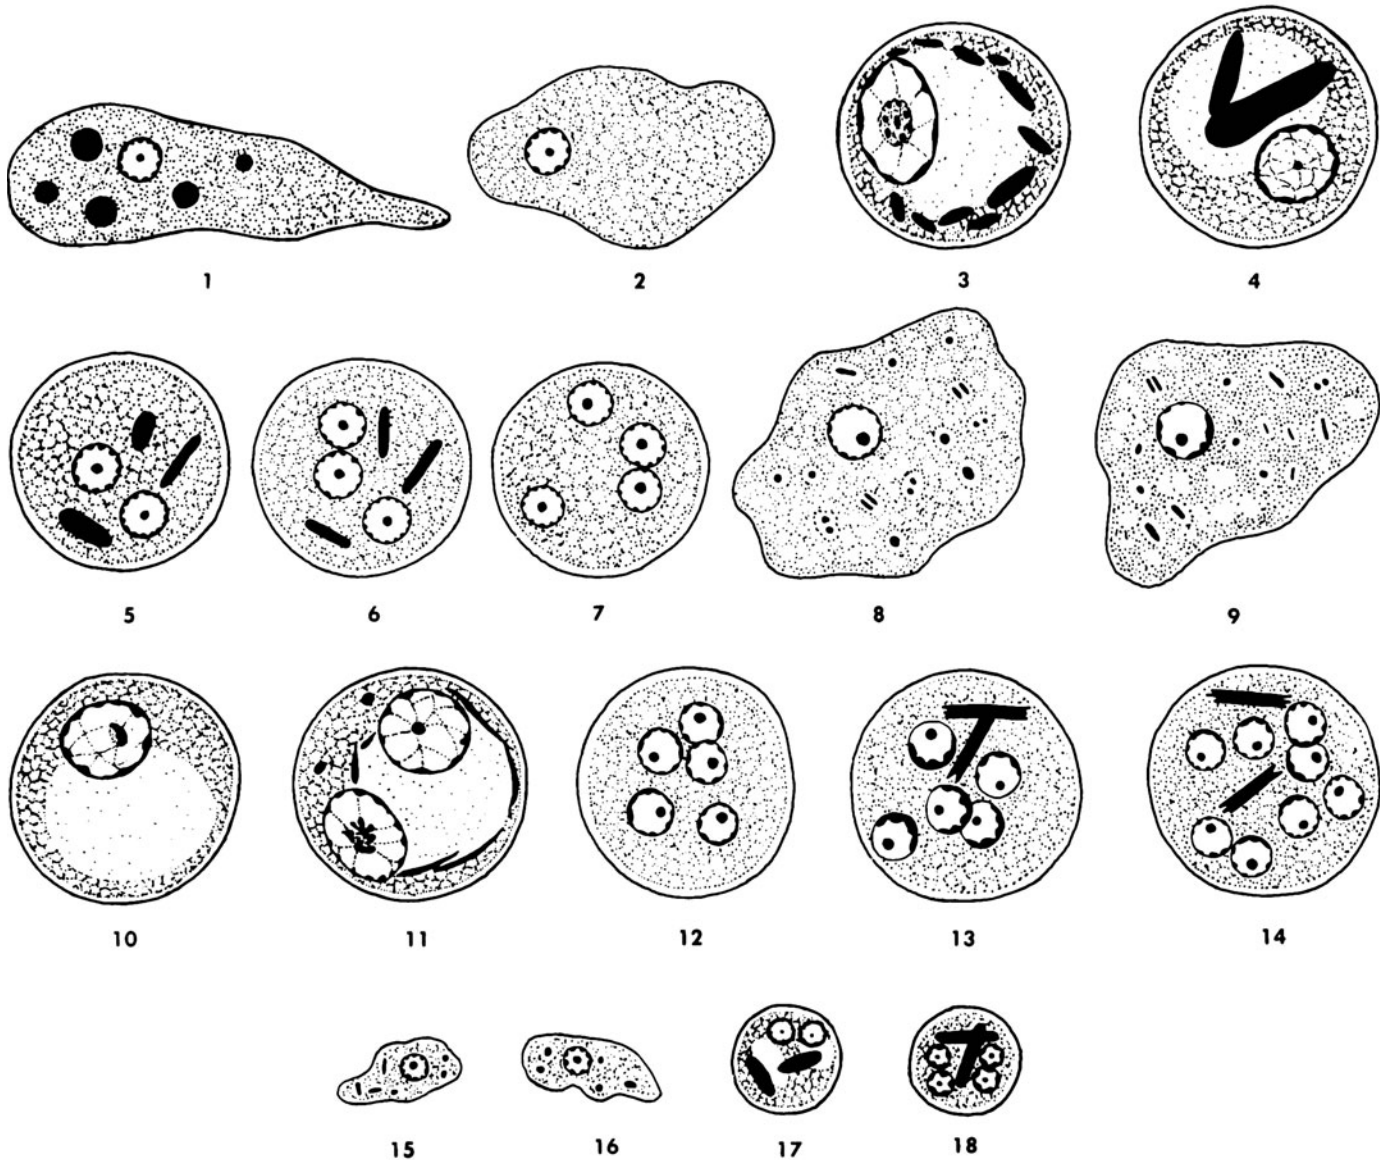

^a Wet preparation measurements (on permanent stains, organisms usually measure 1 to 2 µm less).

an asymptomatic individual (Figures 2.2 and 2.3). The motility has been described as rapid and unidirectional, with pseudopods forming quickly in response to the conditions around the organism. The motility may appear to be sporadic. Although this characteristic motility is often described, it is rare to diagnose amebiasis on the basis of motility seen in a direct mount. The cytoplasm is differentiated into a clear outer ectoplasm and a more granular inner endoplasm.

When the organism is examined on a permanent stained smear (trichrome or iron hematoxylin), the mor-

phological characteristics of *E. histolytica/E. dispar* are readily seen. The nucleus is characterized by having evenly arranged chromatin on the nuclear membrane and having a small, compact, centrally located karyosome. The cytoplasm is usually described as finely granular with few ingested bacteria or debris in vacuoles. In organisms isolated from a patient with dysentery, red blood cells (RBCs) may be visible in the cytoplasm, and this feature is diagnostic for *E. histolytica*. Most often, infection with *E. histolytica/E. dispar* is diagnosed on the basis of organism morphology without the presence of RBCs.

Figure 2.2 (1) Trophozoite of *Entamoeba histolytica*; (2) trophozoite of *E. histolytica/E. dispar/E. moshkovskii*; (3 and 4) early cysts of *E. histolytica/E. dispar/E. moshkovskii*; (5 to 7) cysts of *E. histolytica/E. dispar/E. moshkovskii*; (8 and 9) trophozoites of *Entamoeba coli*; (10 and 11) early cysts of *E. coli*; (12 to 14) cysts of *E. coli*; (15 and 16) trophozoites of *Entamoeba hartmanni*; (17 and 18) cysts of *E. hartmanni*.

Morphology of Cysts (Table 2.2). For reasons that are not specifically known, the trophozoites may condense into a round mass (precyst), and a thin wall is secreted around the immature cyst. There may be two types of inclusions within this immature cyst, a glycogen mass and highly refractile chromatoidal bars with smooth, rounded edges. As the cysts mature (metacyst), there is nuclear division with the production of four nuclei; on rare occasions, eight nuclei are produced and the cysts range in size from 10 to 20 μm . Often, as the cyst matures, the glycogen completely disappears; the chromatoidals may also be absent in the mature cyst. Cyst morphology does not differentiate between *E. histolytica* and *E. dispar*. Cyst formation occurs only within the intestinal tract; once the stool has left the body, cyst formation does not occur. The one-, two-, and four-nucleated cysts are infective and represent the mode of transmission from one host to another (Figures 2.1 to 2.3).

Infection. After cyst ingestion, no changes occur in an acidic environment; however, once the pH becomes neutral or slightly alkaline, the encysted organism becomes active, with the outcome being four separate trophozoites (small, metacystic trophozoites). These organisms develop into the normal trophozoites when they become established in the large intestine.

Clinical Disease

The presentations of disease are seen with invasion of the intestinal mucosa and/or dissemination to other organs, the most common being the liver. However, it is estimated that only a small proportion (2 to 8%) of infected individuals will have invasive disease beyond the lumen of the bowel. Also, organisms may be spontaneously eliminated with no disease symptoms.

Asymptomatic Infection. Individuals harboring *E. histolytica* may have either a negative or weak antibody titer and negative stools for occult blood and may be passing cysts that can be detected if the routine ova and parasite examination is performed. Although trophozoites may also be found, they do not contain any phagocytized RBCs and cannot be differentiated from *E. dispar*. Isoenzyme analyses of organisms isolated from asymptomatic individuals generally indicate that the isolates belong to nonpathogens (*E. dispar*). Generally, asymptomatic patients never become symptomatic and may excrete cysts for a short period.

Figure 2.3 (A) Trophozoite of *Entamoeba histolytica*; (B) trophozoite of *Entamoeba histolytica*/*E. dispar*/*E. moshkovskii*; (C and D) cysts of *E. histolytica*/*E. dispar*/*E. moshkovskii*; (E and F) trophozoites of *Entamoeba coli*; (G to J) cysts of *E. coli*. Note the chromatoidal bars in panels H and I and the shrunken cyst (which is often seen in permanent stained smears) in panel J.

Table 2.2 Intestinal protozoa: cysts of common amebae

Characteristic	<i>Entamoeba histolytica</i> / <i>Entamoeba dispar</i> / <i>Entamoeba moshkovskii</i>	<i>Entamoeba hartmanni</i>	<i>Entamoeba coli</i>	<i>Endolimax nana</i>	<i>Iodamoeba bütschlii</i>
Size ^a (diam or length)	10–20 µm (usual range, 12–15 µm)	5–10 µm (usual range, 6–8 µm)	10–35 µm (usual range, 15–25 µm)	5–10 µm (usual range, 6–8 µm)	5–20 µm (usual range, 10–12 µm)
Shape	Usually spherical	Usually spherical	Usually spherical; may be oval, triangular, or other shapes; may be distorted on permanent stained slide because of inadequate fixative penetration	Usually oval, may be round	May vary from oval to round; cyst may collapse because of large glycogen vacuole space
Nucleus: no. and visibility	Mature cyst, 4; immature, 1 or 2 nuclei; nuclear characteristics difficult to see on wet preparation	Mature cyst, 4; immature, 1 or 2 nuclei; two nucleated cysts very common	Mature cyst, 8; occasionally 16 or more nuclei are seen; immature cysts with 2 or more nuclei are occasionally seen	Mature cyst, 4; immature cysts, 2; very rarely seen and may resemble cysts of <i>Enteromonas hominis</i>	Mature cyst, 1
Peripheral chromatin (stained)	Peripheral chromatin present; fine, uniform granules, evenly distributed; nuclear characteristics may not be as clearly visible as in trophozoite	Fine granules evenly distributed on the membrane; nuclear characteristics may be difficult to see	Coarsely granular; may be clumped and unevenly arranged on membrane; nuclear characteristics not as clearly defined as in trophozoite; may resemble <i>E. histolytica</i> / <i>E. dispar</i>	No peripheral chromatin	No peripheral chromatin
Karyosome (stained)	Small, compact, usually centrally located but occasionally eccentric	Small, compact, usually centrally located	Large, may or may not be compact and/or eccentric; occasionally centrally located	Smaller than karyosome seen in trophozoites, but generally larger than those of the genus <i>Entamoeba</i>	Large, usually eccentric refractile granules may be on one side of karyosome (“basket nucleus”)
Cytoplasm, chromatoidal bodies (stained)	May be present; bodies usually elongate, with blunt, rounded, smooth edges; may be round or oval	Usually present; bodies usually elongate, with blunt, rounded, smooth edges; may be round or oval	May be present (less frequently than in <i>E. histolytica</i> / <i>E. dispar</i>); splinter shaped with rough, pointed ends	Rare chromatoidal bodies present; occasionally small granules or inclusions seen; fine linear chromatoidals may be faintly visible on well-stained smears	No chromatoidal bodies present; small granules occasionally present
Glycogen (stained with iodine)	May be diffuse or absent in mature cyst; clumped chromatin mass may be present in early cysts (stains reddish brown with iodine)	May or may not be present as in <i>E. histolytica</i> / <i>E. dispar</i>	May be diffuse or absent in mature cyst; clumped mass occasionally seen in mature cysts (stains reddish brown with iodine)	Usually diffuse if present (stains reddish brown with iodine)	Large, compact, well-defined mass (stains reddish brown with iodine)

^a Wet preparation measurements (on permanent stains, organisms usually measure 1 to 2 µm less).

This pattern is found for patients infected with either nonpathogenic or pathogenic species.

Intestinal Disease. Although the exact mode of mucosal penetration is not known, microscopy studies suggest that amebae have enzymes which lyse host tissue, possibly from lysosomes on the surface of the amebae or from ruptured organisms. Amebic ulcers most often develop in the cecum, appendix, or adjacent portion of the ascending colon; however, they can also be found in the sigmoidorectal area. From these primary sites, other lesions may occur. Ulcers are usually raised, with a small opening on the mucosal surface and a larger area of destruction below the surface, i.e., “flask shaped.” The mucosal lining may appear normal between ulcers.

Although the incubation period varies from a few days to a much longer time, in an area where *E. histolytica* is endemic it is impossible to determine exactly when the exposure took place. Normally, the time frame ranges from 1 to 4 weeks. Certainly not every patient infected with *E. histolytica* will develop invasive amebiasis; the outcome will depend on the interaction between parasite virulence factors and the host response.

There are four clinical forms of invasive intestinal amebiasis, all of which tend to be acute. They include dysentery or bloody diarrhea, fulminating colitis, amebic appendicitis, and ameboma of the colon. Dysentery and diarrhea account for 90% of cases of invasive intestinal amebiasis (10). Symptoms may range from none to those mimicking ulcerative colitis. Patients with colicky abdominal pain, frequent bowel movements, and tenesmus may present with a gradual onset of disease. With the onset of dysentery, bowel movements characterized by blood-tinged mucus are frequent (up to 10 per day). Although dysentery may last for months, it usually varies from severe to mild over that time and may lead to weight loss and prostration. In patients with severe cases, symptoms may begin very suddenly and include profuse diarrhea (over 10 stools per day), fever, dehydration, and electrolyte imbalances. If the clinical picture is acute, the illness may mimic appendicitis, cholecystitis, intestinal obstruction, or diverticulitis.

Hepatic Disease. Blood flow draining the intestine tends to return to the liver, most commonly the upper right lobe (Figure 2.4). The organisms present in the submucosa can therefore be carried via the bloodstream to the liver. Onset of symptoms may be gradual or sudden; upper right abdominal pain with fever from 38 to 39°C is the most consistent finding. Weakness, weight loss, cough, and sweating are less commonly seen. There tends to be hepatomegaly with tenderness; however, liver function tests may be normal or slightly abnormal, with jaundice being very rare. There may be changes at the base of the right lung owing to the elevated

Figure 2.4 Liver containing multiple amebic abscesses. The necrotic tissue has been removed from one portion, leaving a cavity. $\times 0.4$. (Armed Forces Institute of Pathology photograph.)

diaphragm. The abscess can be visualized radiologically, sonically, or by radionuclear scan, and the majority of patients have a single abscess in the right lobe of the liver. The most common complication is rupture of the abscess into the pleural space. An abscess can also extend into the peritoneum and through the skin. Hematogenous spread to the brain, as well as to the lungs, pericardium, and other sites, is possible. For patients living in areas of endemic infection and patients with a relevant travel history, amebic abscess should be suspected in those with spiking fever, weight loss, and abdominal pain in the upper right quadrant or epigastrium and those with tenderness in the liver area. The presence of leukocytosis, a high alkaline phosphatase level, and an elevated right diaphragm suggests a hepatic abscess. Pyogenic and amebic liver abscesses are the two most common hepatic abscesses. The severity of a pyogenic abscess depends on the bacterial source and the patient's underlying condition. Amebic abscess tends to be more prevalent in individuals with suppressed cell-mediated immunity, men, and younger individuals (20, 24, 32, 42, 56).

E. histolytica cysts and trophozoites are found in the stools of only a few patients with liver abscess. About 60% of these patients have no intestinal symptoms or any history of dysentery.

Although hepatic abscess is secondary to earlier colonization in the wall of the large intestine and is the most common site for extraintestinal amebiasis, *E. histolytica* has been seen in almost every soft organ and tissue of the body, including the lungs, heart, skin, and brain. Amebiasis of the lungs usually develops as an extension of a hepatic abscess that has ruptured through the diaphragm; however, it can also originate as a secondary site from the original infection in the intestine. Typically, the patient experiences expectoration of liver-colored sputum. In a very low percentage of

cases, the pericardium can be involved; this is more likely to occur in patients with an abscess in the left lobe of the liver.

Amebiasis of the skin usually develops as a perianal extension of acute amebic colitis or on the abdominal wall due to rupture or open drainage of an internal intestinal or hepatic lesion (36). Amebiasis cutis may also occur as a venereal infection of the penis after anal intercourse.

Amebic abscess in the brain is quite rare and usually arises from either hepatic or pulmonary involvement. Other rare ectopic sites include the spleen, adrenals, kidneys, ureters, urinary bladder, urethra, clitoris, and pericardium.

Pathogenesis

It has been estimated that *E. histolytica* infection kills more than 100,000 people each year. Key to the pathogenesis of this organism is its ability to directly lyse host cells and cause tissue destruction. Amebic lesions show evidence of cell lysis, tissue necrosis, and damage to the extracellular matrix. There is evidence that *E. histolytica* trophozoites interact with the host through a series of steps: adhesion to the target cell, phagocytosis, and cytopathic effect (6, 10, 45, 47). Numerous other parasite factors also play a role. From the perspective of the host, *E. histolytica* induces both humoral and cellular immune responses, with cell-mediated immunity representing the major human host defense against this complement-resistant cytolytic protozoan.

Our understanding of pathogenesis has expanded dramatically within the past few years. We now know that invasive strains of *E. histolytica* are resistant to complement-mediated lysis. These organisms activate complement via cleavage of C3 by an extracellular cysteine proteinase. Cysteine proteinases are important virulence factors encoded by at least three genes, one of which is unique to invasive strains (41). The amebic cysteine proteinases are homologous to proteinases released by transformed cells and probably represent a common mechanism of tissue invasion. The proteinase activity of amebae shows excellent correlation with their virulence. Cysteine proteinase can cleave the extracellular structural matrix and can degrade fibronectin and laminin, as well as type I collagen; this suggests that degradation of basement membrane is an important step in tissue invasion (41). Hemoglobin-degrading cysteine proteases also play an important role in iron acquisition by *E. histolytica*. Differences in the pathogenesis of *E. histolytica* and *E. dispar* also help explain the epidemiology, clinical syndromes, and pathology of amebiasis. Antibodies to the neutral cysteine proteinase have been detected in 83% of patients with invasive *E. histolytica* infections but not in patients with noninvasive *E. dispar* infections (46). Apparently, inhibition of the expression of cysteine proteinases does not affect *E. histolytica* cytopathic or hemolytic activity but inhibits phagocytosis. There is

recent evidence that a cysteine protease (EhCP112) and a protein with an adherence domain (EhADH112) form the *E. histolytica* 112-kDa adhesin.

The first evidence of amebic pathology is depletion of the intestinal mucus and disruption of the epithelial barrier, which results from the action of cysteine proteinases as well as other factors (6, 41). Clinical isolates of *E. histolytica* in culture release 10- to 1,000-fold more cysteine proteinases than do *E. dispar* isolates. Trophozoites use cysteine proteinases to cleave and penetrate the extracellular matrix (collagen, elastin, fibrinogen, and laminin) in order to cause invasive disease (41). These enzymes also interfere with the host immune system; hence, the data supporting a key role of cysteine proteinases in virulence are quite compelling, especially since specific genes for cysteine proteinases appear to be present and overexpressed in *E. histolytica* and absent or underexpressed in *E. dispar*.

Several molecules that may be involved in the parasite-host interaction processes have been identified. A lectin inhibitable by galactose and *N*-acetyl-D-galactosamine (Gal/GalNAc) is present on the trophozoite surface. Adherence of *E. histolytica* trophozoites to colonic mucin, epithelium, and other target cells is mediated by the amebic Gal/GalNAc lectin (39). Lectin activity in the parasite is regulated by inside-out signaling; this inside-out signaling via the lectin cytoplasmic domain may control the extracellular adhesive activity of the amebic lectin and provides evidence of the role of lectin in virulence (54). Studies also confirm that dominant-negative mutations in the Gal/GalNAc lectin affect adhesion and cytolysis while mutations in meromyosin affect cytoskeletal function (14). Myosin IB also is involved in phagocytosis of human erythrocytes by *E. histolytica* (55). Recently, a distinct β_2 integrin-like molecule with a potential role in cellular adherence was identified. This amebic β_2 integrin appeared to be distinct from the amebic Gal/GalNAc lectin based on recombinant expression, amebic colocalization, and enzyme-linked immunosorbent assay (ELISA) studies. The presence of integrin-dependent binding may allow trophozoites to opportunistically adhere to activated intestinal epithelium or vascular endothelium during amebic colitis or hepatic abscess (38).

There are also correlations between differences in the cell surface phosphorylated glycolipids and virulence; lipophosphoglycan and lipophosphopeptidoglycan molecules are abundant in virulent strains of *E. histolytica* and are absent or present at low levels in avirulent *E. histolytica* strains and *E. dispar* (31).

Various amebic pore-forming proteins are known, of which the 5-kDa protein (amebapore) has been extensively studied. These proteins can insert into the lipid bilayers of target cells, forming ion channels (10).

Data obtained by using human myeloid cells as target cells in vitro have revealed that the target cells die due to

necrosis with cell swelling, rupture of plasma membranes, and release of cell contents including nucleic acids. These findings confirm the notion that these particular target cells undergo necrosis when killed by viable trophozoites, as well as by isolated amebapores (10).

The role of zinc in the pathogenicity of *E. histolytica* may also be relevant. Apparently, zinc alters the functionality of the amebae in vitro by causing a decrease in replication and adhesion and in vivo by inhibiting amebic pathogenicity.

Diagnosis

Routine Diagnostic Procedures. The laboratory diagnosis of amebiasis, particularly intestinal amebiasis, depends on a number of procedures, any one of which can prevent organism recovery if not performed properly (Table 2.3). Organism detection depends on collection of the correct specimens, the number of specimens submitted, processing methods and diagnostic tests used, and examination by personnel who are well trained in identification of protozoa. This diagnosis can be one of the more difficult to achieve. Lack of appropriate training and diagnostic testing may lead to missed infections. In some cases, false positives may be due to identification of human white blood cells as amebae. A complete discussion of specimen collection and submission to the laboratory is presented in chapter 26.

The standard ova and parasite examination is the recommended procedure for recovery and identification of *E. histolytica* in stool specimens. Microscopic examination of a direct saline wet mount may reveal motile trophozoites, which may contain RBCs. However, the number of times these trophozoites with RBCs are present is limited. In many patients who do not present with acute dysentery,

trophozoites may be present but do not contain RBCs and the organisms may be *E. histolytica* or *E. dispar*. An asymptomatic individual may have few trophozoites and possibly only cysts in the stool. Although the concentration technique is helpful in demonstrating cysts, *the most important technique for the recovery and identification of protozoan organisms is the permanent stained smear* (normally stained with trichrome or iron hematoxylin). A minimum of three specimens collected over a time frame of not more than 10 days is recommended (21).

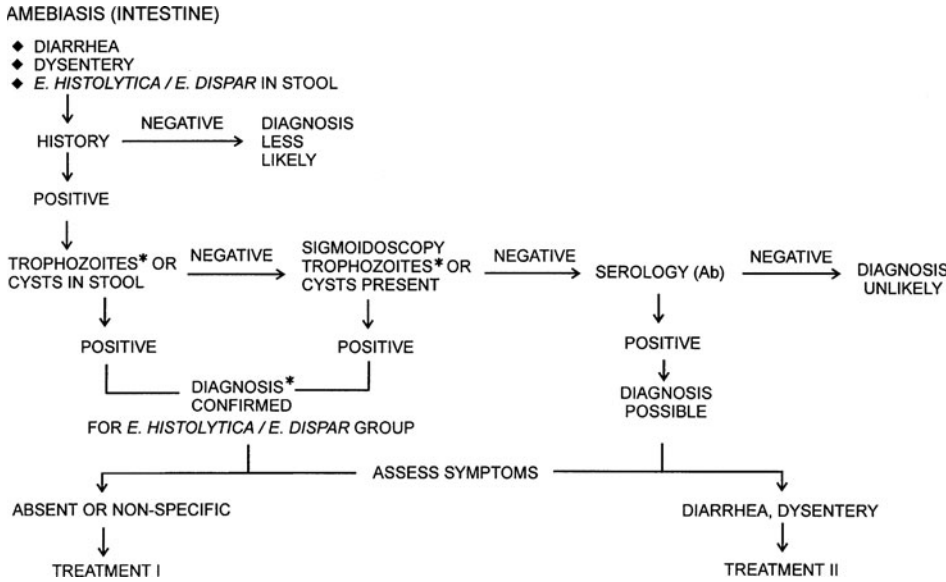

Note that if the permanent stained smear is quite dark, a delicate *E. histolytica/E. dispar* organism may appear more like *Entamoeba coli*; on a very thin, pale smear, *E. coli* can appear more like *E. histolytica/E. dispar*. Also, when the organisms are dying or have been poorly fixed, they appear more highly vacuolated, thus looking like *E. coli* trophozoites rather than *E. histolytica/E. dispar*.

If slides are prepared properly and examined carefully, sigmoidoscopy specimens may be very helpful. At least six areas of the mucosa should be sampled. Smears from these areas should be examined after permanent staining. This does not take the place of the recommended minimum of three stool specimens submitted for ova and parasite examinations (direct, concentration, and permanent stained smear). Refer to Algorithm 2.1 for detailed information.

Definitive diagnosis of liver abscess can be achieved by identification of organisms from liver aspirate material. However, this procedure is rarely performed, and often the specimen obtained is not collected properly. Aspirated material must be aliquoted into several different containers as it is removed from the abscess; amebae may be found only in the last portion of the aspirated material, theoretically material from the abscess wall, not necrotic debris from the abscess center. Refer to Algorithm 2.2 for detailed information.

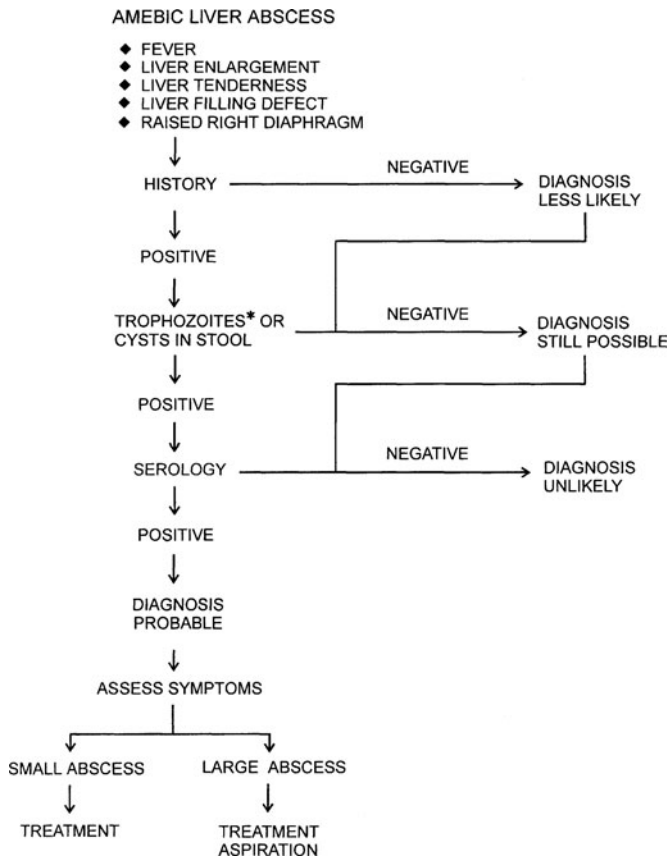

Table 2.3 Intestinal amebae: recommended diagnostic procedures

Organism	Recommended specimen	Diagnostic procedure
<i>Entamoeba histolytica</i>	Stool	Complete ova and parasite exam Immunoassays for antigen detection
	Sigmoidoscopy material	Permanent stain
	Hepatic abscess aspirate	Digestion/wet preparations
<i>Entamoeba dispar</i>	Stool	Complete ova and parasite exam
<i>Entamoeba moshkovskii</i>	Stool	Complete ova and parasite exam
<i>Entamoeba hartmanni</i>	Stool	Complete ova and parasite exam
<i>Entamoeba coli</i>	Stool	Complete ova and parasite exam
<i>Entamoeba polecki</i>	Stool	Complete ova and parasite exam
<i>Entamoeba gingivalis</i>	Gingival scrapings	Wet preparations and permanent stains
	Pyorrheal material	Wet preparations and permanent stains
<i>Endolimax nana</i>	Stool	Complete ova and parasite exam
<i>Iodamoeba bütschlii</i>	Stool	Complete ova and parasite exam
<i>Blastocystis hominis</i>	Stool	Complete ova and parasite exam

Algorithm 2.1 Intestinal amebiasis. Fecal immunoassay kits can be used on human stool specimens to identify organisms in the group *E. histolytica*/*E. dispar* or to differentiate *E. histolytica* from *E. dispar*. Currently available reagents require fresh or frozen specimens only. *, trophozoites containing RBCs confirmatory for *E. histolytica*; trophozoites with no ingested RBCs and/or cysts confirm only the *E. histolytica*/*E. dispar* group.

Algorithm 2.2 Amebic liver abscess. *, trophozoites containing RBCs confirmatory for *E. histolytica*; trophozoites with no ingested RBCs and/or cysts confirm only the *E. histolytica*/*E. dispar* group.

Immunodetection. A number of enzyme immunoassay reagents are commercially available, and their specificity and sensitivity provide excellent options for the clinical laboratory (Table 2.4) (2, 3, 5, 12, 15, 18, 53). These tests can determine the presence of the *E. histolytica*/*E. dispar* group as being distinct from the rest of the *Entamoeba* species such as nonpathogenic *E. coli* or *E. hartmanni*. Other test reagents can actually separate *E. histolytica* from *E. dispar*. The majority of these procedures use the enzyme-linked immunosorbent assay (ELISA) or enzyme immunoassay (EIA) formats (11). However, in some cases they have been found to be less sensitive than PCR (15) and in other instances they have been found equal to PCR (11). Another product is available as a cartridge format that uses an immunochromatographic strip-based detection system for the *E. histolytica*/*E. dispar* group, *Giardia lamblia*, and *Cryptosporidium* spp. (51). These commercially available reagent kits require fresh or frozen stools; formalin has been found to interfere with the *Entamoeba* reagents. Any available antigen detection system should always be reviewed for compatibility with stools submitted in preservatives rather than fresh specimens. There are limitations when using kits that include organisms in the genus *Entamoeba* (51). However, almost all reagent kits for the detection of *G. lamblia* and *Cryptosporidium* spp. can be used with formalin-based stool preservatives, as well as fresh or frozen specimens.

To provide clinically relevant information to physicians for treatment of patients infected with pathogenic *E. histolytica*, methods involving monoclonal antibodies, purified antigens, or DNA probes are now available. Reagents have been developed to differentiate pathogenic

Table 2.4 Commercial assays used to identify *E. histolytica*

Assay	Manufacturer	Sensitivity (%)	Specificity (%)	Comments ^a
Antigen detection TechLab <i>E. histolytica</i> II	TechLab, Blacksburg, Va.	100	~95	EIA; requires fresh or frozen stool; reagents differentiate between <i>E. histolytica</i> and <i>E. dispar</i>

E. histolytica from nonpathogenic *E. dispar* (5, 11, 15, 19). Although some of these reagents are now available, routine use in clinical laboratories may not be accepted because of cost, limited numbers of cases, and infrequent identification of organisms in the genus *Entamoeba*. Reliable probes based on the hypothesis of zymodeme stability and two separate species (one pathogenic and one nonpathogenic) offer significant improvements over current serologic or direct detection methods; these probes may also help eliminate false-positive results due to misidentification of human cells or other nonpathogenic protozoa in patient specimens.

The laboratory now has the ability to routinely indicate to the physician whether the *E. histolytica/E. dispar* organisms seen in the stool specimen are pathogenic *E. histolytica* or nonpathogenic *E. dispar*. Without the use of these types of reagents, the only way to morphologically identify true pathogenic *E. histolytica* would be to observe the rare presence of trophozoites containing ingested RBCs. In the event the laboratory does not use these reagents, the presence of *E. histolytica/E. dispar* should be reported to the physician, along with some additional commentary related to the newer information on pathogenicity. Ultimately, the physician will have to

decide on the issue of therapy on the basis of the patient's clinical condition. However, without more accurate information on the pathogenicity of organisms seen in clinical specimens, from a public health point of view it may be appropriate to treat all infected patients. Also, depending on each state's requirements, pathogenic *E. histolytica*, as well as *E. histolytica*/*E. dispar*, is generally reported to the Public Health Facility (County).

Antibody Detection. Serologic testing for intestinal disease is normally not recommended unless the patient has true dysentery; even in these cases, the titer (indirect hemagglutination as an example) may be low and thus difficult to interpret. The definitive diagnosis of intestinal amebiasis should not be made without demonstrating the organisms. For patients suspected of having extraintestinal disease, serologic tests are much more relevant (5, 19, 58). Indirect hemagglutination and indirect fluorescent-antibody tests have been reported positive with titers of $\geq 1:256$ and $\geq 1:200$, respectively, in almost 100% of cases of amebic liver abscess (19, 51). Positive serologic results, in addition to clinical findings, make the diagnosis highly probable. In the absence of STAT serologic tests for amebiasis (tests with very short turnaround times for results), the decision about the identity of the causative agent often must be made on clinical grounds and on the basis of results of other diagnostic tests such as scans.

Serologic tests based on recombinant *E. histolytica* antigens, using SREHP and the 170-kDa subunit of the galactose-specific adhesin, have been developed. More than 50% of the patients examined had become seronegative by one or both recombinant tests within 180 days of their diagnosis of amebic liver abscess. In contrast, all patients remained seropositive by a standard conventional indirect-hemagglutination test at more than 6 months after presentation (3, 5). These findings may make the recombinant-antigen tests more useful for the serologic diagnosis of amebiasis in areas of endemic infection.

Recombinant human monoclonal antibody Fab fragments specific for *E. histolytica* have also been developed. These antibodies may be applicable for distinguishing *E. histolytica* from *E. dispar* and for use in the serodiagnosis of amebiasis (48).

In a study in Bangladesh, 199 (69%) of children tested were positive at least once using the *E. histolytica* antigen detection test. Although the incidence rate was not related to baseline nutritional status, age, sex, blood group, or duration of breast feeding, it was significantly related to the baseline *E. histolytica* anti-lectin immunoglobulin IgG status of the children. Children who had recovered from a diarrheal episode with *E. histolytica*,

but not *E. dispar*, had half the chance of developing subsequent *E. histolytica*-associated diarrhea, consistent with the development of species-specific acquired immunity (18).

In another study in Brazil, 30% of a sample population was colonized with *E. histolytica*. However, no correlation between seropositivity for anti-GalNAc lectin antibody and colonization was found. These results suggest that colonization does not necessarily produce immunity to reinfection (5).

Histology. A histologic diagnosis of amebiasis can be made when the trophozoites within the tissue are identified. Organisms must be differentiated from host cells, particularly histiocytes and ganglion cells. Periodic acid-Schiff staining is often used to help locate the organisms. The organisms appear bright pink with a green-blue background (depending on the counterstain used). Hematoxylin and eosin staining also allows the typical morphology to be seen, thus allowing accurate identification. As a result of sectioning, some organisms exhibit the evenly arranged nuclear chromatin with the central karyosome and some no longer contain the nucleus.

KEY POINTS—LABORATORY DIAGNOSIS

Entamoeba histolytica

1. When routine ova and parasite examinations are ordered, three specimens (stool) should be submitted for the diagnosis of intestinal amebiasis.
2. Any examination for parasites in stool specimens must include the use of a permanent stained smear (even on formed stool).
3. Presumptive identification on a wet preparation must be confirmed by using the permanent stained smear. Without using *E. histolytica*-specific antigen detection tests, the presence of the organism(s) should be reported as follows: Trophozoites containing ingested RBCs within the cytoplasm should be reported as the true pathogen ("*Entamoeba histolytica* trophozoites present"). However, if cysts or trophozoites containing no ingested RBCs are seen, the report should indicate that the *Entamoeba* group is present ("*Entamoeba histolytica*/*E. dispar* group trophozoites and cysts present").
4. The six smears should be prepared at sigmoidoscopy but should not take the place of the ova and parasite examination.
5. Immunoassay procedures can be performed to confirm the presence of the *E. histolytica*/*E. dispar* group or can be used to differentiate pathogenic *E. histolytica* from nonpathogenic *E. dispar*. Remember

that some of these reagent kits may require fresh or frozen stools only; formalin-preserved stool or stool containing polyvinyl alcohol are not acceptable.

6. The serologic test result for antibody may *or may not* be positive in intestinal disease and is much more likely to be positive in extraintestinal disease.

Treatment

Over the years, there has been much controversy concerning the possibility of pathogenic and nonpathogenic strains of *E. histolytica* and whether every patient found to harbor this parasite should be treated. Brumpt is credited with the first suggestion that *E. histolytica* consists of two morphologically identical organisms, one pathogenic and invasive (*E. histolytica*) and the other a harmless commensal (*E. dispar*). While carriers usually harbor nonpathogenic *E. dispar*, pathogenic *E. histolytica* also may be found in these individuals. At present, tests which routinely differentiate between *E. histolytica* and *E. dispar* are not used routinely by all diagnostic laboratories. The diagnosis of *E. histolytica/E. dispar* infection is most often based on organism morphology. For this reason, in general, patients in the United States who harbor these organisms may be treated, regardless of the presence or absence of symptoms.

There are two classes of drugs used in the treatment of amebic infections: luminal amebicides such as iodoquinol or diloxanide furoate and tissue amebicides such as metronidazole, chloroquine, or dehydroemetine. Because differences in drug efficacy exist, it is important that the laboratory report for the physician indicate whether cysts, trophozoites, or both are present in the stool specimen.

Asymptomatic Infection. Patients found to have true *E. histolytica* in the intestinal tract, even if they are asymptomatic, should be treated to eliminate the organisms. Both diloxanide furoate and iodoquinol or paromomycin are available for treatment of patients who have cysts in the lumen of the gut. A study encompassing 14 years of experience of using diloxanide furoate for treating asymptomatic cyst passers in the United States indicates that the drug is safe and effective and may be particularly well tolerated in children (29). In general, these treatments are ineffective against extraintestinal disease. If the patient is passing both trophozoites and cysts, the recommended treatment is metronidazole plus iodoquinol (29).

Mild to Moderate Disease. For patients with mild to moderate disease, metronidazole (Flagyl) should be used when tissue invasion occurs, regardless of the tissue involved. Drugs directed against the lumen organisms should also be used in these instances.

Severe Intestinal Disease. Metronidazole plus one of the luminal drugs should be used for therapy.

Hepatic Disease. Metronidazole plus one of the luminal drugs should be used to treat hepatic disease. Some other combinations can also be used; some contain emetine, in which case the patient must be monitored very carefully for possible cardiotoxicity. The importance of using both luminal and tissue amebicides to treat patients with amebic liver abscess is emphasized. Asymptomatic colonization may be present with the true pathogen, *E. histolytica*. In patients treated with metronidazole (tissue amebicide), there is generally 100% clinical response to the hepatic lesions; however, failure to eliminate the organism from the bowel can lead to second bouts with invasive disease and intestinal colonization. Also, these carriers constitute a public health hazard since they are shedding infective cysts. Specific drugs and dosages are discussed in chapter 25.

Epidemiology and Prevention

Infections with *E. histolytica* are worldwide in distribution and are generally most prevalent in the tropics. In 1984, 500 million people were estimated to be infected with *E. histolytica*, and 40 to 50 million of these had extensive symptoms including colitis or extraintestinal abscesses. Prevalence figures for the United States are generally thought to be <5%. It has also been estimated that for every case of invasive disease diagnosed, there are at least 10 to 20 asymptomatic individuals excreting infective cysts.

Population groups with a higher incidence of amebiasis include recent immigrants and refugees from South and Central America and from Southeast Asia. Residents in southeastern and southwestern parts of the United States also tend to have more infections with intestinal parasites, as do groups such as patients in mental institutions.

Following broad social changes seen in the late 1960s, the open expression of homosexuality, increased numbers of sexual contacts, increased frequency of sexual activities, and anonymity of sexual partners contributed to dramatic increases in the prevalence of sexually transmitted organisms, including *E. histolytica*. Although infections with this organism are usually associated with poor sanitation and underdeveloped areas of the world, epidemiologic studies in both Europe and the United States in the 1970s documented that sexual transmission of amebiasis occurred mainly among urban homosexual men. With the increase in sexually transmitted pathogens, a number of clinical syndromes have been recognized; these clinical presentations have been grouped together and referred to as "the gay bowel syndrome." Many published reports confirm that *E. histolytica* is one of the major pathogens in the gay bowel syndrome. It is

also well known that the clinical presentations within the homosexual community often differ from those seen in the heterosexual population.

Epidemiologic evidence of sexual transmission of *E. histolytica* has grown significantly since the early 1970s, particularly in areas such as New York City and San Francisco. In San Francisco, the incidence of reported symptomatic intestinal amebiasis among homosexual men between 20 and 39 years of age has increased over 1,000% during the last 10 years. Although percentages vary, it appears that approximately 30% of urban homosexual men may be infected with *E. histolytica*, a sharp increase over the estimated rate of less than 5% seen in the general population within the United States.

Direct oral-anal contact (anilingus) is a common practice among homosexual men, leading to both fecal exposure and oral contact with a variety of intestinal pathogens. Although anilingus has often been listed as a key risk factor in potential exposure, transmission can also occur during oral-genital sex after anal intercourse has occurred. It has also been shown that active heterosexuals can acquire infection with *E. histolytica* through sexual activities that provide an opportunity for fecal-oral contamination. The key factor is not necessarily homosexuality but the frequency of sexual activity and the potential for fecal-oral contact.

It is important to remember that in earlier studies in which "*E. histolytica*" was specifically mentioned, reference is actually being made to the *E. histolytica/E. dispar* group rather than the actual pathogen, *E. histolytica*. Genotyping of *E. histolytica* isolates could serve as a tool to fingerprint individual isolates, thus helping to determine geographic origins of isolates and routes of transmission (16).

With the advent of AIDS and the subsequent modifications in sexual practices within homosexual communities, the incidence of *E. histolytica* infection is thought to be much lower than before. In recent years, the coccidian parasites *Isospora belli* and *Cryptosporidium* spp. and the microsporidia *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* have become much more of a problem in patients with AIDS.

There are certain urban areas (Mexico City, Mexico; Medellin, Colombia; and Durban, South Africa) where the incidence of invasive disease is considerably higher than in the rest of the world. Contributing factors (not well delineated) may include poor nutrition, tropical climate, decreased immunologic competence of the host, stress, altered bacterial flora in the colon, traumatic injuries to the colonic mucosa, alcoholism, and genetic factors.

Humans are the reservoir host for *E. histolytica* and can transmit the infection to other humans, primates, dogs, cats, and possibly pigs. However, contact with

sewage-contaminated water provides another route of infection; therefore, amebiasis can be considered a zoonotic waterborne infection as well as being transmitted through human-to-human transmission (43). The cyst stages are very resistant to environmental conditions and can remain viable in the soil for 8 days at 28 to 34°C, 40 days at 2 to 6°C, and 60 days at 0°C. Cysts are normally removed by sand filtration or destroyed by 200 ppm of iodine, 5 to 10% acetic acid, or boiling. The asymptomatic cyst passer who is a food handler is generally thought to play the most important role in transmission.

A colonization-blocking vaccine could eliminate *E. histolytica* as a cause of human disease, particularly since humans serve as the only significant reservoir host (46). The application of molecular biological techniques has led to the identification and structural characterization of three amebic antigens, SREHP, the 170-kDa subunit of the Gal/GalNAc binding lectin, and the 29-kDa cysteine-rich protein, which all show promise as recombinant antigen-based vaccines to prevent amebiasis (46). An immunogenic dodecapeptide derived from the SREHP molecule has been genetically fused to the B subunit of cholera toxin to create a recombinant protein capable of inducing both antiamebic and anti-cholera toxin antibodies when administered by the oral route. Continued research should lead to the development of a cost-effective oral combination "enteric-pathogen" vaccine capable of inducing protective mucosal immune responses to several important enteric diseases including amebiasis (46).

Entamoeba dispar

Until relatively recently, an unexplained aspect of the epidemiology of amebiasis was the number of asymptomatic individuals who were passing cysts but had no clinical evidence of invasive disease. Extensive work involving isoenzyme analysis and molecular techniques has demonstrated conclusively that there are two genetically distinct but morphologically identical species of what was formerly known as *E. histolytica*. After many years of debate, the species that is associated with amebiasis in humans is now classified as *E. histolytica*. The other species, which is more common but is not capable of causing invasive disease, is called *E. dispar*. Studies confirming the differences between the two organisms include direct sequencing of the PCR-amplified small-subunit rRNA gene of *E. dispar* and the design of primers for rapid differentiation from *E. histolytica*, detection of differences in the phosphoglucosyltransferases and cysteine proteinases from *E. histolytica* and *E. dispar*, molecular biology of the differences in the hexokinase isoenzyme pattern, detection of differences in the secretion of acid phosphatase, and detection of DNA sequences unique to *E. histolytica* (2, 8, 10, 14, 30, 31, 39, 41, 42, 46, 48, 53, 57).

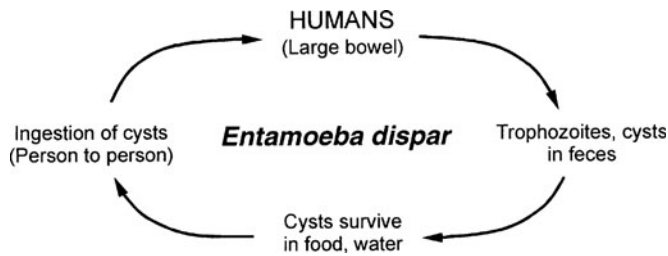

Figure 2.5 Life cycle of *Entamoeba dispar* (and *E. moshkovskii*).

Life Cycle and Morphology

The life cycle is essentially identical to that of *Entamoeba coli* or any of the other nonpathogenic intestinal protozoa, and the cyst form is the infective form for humans (Figure 2.5).

Morphology of Trophozoites (Table 2.1). Living trophozoites vary in diameter from about 12 to 60 μm . Motility has been described as rapid and unidirectional, with pseudopods forming quickly in response to the conditions around the organism; it may appear to be sporadic. Although this characteristic is often described, it is rare to diagnose these organisms on the basis of motility seen in a direct wet mount. The cytoplasm is differentiated into a clear outer ectoplasm and a more granular inner endoplasm. Based on the recent ability to culture these organisms in axenic culture systems and on light and electron microscopy studies, there may be some morphologic differences between *E. histolytica* and *E. dispar*. However, these differences would not be recognized by routine diagnostic methods such as the permanent stained smear. If organisms were seen that were consistent with *E. histolytica/E. dispar* on the permanent stained smear, the laboratory report would indicate that fact and would be written as “*Entamoeba histolytica/E. dispar*.”

When the organism is examined on a permanent stained smear (trichrome or iron hematoxylin), the morphological characteristics are easily seen. The nucleus generally has evenly arranged chromatin on the nuclear membrane and has a small, compact, centrally located karyosome. The cytoplasm is described as finely granular with few ingested bacteria or debris in vacuoles. Ingested RBCs are never seen in the trophozoites; if ingested RBCs are seen, this finding identifies the organism as *E. histolytica*, not *E. dispar*.

Morphology of Cysts (Table 2.2). Within the immature cyst, there may be two types of inclusions, a glycogen mass and highly refractile chromatoidal bars with smooth, rounded edges. As the cysts mature, nuclear

division occurs with the production of four nuclei; the cysts range in diameter from 10 to 20 μm . Usually, as the cyst matures, the glycogen disappears and chromatoidal bars may or may not be present. Cyst morphology does not differentiate between *E. histolytica* and *E. dispar*. Cyst formation occurs only within the intestinal tract; once the stool has been passed from the body, cyst formation does not occur. The one-, two-, and four-nucleated cysts are infective and represent the mode of transmission from one host to another (Figures 2.1 to 2.3).

Clinical Disease

Prior to the separation of *E. histolytica* into two distinct species (*E. histolytica* and *E. dispar*), it was suggested that some *E. histolytica* strains were pathogenic and some were not. Now that *E. dispar* has been classified as a nonpathogenic organism, totally separated from the pathogenic *E. histolytica*, treatment is usually not recommended. However, this recommendation is based on the separation of the two species by molecular means, not by morphology alone. Since few laboratories will be routinely identifying the two *Entamoeba* species to the level of *E. histolytica* or *E. dispar*, the clinician will have to decide on the basis of clinical findings whether the patient has true pathogenic *E. histolytica* or nonpathogenic *E. dispar* infection. The laboratory report will merely indicate the presence of the “*Entamoeba histolytica/E. dispar*” group.

Diagnosis

Routine Diagnostic Procedures. Infection with *E. dispar* cannot be diagnosed on the basis of morphologic criteria alone, even from the permanent stained smear. When the organism is seen in the routine ova and parasite examination, it cannot be differentiated from *E. histolytica* unless trophozoites are seen to contain RBCs in the cytoplasm, a finding that is diagnostic for *E. histolytica*. Using routine diagnostic methods and not immunoassay procedures specific for *E. histolytica*, morphologic criteria would provide characteristics of both; the laboratory report would indicate “*Entamoeba histolytica/E. dispar*.”

Immunodetection. Immunoassay procedures are available that can determine the presence of the *E. histolytica/E. dispar* group as being distinct from the rest of the *Entamoeba* species such as nonpathogenic *E. coli* or *E. hartmanni*. Other test reagents can actually separate *E. histolytica* from *E. dispar*. Most of these procedures use the ELISA or EIA formats (8). In some cases they have been found to be less sensitive than PCR (15), and in other instances they have been found equal to PCR (11). Another product is available as a cartridge format that uses an immunochromatographic strip-based detection

system for the *E. histolytica*/*E. dispar* group, *G. lamblia*, and *Cryptosporidium* spp. (51). These commercially available reagent kits require fresh or frozen stools; formalin has been found to interfere with the *Entamoeba* reagents. Any available antigen detection system should always be reviewed for compatibility with stools submitted in preservatives rather than fresh specimens.

Epidemiology and Prevention

The mode of transmission is similar to that found with other protozoa and is related to the ingestion of infective cysts in contaminated food or water. Based on differences in numbers between symptomatic patients with amebiasis (*E. histolytica*) and those who remain asymptomatic (*E. dispar*), it is obvious that many more patients are infected with nonpathogenic *E. dispar* than with pathogenic *E. histolytica*. Since travel from temperate zones to tropical and subtropical areas continues to become more common, it is necessary to consider imported amebiasis in many areas of the world where the infection is normally seen less frequently than infections with the nonpathogenic *E. dispar*.

Entamoeba moshkovskii

Entamoeba moshkovskii is found worldwide and is generally considered to be a free-living ameba. Based on microscopic morphology, this organism is indistinguishable from *E. histolytica* and *E. dispar*, except in cases of invasive disease when *E. histolytica* contains ingested RBCs. Although first isolated from sewage, *E. moshkovskii* can also be found in clean riverine sediments to brackish coastal pools. Apparently, there are some differences that separate this organism from *E. histolytica* and *E. dispar*. However, these differences pertain to physiology rather than morphology; *E. moshkovskii* is osmotolerant, can be cultured at room temperature, and is resistant to emetine (1).

Life Cycle and Morphology

The life cycle is essentially identical to that of *E. dispar*, and morphological differences are minimal to none (Figure 2.5). In wet preparations, trophozoites usually range in size from 15 to 20 μm and cysts normally range in size from 12 to 15 μm . It is important to remember that on the permanent stained smear there is a certain amount of artificial shrinkage due to dehydration; therefore, all of the organisms, including pathogenic *E. histolytica*, may be somewhat smaller (from 1 to 1.5 μm) than the sizes quoted for the wet-preparation measurements.

Morphology of Trophozoites (Table 2.1). Trophozoites do not ingest RBCs, and the motility is similar to that of both *E. histolytica* and *E. dispar* (Figure 2.3). Nuclear and cytoplasmic characteristics are very similar to those seen

in *E. histolytica*; however, trophozoites of *E. moshkovskii* do not contain ingested RBCs.

Morphology of Cysts (Table 2.2). Nuclear characteristics and chromatoidal bars are similar to those in *E. histolytica* and *E. dispar* (Figure 2.3).

Clinical Disease

Although human isolates have been found in a number of geographic areas (North America, Italy, South Africa, and Bangladesh), they have not been associated with disease. Because *E. moshkovskii* is generally accepted as being nonpathogenic, treatment is usually not recommended. However, few studies have been undertaken to actually identify infections with this organism. Unfortunately, it is quite likely that infections with this ameba have been diagnosed as being caused by *E. histolytica* and that the patients have been treated unnecessarily with antiamebic chemotherapy.

Diagnosis

Because *E. moshkovskii* can be easily confused with other amebae, particularly in a wet preparation, it is almost mandatory that the final identification be obtained from the permanent stained smear. However, without the use of molecular tools to specifically identify this organism, the results are usually reported as "*Entamoeba histolytica*/*E. dispar* group" with no mention of *E. moshkovskii*. The true prevalence of this organism may be much higher than suspected; this may also explain some of the microscopy-positive/antigen-negative results obtained when using the *Entamoeba* test kit.

Epidemiology and Prevention

The mode of transmission is similar to that for other protozoa and is related to ingestion of cysts in contaminated food or water. In areas where accurate identifications have been made, the prevalence of *E. moshkovskii* may be similar to or higher than that of *E. histolytica* (1). Using PCR techniques, in one study from Bangladesh *E. dispar*-infected children were almost twice as likely to have a mixed infection with *E. moshkovskii* (35%) than with *E. dispar* and *E. histolytica* (18%) or with *E. dispar* alone (18%) (1). Future epidemiologic studies of *E. histolytica* infection should include the capability of diagnosing all three species individually (*E. histolytica*, *E. dispar*, and *E. moshkovskii*).

Entamoeba hartmanni

Entamoeba hartmanni is found worldwide and until 1957 was generally considered to be a small race of *E. histolytica*. Consequently, the prevalence figures prior to that

time are thought to be inaccurate. It is now well accepted that this amoeba is a separate species from *E. histolytica*.

Life Cycle and Morphology

The life cycle is essentially identical to that of *E. dispar*, and morphological differences involve size, although there is even an overlap in size between the two species (Figure 2.6). In wet preparations, trophozoites range in size from 4 to 12 μm and cysts range in size from 5 to 10 μm . It is important to remember that on the permanent stained smear there is a certain amount of artificial shrinkage due to dehydration; thus, all of the organisms, including pathogenic *E. histolytica*, may be somewhat smaller (from 1 to 1.5 μm) than the sizes quoted for the wet-preparation measurements.

Morphology of Trophozoites (Table 2.1). Trophozoites do not ingest RBCs, and the motility is usually less rapid (Figures 2.2 and 2.7). The nuclear and cytoplasmic characteristics are very similar to those seen in *E. histolytica*, with two exceptions. Frequently, cysts contain only one or two nuclei, even though the mature cyst contains four nuclei. Mature cysts of *E. hartmanni* also tend to retain their chromatoidal bars, a characteristic which is often not seen in *E. histolytica*/*E. dispar*.

Morphology of Cysts (Table 2.2). Chromatoidal bars are similar to those in *E. histolytica* and *E. dispar* but are smaller and more numerous (Figures 2.2 and 2.7). Because differentiation between *E. hartmanni* and *E. histolytica*/*E. dispar* at the species level depends primarily on size, it is mandatory that laboratories use calibrated microscopes which are rechecked periodically for accuracy.

Clinical Disease

Although early studies incriminated *E. hartmanni* as a possible animal pathogen and suggested that it could

Figure 2.6 Life cycle of *Entamoeba hartmanni*, *Entamoeba coli*, *Entamoeba polecki*, *Endolimax nana*, and *Iodamoeba bütschlii*.

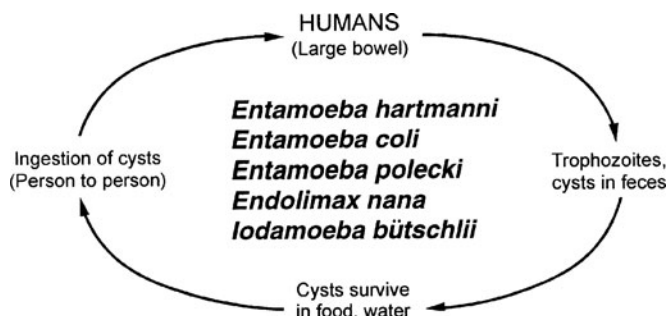

Figure 2.7 (A and B) Trophozoites of *Entamoeba hartmanni*; (C and D) cysts of *E. hartmanni*.

transform from small “nonpathogenic” strains to large “pathogenic” ones, none of this information has been adequately confirmed by subsequent studies. Because *E. hartmanni* is generally accepted as being nonpathogenic, treatment is usually not recommended.

Diagnosis

Because *E. hartmanni* can be easily confused with other small amoebae, particularly in a wet preparation, it is almost mandatory that the final identification be obtained from the permanent stained smear. Accurate measurement of organisms also confirms the tentative visual diagnosis (Table 2.3).

Epidemiology and Prevention

The mode of transmission is similar to that found with other protozoa and is related to ingestion of cysts in contaminated food or water. In areas where accurate identifications have been made, the prevalence of *E. hartmanni* is similar to that of *E. histolytica*.

Entamoeba coli

Although *Entamoeba coli* was probably recognized and described in the late 1800s, it was not until 1913 that the organism was proven to be nonpathogenic in human volunteers. *E. coli* is worldwide in distribution. Like *E. histolytica*, it tends to be more common in the warmer climates, but it has also been found in colder areas such as Alaska.

Life Cycle and Morphology

The life cycle is identical to that of *E. dispar* (Figure 2.6).

Morphology of Trophozoites (Table 2.1). Living trophozoites tend to be somewhat larger than those of *E. histolytica* or *E. dispar* and range from 15 to 50 μm (Figures 2.2 and 2.3). Motility has been described as sluggish with broad, short pseudopods. It may be extremely difficult to differentiate nonpathogenic *E. coli* from pathogenic *E. histolytica* in wet preparations. On the permanent stained smear, the cytoplasm appears granular with few to numerous vacuoles containing bacteria, yeasts, and other food materials. The nucleus has a moderately large karyosome that is frequently eccentric in position. The chromatin on the nuclear membrane is usually clumped and irregular in placement. If there are RBCs in the intestinal tract, *E. coli* may ingest these rather than bacteria; occasionally, the cytoplasm also contains ingested spores of *Sphaerita* sp. and possibly a *Giardia lamblia* cyst.

Morphology of Cysts (Table 2.2). Again, for reasons that are not specifically known, trophozoites discharge their undigested food and begin to round up prior to precyst and cyst formation. Early cysts usually contain a dense glycogen mass and may also contain chromatoidal bars, which tend to be splinter shaped and irregular. Eventually, the nuclei divide until the mature cyst, containing eight nuclei, is formed (Figures 2.2 and 2.3). Occasionally, the number of nuclei reaches 16. The cysts measure 10 to 35 μm and almost always lose their chromatoidal bars as they mature. For some reason, as the cyst of *E. coli* matures, it becomes more resistant to fixation with various preservatives. Therefore, the cyst may be seen on the wet preparation but not on the permanent stained smear. Occasionally, on trichrome smears, the cysts appear distorted and somewhat pink. This is not an indication of poor reagents or techniques but, rather, an indication that these cysts do not fix well with the routinely used preservatives. Better fixation and more detailed morphology can be obtained by heating some of the fixatives prior to specimen preservation, although for most laboratories, this is not a practical approach.

Studies suggest that after cyst ingestion, the metacyst undergoes division of the cytoplasm, thus becoming metacystic trophozoites that will grow and divide within the lumen of the intestine. It is interesting that the total number of trophozoites formed from the mature cyst usually is fewer than eight.

Diagnosis

With the exception of the mature cyst, the morphologies of *E. histolytica*, *E. dispar*, *E. moshkovskii*, and *E. coli* are similar in most of the stages. Therefore, it is very

important to examine permanent stained smears, even if a tentative identification has been made from a wet preparation examination. Specific treatment is not recommended for this nonpathogen (Table 2.3). Consequently, correct differentiation between the four species is critical to good patient care. Since the four species are acquired in the same way, it is also important to remember that all four can be found in the same patient. If few *E. histolytica*/*E. dispar* organisms are present among many *E. coli* organisms, additional searching and/or the use of species-specific immunoassay testing may be necessary to correctly identify the different species.

Epidemiology and Prevention

The mode of transmission is ingestion of cysts from contaminated food or water. Apparently, the infection is readily acquired, and in some warmer climates or areas with primitive hygiene conditions, the infection rate can be quite high. Prevention depends on adequate disposal of human excreta and improved personal hygiene (preventive measures which apply to the majority of the intestinal protozoa).

Entamoeba polecki

Entamoeba polecki was originally found in the intestines of pigs and monkeys and has also been found as a human parasite (Figure 2.6). In certain areas of the world, such as Papua New Guinea, it is the most common intestinal ameba of humans. Few cases are reported, possibly in part because the organism resembles *E. histolytica*/*E. dispar*, *E. moshkovskii*, and *E. coli*. The trophozoites resemble *E. coli* in that the cytoplasm is granular, containing ingested bacteria, and the motility tends to be sluggish (Table 2.5). The nuclear morphology is almost a composite of those of *E. histolytica*/*E. dispar*, *E. moshkovskii*, and *E. coli*. Without some of the cyst stages for comparison, it would be very difficult to identify this organism to the species level on the basis of the trophozoite alone. The cyst normally has only a single nucleus, chromatoidal material like that seen in *E. histolytica*, and frequently an inclusion body (Figure 2.8; Table 2.6). This mass tends to be round or oval and is not sharply defined on the edges. The material, which is not glycogen, remains on the permanent stained smear and stains less intensely than nuclear material or chromatoidal bars. Differentiation of this organism from either *E. histolytica* or *E. coli* is rarely accomplished on the basis of a wet preparation examination. The size on the permanent stained smear would range from 10 to 12 μm for the trophozoite and from 5 to 11 μm for the cyst. To date, there is no evidence of pathogenicity in humans; therefore, no therapy is recommended.

Table 2.5 Intestinal protozoa: trophozoites of less common amebae

Characteristic	<i>Entamoeba polecki</i>	<i>Entamoeba gingivalis</i>
Size (diam or length)	10–12 μm	5–20 μm (avg, 10–15 μm)
Motility	Usually nonprogressive, sluggish (like <i>E. coli</i>)	Multiple pseudopodia, vary from long and lobose to short and blunt
Nucleus: no. and visibility	Can occasionally be seen on a wet preparation; intermediate between <i>E. histolytica</i> and <i>E. coli</i> ; 1 nucleus	Similar to <i>E. histolytica</i> , 1 nucleus
Peripheral chromatin (stained)	Fine granules (may be interspersed with large granules) evenly arranged on membrane; chromatin may also be clumped at one or both edges of membrane	Fine granules, closely packed
Karyosome (stained)	Small, usually centrally located	Small, well defined, usually centrally located
Cytoplasm appearance (stained)	Finely granular	Finely granular
Inclusions (stained)	May contain ingested bacteria	Ingested epithelial cells and host leukocytes

Figure 2.8 (Upper) Cyst of *Entamoeba polecki* (illustration); (lower) cyst of *E. polecki* (note the large inclusion in the cytoplasm as seen in the drawing).

Entamoeba gingivalis

Entamoeba gingivalis was the first parasitic ameba of humans to be described. It was recovered from the soft tartar between the teeth. It has also been recovered from the tonsillar crypts and can multiply in bronchial mucus, thus appearing in sputum (Figure 2.9). Since morphologically it is very similar to *E. histolytica*, it is important to make the correct identification from a sputum specimen, that is, *E. gingivalis*, which is considered to be a nonpathogen, rather than *E. histolytica* from a possible pulmonary abscess. The trophozoite measures approximately 5 to 15 μm, and the cytoplasm most often contains ingested

Table 2.6 Intestinal protozoa: cysts of less common amebae

Characteristic	<i>Entamoeba polecki</i>	<i>Entamoeba gingivalis</i>
Size (diam or length)	5–11 μm	No known cyst stage
Shape	Usually spherical	
Nucleus: no. and visibility	Mature cyst, 1; may be visible in wet preparations (rarely 2 or 4 nuclei)	
Peripheral chromatin (stained)	Similar to that seen in trophozoite	
Karyosome	Similar to that seen in trophozoite	
Cytoplasm (chromatoidal bodies, glycogen, inclusions [stained])	Abundant, angular pointed ends; threadlike chromatoidals may be present; half of cysts contain spherical or ovoid “inclusion mass”	

Figure 2.9 (Upper) Trophozoite of *Entamoeba gingivalis* (illustration by Sharon Belkin); (lower three images) trophozoites of *E. gingivalis* (note the ingested polymorphonuclear leukocytes).

leukocytes (Table 2.5). On the permanent stained smear, nuclear fragments of the white cells can be seen within the food vacuoles, which are usually larger than the vacuoles seen in *E. histolytica* (Figure 2.9). This fact will help to differentiate the two, since *E. gingivalis* is the only species that ingests white cells. No cysts are formed by this species (Table 2.6). Although these amebae are most often recovered from patients with pyorrhea alveolaris, *E. gingivalis* is still considered to be nonpathogenic.

Organisms identified as *E. gingivalis* have been recovered in vaginal and cervical smears from women using intra-uterine devices; the organisms spontaneously disappeared after removal of the devices. In an unusual case, *E. gingivalis* was identified in a left upper neck nodule by fine-needle aspiration. Apparently, the patient had an increased number of amebae within the oral cavity secondary to radiation therapy. Radiation therapy may have contributed to a fistula tract between the oral cavity and the surgical incision site, thus resulting in the formation of a small inflammatory nodule in the upper portion of the neck (37). Generally, no treatment is indicated, regardless of the body site from which the organisms are recovered. The infection does suggest a need for better oral hygiene and can be prevented by proper care of teeth and gums.

Although *E. gingivalis* is considered a nonpathogen, it has been found in the oral cavities of human immunodeficiency virus type 1 (HIV-1)-infected patients with periodontal disease. Its presence was not related to the degree of immunodeficiency but to the HIV diagnosis (26). In another study, the risk for severe gingival inflammation and/or increased probing depth of the gums was not associated with the presence of *E. gingivalis* (40).

Endolimax nana

Endolimax nana is one of the smaller nonpathogenic amebae and was distinguished as a separate ameba around 1908. It is also worldwide in distribution and is seen in most populations at least as frequently as *E. coli*.

Life Cycle and Morphology

E. nana has the same stages in the life cycle as does *E. dispar*: trophozoite, precyst, cyst, and metacystic forms (Figure 2.6). The trophozoite usually measures from 6 to 12 μm , with the normal range being 8 to 10 μm (Table 2.1).

Motility has been described as sluggish and non-progressive with blunt, hyaline pseudopods. In the permanent stained smear, the nucleus is more easily seen. There is normally no peripheral chromatin on the nuclear membrane, and the karyosome tends to be large, with either a central or eccentric location within the nucleus (Figures 2.10 and 2.11). There is tremendous nuclear variation in this organism, and occasionally it

Figure 2.10 (1 to 5) Trophozoites of *Endolimax nana*; (6 to 10) cysts of *E. nana*; (11 to 13) trophozoites of *Iodamoeba bütschlii*; (14 to 16) cysts of *I. bütschlii*.

mimics *Dientamoeba fragilis* and *E. hartmanni*. The more organisms there are on the smear, the more likely it is that some of them will mimic other species of the amoebae. The cytoplasm may have small vacuoles containing ingested debris or bacteria.

Cysts usually measure 5 to 10 μm , with a normal range of 6 to 8 μm (Table 2.2). In some instances, cysts

Figure 2.11 (A and B) Trophozoites of *Endolimax nana* (note the nuclear variation in panel B); (C and D) cysts of *E. nana*.

as large as 14 μm have been seen. The cyst is usually oval to round, with the mature cyst containing four nuclei. Occasionally, very small, slightly curved chromatoidal bars are present (Figures 2.10 and 2.11). It is unusual to see the two-nucleated stage, and there are frequently both trophozoites and cysts in clinical specimens.

Diagnosis

Although *E. nana* is a nonpathogen and no therapy is recommended, it is still important to differentiate it from other amoebae, some of which are pathogenic. Because these organisms are small, the definitive diagnosis of *E. nana* may have to be made on the basis of the permanent stained smear (Table 2.3). If the original fixation is good, the cysts may be identified on the basis of the wet preparation such as the concentration sediment or flotation surface film. The four nuclear karyosomes appear very refractile in the wet preparation.

Epidemiology and Prevention

As with the other organisms that have been discussed, the mode of transmission is ingestion of the mature cysts in contaminated food or water. The cysts of *E. nana* tend to be less resistant to desiccation than do those of *E. coli*. This organism is also found in the same areas of the world as are the other amoebae, that is, in warm, moist climates and in other areas where there is a low standard of personal hygiene and poor sanitary conditions. Prevention would depend on improved personal

hygiene and an overall upgrading of sanitary conditions and waste disposal.

Iodamoeba bütschlii

Iodamoeba bütschlii, one of the nonpathogenic amebae, is also worldwide in distribution and was identified in the early 1900s. The original species name of “williamsi” probably referred to atypical cysts of *E. coli*. Although it is found in areas where the other amebae have been recovered, its incidence is not as high as that of *E. coli* or *E. nana*. One of the most striking morphological features of this organism is the large glycogen vacuole which appears in the cyst and readily stains with iodine on a wet preparation smear.

Life Cycle and Morphology

The stages within the life cycle are exactly the same as those seen with *E. nana*. The trophozoite normally varies from 8 to 20 μm and is described as having fairly active motility in a fresh stool preparation (Table 2.1). The cytoplasm is rather granular, containing numerous vacuoles with ingested debris and bacteria. In general, the vacuolated cytoplasm is more obvious than that seen in *E. nana* trophozoites. The nucleus has a large karyosome, which can be either centrally located or eccentric (Figures 2.10 and 2.12). On the permanent stained smear, the nucleus may appear to have a halo. Chromatin granules fan out around the karyosome. If the granules are on one side, the nucleus may appear to have the “basket nucleus” arrangement of chromatin, which is often found in the cyst stage. The trophozoites of *I. bütschlii* and *E. nana* may be very similar and difficult to differentiate at the species level, even on the permanent stained smear. Both organisms are considered to be nonpathogens, and *E. nana* is recovered in clinical specimens much more frequently than *I. bütschlii*.

The cysts rarely have a classic round appearance but tend to be somewhat oval (Table 2.2). The glycogen

Figure 2.12 (A) Trophozoite of *Iodamoeba bütschlii*; (B) cyst of *I. bütschlii* (note the large glycogen vacuole).

vacuole is so large that occasionally the cyst collapses on itself. Since there is no nuclear multiplication in the cyst form, the mature cyst contains only a single nucleus. The cysts measure approximately 5 to 20 μm and are rarely confused with those of other amebae (Figures 2.10 and 2.12).

Diagnosis

Although the cyst can often be identified from the wet smear preparation, particularly if the vacuole is stained with iodine, the trophozoites may be difficult to detect and identify without the permanent stained smear (Table 2.3).

Epidemiology and Prevention

The mode of transmission is ingestion of infective cysts in contaminated food or water. Prevention would depend on improved personal hygiene and sanitary conditions.

Blastocystis hominis

Blastocystis hominis, an inhabitant of the human intestinal tract, was first described in 1912. Over the years, this organism been classified as an organism related to *Blastomyces* spp., the cyst form of a flagellate, a yeast of the genus *Schizosaccharomyces*, and a member of the stramenopiles (examples are brown algae such as kelp, diatoms, slime nets, and water molds). However, currently this organism is classified as a protozoan (52). It has been suggested that it be placed in a new class, Blastocystea, and a new order, Blastocystida. Analysis of 10 stocks of *B. hominis* isolated from human stools revealed two distinct groups of organisms. Proteins of the two groups were immunologically distinct, and hybridization studies showed that the DNA contents of the two groups were different. Other studies of 61 isolates suggest that there may be four separate serologic groups (33). Further studies are under way to determine whether these groups should be classified as separate species and whether there is any epidemiologic significance related to the two groups (4, 5, 7, 22, 27, 34, 50, 59). Based on PCR-based genotype classification data, there may be as many as 12 or more different species within the genus (34). Confirmation of the existence of these species and determination of their pathogenic status may also explain why some patients are asymptomatic and some have clinical symptoms.

Life Cycle and Morphology

B. hominis is capable of pseudopod extension and retraction, reproduces by binary fission or sporulation, and has a membrane-bound central body (previously called a vacuole) that takes up 90% of the cell and functions in

Figure 2.13 Life cycle of *Blastocystis hominis*. The central-body forms (or vacuolar forms) can be seen at the bottom of the life cycle (generally seen in clinical specimens); the development of the granular forms can be seen in the left portion of the life cycle; the ameboid forms can be seen in the right portion of the life cycle. Both the granular and ameboid forms can arise from the vacuolated forms (central-body forms); multiplication can occur through binary fission (vacuolar and granular forms), budding (ameboid forms), schizogony (central-body form), and sporulation (less common in the vacuolated form). Modified from reference 60.

sexual and asexual reproduction (Figures 2.13 to 2.15; Table 2.7). Other structures with unknown function are not yet defined. The organism is strictly anaerobic, normally requires bacteria for growth, and is capable of ingesting bacteria and other debris.

The classic form that is usually seen in the human stool specimen varies tremendously in size, from 6 to 40

µm, and is characterized by a large central body, which may be involved with carbohydrate and lipid storage (visually like a large vacuole) (Figures 2.14 and 2.15; Table 2.7). The more amebic form is occasionally seen in diarrheal fluid but may be extremely difficult to recognize. Generally, *B. hominis* is identified on the basis of the more typical round form with the central body.

Figure 2.14 (A and B) Central-body forms of *Blastocystis hominis* (note the multiple nuclei around the edges, outside the central-body area).

Figure 2.15 *Blastocystis hominis* classical shape showing binary fission and the large central “vacuole.”

Table 2.7 Morphological criteria used to identify *Blastocystis hominis*

Shape and size	Other features
Organisms are generally round, measure approximately 6–40 μm , and are usually characterized by a large central body (looks like a large vacuole) surrounded by small, multiple nuclei; central-body area can stain various colors (trichrome) or remain clear	The more amebic form can be seen in diarrheal fluid but is difficult to identify; because of variation in size, may be confused with various yeast cells

Both thin- and thick-walled cysts have been confirmed. It is suggested that the thin-walled cysts are autoinfectious, leading to multiplication of the organism in the intestinal tract. The thick-walled cysts are probably responsible for external transmission via the fecal-oral route. This type of life cycle might explain the high percentage of positive carriers in many studies, showing that the percentage of patients infected with *B. hominis* is often much higher than the percentage of those infected with other intestinal protozoa (34).

Clinical Disease

When *B. hominis* is present in the absence of other pathogenic parasites, bacteria, or viruses, it may be the cause of diarrhea, cramps, nausea, fever, vomiting, and abdominal pain and may require therapy. In one recent study of patients with irritable bowel syndrome, there was a set of patients in whom the presence of *B. hominis* did not appear to be incidental (13). Possible relationships between *B. hominis* and intestinal obstruction and perhaps even infective arthritis have been suggested. In patients with other underlying conditions, the symptoms may be more pronounced (22). The incidence of this organism appears to be higher than suspected in stools submitted for parasite examination. For symptomatic patients in whom no other etiologic agent has been identified, *B. hominis* should certainly be considered a possible candidate. Other recent studies suggest that when a symptomatic *B. hominis* infection responds to therapy, the improvement probably represents elimination of some other undetected pathogenic organism (*E. histolytica*, *G. lamblia*, or *D. fragilis*) (28). Data from other geographic areas indicate that although it is commonly seen in stool samples, *B. hominis* is thought to be nonpathogenic (44). Although for a number of years the true role of this organism in terms of colonization or disease was still somewhat controversial, it is now generally considered a causative agent of intestinal disease (9, 34). It has also been suggested that ribodemes I, III, and VI may be responsible for gastrointestinal symptoms (23).

In a study of 1,216 adults, including immunocompromised patients, institutionalized psychiatric or elderly subjects, immigrants from developing countries, travelers

to developing tropical countries, and controls, the results showed a high prevalence of parasites in all the risk groups studied, and *B. hominis* was the parasite most frequently detected in each studied group. *B. hominis* showed a significant correlation with gastrointestinal symptoms only when detected in the group including subjects with a severe immunodepression (7).

Diagnosis

Routine stool examinations are very effective in recovering and identifying *B. hominis* (Table 2.7), although the permanent stained smear is the procedure of choice since the examination of wet preparations may not easily reveal the organism. If the fresh stool is rinsed in water before fixation (for the concentration method), *B. hominis* organisms, other than the cysts, are destroyed, thus possibly yielding a false-negative report (21). The organisms should be quantitated on the report form, i.e., as rare, few, moderate, or many. It is also important to remember that other possible pathogens should be adequately ruled out before a patient is treated for *B. hominis*.

Both ELISA and fluorescent-antibody tests have been developed for detection of serum antibody to *B. hominis* infections (23, 61). By using ELISA and a threshold dilution of 1/50, 27 of 30 serum samples (28 patients with no protozoan parasites other than *B. hominis*) were positive at 1/50 or higher; 42 control blood bank serum samples were all negative at 1/50 (61). A strong antibody response is consistent with the ability of this organism to cause symptoms. Also, demonstration of serum antibody production both during and after *B. hominis* symptomatic disease provides immunological evidence for the pathogenic role for this protozoan, although it may take 2 years or more with chronic infections before a serologic response is detected (23).

KEY POINTS—LABORATORY DIAGNOSIS

Blastocystis hominis

1. Although the intestinal protozoa are not quantitated routinely on the report, *B. hominis* should be quantitated (rare, few, moderate, many).

2. A minimum of three ova and parasite examinations (including the permanent stained smear) and/or some of the immunoassays should be performed to ensure that no other protozoa are found before attributing symptoms to *B. hominis*.
3. Other possible microbial agents should also be considered.
4. Remember that there is still controversy regarding quantitation of these organisms on the laboratory report form. Although there was thought to be correlation between numbers of organisms present and patient symptoms, some physicians have seen symptomatic patients in whom even small numbers of *B. hominis* are present, apparently with no other causative agents present in the stool specimen(s). For this reason, quantitation of the organisms is still recommended. However, it is important to communicate with your physician clients so that they know how you are reporting and/or quantitating this organism. The approach must be determined by each laboratory after discussions with physician clients.

Treatment

Although there is not a great deal of clinical evidence, there have been studies on the in vitro susceptibility of *B. hominis* to numerous drugs (60). At present, metronidazole (Flagyl) appears to be the most appropriate drug. Diiodohydroxyquin (Yodoxin) has also been effective, and dosage schedules for these two drugs are as recommended for other intestinal protozoa. The development of a new drug sensitivity assay may improve our ability to scientifically evaluate the activities of various drugs against this organism.

Epidemiology and Prevention

From present information, it appears that *B. hominis* is transmitted via the fecal-oral route through contaminated food or water. Although other possible modes of transmission are not defined, the incidence and apparent worldwide distribution indicate the traditional route of infection. Recent studies suggest the existence of numerous zoonotic isolates, with frequent animal-to-human and human-to-animal transmissions, and of a large potential reservoir in animals for infections in humans. Prevention would probably involve improved personal hygiene and sanitary conditions (34, 52).

Very specific prevention measures for all of the intestinal protozoa can be seen in Table 2.8. These recommendations are relevant for all organisms that can be acquired through the ingestion of food or water contaminated with fecal material.

Table 2.8 Measures for the prevention of infection with intestinal protozoa

1. Wash hands with soap and water after using the toilet and before handling food.
2. Avoid water or raw food that may be contaminated.
3. Wash and peel all raw vegetables and fruits before eating.
4. When traveling in countries where the water supply may be unsafe, avoid drinking unboiled tap water and avoid uncooked foods washed with unboiled tap water. Bottled or canned carbonated beverages, seltzers, pasteurized fruit drinks, and steaming hot coffee and tea are safe to drink.
5. If you work in a child care center where you change diapers, be sure to wash your hands thoroughly with plenty of soap and warm water after every diaper change, even if you wear gloves.

Intestinal Protozoa: Flagellates and Ciliates

Giardia lamblia

Dientamoeba fragilis

Pentatrichomonas hominis
(*Trichomonas hominis*)

Trichomonas tenax

Chilomastix mesnili

Enteromonas hominis

Retortamonas intestinalis

Balantidium coli

Giardia lamblia

The flagellate *Giardia lamblia* (syn. *Giardia intestinalis*, *Giardia duodenalis*) was first discovered by Leeuwenhoek in 1681 in his own stool specimens but was not described until 1859 by Lambl. The organism was named after Professor A. Giard of Paris and Dr. F. Lambl of Prague (6). *G. lamblia* is worldwide in distribution and apparently is more prevalent in children than in adults and more common in warm climates than in cool ones. It is the most commonly diagnosed flagellate in the intestinal tract, and it may be the most commonly diagnosed intestinal protozoan in some areas of the world.

Although various criteria, including host specificity, various body dimensions, and variations in structure, have been used to differentiate species of *Giardia*, there is still considerable debate over the appropriate classification and nomenclature regarding this group of organisms. On the basis of work by Filice related to structural variations, three groups have been proposed: amphibian *Giardia* spp. (represented by *G. agilis*), the muris group from rodents and birds (represented by *G. muris*), and the intestinalis group from a variety of mammals (including humans), birds, and reptiles (represented by *G. duodenalis*) (1). During the 1980s, the name *G. duodenalis* was supported and in the 1990s *G. intestinalis* was supported by various investigators. Despite disagreement concerning the various species names, all three continue to be used to describe this organism. Meyer prefers to use *Giardia duodenalis*, which is often followed by the name of the animal from which the organism was obtained (47). Within the United States, the term *Giardia lamblia* has been commonly used for many years and will continue to be used throughout this text to refer to those organisms found in humans and other mammals; this designation will, we hope, eliminate any confusion, since the majority of health workers are used to this name and continue to report the presence of the organism by using the term “*Giardia lamblia*” (Table 3.1).

Molecular classification methods have been helpful in understanding the pathogenesis and epidemiology of human and animal *Giardia* infections. These studies have confirmed the division of *G. lamblia* human isolates into two major genotypes (Table 3.2). Adam has proposed that genotype A be accepted as the designation for Nash group 1 (A-1), Nash group 2 (A-2), assemblage A, and the Polish isolates. Genotype B would designate Nash group 3, assemblage B,

Table 3.1 *Giardia* species^a

Species	Hosts	Morphology		Molecular data
		Light microscopy	Electron microscopy	
<i>G. agilis</i>	Amphibians	Long, slender; long teardrop-shaped median body	Focal contacts by the lateral crest of the ventral disk, the ventrolateral flange, the lateral shield, and by numerous microvillus-like appendages found along the lateral border of the trophozoite	NA ^b
<i>G. ardeae</i>	Hérons	Pear shaped; 1 or 2 transverse, claw hammer-shaped median bodies	Ventral disk and caudal flagellum similar to <i>G. muris</i>	Closer to <i>G. lamblia</i> than to <i>G. muris</i>
<i>G. lamblia</i>	Humans and many other mammals	Pear shaped; 1 or 2 transverse, claw hammer-shaped median bodies; sucking disk shorter than half the body length	Nuclei have a defined position, and fibrils perform an anchoring system; median bodies vary in number, shape, and position, are found in mitotic and interphasic trophozoites, are present in about 80% of the cells, and are not completely free in the cells	Clade with multiple genotypes
<i>G. microti</i>	Voles and muskrats	Pear shaped; 1 or 2 transverse, claw hammer-shaped median bodies	Cysts contain 2 trophozoites with mature ventral disks	Similar to <i>G. lamblia</i> genotypes
<i>G. muris</i>	Rodents	Short and rounded; small round median body		Distant from <i>G. lamblia</i>
<i>G. psittaci</i>	Psittacine birds	Pear shaped; 1 or 2 transverse, claw hammer-shaped median bodies	Incomplete ventrolateral flange, no marginal groove bordering adhesive disk	NA

^b NA, not available.

and the isolates from Belgium. He feels it may also be appropriate to use a similar designation for assemblages C through G, since these also reflect both genetic and host differences (1).

Life Cycle and Morphology

The life cycle is seen in Figure 3.1. Both the trophozoite and the cyst are included in the life cycle of *G. lamblia*. Trophozoites divide by means of longitudinal binary fission, producing two daughter trophozoites. The most common location of the organisms is in the crypts within the duodenum. The trophozoites are the intestinal dwelling stage and attach to the epithelium of the host villi by means of the ventral disk. The attachment is substantial and results in disk “impression prints” when the organism detaches from the surface of the epithelium. Trophozoites may remain attached or detach from the mucosal surface. Since the epithelial surface sloughs off the tip of the villous every 72 h, apparently the trophozoites detach at that time.

There are several hypotheses on possible mechanisms for attachment by the ventral disk; these include microtubule mediation, hydrodynamic action, contractile protein activity, and the interaction of lectins with surface-bound sugars. Because there is conflicting information, the attachment process probably depends on multiple mechanisms. A study by Katelaris et al. indicates that attachment to enterocyte-like differentiated Caco-2 cells is primarily by cytoskeletal mechanisms, which can be inhibited by interfering with contractile filaments and microtubules; attachment by mannose-binding lectin also seems to mediate binding (38).

For reasons which are not fully known, cyst formation takes place as the organisms move down through the jejunum after exposure to biliary secretions. The trophozoites retract the flagella into the axonemes, the cytoplasm becomes condensed, and the cyst wall is secreted. As the cyst matures, the internal structures are doubled, so that when excystation occurs the cytoplasm divides, thus producing two trophozoites. Excystation would normally occur in the duodenum or appropriate culture medium (Figure 3.1) (1).

Figure 3.1 Life cycle of *Giardia lamblia*.

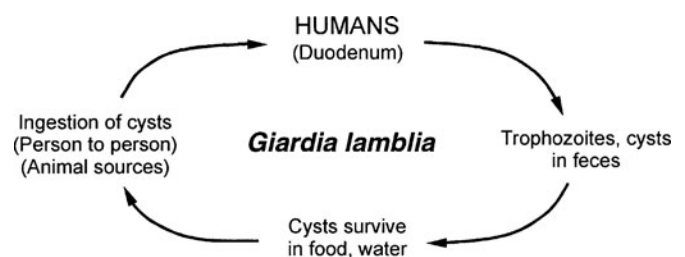

Table 3.2 *Giardia* genotypes^a

Adam designation	Nash group	Mayrhofer assemblage	Origin	Hosts
Genotype A-1	1	A (group 1)	Poland	Human, beaver, cat, lemur, sheep, calf, dog, chinchilla, alpaca, horse, pig, cow
Genotype A-2	2	A (group 2)		Human, beaver
Genotype B	3	B (groups 3 and 4)	Belgium	Human, beaver, guinea pig, dog, monkey
		C		Dog
		D		Dog
		E (or A-livestock)		Cow, sheep, alpaca, goat, pig
		F		Cat
		G		Rat

^a Adapted from references 1 and 65.

The process of encystment consists of two morphologically different stages (intracellular and extracellular) and requires approximately 16 h to complete. The extracellular phase is initiated with the appearance of cyst wall antigen on small protrusions of the trophozoite membrane, which becomes enlarged over time to form caplike structures ranging up to 100 nm in diameter. Caplike structures involved with filament growth have been detected over the entire surface of the trophozoite including the adhesive disk and flagella. Encysting cells round up, lose attachment to the substratum, and become enclosed in a layer of filaments. The internal portion includes two trophozoites with four nuclei. If methods could be found to interfere with the development of the filamentous layer of the cyst wall, regulation of viable *Giardia* cyst release from the host could be modified or eliminated (2).

Changes observed in *G. lamblia* lipids (increased fatty acid unsaturation and the accumulation of storage lipids) are consistent with parasite differentiation into a cyst stage that can survive outside the host at reduced temperatures and with reduced available nutrient resources. *G. lamblia* not only has the capacity to synthesize isoprenoid lipids de novo but also can metabolize fatty acids by the addition of double bonds (1). Studies have also shown that bile acids found in high concentrations in the small intestine enhance trophozoite survival, multiplication, and differentiation into the cyst stage (16). Results also indicate that cholesterol starvation is necessary and sufficient for the stimulation of *Giardia* encystations in vitro and probably in the intestines of mammalian hosts (44).

It has been determined that oxygen uptake rate and metronidazole sensitivity in *Giardia* cysts are greatly reduced compared with those in trophozoites. The resistance to metronidazole may be due to a change in metabolic flux away from the pyruvate ferredoxin oxireductase pathway.

However, after the induction of excystation, oxygen uptake increases exponentially during the following 30 min and metronidazole sensitivity returns within 15 min and is fully restored within 30 min (1). Excystation occurs with exposure to the contents of the proximal small intestine; the process is quite rapid. Externally, the flagella emerge through the cyst wall, followed by the entire trophozoite. Recent findings on several aspects of *Giardia* differentiation can be found in the review by Adam (1). The process is divided into three distinct parts: (i) the stimulus for encystations and the regulation of encystations-specific gene expression, (ii) the synthesis and intracellular transport of cyst wall components, and (iii) the assembly of the extracellular cell wall.

Although *Giardia* has many features of the prokaryotes (anaerobic metabolism, an enzyme that reduces oxygen directly to water, cysteine as the “keeper” of the redox balance, a plasmid, and toxin-like genes), unlike prokaryotes it also has a sophisticated, highly developed cytoskeleton, bounded nuclei, linear chromosomes capped with telomeric repeats, and telomere positional regulation of gene expression (5, 64). Studies have also clarified the pathway of formation of ethanol, one of the major end products of the fermentative metabolism of the amitochondriate protist, *G. lamblia*. In contrast to most eukaryotes, in which ethanol formation proceeds from pyruvate via acetaldehyde, the *G. lamblia* pathway starts from acetyl coenzyme A, a more distal product of extended glycolysis (53).

Morphology of Trophozoites (Table 3.3). The trophozoite is usually described as being teardrop shaped from the front, with the posterior end being pointed (Figures 3.2 to 3.4). If one examines the trophozoite from the side, it resembles the curved portion of a spoon. The concave portion is the area of the sucking disk (Figure 3.2). There are four pairs of flagella, two nuclei, two axonemes, and two slightly curved bodies called the median bodies. The

Table 3.3 Intestinal protozoa: trophozoites of flagellates

Characteristic	Shape and size	Motility	No. of nuclei and visibility	No. of flagella (usually difficult to see)	Other features
<i>Dientamoeba fragilis</i>	Shaped like amebae; 5–15 μm ; usual range, 9–12 μm	Usually nonprogressive; pseudopodia are angular, serrated, or broad lobed and almost transparent	Percentage may vary, but 40% of organisms have 1 nucleus and 60% have 2 nuclei; not visible in unstained preparations; no peripheral chromatin; karyosome is composed of a cluster of 4–8 granules	No visible flagella	Cytoplasm finely granular and may be vacuolated with ingested bacteria, yeasts, and other debris; may be great variation in size and shape on a single smear
<i>Giardia lamblia</i>	Pear shaped; length, 10–20 μm ; width, 5–15 μm	“Falling-leaf” motility may be difficult to see if organism is in mucus	2; not visible in unstained mounts	4 lateral, 2 ventral, 2 caudal	Sucking disc occupying 1/2–3/4 of ventral surface; pear-shaped front view; spoon-shaped side view
<i>Chilomastix mesnili</i>	Pear shaped; length, 6–24 μm (usual range, 10–15 μm); width, 4–8 μm	Stiff, rotary	1; not visible in unstained mounts	3 anterior, 1 in cytostome	Prominent cytostome extending 1/3–1/2 length of body; spiral groove across ventral surface
<i>Pentatrichomonas hominis</i> (<i>Trichomonas hominis</i>)	Pear shaped; length, 5–15 μm (usual range, 7–9 μm); width, 7–10 μm	Jerky, rapid	1; not visible in unstained mounts	3–5 anterior, 1 posterior	Undulating membrane extends length of the body; posterior flagellum extends free beyond end of body
<i>Trichomonas tenax</i>	Pear shaped; length, 5–12 μm (avg, 6.5–7.5 μm); width, 7–9 μm	Jerky, rapid	1; not visible in unstained mounts	4 anterior, 1 posterior	Seen only in preparations from mouth; axostyle (slender rod) protrudes beyond the posterior end and may be visible; posterior flagellum extends only halfway down body and there is no free end
<i>Enteromonas hominis</i>	Oval; length, 4–10 μm (usual range, 8–9 μm); width, 5–6 μm	Jerky	1; not visible in unstained mounts	3 anterior, 1 posterior	One side of body flattened; posterior flagellum extends free posteriorly or laterally
<i>Retortamonas intestinalis</i>	Pear shaped or oval; length, 4–9 μm (usual range, 6–7 μm); width, 3–4 μm	Jerky	1; not visible in unstained mounts	1 anterior, 1 posterior	Prominent cytostome extending approximately 1/2 length of body

Figure 3.2 *Giardia lamblia* trophozoites on the mucosal surface. (Scanning electron micrographs courtesy of Marietta Voge.)

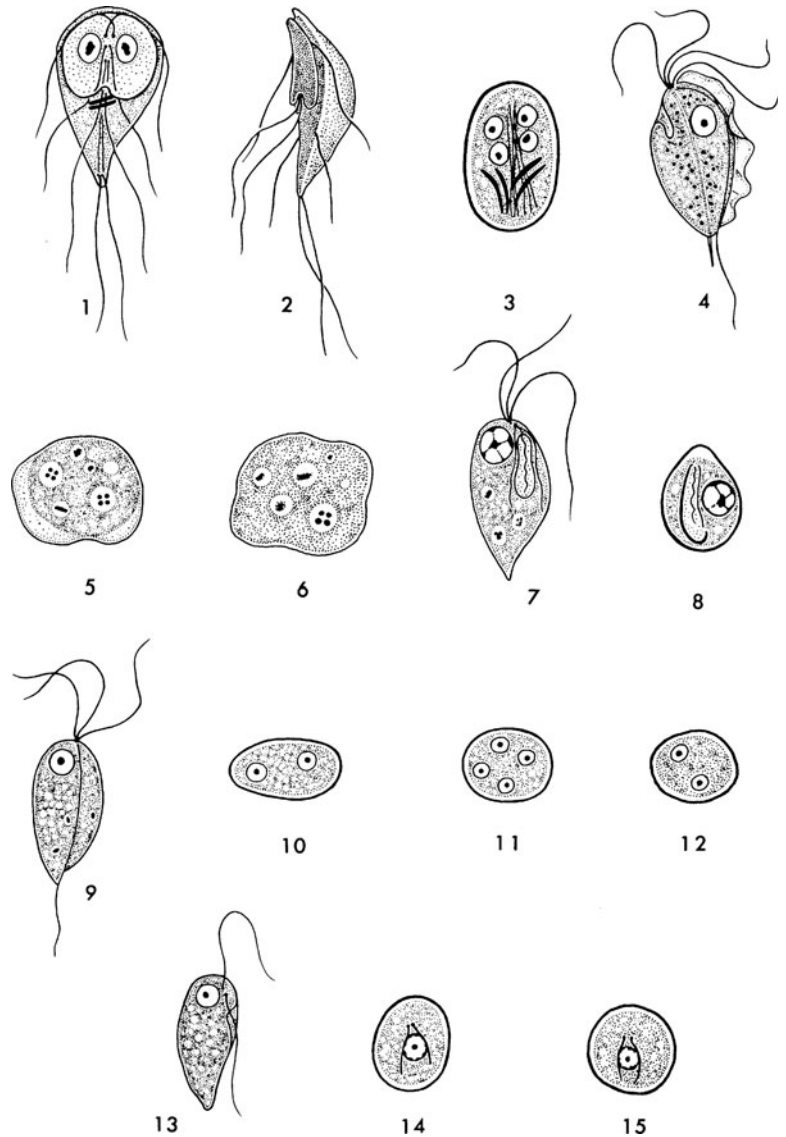

Figure 3.3 (1) Trophozoite of *Giardia lamblia* (front view); (2) trophozoite of *G. lamblia* (side view); (3) cyst of *G. lamblia*; (4) trophozoite of *Pentatrichomonas hominis*; (5) trophozoite of *Dientamoeba fragilis* (two fragmented nuclei); (6) trophozoite of *D. fragilis* (one fragmented nucleus); (7) trophozoite of *Chilomastix mesnili*; (8) cyst of *C. mesnili*; (9) trophozoite of *Enteromonas hominis*; (10–12) cysts of *E. hominis*; (13) trophozoite of *Retortamonas intestinalis*; (14 and 15) cysts of *R. intestinalis*. (Illustrations by Sharon Belkin.)

trophozoites usually measure 10 to 20 μm in length and 5 to 15 μm in width (Figures 3.2 to 3.4).

Morphology of Cysts (Table 3.4). The cysts may be either round or oval, and they contain four nuclei, axonemes, and median bodies (Figures 3.3 and 3.4). Often, some cysts appear to be shrunk or distorted, and one may see two halos, one around the cyst wall itself and one

inside the cyst wall around the shrunken organism. The halo effect around the outside of the cyst is particularly visible on the permanent stained smear. Cysts normally measure 11 to 14 μm in length and 7 to 10 μm in width.

Clinical Disease

From available data, it appears that the incubation time for giardiasis ranges from approximately 12 to 20 days.

Table 3.4 Intestinal protozoa: cysts of flagellates

Species	Size	Shape	No. of nuclei	Other features
<i>Dientamoeba fragilis</i> , <i>Pentatrichomonas hominis</i> (<i>Trichomonas hominis</i>), <i>Trichomonas tenax</i>	No cyst stage			
<i>Giardia lamblia</i>	Length, 8–19 μm (usual range, 11–14 μm); width, 7–10 μm	Oval, ellipsoidal, or may appear round	4; not distinct in unstained preparations; usually located at one end	Longitudinal fibers in cysts may be visible in unstained preparations; deep-staining median bodies usually lie across the longitudinal fibers; there is often shrinkage, and the cytoplasm pulls away from the cyst wall; there may also be a halo effect around the outside of the cyst wall because of shrinkage caused by dehydrating reagents
<i>Chilomastix mesnili</i>	Length, 6–10 μm (usual range, 7–9 μm); width, 4–6 μm	Lemon shaped with anterior hyaline knob	1; not distinct in unstained preparations	Cytostome with supporting fibrils, usually visible in stained preparation; curved fibril along side of cytostome usually referred to as “shepherd’s crook”
<i>Enteromonas hominis</i>	Length, 4–10 μm (usual range, 6–8 μm); width, 4–6 μm	Elongate or oval	1–4; usually 2 lying at opposite ends of cyst; not visible in unstained mounts	Resembles <i>E. nana</i> cyst; fibrils or flagella usually not seen
<i>Retortamonas intestinalis</i>	Length, 4–9 μm (usual range, 4–7 μm); width, 5 μm	Pear shaped or slightly lemon shaped	1; not visible in unstained mounts	Resembles <i>Chilomastix</i> cyst; shadow outline of cytostome with supporting fibrils extends above nucleus; bird beak fibril arrangement

**Figure 3.4** (A to D) Trophozoites of *Giardia lamblia*; (E and F) cysts of *G. lamblia*.

Because the acute stage usually lasts only a few days, giardiasis may not be recognized as the cause but may mimic acute viral enteritis, bacillary dysentery, bacterial or other food poisoning, acute intestinal amebiasis, or “traveler’s diarrhea” (toxigenic *Escherichia coli*). However, the type of diarrhea plus the lack of blood, mucus, and cellular exudate is consistent with giardiasis.

Although the organisms in the crypts of the duodenal mucosa may reach very high densities, they may not cause any pathology. The organisms feed on the mucous secretions and do not penetrate the mucosa as *G. muris* has been shown to do in mice, from which trophozoites have been recovered in the deeper tissues. Although organisms have been seen in biopsy material obtained from inside the intestinal mucosa, others have been seen attached only to the epithelium. For some reason, in symptomatic patients there may be irritation of the mucosal lining, increased mucus secretion, and dehydration (68).

A study by Chen et al. has demonstrated a *G. duodenalis* cysteine-rich surface protein (CRP136) that has 57%

homology to the product of the gene encoding the precursor of the sarafotoxins, a group of snake toxins from the burrowing adder that are known to cause symptoms similar to those of humans acutely infected with *Giardia* species (10). Thus, CRP136 represents the first evidence for a potential *Giardia* toxin.

Onset may be accompanied by nausea, anorexia, malaise, low-grade fever, and chills, and there may be a sudden onset of explosive, watery, foul-smelling diarrhea. Other symptoms include epigastric pain, flatulence, and diarrhea with increased amounts of fat and mucus in the stool but no blood (68). Weight loss often accompanies these symptoms. Although there is speculation that the organisms coating the mucosal lining may act to prevent fat absorption, this does not completely explain why the uptake of other substances normally absorbed at other intestinal levels is prevented. During the acute phase of giardiasis, jejunal active-antigen uptake is increased, leading to a delayed recruitment of mucosal and connective tissue mast cells. These changes may play a role in the increased incidence of hypersensitivity reactions and allergic disease associated with *Giardia* infection (31). Severe malabsorption has also been linked with isolated levothyroxine malabsorption, leading to severe hypothyroidism (54) and secondary impairment of pancreatic function (8). In both cases, treatment with metronidazole led to complete remission of symptoms. Occasionally, the gallbladder is also involved, causing gallbladder colic and jaundice. *G. lamblia* has also been identified in bronchoalveolar lavage fluid (59).

The acute phase is often followed by a subacute or chronic phase. Symptoms in these patients include recurrent, brief episodes of loose, foul-smelling stools; there may be increased distention and foul flatus. Between passing the mushy stools, the patient may have normal stools or may be constipated. Abdominal discomfort continues to include marked distention and belching with a rotten-egg taste. Chronic disease must be differentiated from amebiasis; disease caused by other intestinal parasites such as *Dientamoeba fragilis*, *Cryptosporidium* spp., *Cyclospora cayetanensis*, *Isospora belli*, and *Strongyloides stercoralis*; and inflammatory bowel disease and irritable colon. On the basis of symptoms such as upper intestinal discomfort, heartburn, and belching, giardiasis must also be differentiated from duodenal ulcer, hiatal hernia, and gallbladder and pancreatic disease.

Ophthalmic examinations were performed on 141 children with active or past giardiasis. Salt-and-pepper retinal changes (with normal electroretinographic findings) were diagnosed in 28 (19.9%) of the children, all of whom were consistently younger than those with normal retinas. Although these findings indicate that asymptomatic, nonprogressive retinal lesions were particularly

common in younger children with giardiasis, the risk does not seem to be related to the severity of the infection, its duration, or the use of metronidazole but may reflect a genetic disposition (13).

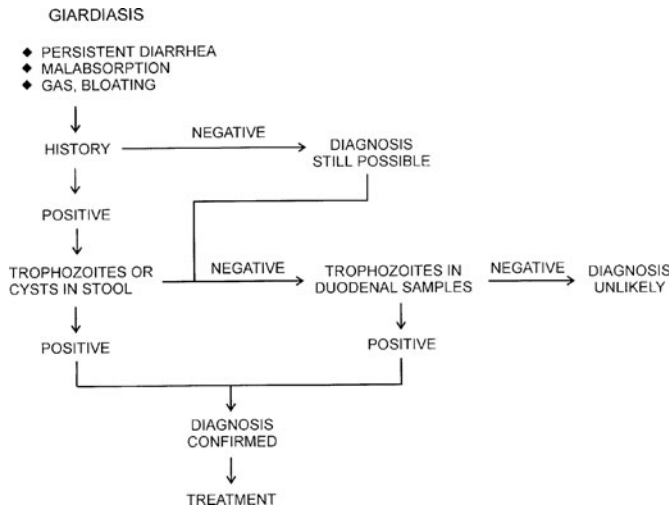

Recent studies document antigenic variation with surface antigen changes during human infections with *G. lamblia*; although the biological importance of this work is not clear, it suggests that this variation may provide a mechanism for the organism to escape the host immune response (48). The variant-specific surface proteins are a family of related, highly unusual proteins that cover the surface of the organism; the variant-specific surface proteins are resistant to the effects of intestinal proteases, thus allowing the parasites to survive in the protease-rich small intestine. Antigenic variation at the surface membrane of trophozoites occurs frequently; one would suspect that the higher the rate of change, the more likely that a chronic infection would be seen. However, certain surface antigens that allow the organisms to survive better in the intestinal tract may not be immunologically selected.

Although patients with symptomatic giardiasis usually have no underlying abnormality of serum immunoglobulins, a high incidence of giardiasis occurs in patients with immunodeficiency syndromes, particularly in those with common variable hypogammaglobulinemia (19). Giardiasis was the most common cause of diarrhea in these patients and was associated with mild to severe villous atrophy. Successful treatment of giardiasis led to symptomatic cure and improvement in mucosal abnormalities, with the exception of nodular lymphoid hyperplasia.

With the advent of AIDS, there was speculation that *G. lamblia* might be an important pathogen in this group of individuals. However, clinical findings to date do not seem to confirm this possibility (56). Despite a suppressed immune system in AIDS patients, the immune response to *Giardia* does not seem to be very different from that seen in non-AIDS patients (19). It does not appear that drugs such as corticosteroids, cyclosporin A, and other immunosuppressive agents of cell-mediated immunity affect the outcome of *Giardia* infections in humans.

Diagnosis

Routine Diagnostic Procedures. Routine stool examinations are normally recommended for the recovery and identification of intestinal protozoa (11). However, in the case of *G. lamblia*, because the organisms are attached so securely to the mucosa by means of the sucking disk, a series of even five or six stool samples may be examined without recovering the organisms. The organisms also tend to be passed in the stool on a cyclical basis. The Entero-Test

Algorithm 3.1 Giardiasis. Fecal immunoassay kits can be used on human stool specimens to confirm the presence of *Giardia* spp. Currently available reagents can be used with fresh, frozen, or preserved specimens (not those containing polyvinyl alcohol). If fluorescent testing is performed, the specimen should not be frozen (the actual organisms are disrupted during the freeze-thaw cycle); however, fresh or preserved specimens are acceptable. Check with each manufacturer for compatibility of the fixative with the proposed test; not all fixatives are compatible with all types of fecal immunoassays.

capsule can be helpful in recovering the organisms, as can the duodenal aspirate. Although cysts can often be identified on the wet stool preparation, many infections may be missed without the examination of a permanent stained smear (11, 12). If material from the string test (Entero-Test) or mucus from a duodenal aspirate is submitted, it should be examined as a wet preparation for motility; however, motility may be represented by nothing more than a slight flutter of the flagella because the organism is caught up in the mucus. After diagnosis, the rest of the positive material can be preserved as a permanent stain.

Fluoroscopy may reveal hypermotility at the duodenal and jejunal levels, and X rays may reveal mucosal defects. If the cause is *G. lamblia*, the organisms may be recovered in a series of stool examinations. However, because giardiasis may not produce any symptoms at all, demonstration of the organism in symptomatic patients may not rule out other possibilities such as peptic ulcer, celiac disease of some other etiology, strongyloidiasis, and possibly carcinoma. Refer to Algorithm 3.1 for detailed information.

Antigen Detection. The development of fecal immunoassays for the detection of *Giardia* and/or *Cryptosporidium* antigen in stool has dramatically improved the sensitivity over that seen with the routine ova and parasite examination and/or modified acid-fast stains (46) (Table 3.5).

Procedures involving the enzyme-linked immunosorbent assay (ELISA) have been developed to detect *Giardia* antigen in feces. The ELISA is at least as sensitive as microscopic wet examinations (3, 4, 20, 21). Fluorescent methods with monoclonal antibodies have also proven to be extremely sensitive and specific in detecting *G. lamblia* in fecal specimens (17, 20, 21, 24). A number of studies have compared the newer immunoassay products, with excellent and comparable results (3, 4, 17, 20–24, 37, 58). Other products are available as a cartridge format that uses an immunochromatographic strip-based detection system for *G. lamblia* and/or *Cryptosporidium* spp. (23, 37). Another cartridge format is used to test for the *Entamoeba histolytica/Entamoeba dispar* group, *Giardia lamblia*, and *Cryptosporidium* spp. This commercially available reagent kit requires fresh or frozen stools, since formalin interferes with the *Entamoeba* reagents (22). Any available antigen detection system should always be reviewed for compatibility with stools submitted in preservatives rather than fresh specimens. There are limitations when using kits that include organisms in the genus *Entamoeba*. However, commercial reagent kits for the detection of *Giardia* and *Cryptosporidium* can be used with formalin-based stool preservatives, as well as fresh or frozen specimens. Many of these cartridge format tests are now available that detect both *G. lamblia* and *C. parvum*, provide an answer within 10 min, and are equal to or better than other immunoassays in their sensitivity and specificity. Many of these newer methods are being used to test patients suspected of having giardiasis or those who may be involved in an outbreak situation. The detection of antigen in stool or visual identification of organisms by using monoclonal antibody reagents indicates current infection. With the increase in *Giardia* infections and awareness of particular situations such as nursery school settings, these detection assays are rapid and reliable immunodiagnostic procedures. However, it has been well documented that the use of a fecal immunoassay does not eliminate the need to analyze multiple stool specimens for sensitive detection of *G. lamblia* (30).

Antibody Detection. Unfortunately, serodiagnostic procedures for giardiasis do not yet fulfill the criteria necessary for wide clinical use, particularly since they may indicate either past or present infection (19). Studies comparing serum antibody responses to giardiasis in symptomatic and asymptomatic patients revealed that antigen recognition by anti-parasite immunoglobulin M (IgM), IgA, IgG1, and IgG3 of these patients, determined by immunoblotting, was heterogeneous and revealed only minor differences in the responses of the two groups (19, 57). In a study investigating the secretory immune response to membrane antigens during giardiasis in

humans, the saliva samples showed a heterogeneous response to the membrane fraction when they were assayed by immunoblotting. Among the antigens recognized by patient saliva samples, those of 170, 105, 92, 66, 32, 29, and 14 kDa stood out since they were not recognized by saliva samples from healthy individuals. These findings may become more relevant in future studies of protection from or diagnosis of *G. lamblia* infections (52). Since *Giardia* trophozoites rarely invade the tissues or stimulate the systemic immune response, serodiagnostic assays fail to show differences in serum antibody responses between symptomatic and asymptomatic patients and are not recommended.

Histology. Trophozoites are detectable in the duodenum and proximal jejunum of infected patients. Although there has been some suggestion of mucosal invasion by this parasite, mucosal invasion has generally been found in areas where necrosis or mechanical trauma was present. In reviewing descriptions of general mucosal appearances, there can be a spectrum of change from normal to almost complete villous atrophy, with a greater density of inflammatory infiltrate in the lamina propria when villous atrophy is present. Apparently, patients with giardiasis also have reduced mucosal surface areas compared with controls, and the degree of abnormality correlates with indices of malabsorption. Enumeration of lamina propria plasma cells of different immunoglobulin classes reveals no clear patterns, however, suggesting that *Giardia* infection initially provokes IgM and IgE synthesis, with relative suppression of local IgA production.

Histologic changes in the mucosal architecture in immunodeficient patients with giardiasis also range from mild to severe villous atrophy. Nodular lymphoid hyperplasia has been reported, as well as mixed lesions. Again, the amount of villous damage seems to correlate with the degree of malabsorption. It appears that giardiasis produces a more severe degree of villous damage in patients with hypogammaglobulinemia. Giardiasis does not appear to be an important pathogen in patients with AIDS, although the infection has certainly been found in this group and in homosexual men.

In a study of 567 patients with giardiasis, a retrospective analysis of cases reported between 1988 and 1994 was performed. On histologic slides, trophozoites were found in duodenal (82.5%) and jejunal (2.1%) mucosa and also in gastric antral (8.7%) and ileal (12.1%) mucosa but rarely in the colon (0.4%). An entirely normal light-microscopic appearance of the duodenal mucosa was found in 462 patients (93.6%). Mild villous shortening and mild inflammation of the lamina propria were observed in the duodenal mucosa in 3.7% of the patients. Since the histology of the small-bowel mucosa is inconspicuous in

the majority of patients with giardiasis, careful review of biopsy specimens must be performed (49).

KEY POINTS—LABORATORY DIAGNOSIS

Giardia lamblia

1. Even if a series of three stool specimens is submitted and examined correctly using the ova and parasite examination, the organisms may not be recovered and identified.
2. Motility on wet preparations may be difficult to see because the organisms may be caught up in mucus. Do not use the ethyl acetate step in the concentration procedure if the specimen contains a lot of mucus.
3. Any examination for parasites in stool specimens must include the use of a permanent stained smear (even on formed stool).
4. Duodenal drainage (centrifuge and examine sediment; do not use the ethyl acetate step) and/or the use of the Entero-Test capsule may be very helpful in organism recovery. However, this technique does not take the place of the ova and parasite examination.
5. It has been well documented that the use of a fecal immunoassay (enzyme immunoassay, fluorescent-antibody assay, or rapid cartridge) does not eliminate the need to analyze multiple stool specimens for sensitive detection of *G. lamblia*; two different stool samples are recommended unless the first specimen is positive.
6. When performing the enzyme immunoassay, make sure that the wells are washed thoroughly according to directions; in order to avoid false-positive results, do not skip any wash steps. Make sure that the stream of buffer goes directly into the wells. Also, make sure that you use a wash bottle with a small opening, so that you have to squeeze the bottle to get the fluid to squirt directly into the wells.
7. When the directions tell you to “slap” the tray down onto some paper towels to remove all the fluid, make sure you slap it several times. Don’t be too gentle; the cups will not fall out of the holder.
8. It is recommended that the fluorescent-antibody assay procedures be performed using centrifuged stool ($500 \times g$ for 10 min); prepare thin (rather than thick) smears and perform the rinse step *gently*. Remember that not all clinical specimens will provide the 3+ to 4+ fluorescence that we often see in the positive control. Also, from time to time, you may see fluorescing bacteria and/or some yeast in certain patient specimens. This is not particularly common, but the shapes can be distinguished from *Giardia* cysts and/or *Cryptosporidium* oocysts.

9. When using the cartridge (lateral-flow) test, if the stool is too thick, addition of reagents will not thin it out enough. If the specimen poured into the well remains too thick, the fluid will not flow up the membrane. If your specimens arrive in fixative and there is no fluid at the top of the vial overlaying the stool, this means that the vial may have been overfilled with stool. These specimens will have to be diluted with the appropriate diluent before being tested. It is always important to see the control line indicated as positive all the way across the membrane, not just at the edges. *A positive test result may be much lighter than the control line; this is normal.* At the cutoff time to read the result, any color visible in the test area should be interpreted as a positive. Do not read/interpret the results after the time indicated in the directions; you may get a false-positive result.

Treatment

The incidence of giardiasis worldwide may be as high as 1 billion cases. If giardiasis is diagnosed, the patient should be treated (Table 3.6); more complete dosage information can be found in chapter 25. Current recommended treatments include the nitroheterocyclic drugs tinidazole, metronidazole, and furazolidone, the substituted acridine quinacrine, and the benzimidazole albendazole. Paromomycin is also used, as is nitazoxanide. Treatment failures have been reported with all the common anti-giardial agents, and resistance to these drugs has been demonstrated in the laboratory. Clinical resistance has been reported, and includes situations in which patients have failed to respond to both metronidazole and albendazole treatments (25, 69). Metronidazole is not recommended for pregnant women; although not well absorbed and not highly effective, paromomycin may be used to treat giardiasis in pregnancy (25). Tinidazole has also been used and has proven more effective than metronidazole as a single dose (25). Furazolidone is another option, but it has been reported to be mutagenic and carcinogenic. Within the United States, metronidazole is the only member of the nitroimidazole class available to treat giardiasis. Additional information can be found in chapter 25. Metabolic pathways related to anaerobic metabolism (25) and the presence of phosphatidylglycerol and other glycerol-based phospholipids (26) may also serve as potential targets for chemotherapy of giardiasis.

A new and simple colorimetric method has been determined for determining in vitro activity against *G. lamblia*. The microtiter plate assay is based on the nucleoside hydrolase activity released from the organism by lysis. Action of the nucleoside hydrolase on the substrate analog, 4-nitrophenyl β -D-ribofuranoside, gives rise to a colored

product which can be determined by the change in absorbance. Values obtained using this method for metronidazole, tinidazole, and furazolidone were consistent with published values. This simple method, which does not involve radioisotopes or complex instrumentation, provided a convenient method for screening potential anti-giardial agents (36).

Wheat germ (WG) agglutinin inhibits excystation and trophozoite growth in vitro, as well as reducing cyst passage in mice. In a double-masked, placebo-controlled study of dietary supplementation with WG, there appeared to be no clinically important differences between the two groups. However, symptoms appear to have resolved more rapidly in those taking WG in addition to metronidazole, and the WG was well tolerated in both the symptomatic and asymptomatic groups. Thus, in combination with antiprotozoal drugs, WG may be able to modify symptomatic giardiasis (28).

In the absence of a parasitologic diagnosis, the treatment of suspected giardiasis is a common question with no clear-cut answer. The approach depends on the alternatives and the degree of suspicion of giardiasis, both of which vary among patients and physicians. However, it is not recommended that treatment be given without a good parasitologic workup, particularly since relief of symptoms does not allow a retrospective diagnosis of giardiasis; the most commonly used drug, metronidazole, targets other organisms besides *G. lamblia*.

Another question involves treatment of asymptomatic patients. Generally, it is recommended that all cases of proven giardiasis be treated because the infection may cause subclinical malabsorption, symptoms are often periodic and may appear later, and a carrier is a potential source of infection for others. Certainly, in areas of the world where infection rates, as well as the prospect of reinfection, are extremely high, the benefit-per-cost ratio would also have to be examined.

Epidemiology and Prevention

Transmission is by ingestion of viable cysts. Although contaminated food or drink may be the source, intimate contact with an infected individual may also provide the infection mechanism (33, 41, 55, 60, 70). This organism tends to be found more frequently in children or in groups that live in close quarters (14, 40). Often, there are outbreaks due to poor sanitation facilities or breakdowns as evidenced by infections of travelers and campers (42, 43). There is also an increase in the prevalence of giardiasis in the male homosexual population, probably because of anal and/or oral sexual practices (25).

Although seasonal patterns have been identified for some infectious diseases, limited information is available for giardiasis. Some data suggest an association with the cooler, wetter months of the year; this is not surprising if

Table 3.6 Recommendations for therapy for giardiasis^a

Clinical picture	Drug and duration of treatment	Side effects
Symptomatic infection, USA		
Adult and pediatric	Metronidazole, 5–7 days	Headache, vertigo, nausea, metallic taste, urticaria; disulfiram-like reaction with alcohol ingestion; rare side effects include pancreatitis, central nervous system toxicity, reversible neutropenia, peripheral neuropathy, T-wave flattening with prolonged use; mutagenic, carcinogenic?
Alternatives	Furazolidone, 7–10 days	Nausea, vomiting, diarrhea; brown discoloration of urine; disulfiram-like reaction with alcohol ingestion; reacts unfavorably with monoamine oxidase inhibitors; mild hemolysis in glucose 6-phosphate dehydrogenase deficiency; carcinogenic?
	or quinacrine, 5–7 days	Nausea and vomiting, dizziness, headache; yellow/orange discoloration of skin, mucous membranes; rare side effects include toxic psychosis
	or albendazole, 5–7 days	Anorexia, constipation; rare side effects include reversible neutropenia and elevated liver function tests; teratogenic?
Symptomatic infection, non-USA		
Adult and pediatric	Tinidazole (single dose) or ornidazole (single dose)	As for metronidazole As for metronidazole
Pregnancy		
First trimester	Paromomycin, 5–10 days	Ototoxicity and nephrotoxicity with systemic administration
Second and third trimesters	Paromomycin, 5–10 days or metronidazole, 5–7 days	
Resistant infection or relapse	Drug of different class or combination nitroimidazole plus quinacrine, 2 wk or more	See above

^a Adapted from references 1, 14, 25, 68, and 69.

one considers the issue of environmental conditions advantageous to cyst survival.

It has been documented that certain occupations may place an individual at risk for infection; such at-risk individuals include sewage and irrigation workers, who may become exposed to infective cysts. In situations where young children are grouped together, such as nursery schools, there may be an increased incidence of exposure and subsequent infection of both children and staff.

Most experts agree that the single most effective practice that prevents the spread of infection in the child care setting is thorough handwashing by the children, staff, and visitors. Specific guidelines can be found in Table 3.7. Rubbing the hands together under running water is the most important part of washing away infectious organisms. Premoistened towelettes or wipes and waterless hand cleaners should not be used as a substitute for washing hands with soap and running water. These guidelines are not limited to giardiasis but include all potentially infectious organisms.

The possible association between gastric acidity and giardiasis has been debated for some time. Evidence indi-

cates that decreased gastric acid production may predispose people to *Giardia* infection. It is thought that normal gastric acidity acts as a barrier to the establishment of an infection; patients who have had a gastrectomy are prone to *Giardia* infection. Although achlorhydria is associated with blood group A and some evidence suggests that members of this group are more susceptible to giardiasis, subsequent evidence has not confirmed this information. Since reduction in gastric acid also occurs as a result of malnutrition, these factors may be linked and, as a group, increase the susceptibility to infection with this organism. This link between malnutrition and giardiasis may also be explained by the impairment of the host immune system.

The issue of whether breast milk modifies *Giardia* infection has also been discussed in terms of different interpretations of the results. A lower incidence of giardiasis in children younger than 6 months may be related to an association with breast-feeding and some protection against infection via secretory IgA; however, the lower incidence may also be related to decreased exposure to *Giardia* organisms in breast-fed infants.

Giardiasis is one of the more common causes of traveler's diarrhea and has been recorded in all parts of the world. It has also been speculated that visitors in areas where *Giardia* infections are endemic are more likely to present with symptoms than are individuals who live in the area; this difference is most probably due to the development of immunity of residents from prior and possibly continued exposure to the organism.

There have been a number of outbreaks attributed to either resort or municipal water supplies in Oregon, Colorado, Utah, Washington, New Hampshire, and New York (25, 41, 55, 60, 70). High rates of infection were also reported for hikers and campers who drank stream water. Because some of these areas were remote from human habitation, infected wild animals, especially beaver, are suspected (18).

During the past few years, this infection has received much publicity. With increased travel, there has been a definite increase in symptomatic giardiasis within the United States (2). Various surveys show infection rates of 2 to 15% in various parts of the world.

Because of the potential for wild-animal and possibly domestic-animal reservoir hosts, measures in addition to personal hygiene and improved sanitary measures have to be considered (17). Iodine has been recommended as an effective disinfectant for drinking water, but it must be used as directed (71, 72). Filtration systems have also been recommended, although they have certain drawbacks, such as clogging.

Water Testing. Over the past few years, concern over safe drinking water has increased, and these issues have

Table 3.7 Guidelines for hand washing

Children

- When they arrive at the child care setting
- Immediately before and after eating
- After using the toilet or having their diapers changed
- Before using water tables
- After playing on the playground
- After handling pets, pet cages, or other pet objects such as toys
- Whenever hands are visibly dirty
- Before going home

Staff, visitors

- When they arrive at the child care setting
- Immediately before handling food, preparing bottles, or feeding children
- After using the toilet, assisting a child in using the toilet, or changing diapers
- After contact with a child's body fluids, including wet or soiled diapers, runny noses, spit, and vomit
- After handling pets, pet cages, or other pet objects such as toys
- Whenever hands are visibly dirty or after cleaning up a child, the room, bathroom items, or toys
- After removing gloves for any purpose (if gloves are worn, hands should be washed immediately after the gloves are removed, even if the hands appear to be clean; use of gloves alone will not prevent contamination of hands or spread of organisms and should not be considered a substitute for handwashing)
- Before giving or applying medication or ointment to a child or self
- Before going home

Table 3.8 Questions for consideration when testing well water

-
1. Are other members of your family or users of your well water ill?
(If yes, the well water may be a source of infection.)
 2. Is your well located at the bottom of a hill or is it considered shallow?
(If either of these is true, runoff from rainwater or floodwater may be draining into the well, causing contamination.)
 3. Is your well in a rural area where animals graze?
(Well water can be contaminated with animal waste seepage contaminating the groundwater. This can occur if the well has cracked casings, is poorly constructed, or is too shallow.)
-

led to the development of a new industry related to water treatment and testing. Untreated surface water is more likely than groundwater to contain organisms, because of the possibility of direct contamination with animal feces, treated and untreated human sewage, or fecal runoff from adjacent land after heavy rain or snow melt. Wells that have been poorly located, constructed, or damaged have also been implicated in outbreaks. Specific points to consider when testing well water are listed in Table 3.8; because specific testing for *Giardia* is difficult and expensive, the well water can also be tested for fecal coliforms as an indicator of fecal contamination. In some areas of the world, the percent positivity for water supplies can be very high for both *Cryptosporidium* and *Giardia* in both raw water and treated water samples (40).

The conventional filtration process used by most surface water treatment plants usually includes several steps: coagulation-flocculation, sedimentation, and filtration. During the first step, a chemical coagulant is added to the water to cause small suspended particles to stick together to form larger particles (flocculation), which either settle to the bottom (sedimentation) or are removed by filtration, primarily through fine sand. The coagulation-flocculation step is critical for successful removal of chlorine-resistant protozoa (1 to 20 μm in size), which could slip through the 50- to 70- μm spaces between grains of sand in a water treatment filter. Unfortunately, there are a number of variables that influence adequate filtration (amount of coagulant added, degree of mixing of coagulant with water, and changes in raw water pH, temperature, or turbidity). Conventional water filtration should trap nearly all protozoan parasites, including *Giardia* and *Cryptosporidium*, if appropriate procedures are followed (7).

Environmental sampling methods were originally developed to assist in the investigation of suspected waterborne outbreaks of infection. The sample volumes generally recommended are 100 liters for source water and 1,000 liters or more for finished water. The usual

procedure involves filtration through 1- μm polypropylene filter cartridges or fiberglass-resin cartridges. The filters are then eluted in a laboratory with detergent solutions, and recovered particulates are concentrated by centrifugation. A flotation purification step using density gradients is then used to separate the organisms from inorganic materials and debris. Currently, the most commonly used method for examining purified material for protozoa is an antibody-based immunofluorescence assay. This approach has several limitations, including the lack of information on the infectivity or viability of cysts or oocysts; the lack of indication of the host species or origin of the organisms; the chance of false identification of algal or other protozoal species; poor recovery efficiency; the labor-intensive procedures; and the need for skilled microscopists. It also appears that different organism numbers from the same water source can be attributed to method artifact rather than true differences in counts (50). A newer method for the determination of *Giardia* cyst viability in environmental and fecal samples involves fluorogenic dye staining and differential interference contrast microscopy (62). This method has proved significantly better than the routine counting methods being used.

Newer methods that have been tried include a portable differential continuous-flow centrifuge for concentration of *Cryptosporidium* oocysts and *Giardia* cysts from large volumes of water (72). The effect of electroporation (very short pulses of high-voltage electricity) alone and in combination with various chemicals has been examined. While electroporation had a minor effect on oocyst and cyst survival, the combination of electrical and chemical treatment produced superior inactivation, particularly when chlorine, hydrogen peroxide, or potassium permanganate was used (29). Additional kinetic and optimum treatment combinations continue to be developed. The use of immunomagnetic beads to separate *Giardia* cysts from complex matrixes of environmental surface waters followed by DNA release and PCR amplification of the target giardin gene has improved the reliability of detection of *Giardia* with increased sensitivity (45).

Studies of the epidemic and endemic seroprevalence of antibodies to *Cryptosporidium* and *Giardia* in residents of three communities with different drinking water supplies were undertaken to review possible differences or similarities (34). The findings were consistent with a lower risk of exposure from drinking water obtained from deep well sources and increased seropositivity associated with an outbreak situation. Although intriguing associations were found between seroprevalence, outbreak-related serologic data, and patterns of parasite contamination of drinking water, further studies are required to validate this approach to risk assessment of waterborne parasitic infections at the community level.

Phagocytosis of *Giardia* cysts by hemocytes of the Asian freshwater clam, *Corbicula fluminea*, has been documented, and the mean number of cysts ingested per hemocyte increased significantly over time. These findings may result in this biological system being used to serve as an indication of contamination of wastewaters and agricultural drainage with *Giardia* cysts (27). Also, it is well known that rotifers thrive in environments such as wastewater and domestic sewage; they have been found to ingest *Giardia* cysts in an artificial setting. If this finding is consistent with results from natural environmental studies, perhaps the information will further explain the environmental dispersion of the cysts and suggest how this dispersion could be curtailed (63).

Characterization of *Giardia* Isolates. Isoenzyme studies, designed primarily to assist in organism identification and classification, have also provided additional information regarding pathogenicity, implication in waterborne outbreaks, and human disease. In one study in which isoenzyme patterns of 32 *Giardia* isolates obtained from both humans and animals were examined, there was no obvious correlation between clinical symptoms and isoenzyme patterns. Isolates from asymptomatic individuals were found in the same zymodemes (isoenzyme groups) as were isolates from symptomatic hosts. This study also confirmed previous observations regarding genetic heterogeneity and demonstrated significant differences between isolates from within a single region and other widely separated geographic locations (1). Australian data on two *Giardia* demes indicated that both appeared to be pathogenic and were derived from children with similar chronic symptoms (64).

Various studies have published data suggesting that zoonotic transmission between humans and animals is, at times, more likely or less likely to occur (65). One study of canine and human isolates indicated that zoonotic

transmission of *Giardia* between humans and dogs does not occur frequently in these communities (32). Data also suggest that *Giardia* isolates of human and rabbit origins do not have strict host specificity and that cross-transmission may occur (1).

Dientamoeba fragilis

Dientamoeba fragilis was first seen in 1909 but was not described until 1918. In 1940, Dobell recognized the close morphologic similarities between *D. fragilis* and *Histomonas meleagridis*, the ameboflagellate parasite of turkeys. A key scientific advance was made in 1934 when Tyzzer reported that *H. meleagridis* is transmitted in the eggs of *Heterakis*, the cecal worm of chickens and turkeys, a fact that has relevance to the life cycle of *D. fragilis* (6). On the basis of electron microscopy studies, *D. fragilis* has been reclassified as an ameboflagellate rather than an amoeba and is closely related to *Histomonas* and *Trichomonas* spp. (35). It has a cosmopolitan distribution, and past surveys demonstrate incidence rates of 1.4 to 19%. Much higher incidence figures have been reported for mental institution inmates, missionaries, and Native Americans in Arizona. *D. fragilis* tends to be common in some pediatric populations, and incidence figures are higher for patients younger than 20 years in some studies. Currently, it is in the phylum Parabasala, class Trichomonadea, family Trichomonadidae, and possibly the subfamily Trichrichomonidinae. This classification will probably undergo change in the near future.

Life Cycle and Morphology

The life cycle and mode of transmission of *D. fragilis* are not known, although transmission via helminth eggs such as those of *Ascaris* and *Enterobius* spp. has been postulated (35) (Figure 3.5). The cyst stage has not been confirmed to date (Tables 3.3 and 3.4).

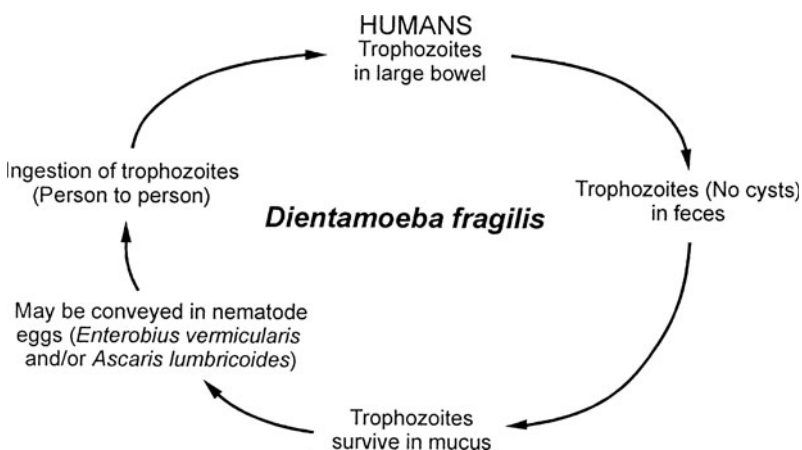

Figure 3.5 Life cycle of *Dientamoeba fragilis*.

Figure 3.6 Trophozoites of *Dientamoeba fragilis*. (Illustration by Sharon Belkin.)

The trophozoite is characterized as having one (20 to 40%) or two (60 to 80%) nuclei. The nuclear chromatin is usually fragmented into three to five granules, and there is normally no peripheral chromatin on the nuclear membrane (Figures 3.6 and 3.7). In some organisms, the nuclear chromatin tends to mimic that of *Endolimax nana*, *Entamoeba hartmanni*, or even *Chilomastix mesnili*, particularly if the organisms are overstained. The cytoplasm is usually vacuolated and may contain ingested debris as well as some large, uniform granules. The cytoplasm can also appear uniform and clean with few inclusions. There can also be considerable size and shape variation among organisms, even on a single smear.

Clinical Disease

Although its pathogenic status is still not well defined, *D. fragilis* has been associated with a wide range of symptoms (15, 35, 39, 51, 61, 66, 67). The significance of two genetically distinct forms of *D. fragilis* may ultimately serve to clarify the issues of virulence and clinical perceptions regarding pathogenicity (35). Case reports of children infected with *D. fragilis* reveal a number of

Figure 3.7 (A, B) Trophozoites of *Dientamoeba fragilis*. (A) The trophozoite contains a single nucleus fragmented into four parts; (B) the trophozoite contains two nuclei, both of which are also fragmented.

symptoms, including intermittent diarrhea, abdominal pain, nausea, anorexia, malaise, fatigue, poor weight gain, and unexplained eosinophilia. The most common symptoms in patients infected with this parasite appear to be intermittent diarrhea and fatigue (39). In some patients, both the organism and the symptoms persist or reappear until appropriate treatment is initiated.

Eleven pediatric patients, seven of whom had peripheral eosinophilia and a history of recent travel, were diagnosed with *D. fragilis* infection and reported symptoms of anorexia, intermittent vomiting, abdominal pain, and diarrhea. Based on findings in these patients, including bovine protein allergy and eosinophilic colitis, the authors recommended that *D. fragilis* should be included in the differential diagnosis of chronic diarrhea and eosinophilic colitis. The identification of this pathogen requires clinical awareness of epidemiologic risk factors and presenting complaints, as well as proper laboratory permanent staining procedures essential to proper identification (14).

Diagnosis

Routine Diagnostic Procedures. Clinicians should include infection with *D. fragilis* in their differential diagnosis of patients presenting with abdominal pain, diarrhea, unexplained flatulence, nausea, and vomiting. Diagnosis of *D. fragilis* infections depends on proper collection and processing techniques (a minimum of three fecal specimens) (11). Although the survival time for this parasite has been reported as 24 to 48 h, the survival time in terms of morphology is limited, and stool specimens must be examined immediately or preserved in a suitable fixative soon after defecation (35). It is particularly important that permanently stained smears of stool material be examined with an oil immersion lens (100 \times). These organisms have been recovered in formed stool; therefore, a permanent stained smear must be prepared for every stool sample submitted for a parasite examination. Organisms seen in direct wet mounts may appear as refractile, round forms; the nuclear structure cannot be seen without examination of the permanent stained smear.

Antigen Detection. Although fecal immunoassays for antigen detection are not yet available commercially, they have been developed using the immunofluorescence format (35). Studies using the enzyme immunoassay method are also under way. It is anticipated that at publication time these assays may be available commercially, since preliminary results look very promising. The potential for detection of DNA from feces is also being investigated; certainly the development of rapid, specific, and sensitive tests would be extremely helpful within the diagnostic laboratory setting (35).

Antibody Detection. Using an indirect immunofluorescence assay, Chan et al. (9, 35) found that serum samples from patients with confirmed *D. fragilis* infections had positive titers of 80, and all 12 matched controls had positive titers ranging from 20 to 160. The specificity of this assay was reinforced by immunoblotting 20 representative serum samples against *D. fragilis*; in all 17 indirect immunofluorescence-positive serum samples, a 39-kDa protein band of *D. fragilis* was identified.

KEY POINTS—LABORATORY DIAGNOSIS

Dientamoeba fragilis

1. A minimum of three specimens (stool) should be submitted for the diagnosis of *Dientamoeba* infections.
2. Since there is no known cyst stage, these organisms will not be seen on a wet preparation. Consequently, it is mandatory that a permanent stained smear be included in the ova and parasite examination. Trophozoites with either one or two nuclei can be found in the same specimen; there may also be tremendous size variation among the organisms seen in a single smear.
3. The trophozoite forms have been recovered from formed stool, hence the need to perform the permanent stained smear on specimens other than liquid or soft stools.
4. Organisms with a single nucleus can easily be confused with *Endolimax nana* or *Entamoeba hartmanni*, both of which are considered nonpathogens.

Treatment

Clinical improvement has been observed in adults receiving tetracycline; symptomatic relief has been observed in children receiving either diiodohydroxyquin, metronidazole, or tetracycline. Current recommendations include iodoquinol, paromomycin, or tetracycline. Since symptomatic relief has been observed to follow appropriate therapy, *D. fragilis* is probably pathogenic in infected individuals who are symptomatic. Although limited studies have been undertaken regarding the efficacy of various therapies, information continues to support the fact that the elimination of this organism from symptomatic patients leads to clinical improvement. Additional information can be found in chapter 25.

Epidemiology and Prevention

As reported for many of the intestinal protozoa, *D. fragilis* is worldwide in distribution. It is suspected that the true incidence of this infection is considerably higher than reported, particularly since many laboratories do not yet emphasize diagnostic methods such as the permanent stained smear that would confirm the diagnosis (67). Infection with

D. fragilis is particularly common in Canada. This parasite has been associated with diarrhea and abdominal pain in some patients. In looking at seroprevalence data for a large group of randomly selected patients aged from 6 months to 19 years, 172 (91%) of 189 gave positive results at titers of 1:10 or higher. The specificity of the indirect-immunofluorescence assay was reinforced by immunoblotting of 20 representative serum samples against *D. fragilis*. Findings over a 5-year period indicate that *D. fragilis* was the most common protozoan, followed closely by *G. lamblia* and more distantly by *C. parvum*. Previous data reported 85.6% for *G. lamblia* and 86% for *C. parvum* (9).

Since fecal-oral transmission has not been documented, it is difficult to speculate on preventive measures. However, if transmission does occur from the ingestion of certain helminth eggs, the use of hygiene and sanitary measures to prevent contamination with fecal material would be appropriate. There is speculation that *D. fragilis* may be infrequently recovered and identified; low incidence or absence from survey studies may be due to poor laboratory techniques and a general lack of knowledge about the organism (11, 35).

Pentatrichomonas hominis (*Trichomonas hominis*)

It is generally thought that *Trichomonas hominis* was first observed by Davaine in 1854 and described by him with the species name *hominis*. Although other protozoologists doubt that he actually saw this organism, the species name has been accepted. The genus name has been changed to *Pentatrichomonas* based on the five anterior flagella and a granular parabasal body. Although most readers are familiar with the generic term *Trichomonas*, this name will be changed to *Pentatrichomonas* for this edition of the book.

P. hominis is probably the most commonly identified flagellate other than *G. lamblia* and *D. fragilis*. It has been recovered from all parts of the world, in both warm and temperate climates. It is considered to be nonpathogenic, although it is often recovered from diarrheic stools (Tables 3.3 and 3.4). Statistics generated over the years include college students (0.16%); rural Georgia (0.3%); New Orleans clinic population in 1935 (1.2%); Peking, China, clinic patients (3.5%); and a Cali, Colombia, survey (1956 to 1961) (2.0 to 13.5%) (6).

Life Cycle and Morphology

There is no known cyst stage (Figure 3.8). The trophozoites live in the cecal area of the large intestine and feed on bacteria. The organism is not considered to be invasive. The trophozoite measures 5 to 15 μm in length and 7 to 10 μm in width. It has a pyriform shape and has both an axostyle and undulating membrane, which help in the

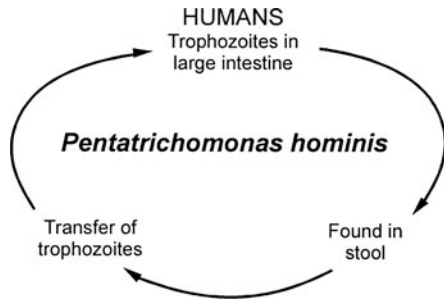

Figure 3.8 Life cycle of *Pentatrichomonas hominis*.

identification (Figure 3.3). The undulating membrane extends the entire length of the body, in contrast to that seen in *Trichomonas vaginalis*.

Diagnosis

In freshly passed stool specimens, particularly in unformed stool, the motility may be visible. In a wet preparation, one specifically looks for the flagellar movement from the undulating membrane and the presence of the axostyle. These small flagellates are difficult to stain and may even be missed on a permanent stained smear, especially if the stain is pale. In more formed stools, the trophozoites may round up (not encysted) and may not exhibit the characteristic motility seen in more active forms. When preserved fecal specimens are received in the laboratory, the permanent stained smear is the most sensitive method for finding and identifying *P. hominis*.

Epidemiology and Prevention

Since there is no known cyst stage, transmission probably occurs in the trophic form. If ingested in a protecting substance such as milk, these organisms can apparently survive passage through the stomach and small intestine in patients with achlorhydria. *P. hominis* cannot be transplanted into the vagina, the natural habitat of *T. vaginalis*. The incidence of this organism is relatively low, but it tends to be recovered more often than *Enteromonas hominis* or *Retortamonas intestinalis*. The infection is diagnosed more often in warm climates and in children rather than adults. Because of the fecal-oral transmission route, preventive measures should emphasize improved hygienic and sanitary conditions.

Trichomonas tenax

Trichomonas tenax was first recovered from the mouth, specifically in tartar from the teeth. It is worldwide in distribution. There is no known cyst stage (Tables 3.3 and 3.4; Figure 3.9). The trophozoite has a pyriform shape and is

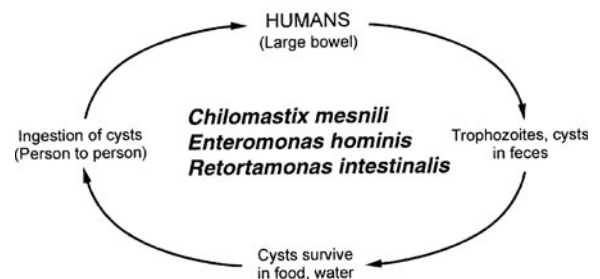

Figure 3.9 Life cycle of *Trichomonas tenax*.

smaller and more slender than that of *P. hominis*. The undulating membrane extends for the length of the body, like that seen in *P. hominis*. There is also the typical axostyle and a single nucleus. *T. tenax* cannot survive passage through the stomach and cannot be established in the vagina. Although the exact mode of transmission is not known, it is assumed to be by direct contact or use of contaminated dishes and glasses. Prevalence rates vary from 0 to 25%, depending on opportunities for exposure and on oral hygiene. Although *T. tenax* is considered a harmless commensal in the mouth, there are reports of respiratory infections and thoracic abscesses, particularly in patients with underlying cancers or other lung diseases. The majority of these cases were reported from western Europe. Diagnosis is based on recovery of the organisms from the teeth, gums, or tonsillar crypts, and no therapy is indicated. Better oral hygiene will rapidly eliminate the infection.

Chilomastix mesnili

Chilomastix mesnili tends to have a cosmopolitan distribution, although it is found more frequently in warm climates. It has both trophozoite and cyst stages and is somewhat more easily identified than are some of the smaller flagellates such as *E. hominis* and *R. intestinalis* (Tables 3.3 and 3.4; Figure 3.10). The trophozoite is described as being

Figure 3.10 Life cycle of *Chilomastix mesnili*, *Enteromonas hominis*, and *Retortamonas intestinalis*.

Figure 3.11 (A) Trophozoite of *Chilomastix mesnili* (note the feeding groove; flagella are not visible); (B) cyst of *C. mesnili* (note the “lemon or pear” shape and the curved fibril, the shepherd’s crook).

pear shaped, measuring 6 to 24 μm in length and 4 to 8 μm in width. There is a single nucleus and a distinct oral groove or cytostome close to the nucleus (Figures 3.3 and 3.11). Flagella are difficult to see unless there is obvious motility in a wet preparation. The morphology can be confirmed by using a permanent stained smear, particularly when the cytostome is visible. The cysts are pear or lemon shaped, and they range from 6 to 10 μm in length and 4 to 6 μm in width (Figure 3.11). There is also a single nucleus in the cyst and the typical curved cytostomal fibril, which is called the shepherd’s crook. Again, more definitive morphology can be seen on a permanent stain. *C. mesnili* normally lives in the cecal region of the large intestine, where the organisms feed on bacteria and debris. It is considered to be a nonpathogen, and no treatment is recommended. Since transmission is through ingestion of infective cysts, prevention depends on improved personal hygiene and upgraded sanitary conditions.

Enteromonas hominis

The flagellate *Enteromonas hominis* is considered to be nonpathogenic and has been reported from both warm and temperate climates (Tables 3.3 and 3.4; Figure 3.10). The trophozoites are somewhat pear shaped, measuring approximately 4 to 10 μm by 3 to 6 μm (Figure 3.3). There is no cytostome, and the flagella are rarely visible unless motile organisms are seen. The cyst measures approximately 6 to 10 μm by 4 to 6 μm and tends to be oval. There are two nuclei, and the cyst may mimic a two-nucleated *Endolimax nana* cyst. However, *E. nana* cysts containing two nuclei are quite rare in most clinical specimens. Also, *E. hominis* is not often reported, perhaps in part because of the small size of the organism and the difficulties in identification. Even on a permanent stained smear, this organism is often difficult to identify accurately.

Infection is considered to be caused by ingestion of the infective cysts. No symptoms have been attributed to this infection, and therapy is not indicated.

Retortamonas intestinalis

Retortamonas intestinalis has been recovered from both warm and temperate areas of the world (Figure 3.10). It has also been found in certain groups such as mental hospital patients. Like *E. hominis*, it is not commonly found in patient stools (Tables 3.3 and 3.4). *R. intestinalis* is also a small flagellate with trophozoites that are elongate pyriform or ovoidal (Figure 3.3). They measure 4 to 9 μm in length by 3 to 4 μm in width. This flagellate does have a cytostome, which may be difficult to see, even in a permanent stained smear. The cysts are somewhat pear shaped, measuring 4 to 9 μm in length and 4 to 6 μm in width (Figure 3.3). Both the trophozoite and the cyst have a single nucleus. This organism is rarely found in clinical specimens, possibly in part because of the difficulties in accurate identification of this and other smaller flagellates, even when the permanent stain technique is used. Infection is through ingestion of the cysts, and improved hygienic conditions would certainly prevent spread of the infection. *R. intestinalis* is considered a nonpathogen; thus, no therapy is indicated.

Balantidium coli

Balantidium coli was first isolated by Malmsten in 1857 from the dysenteric stools of two patients and was soon also observed by Leuckart in 1861 and Stein in 1862, who transferred the species to the genus *Balantidium* (prior genera were *Paramoecium*, *Leukophyra*, and *Holophyra*) (6).

B. coli is widely distributed in hogs, particularly in warm and temperate climates, and in monkeys in the tropics. Human infection is found in warmer climates, sporadically in cooler areas, and in institutionalized groups with low levels of personal hygiene. It is rarely recovered in clinical specimens within the United States.

Life Cycle and Morphology

B. coli is the only pathogenic ciliate and is the largest of the protozoa that parasitize humans (Tables 3.9 and 3.10; Figure 3.12). Both the trophozoite and cyst forms are found. The trophozoite is quite large, oval, and covered with short cilia; it measures approximately 50 to 100 μm in length and 40 to 70 μm in width (Figures 3.13 and 3.14). The organism can easily be seen in a wet preparation on lower power. The anterior end is somewhat pointed and has a cytostome present; in contrast, the posterior end is broadly rounded. The cytoplasm contains many vacuoles with ingested bacteria and debris. There are two nuclei within the trophozoite, a very

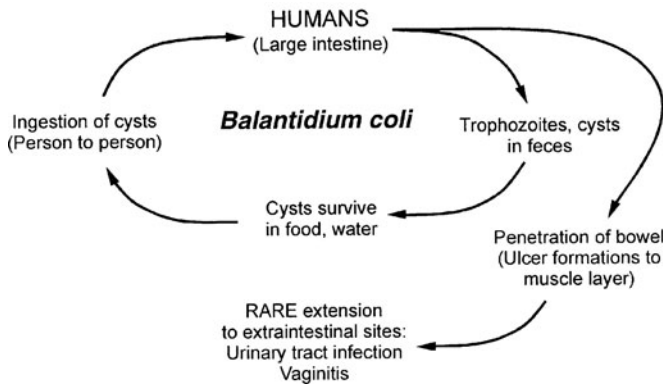

Figure 3.12 Life cycle of *Balantidium coli*.

large bean-shaped macronucleus and a smaller round micronucleus. The organisms normally live in the large intestine.

The cyst is formed as the trophozoite moves down the intestine. Nuclear division does not occur in the cyst; therefore, only two nuclei are present, the macronucleus and the micronucleus (Figures 3.13 and 3.14). The cysts measure from 50 to 70 μm in diameter.

Clinical Disease

Some individuals with *B. coli* infections are totally asymptomatic, whereas others have symptoms of severe dysentery similar to those seen in patients with amebiasis. Symptoms usually include diarrhea or dysentery, tenesmus, nausea, vomiting, anorexia, and headache. Insomnia, muscular weakness, and weight loss have also been reported. The diarrhea may persist for weeks to months prior to the development of dysentery. There may be tremendous fluid loss, with a type of diarrhea similar to that seen in cholera or in some coccidial or microsporidial infections.

B. coli has the potential to invade tissue. On contact with the mucosa, *B. coli* may penetrate the mucosa with cellular infiltration in the area of the developing ulcer

Figure 3.13 (1) Trophozoite of *Balantidium coli*; (2) cyst of *B. coli*. (Illustration by Sharon Belkin.)

Figure 3.14 (A) Trophozoite of *Balantidium coli* (note the large bean-shaped macronucleus and evidence of cilia around the organism); (B) cyst of *B. coli* (note the large bean-shaped macronucleus).

Table 3.9 Intestinal protozoa: ciliate

<i>Balantidium coli</i>	Shape and size	Motility	No. of nuclei	Other features
Trophozoite	Ovoid with tapering anterior end; 50–100 μm in length; 40–70 μm in width (usual range, 40–50 μm)	Ciliates: rotary, boring; may be rapid	1 large kidney-shaped macronucleus; 1 small, round micronucleus, which is difficult to see even in the stained smear; macronucleus may be visible in unstained preparation	Body covered with cilia, which tend to be longer near cytostome; cytoplasm may be vacuolated
Cyst	Spherical or oval; 50–70 μm (usual range, 50–55 μm)		1 large macronucleus visible in unstained preparation; micronucleus difficult to see	Macronucleus and contractile vacuole are visible in young cysts; in older cysts, internal structure appears granular; cilia difficult to see within the cyst wall

Table 3.10 Intestinal flagellates and ciliates: recommended diagnostic procedures

Organism	Specimen	Diagnostic procedure
<i>Giardia lamblia</i>	Stool	Complete ova and parasite exam, fluorescent antibody, enzyme and immunochromatographic immunoassays
	Duodenal contents	Wet preparation and permanent stains
	Entero-Test	Wet preparation and permanent stains
	Aspirate	Wet preparation and permanent stains
	Biopsy	Routine histology
<i>Dientamoeba fragilis</i>	Stool	Complete ova and parasite exam
<i>Enteromonas hominis</i>	Stool	Complete ova and parasite exam
<i>Retortamonas intestinalis</i>	Stool	Complete ova and parasite exam
<i>Chilomastix mesnili</i>	Stool	Complete ova and parasite exam
<i>Pentatrichomonas hominis</i> (<i>Trichomonas hominis</i>)	Stool	Complete ova and parasite exam
<i>Trichomonas tenax</i>	Gingival scrapings	Wet preparation and permanent stains
	Pyorrhoeal material	Wet preparation and permanent stains
<i>Balantidium coli</i>	Stool	Complete ova and parasite exam
	Biopsy	Routine histology

(Figure 3.15). Some of the abscess formations may extend to the muscular layer. The ulcers may vary in shape, and the ulcer bed may be full of pus and necrotic debris. Although the number of cases is small, extraintestinal disease has been reported (peritonitis, urinary tract infection, and inflammatory vaginitis).

Figure 3.15 Trophozoite of *Balantidium coli* in tissue. Note the cytostome (oral groove) and a portion of the macronucleus. The cilia are not clearly visible.

Diagnosis

Routine stool examinations, particularly wet-preparation examinations of fresh and concentrated material, will demonstrate the organisms. Organism recognition and identification on a permanent stained smear may be very difficult. These protozoa are so large that they tend to stain very darkly, thus obscuring any internal morphology. *B. coli* organisms may even be confused with helminth eggs because of their size, particularly when the cilia are not visible. The recovery of *B. coli* from specimens within the United States is rare. Nonetheless, laboratories are expected to be able to identify these organisms and are called upon to do so with proficiency-testing specimens.

KEY POINTS—LABORATORY DIAGNOSIS

Balantidium coli

1. Since the organisms are so large, they can frequently be seen under low power (100×), particularly in a concentration sediment wet mount.
2. If wet mounts are examined using high dry power (400×), the organisms may be confused with vegetable cells (both cells and parasites are larger than other intestinal protozoa). The cilia tend to be short and can be missed on microscopic examination.
3. Although this infection is very rare within the United States, all laboratories may receive positive specimens for proficiency testing.
4. These organisms do not stain well (too large and thick) on the permanent stained smear and

can be confused with fecal debris (including helminth eggs), hence the need to make the diagnosis by using wet smears (from direct mounts or concentrate sediment).

Treatment

For treatment of *B. coli*, tetracycline is the drug of choice, although it is considered investigational for this infection. Iodoquinol or metronidazole may be used as alternatives. Additional information can be found in chapter 25.

Epidemiology and Prevention

Although *B. coli* has been found in many different simian hosts, domestic hogs probably serve as the most important reservoir host for human infection. In areas where pigs are the main domestic animal, the incidence of human infection can be quite high. Particularly susceptible to infection are persons working as pig farmers or in slaughterhouses (28% infection in New Guinea). Human infection is fairly rare in temperate areas, although once the infection is established, it can develop into an epidemic, particularly in areas with poor environmental sanitation and personal hygiene. This situation has been seen in mental hospitals in the United States. Preventive measures involve increased attention to personal hygiene and sanitation measures, since the mode of transmission is ingestion of infective cysts through contaminated food or water.

Intestinal Protozoa (Coccidia and Microsporidia) and Algae

Coccidia

Cryptosporidium spp.

Cyclospora cayetanensis

Isospora (Cystoisospora) belli

Sarcocystis spp.

Microsporidia

Algae (*Prototheca*)

Coccidia

Although most readers understand the main categories related to parasitology classification, the coccidia and microsporidia can be somewhat confusing; a few comments as review may be helpful. The major phyla of protozoa include Sarcomastigophora (includes the amebae and flagellates), the Apicomplexa (malaria parasites, coccidia, and *Babesia*), the Microspora (the microsporidia), and the Ciliophora (*Balantidium coli*). Several protozoan genera are included in the phylum Apicomplexa and are referred to as coccidia. All organisms included in the Apicomplexa are unicellular with an apical complex typically composed of polar rings, rhoptries, micronemes, and usually a conoid; subpellicular microtubules and micropores are common. These structures can be seen in electron microscopy studies and are used to help classify the various coccidia. Genera that develop in the gastrointestinal tract of vertebrates throughout their entire life cycle include *Eimeria*, *Isospora*, *Cyclospora*, and *Cryptosporidium*. Those that are capable of or require extraintestinal development are referred to as cyst-forming coccidia and include *Besnoitia*, *Caryospora*, *Frenkelia*, *Hammondia*, *Neospora*, *Sarcocystis*, and *Toxoplasma*. The coccidian genera that cause disease in humans include *Cryptosporidium*, *Cyclospora*, *Isospora*, *Sarcocystis*, and *Toxoplasma* (see chapter 6 for a discussion of *Toxoplasma*).

Cryptosporidium spp.

The first reported description of *Cryptosporidium parvum* was in 1907 in the gastric crypts of a laboratory mouse (Tyzzer). Subsequently, it has been found in chickens, turkeys, mice, rats, guinea pigs, horses, pigs, calves, sheep, rhesus monkeys, dogs, cats, and humans (Table 4.1) (6, 12, 40). Recent information also supports previous suggestions that cryptosporidiosis is a zoonosis, is not host specific, and is transmitted via the fecal-oral route (40). What was previously called *C. parvum* and was thought to be the primary *Cryptosporidium* species infecting humans is now classified as two separate species, *C. parvum* (mammals, including humans) and *C. hominis* (primarily humans) (6, 32, 41) (Table 4.1). Differentiation of these two species based on oocyst morphology is not possible.

This infection is now well recognized as causing disease in humans, particularly in those who are in some way immunosuppressed or immunodeficient.

Table 4.1 Current species names within the genus *Cryptosporidium*^a

Species	Main host(s)	Less common host(s)
<i>C. andersoni</i>	Cattle, Bactrian camels	Sheep
<i>C. baileyi</i>	Chicken, turkeys	Cockatiels, quails, ostriches, ducks
<i>C. canis</i>	Dogs	Humans
<i>C. felis</i>	Cats	Humans, cattle
<i>C. galli</i>	Finches, chicken, capercalles, grosbeaks	
<i>C. hominis</i>	Humans, monkeys	Dugongs, sheep
<i>C. meleagridis</i>	Turkeys, humans	Parrots
<i>C. molnari</i>	Fish	
<i>C. muris</i>	Rodents, Bactrian camels	Humans, rock hyrax, mountain goats
<i>C. parvum</i>	Cattle, sheep, goats, humans	Deer, mice, pigs
<i>C. saurophilum</i>	Lizards	Snakes
<i>C. serpentis</i>	Snakes, lizards	
<i>C. wrairi</i>	Guinea pigs	

^a Adapted from reference 40.

Cryptosporidium has been implicated as one of the more important opportunistic agents seen in patients with AIDS (6, 12, 22, 40). Unfortunately, at the time of this writing, no totally effective therapy for cryptosporidiosis has been identified, despite the testing of over 100 drugs. Consequently, detection of this parasite in immunocompromised hosts, especially those with AIDS, usually carries a poor prognosis. Also, reports of respiratory tract and biliary tree infections confirm that the developmental stages of this organism are not always confined to the gastrointestinal tract.

Currently, the literature contains over 3,000 published papers related to cryptosporidiosis, including information on nosocomial transmission, day care center outbreaks, and a number of waterborne outbreaks. This is remarkable, since fewer than 30 publications were available prior to 1980. In response to this rapidly expanding area of parasitology, there have been definite improvements in diagnostic procedures, particularly those involving the newer immunoassay detection kits (15, 22, 24, 40).

The pathogenesis of cryptosporidial diarrhea, even in patients with AIDS, is not fully understood. However, patients with no intestinal symptoms who are passing formed stool containing few oocysts contrast sharply with those who are symptomatic with watery diarrhea and are passing large numbers of oocysts. These findings imply a relationship between intestinal dysfunction and injury and the number of organisms infecting the intestinal mucosa.

Age and immune status at the time of primary exposure to *Cryptosporidium* do not appear to be primary factors influencing the susceptibility of humans to infection. Symptomatic intestinal and respiratory cryptosporidiosis

has been seen in both immunocompetent and immunodeficient patients of all ages. However, once the primary infection has been established, the immune status of the host plays a very important role in determining the length and severity of the illness. People who are immunocompetent usually develop a short-term, self-limited diarrhea lasting approximately 2 weeks.

In contrast, those who are immunocompromised initially develop the same type of illness; however, it becomes more severe with time and results in a prolonged, life-threatening, cholera-like illness. These severe infections have been seen in patients undergoing immunosuppressive chemotherapy with drugs that affect both T- and B-lymphocyte function, in patients with hypogammaglobulinemia, and in those with AIDS. From many observations of these types of patients, the difference in outcome can probably be explained by the development, in the immunocompetent host, of an immune response sufficient to eradicate the parasite from the infected individual. This explanation is also supported by the fact that individuals whose immunosuppressive therapy has been discontinued will rapidly clear the body of *Cryptosporidium* once their immune system function is restored. Studies also suggest that the overall immune response to cryptosporidiosis is probably an antibody-dependent, cell-mediated, cytotoxic effect of unknown mechanism.

Life Cycle and Morphology

Cryptosporidium differs from other coccidia infecting warm-blooded vertebrates in that its developmental stages do not occur deep within host cells but are confined to an intracellular, extracytoplasmic location. Each stage is within a parasitophorous vacuole of host cell origin;

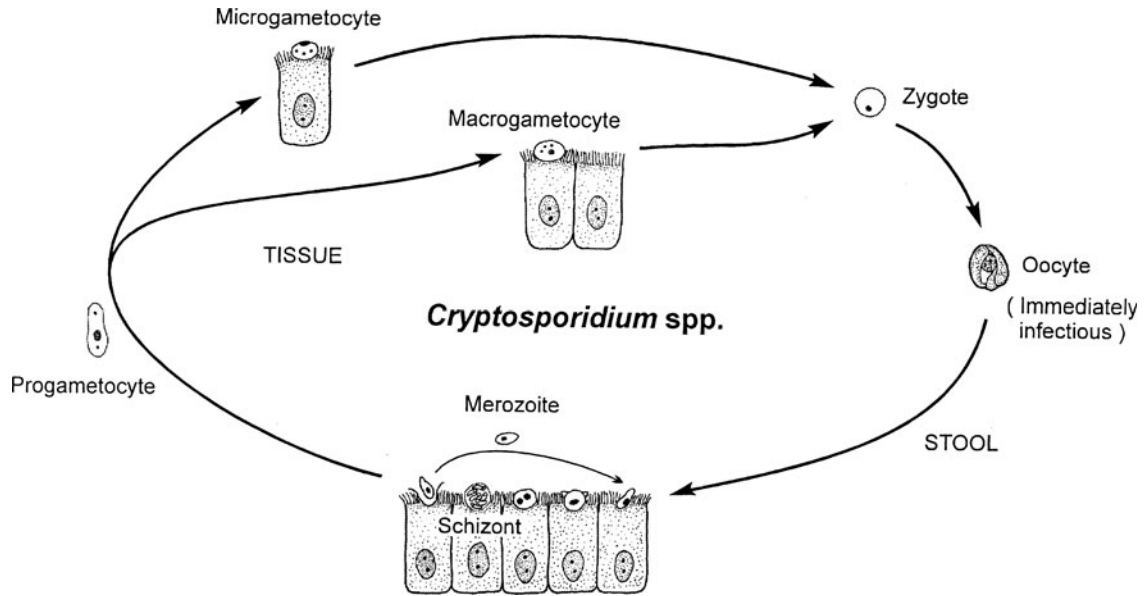

Figure 4.1 Life cycle of *Cryptosporidium* spp. illustrating various stages. (Illustration by Sharon Belkin.)

however, the vacuole containing the organism is located at the microvillous surface of the host cell. Details of the life cycle can be seen in Figure 4.1.

The presence of a thin-walled, autoinfective oocyst may explain why a small inoculum can lead to an overwhelming infection in a susceptible host and why immunosuppressed patients may have persistent, life-threatening infections in the absence of documentation of repeated exposure to oocysts (Figure 4.2). The stages found on the microvillous surface measure 1 μm , and the oocysts recovered in stool specimens measure 4 to 6 μm (Table 4.2).

Each intracellular stage of *Cryptosporidium* resides within a parasitophorous vacuole within the microvillous region of the host cell. Oocysts undergo sporogony while they are in the host cells and are immediately infective when passed in the stool. This is in contrast to the oocysts of *Isospora belli*, which do not sporulate until they are passed from the host and are exposed to oxygen and temperatures below 37°C. Approximately 20% of the oocysts of *Cryptosporidium* do not form the thick, two-layered, environmentally resistant oocyst wall. The four sporozoites within this autoinfective stage are surrounded by a single-unit membrane. After being released from a host cell, this membrane ruptures and the invasive sporozoites penetrate the microvillous region of other cells within the intestine and reinitiate the life cycle. As mentioned above, these thin-walled oocysts that can recycle are thought to be responsible for the development of severe, life-threatening disease in immunocompromised patients, even those who are no longer exposed to the environmentally resistant oocysts.

The prepatent period from the time of ingestion of infective oocysts to completion of the life cycle with excretion of newly developed oocysts in the human is approximately 4 to 22 days. The patent period during excretion of oocysts can range from 1 to 20 days in humans. Previous studies have suggested that persons infected with *Cryptosporidium* develop antibody responses to several antigens. Results now suggest that characteristic antibody responses develop following infection and that persons with preexisting antibodies may be less likely to develop illness, particularly when infected with low oocyst doses (22, 40).

Oocysts recovered in clinical specimens are difficult to see without special staining techniques, such as the modified acid-fast, Kinyoun, and Giemsa methods, or the newer immunoassay methods. The four sporozoites may be seen within the oocyst wall in some of the organisms, although they are not always visible in freshly passed specimens.

Information Based on Electron Microscopy. The oocyst wall has distinct inner and outer layers and is unique in having a suture at one end; the suture dissolves during excystation, opening the wall, through which the sporozoites leave the oocyst. Excystation of sporozoites is enhanced by exposure to reducing conditions followed by exposure to pancreatic enzymes and/or bile salts. Recent data suggest that a novel parasite protein, CP47, may play an important role in attachment of sporozoites to the host cell; this protein exhibits significant binding affinity for the surfaces of both human and animal ileal

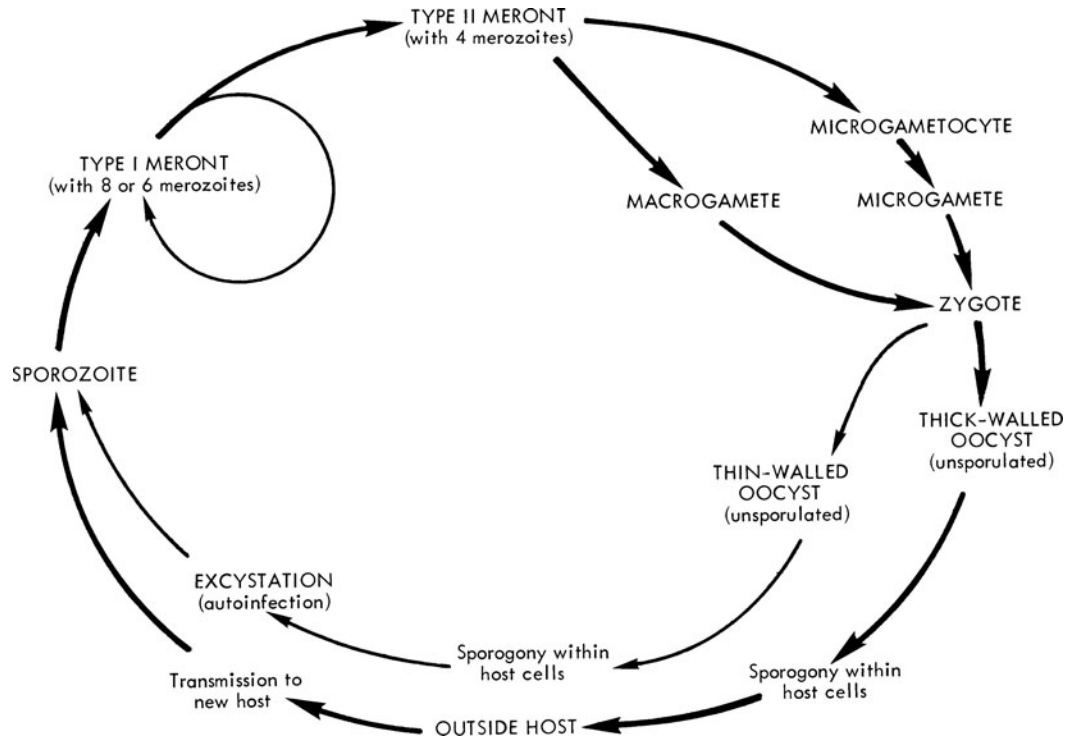

Figure 4.2 Life cycle of *Cryptosporidium* spp. (Adapted from W. L. Current and L. S. Garcia, *Clin. Microbiol. Rev.* 4:325–358, 1991.)

Table 4.2 Coccidia

Species	Shape and size	Other features
<i>Cryptosporidium</i> spp.	Oocyst generally round, 4–6 μm, each mature oocyst containing sporozoites	Oocyst usual diagnostic stage in stool; various other stages in life cycle can be seen in biopsy specimens taken from gastrointestinal tract (brush border of epithelial cells, intestinal tract) and possibly other tissues (respiratory tract, biliary tract)
<i>Cyclospora cayetanensis</i>	Organisms generally round, 8–10 μm; they mimic <i>Cryptosporidium</i> spp. (acid fast) but are larger	In wet smears they look like nonrefractile spheres; they will also autofluoresce with epifluorescence; are acid-fast variable from no color to light pink to deep red; those that do not stain may appear wrinkled; in a trichrome-stained stool smear, they will appear as clear, round, somewhat wrinkled objects; they cause diarrhea in both immunocompetent and immunosuppressed patients
<i>Isospora belli</i>	Ellipsoidal oocyst; usual range, 20–30 μm long and 10–19 μm wide; sporocysts rarely seen broken out of oocysts but measure 9–11 μm	Mature oocyst contains 2 sporocysts with 4 sporozoites each; usual diagnostic stage in feces is immature oocyst containing spherical mass of protoplasm (diarrhea, intestinal tract)
<i>Sarcocystis hominis</i> , <i>S. suihominis</i> , <i>S. bovis</i>	Oocyst thin-walled and contains 2 mature sporocysts, each containing 4 sporozoites; thin oocyst wall frequently ruptures; ovoid sporocysts each measure 9–16 μm long and 7.5–12 μm wide	Thin-walled oocyst or ovoid sporocysts occur in stool (intestinal tract)
<i>S. "lindemanni"</i>	Shapes and sizes of skeletal and cardiac muscle sarcocysts vary considerably	Sarcocysts contain several hundred to several thousand trophozoites, each of which measures 4–9 μm in width and 12–16 μm in length; the sarcocysts may also be divided into compartments by septa, not seen in <i>Toxoplasma</i> cysts (tissue/muscle)

cells. Both sporozoites and merozoites appear similar to those of other coccidia, with organelles such as the pellicle, rhoptries, micronemes, electron-dense granules, nucleus, ribosomes, subpellicular microtubules, and apical rings. Once they are inside the parasitophorous vacuole, changes in the apex of the host cell and the parasite result in an attachment or feeder organelle. The fertilized macrogamont, or zygote, develops into an oocyst with either the thick wall (80%, which are passed in the stool) or the thin wall (20%, which remain internal, causing internal autoinfection). The zygotes that develop into the thin-walled oocysts do not contain the characteristic wall-forming bodies. The thick-walled oocysts are characterized by having a thin, moderately coarse outer layer and a finely granular inner layer. Between these two layers of the oocyst wall is an electron-lucent zone that consists of the two oocyst membranes sandwiched between the outer and inner layers of the oocyst wall. The outer layer of the wall is continuous and of a uniform thickness, while the inner layer contains a suture at one pole.

Clinical Disease

Immunocompetent Individuals. Clinical symptoms include nausea, low-grade fever, abdominal cramps, anorexia, and 5 to 10 watery, frothy bowel movements per day, which may be followed by constipation. Some patients may present with diarrhea as described above, and others may have relatively few symptoms, particularly later in the course of the infection. In patients with the typical watery diarrhea, the stool specimen contains very little fecal material but consists mainly of water and mucus flecks. Often the organisms are entrapped in the mucus, and diagnostic procedures are performed accordingly. Generally, a patient with a normal immune system has a self-limited infection; however, patients who are compromised may have a chronic infection with a wide range of symptoms (asymptomatic to severe).

Occasionally, these patients require fluid replacement and the diarrhea persists for more than 2 weeks. This is particularly true of infants, in whom excessive fluid loss may last for over 3 weeks. In general, when CD4⁺ cells are present at levels greater than 200/μl, infections are acute and resolve in approximately 2 weeks; however, when the CD4⁺ cell count drops below 200/μl, the infection may be chronic and may not resolve.

Based on questions that arose from the 1993 Milwaukee outbreak, regarding appropriate management and prognosis of patients with inflammatory bowel disease who are infected with *Cryptosporidium*, it is clear that cryptosporidiosis may present as an acute relapse of

inflammatory bowel disease and responds to standard therapy. Antibiotics confer no benefit. It appears that immunosuppressive therapy does not predispose to chronic or severe illness in these patients. Cryptosporidiosis may present with acute findings initially mimicking Crohn's disease. The total cost of outbreak-associated illness during the Milwaukee outbreak was \$96.2 million: \$31.7 million in medical costs and \$64.6 million in productivity losses. The average total costs for persons with mild, moderate, and severe illness were \$116, \$475, and \$7,808, respectively. The authors also comment that these cost-of-illness estimates are conservative (8).

Failure to thrive has also been attributed to chronic cryptosporidiosis in infants. Since diarrheal illness is a major cause of morbidity and mortality in young children living in developing countries, it is likely that cryptosporidiosis plays a major role in the overall health status of these children. Apparently, cryptosporidiosis has a lasting adverse effect on linear growth (height), especially when acquired during infancy and when children are stunted before they become infected. It has also been suggested that *Cryptosporidium* may be implicated in the respiratory disease that often accompanies diarrheal illness in malnourished children. Those with respiratory infections tend to have coughing, wheezing, croup, hoarseness, and shortness of breath.

Histologically, enteric infections are characterized by villous atrophy, enlarged crypts, and infiltration of the lamina propria by inflammatory cells. Respiratory infections have been characterized by infiltration of the lamina propria by inflammatory cells, loss of cilia, hyperplasia, and hypertrophy of epithelial cells. Similar inflammatory cell infiltration has also been reported for infections involving other organs.

Immunocompromised Individuals. *AIDS (intestinal disease).* The duration and severity of diarrheal illness depend on the immune status of the patient. Most severely immunocompromised patients cannot overcome the infection, the illness becomes progressively worse with time, and the sequelae may be a major factor leading to death. The length and severity of illness may also depend on the ability to reverse the immunosuppression. In these patients, *Cryptosporidium* infections are not always confined to the gastrointestinal tract; additional symptoms (respiratory problems, cholecystitis, hepatitis, and pancreatitis) have been associated with extraintestinal infections. While the clinical features of sclerosing cholangitis secondary to opportunistic infections of the biliary tree in patients with AIDS are well known, the mechanisms by which pathogens such as *Cryptosporidium* actually cause disease are unclear.

In reviewing data from patients with gastric cryptosporidiosis, no clear correlation was found between endoscopy and histologic findings; however, a close correlation between the intensity of the infection and the degree of histologic alterations was observed (22). These findings suggest that in patients with AIDS, cryptosporidiosis, and severe immunodepression, upper endoscopy with random gastric biopsies should be performed, even in the absence of endoscopically identified lesions. The diagnosis of gastric cryptosporidiosis relies on histologic findings; pathologists need to be aware that *Cryptosporidium* organisms are found mainly in areas showing reactive hyperplasia.

When reviewing data from AIDS patients with four clinical syndromes, i.e., chronic diarrhea (36%), cholera-like disease (33%), transient diarrhea (15%), and relapsing illness (15%), there is no statistically significant correlation between the histologic intensity of infection and the clinical severity of illness. However, infected patients had a much shorter survival time than did *Cryptosporidium*-negative AIDS patients, and survival was independent of sex, race, or injection drug use (22).

Patients with CD4 counts of 180/ μ l or greater can usually clear the infection with *Cryptosporidium* over a period of 7 days to 1 month. These data are important in predicting the natural progression of the infection and in designing therapeutic trials. Frequent diagnosis of *Cryptosporidium* infection in patients with neoplasia and diarrhea who are undergoing chemotherapy suggests that for this patient group it is appropriate to routinely submit fecal specimens for examination for oocysts and that the cost of laboratory testing is justified.

AIDS (biliary tract disease). Sclerosing cholangitis is well known as a complication of AIDS. Direct cytopathic effects are noted in infected monolayers (human biliary epithelial cell line) and are associated with widespread programmed cell death (apoptosis) beginning within hours after exposure to the organism. This finding of specific cytopathic invasion of biliary epithelia by *Cryptosporidium* may be relevant to the pathogenesis and possible therapy of secondary sclerosing cholangitis seen in AIDS patients with biliary cryptosporidiosis. It appears that more severely immunocompromised individuals are more likely to exhibit biliary tract disease.

AIDS (pancreatitis). In AIDS patients with pancreatitis, cellular changes are generally not severe, and these patients exhibit hyperplastic squamous metaplasia. The patients usually present with abdominal pain resistant to analgesics, elevated serum amylase levels, and abnormalities on sonography and computed tomography. It is

difficult to clarify the impact of cryptosporidiosis-related pancreatic disease, and this disease complication is apparently not linked to significant morbidity.

AIDS (respiratory tract disease). Because many patients with respiratory cryptosporidiosis also have other pathogens present, it is difficult to determine the significance of this complication in AIDS patients. Certainly for patients with respiratory symptoms, it is important to examine sputum, as well as stool specimens to confirm the diagnosis.

Primary immunodeficiency diseases. Many different primary immunodeficiency diseases have been described; in general, they can be categorized as follows: combined immunodeficiencies (which impact both T and B lymphocytes); antibody deficiencies; complement deficiencies, and defects in phagocytes (decreased number and function). In general, the number of these cases reported in relation to cryptosporidiosis is few; however, the most serious immunodeficiency in terms of risk is severe combined immunodeficiency syndrome. These patients are at risk for disseminated disease; often the prognosis is poor.

Malignant disease. Although cryptosporidiosis can be seen in patients with malignant disease, infection with *Cryptosporidium* spp. does not appear to pose a special risk. Exceptions to this general statement seem to involve leukemia and other hematologic malignancies (22). Certainly there is more interest in patients who are candidates for bone marrow transplantation, particularly when assessing possible risks related to cryptosporidiosis.

Solid-organ transplant patients. Cryptosporidiosis has been found in both liver and kidney transplant recipients, as well as following small bowel transplantation (22, 35). However, in most cases the cryptosporidiosis was not unusually severe and did not involve dissemination to extraintestinal sites.

Diagnosis

Previously, most human cases were diagnosed after examination of small or large bowel biopsy material, often under both light and electron microscopy (Figure 4.3). However, because biopsies may miss the infected area of the mucosa, cases have recently been diagnosed by recovering oocysts from fecal material by a flotation method; several other previously reported cases were also diagnosed by using fecal concentrates (Table 4.3). Fresh fecal specimens can be concentrated by using Sheather's sugar solution, and coverslip preparations can be examined by both phase-contrast and bright-field microscopy.

Figure 4.3 *Cryptosporidium* spp. (A) Organisms on the brush border of the mucosal surface. (Courtesy of Wilfred M. Weinstein.) (B) Organisms on the mucosal surface, human tissue (scanning electron micrograph, $\times 4,000$). (Courtesy of Marietta Voge.)

The oocysts will float, and one must focus directly under the glass coverslip. Most laboratories no longer use this approach and have switched to modified acid-fast stains performed on concentrated stool sediment or the newer immunoassays (15, 23, 24).

Although examination of flotation material by phase-contrast microscopy has proven to be an excellent procedure for the recovery and identification of *Cryptosporidium* oocysts, many laboratories have neither access to such equipment nor experience with phase-contrast microscopy. Also, since the organism is considered to be infectious to

Table 4.3 Intestinal coccidia: recommended diagnostic procedures^a

Organism	Specimen	Diagnostic procedure ^a
<i>Cryptosporidium</i> spp.	Stool	Modified acid-fast stains, fluorescent stains, immunoassays
	Sputum	Immunoassays
	Scraping	Modified acid-fast stains or routine histology
	Biopsy specimen	Routine histology
<i>Cyclospora cayentanensis</i>	Stool	Modified acid-fast stains, autofluorescence
	Biopsy specimen	Routine histology
<i>Isoospora belli</i>	Stool	Concentration sedimentation and modified acid-fast stains
	Biopsy specimen	Routine histology
<i>Sarcocystis</i> spp.	Stool	Concentration sedimentation and special stains
	Biopsy	Routine histology

^a When using immunoassay reagents (FA) or modified acid-fast stains for organism detection, these procedures should be performed with centrifuged stool ($500 \times g$ for 10 min). When using immunoassay reagents for antigen detection, centrifugation of the fecal specimen is not required. Procedure directions must be checked, and compatibility issues between the kit reagents and stool preservatives must be kept in mind.

laboratory personnel, fixed specimens can be processed by using several acid-fast stains, many of which are very satisfactory in demonstrating the organisms in stool material (Figures 4.4 and 4.5). The more formed and normal the specimen, the better the chance for artifact material that can be confused with *Cryptosporidium* spp. It is important to remember that the number of oocysts is directly correlated with the consistency of the stool; the more diarrheic the stool, the more oocysts are present.

For the diagnosis of cryptosporidiosis, stool and other body fluid specimens should be submitted as fresh material or in 5 or 10% formalin, sodium acetate-acetic acid-formalin, or one of the newer single-vial stool collection systems (polyvinyl alcohol prepared with zinc sulfate-based Schaudinn's fixative). Fixed specimens are recommended because of potential biohazard considerations. Some research laboratories routinely use potassium dichromate solution (2 to 3% [wt/vol] in water) as a storage medium to preserve oocyst viability; it is not a fixative and is not recommended for the routine clinical laboratory. Either fresh or preserved specimens can be

Figure 4.4 *Cryptosporidium* oocysts from stool, stained with modified acid-fast stain. Note that in the bottom image some of the sporozoites are visible within the oocyst wall.

examined using the routine stool formalin-ethyl acetate concentration and one of the modified acid-fast stains or the newer immunoassay kit reagents (Table 4.4). It is recommended that the stool specimen be centrifuged at $500 \times g$ for 10 min prior to use of any of the stains or fluorescent-antibody (FA) immunoassay reagents; centrifugation under these conditions ensures maximum recovery of the oocysts. Centrifugation at lower speeds and for shorter times (often mentioned in some procedures) may not guarantee recovery of the oocysts. Uncentrifuged fresh, frozen, or fixed fecal material can be used for the antigen detection immunoassays; these procedures do not rely on visual identification of the oocysts (FA) but

instead rely on antigen detection. The selection of fresh or frozen stool rather than fixed specimens depends on testing parameters; currently, if the test reagents or kit format includes *Entamoeba histolytica*/*E. dispar* or *E. histolytica* alone, the test format requires fresh or frozen stool. If the test format includes *Cryptosporidium* and/or *Giardia*, fresh, frozen, OR preserved stools can be used. However, it is always important to check with the manufacturer to confirm that the particular stool fixative you are currently using will be compatible with the immunoassay test reagents. It is also important to review sensitivity and specificity data prior to test selection; false-positive results have been reported with some reagent test kits. Multiple stool specimens may have to be examined to diagnose the infection; this is particularly true when dealing with formed stool specimens.

Various screening approaches have been used, and the approach varies from testing all specimens submitted for a routine stool examination to testing limited risk groups or testing only on request. There are numerous pros and cons to each approach; each laboratory will have to select its own approach on the basis of the patient base, client preferences, single versus batch testing, opportunity for in-service education for clients, availability of personnel, level of personnel training and expertise, clinical relevance, and cost. Prevalence data tend to be low unless specific risk groups are screened. A comprehensive approach would be to screen all symptomatic patients; however, even this approach often results in the identification of very few patients and is certainly not particularly cost-effective. A selective approach involving all compromised patients or compromised patients with diarrhea might be more reasonable. However, this assumes that the laboratory will always have access to this type of patient information, an assumption that is not realistic. Many laboratories have elected to provide in-service education to their physician clients and will perform these procedures only on request. Options for test ordering can be seen in Table 4.5.

Although there is evidence for regional and seasonal variability of cryptosporidiosis, these possibilities will probably have little impact on the laboratory's overall approach to diagnostic testing.

Respiratory cryptosporidiosis has been found in AIDS patients. Sputum specimens from immunodeficient patients with undiagnosed respiratory illness should be submitted in 10% formalin and examined for *Cryptosporidium* oocysts by the same techniques as used for stool samples. Infection of the gallbladder and biliary tree should result in oocysts being passed in the stool.

Preliminary results from serologic methods for the diagnosis of cryptosporidiosis appear promising; however,

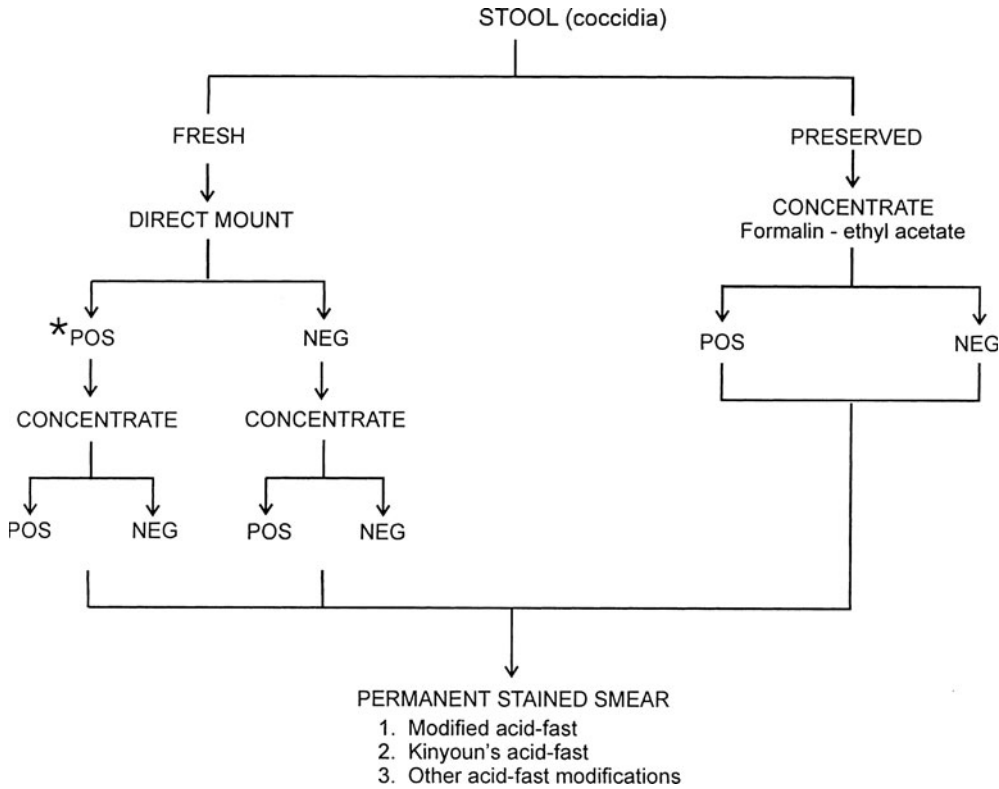

Figure 4.5 Diagnostic work flow diagram leading from submission of stool specimen to final permanent-stained smear for *Cryptosporidium* spp. and *Cyclospora cayetanensis*. *Identification of coccidia may be difficult in a direct wet mount unless there are numerous oocysts present. In many laboratories, the use of fecal immunoassays has replaced acid-fast staining techniques for *Cryptosporidium* spp. The immunoassays can be performed on unconcentrated material (EIA, lateral-flow rapid cartridge) or concentrated material (FA assay).

additional patients must be studied before the actual diagnostic potential of these methods can be evaluated. Serologic tests have been very useful in estimating the prevalence of the infection in different parts of the world. Some of the data reveal very interesting associations between seroprevalence, outbreak-related laboratory serologic data, and patterns of parasite contamination of drinking water (12).

The use of immunoassays has proven to be very helpful in providing a more sensitive method of detecting organisms in stool specimens. A direct FA procedure with excellent specificity and sensitivity has been developed and results in a significantly increased detection rate over conventional staining methods. Enzyme immunoassay (EIA) also provides excellent specificity and sensitivity for laboratories using this approach (15, 24). Some of these reagents, particularly the combination direct-FA product used to identify both *Giardia* cysts and *Cryptosporidium* oocysts, are being widely used in water testing and outbreak situations (3, 12, 18–20, 30, 42).

Flow cytometry methods for the quantitation of *Cryptosporidium* oocysts in stool specimens have been developed as an alternative approach. Studies indicate that the results are approximately 10 times more sensitive than those of conventional immunofluorescence assays.

However, this approach is somewhat impractical for most clinical laboratories.

PCR technology also offers alternatives to conventional diagnosis of *Cryptosporidium* in both clinical and environmental samples. Compared with microscopic examination by conventional acid-fast staining procedures, PCR is more sensitive and easier to interpret but requires more “hands-on” time and expertise, as well as being more expensive. An important advantage of PCR is the ability to directly differentiate between different *Cryptosporidium* genotypes, which is important in outbreak situations. Sensitivity, specificity, ability to genotype, ease of use, and adaptability to batch testing make PCR a useful tool for future diagnostic and molecular epidemiologic studies.

KEY POINTS—LABORATORY DIAGNOSIS

Cryptosporidium spp.

1. If the specimen represents the typically watery diarrhea, numerous organisms should be caught up in mucus.
2. The more normal the stool (semiformed, formed), the fewer the organisms and the more artifact material that will be present. It is unlikely that the oocysts will be seen in a wet preparation unless the parasite load is

Table 4.4 Commercially available kits for immunodetection of *Cryptosporidium* spp.

Organism and kit name	Manufacturer and/or distributor	Type of test	Comments (URLs are given only the first time the company appears in the table)

Triage Parasite Panel	BIOSITE Diagnostics, Inc. (www.biosite.com)	Cartridge device, lateral flow	Requires fresh or frozen stool; combination test with <i>Giardia</i> and <i>E. histolytica</i> / <i>E. dispar</i> group; does not differentiate between <i>E. histolytica</i> and <i>E. dispar</i>

quite heavy; in this case, suspicious objects seen in the wet mount may be suggestive of coccidian oocysts.

- Several concentrates and at least five or six modified acid-fast smears should be examined before a patient is considered negative, especially if the patient has been receiving experimental medications.
- The normal permanent stains (trichrome, iron hematoxylin) do not adequately stain *Cryptosporidium* spp., although oocysts are occasionally seen in these preparations, especially those from patients with heavy infections.

- Although the organisms can be stained with auramine-rhodamine stains, they should be confirmed by using acid-fast stains or the immunoassay reagents (most sensitive). This is particularly true if the stool contains other cells or a lot of artifact material (more normal stool consistency).
- When using immunoassay reagents, it is important to remember that the stool specimen fixative and immunoassay reagents must be compatible. Concentrated stool sediment ($500 \times g$ for 10 min) should always be used for staining tests (modified acid-fast, etc.)

Table 4.5 Testing options for the diagnosis of cryptosporidiosis^a

History	Pros	Cons
No travel outside United States		
Test every stool		
Modified acid-fast stain	Identifies infected patients	May not detect carriers or patients with small number of organisms
Immunoassay	Is more sensitive than the modified acid-fast stains and may identify patients who are carriers with low parasite numbers	High cost; may not be clinically relevant to screen all patients, particularly if there are small numbers in the patient base
Test on order only (after appropriate education of the physician client base)		
Geographic area with little to no reported cases	Is clinically relevant and more cost-effective	Still necessary to set up linkages with public health, water companies, etc., so that appropriate communication can serve as a link and notice of possible early outbreak situation
Geographic area with reported cases and history of outbreak situations	Education of the physician client base targets potential patient risk groups and potential problem situations	Still necessary to continue linkages with public health, water companies, etc., so that appropriate communication can serve as a link and notice of possible early outbreak situation
Travel outside United States		
Order routine ova and parasite examinations (minimum of two; must include the concentration and permanent stained smear)	Facilitates detection and identification of possible other relevant pathogens. If patient has become asymptomatic by the time the ova and parasite examination results are available (negative results), no additional testing is required	Routine ova and parasite exam will not reveal the presence of <i>Cryptosporidium</i> (with rare exceptions based on organism numbers and method selection) If the patient remains symptomatic after the ova and parasite examination results (negative results) are available, more sensitive immunoassay procedures can be performed
Order routine ova and parasite examinations and immunoassay for <i>Cryptosporidium</i>	This approach may be more clinically relevant in terms of turnaround time issues	May result in excess testing

^a It is important to remember that laboratories in different geographic regions may approach this testing differently. The important point is to ensure that physicians and laboratory personnel communicate regarding the pros and cons of each approach. Preliminary education, selection of the most clinically relevant approach, client education and communication, and periodic review of testing options and approaches will result in more cost-effective and better patient care.

and FA immunoassay because the tests are detecting the oocysts. However, when immunoassay reagents are used to detect *Cryptosporidium* antigen, the specimen does not have to be concentrated before being tested. Check specific kit directions.

7. Sputum specimens should be submitted in 5 or 10% formalin and processed in the same way as a stool sample.
8. It is important to remember that microsporidia are also present in approximately 30% of severely immunocompromised patients (≤ 100 CD4⁺ cells) who have cryptosporidiosis. The diagnostic procedures for the identification of *Cryptosporidium* spp. are not appropriate for the identification of microsporidial spores. Modified trichrome stains and optical brightening agents (calcofluor white) can be used for that purpose (23).

When examining histology preparations, developmental stages in the life cycle of *Cryptosporidium* spp. can be found at all levels of the intestinal tract, with the jejunum being the most heavily infected site. Routine hematoxylin and eosin staining is sufficient to demonstrate these parasites. Under regular light microscopy, the organisms are visible as small (~1 to 3 μ m), round structures aligned along the brush border. They are intracellular but extracytoplasmic and are found in parasitophorous vacuoles. Developmental stages are more difficult to identify without using transmission electron microscopy. It is also important to remember that *Cryptosporidium* spp. have been found in other body sites, primarily the lungs, as a disseminated infection in severely immunocompromised patients. Within tissue, confusion with *Cyclospora cayentanensis* is unlikely, because the oocysts of this coccidian are approximately 8 to 10 μ m and the developmental stages occur within a vacuole at the luminal end of the en-

terocyte, rather than at the brush border. Developmental stages of *Isospora belli* also occur within the enterocyte and so should not be confused with *Cryptosporidium* spp.

Newer methods involving PCR have also been used to detect *Cryptosporidium* DNA in fixed, paraffin-embedded tissue (30). This approach could provide a sensitive and specific method for detection of parasite material in paraffin-embedded tissues and could be very valuable in retrospective studies of archival material. PCR has also been used to detect viable *Cryptosporidium* oocysts. Using PCR, confirmation of the presence of *Cryptosporidium* spp. in environmental studies has become more widely used (6, 14, 16, 31, 42).

During the past few years, the issues of water quality and water testing have become more important and controversial. Since the late 1980s, most of the water utilities have either set up in-house water quality testing laboratories or contracted with commercial water laboratories for the recovery and identification of *Cryptosporidium* and *Giardia* species. In a recent study, two methods were evaluated for the recovery of *Cryptosporidium* and *Giardia* species. The American Society for Testing and Materials method involves sampling a minimum of 100 liters of water through a polypropylene yard cartridge filter, extracting the particulates, flotation concentrating the extracted particulates on a Percoll-sucrose gradient with the commercially available *Cryptosporidium*/*Giardia* combination FA reagent, and reviewing the slides for the presence of *Cryptosporidium* oocysts and/or *Giardia* cysts. This method tends to be labor-intensive, complex, and lengthy and depends on the skill and experience of the personnel and the quality control measures in use within the laboratory. Recovery rates tend to be low with this approach. The second method uses sampling by membrane filtration, Percoll-Percoll step gradient, and immunofluorescent staining; this method was characterized by higher recovery rates in all three types of waters tested: raw surface water, partially treated water from a flocculation basin, and filtered water. When seeded specimens were used, much higher recovery rates were obtained when the flotation step was eliminated from the protocol. Oocyst and cyst recovery rates decreased in both methods as the turbidity of the water increased. When smaller tubes were used for flotation, the membrane filter method was less time-consuming and cheaper. However, the lack of a confirmatory step might be a problem, particularly if cross-reacting algae are present in water samples. A number of other test options, including PCR, are currently being used (3, 12, 19, 20, 30, 40, 42). Unfortunately, these procedures emphasize organism detection; the issues of organism viability and infectivity have not yet been totally resolved.

Treatment

Cryptosporidiosis tends to be self-limiting in patients who have an intact immune system. For patients who are receiving immunosuppressive agents, one method of therapy would be to discontinue such a regimen. Other approaches with specific therapeutic drugs have been tried, but to date the results are still somewhat controversial (Table 4.6). Tissue culture systems with cell lines such as human ileocecal adenocarcinoma (HCT-8) cells and animal models that support the entire life cycle have been developed, and these may provide excellent opportunities for in vitro drug studies.

Unfortunately, even the studies reported for oral treatment with spiramycin, a macrolide antibiotic related to erythromycin, have been inconclusive. Studies indicate a statistically significant reduction in median oocyst excretion after 2 weeks of therapy with paromomycin. Several studies have reported success for a combination of paromomycin (1 g twice daily) and azithromycin (600 mg daily) for 4 weeks followed by paromomycin monotherapy for an additional 8 weeks. Data indicate that severely immunocompromised AIDS patients with refractory cryptosporidiosis may show a variable response to letrozuril, with a high rate of relapse and rash as a major side effect. Nitazoxanide has also been used and is currently being tested for its efficacy against chronic cryptosporidiosis in human clinical trials. Ongoing studies with immunologic intervention hold promise, but this approach is still being evaluated in clinical trials.

One approach that has had a dramatic impact on cryptosporidiosis in AIDS patients is highly active antiretroviral therapy leading to an increased CD4 count. Resolution of the diarrhea resulting from cryptosporidiosis is apparently related to the enhanced CD4 count rather than to any change in the viral load or any therapeutic impact of the drugs themselves. Thus, it appears that cellular immunity is critical in clearing *Cryptosporidium* infection in these patients.

Epidemiology and Prevention

Information on the epidemiology of *Cryptosporidium* continues to expand, since its potential pathogenicity in humans is now well documented (Tables 4.7 to 4.9; Figures 4.6 to 4.8). The organism is transmitted by oocysts that are usually fully sporulated and infective at the time they are passed in stool. The oocysts are resistant to some of the disinfectants that are routinely used in medical care facilities. Exactly which of the oocyst layers is primarily responsible for the mechanical rigidity and resistance to disruption exhibited by the intact oocyst is not known. However, it has been suggested that the central glycolipid/lipoprotein layer and the inner filamentous layer may provide rigidity and elasticity to the wall.

Table 4.6 Chemotherapeutic agents and supportive therapy for the treatment of human cryptosporidiosis^a

Chemotherapeutic agent ^b	Comments
Macrolides	
Spiramycin (oral)	Although a number of studies have been reported, divergent results are seen. Placebo results were often comparable to those obtained from patients receiving the drug. Absorption seems to be decreased in the presence of food. Decrease in diarrhea and oocyst excretion was seen in immunocompetent infants randomized to receive spiramycin (100 mg/kg/day) or placebo. A positive clinical response, as well as organism eradication, has also been reported in a group of AIDS patients.
Spiramycin (intravenous)	This approach was taken to circumvent absorption problems. Data revealed a statistically significant drop in oocyst count compared to placebo; however, administration of intravenous spiramycin was associated with paresthesias, taste perversion, nausea, and vomiting. At doses of >75 mg/kg/day there were cases of severe colitis due to intestinal injury.
Azithromycin	This drug has a long half-life (6 to 8 h) and achieves high concentrations in tissue, particularly in the biliary tree and gallbladder. Although decreased oocyst counts have been obtained from patients with high drug levels in serum, marginal improvement has been seen in other patients. A lactose-free form of azithromycin in 300-mg tablets is available through Pfizer's compassionate-use program. There may be a therapeutic effect on biliary tree infection, particularly in patients receiving intravenous azithromycin. Intravenous azithromycin at doses up to 2 g daily for 2 weeks is well tolerated.
Clarithromycin	Little information is available on other macrolides, including clarithromycin, roxithromycin, and dirithromycin; however, studies are in progress.
Benzeneacetonitrile derivatives	
Diclazuril	Interest stems from its efficacy for <i>Eimeria</i> ; however, reports indicate that doses ranging from 50 to 800 mg were no more efficacious than placebo. This may have been due to poor drug bioavailability.
Letrazuril	Poor absorption of diclazuril led to the development of letrazuril. Although bioavailability was improved, patient clinical improvement was minimal. Data also suggest that this drug may interfere with modified acid-fast staining methods.
Miscellaneous agents	
Paromomycin (Humatin)	Paromomycin is synonymous with aminosidine (marketed outside the United States). It is an oligosaccharide aminoglycoside related to kanamycin; it achieves high concentrations in the colon but is poorly absorbed. Studies indicate that the drug effect is probably static rather than cidal for <i>Cryptosporidium</i> . Although decreased bowel movements and oocyst shedding have been reported, a small number of patients developed biliary tract disease and some of these required cholecystectomy. Despite conflicting results, paromomycin currently is used as the first-line drug in treating cryptosporidiosis. Since patients enter treatment trials after paromomycin failure, the question of delay and possible spread to the biliary tree has been raised.
Nitazoxanide	This is a nitrothiazole benzamide with a wide spectrum of activity against coccidia, amebae, nematodes, cestodes, and trematodes. Preliminary data appear promising, with suggested activity against cryptosporidial infection in AIDS patients. The agent appears to be well tolerated. Additional trials are under way.
Difluoromethylornithine (DFMO) (Eflornithine)	Although some success with this agent against <i>Cryptosporidium</i> in AIDS patients has been reported, serious toxicity has been documented (bone marrow suppression, gastrointestinal intolerance, and hearing impairment).
Atovaquone (Mepron)	This drug is an antimalarial that has been evaluated against <i>Pneumocystis jiroveci</i> , <i>Toxoplasma gondii</i> , and <i>Cryptosporidium</i> in AIDS patients. Preliminary results do not look promising.
Supportive therapeutic agents	
Nonspecific antidiarrheal agents (Kaopectate, Imodium, Lomotil, Pepto-Bismol, opiates)	These agents are often helpful, but individual regimens need to be developed for each patient; safety in patients with cryptosporidiosis is not known.
Octreotide (Sandostatin)	This is a synthetic cyclic octapeptide analog of somatostatin; anecdotal reports indicate some success in treating AIDS-related diarrhea. However, most patients had neither cryptosporidial diarrhea nor other identifiable pathogens.

^a Adapted from B. L. Blagburn and R. Soave, Prophylaxis and chemotherapy: human and animal, p. 112–115, in R. Fayer (ed.), *Cryptosporidium and Cryptosporidiosis*, ASM Press, Washington, D.C., 1997, and reference 22.

^b Although other agents have been tried (zidovudine, recombinant interleukin-2), any improvement is most probably due to increased patient immune function rather than to the antiparasitic activity of the drug.

Oocysts are susceptible to ammonia, 10% formalin in saline, freeze-drying, and exposure to temperatures above 65°C for 30 min. Commercial bleach in a 50% solution is also effective (Table 4.10). For most of the chemicals that have been tried for disinfection, effective concentrations are not practical outside the laboratory and high concentrations that significantly reduce oocyst infectivity are either very expensive or quite toxic. Unfortunately, oocysts of *Cryptosporidium* have shown high levels of resistance to most commercial disinfectants, including iodine water purification tablets (4). Although chlorine and related compounds can dramatically reduce the ability of oocysts to excyst or infect, high concentrations and long exposure times are required, making this approach impractical. Although rare, some stool specimen collection kits contain a vial of potassium dichromate specifically for *Cryptosporidium* spp., and the oocysts remain viable in this solution for at least 12 months.

Almost all oocysts exposed to soils that are frozen at -10°C become inactivated within 50 days; inactivation occurs regardless of the presence or absence of freeze-thaw cycles (25). Although oocysts that are purified from fecal material prior to cryopreservation tend to lose viability and infectivity for tissue culture and mice, when the oocysts are cryopreserved in feces a certain number remain viable and maintain infectivity. Based on these studies, fecal material appears to protect the oocysts during cryopreservation stored at -20°C for at least 30 days (26).

Studies have shown that calves and perhaps other animals serve as potential sources of human infections. Contact with these animals may be an unrecognized cause of gastroenteritis in humans in both rural and urban settings. Direct person-to-person transmission is also likely and may occur through direct or indirect contact with stool material. Direct transmission may occur during sexual practices involving oral-anal contact. Indirect transmission may occur through exposure to positive specimens

Table 4.7 Biological factors which impact the epidemiology of *Cryptosporidium*^a

Small (4–6 µm), environmentally resistant, and fully sporulated/infectious oocysts when passed
Large livestock animal and human reservoir host populations
Ubiquitous, able to cross-infect multiple host species (not species specific)
Low infective dose (≤10–100 oocysts)
Large multiplication capability (>10 ¹⁰) in a single host
Resistance to disinfectants
Lack of effective therapy; resistance to available drugs

^a Adapted from D. P. Casmore, S. E. Wright, and R. L. Coop, Cryptosporidiosis—human and animal epidemiology, p. 66–73, in R. Fayer (ed.), *Cryptosporidium and Cryptosporidiosis*, ASM Press, Washington, D.C., 1997.

Table 4.8 Risk factors for acquisition of cryptosporidiosis

Risk factor	Examples
Deficient immunity	AIDS, other acquired or congenital immunodepression syndromes (e.g., boys with mutation of the CD154 gene, congenital X-linked immunodeficiency with hyper-IgM), immunosuppression, malnutrition
Zoonotic contact	Leisure activities such as camping, backpacking, farm visits
Occupational exposure	Veterinary, agricultural, nursing or medical, laboratory, day care centers
Poor sanitary conditions	Drinking water and food, inadequate sewage or waste disposal, inadequate fly control
Exposure to untreated water (surface or recreational)	Leisure activities
Exposure to inadequately treated water supply	Inadequate treatment or breakdown in treatment process
Consumption of raw foods	Unpasteurized milk, raw meat
Travel	Travel from developed to underdeveloped countries and from urban to rural areas
Age (infants, young children)	Weaning, teething, pica, finger sucking, wearing diapers; poor infection control
Contact with case of diarrhea	Day care, household, parents

Table 4.9 Factors related to potential outbreaks of cryptosporidiosis

Factor	Examples
Factors unrelated to water	Sufficient number of parasites (viability, infectivity, virulence) Sufficient number of susceptible individuals for ingestion of oocysts leading to primary infection Sufficient number of susceptible individuals for whom contact with primary case leads to secondary transmission Adequate epidemiologic and laboratory surveillance and reporting
Water-related factors	Abnormal weather conditions (heavy rainfall); increased load for water treatment facilities High turbidity of surface water; increased challenge for water treatment facilities Breakdown in integrity of groundwater aquifers (prolonged rain after drought) Suboptimal water treatment functions Problems with finished-water distribution

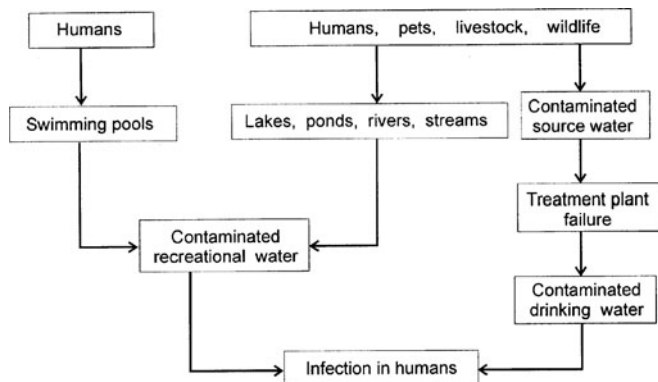

Figure 4.6 Flow diagram demonstrating sources of water-borne transmission of *Cryptosporidium* oocysts.

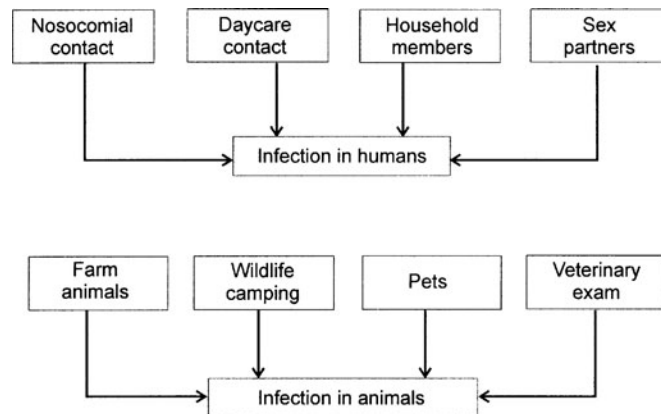

Figure 4.8 Flow diagram demonstrating sources of close-contact transmission of *Cryptosporidium* oocysts.

in a laboratory setting or from contaminated surfaces or food or water (3, 6, 8, 12, 14–22, 27, 31, 40, 42).

In January and February 1987, cryptosporidiosis was associated with an estimated 13,000 cases of gastroenteritis in Carroll County, Ga. *Cryptosporidium* oocysts were identified in the stools of 39% of the persons examined during the outbreak; a randomized telephone survey indicated probable attack rates of 54% within the city of Carrollton and 40% overall for the county. The only significant risk factor associated with illness was exposure to the public water supply, which was filtered and chlorinated. It was interesting that according to records kept during the outbreak, the treatment facility was operating within Environmental Protection Agency guidelines. Additional reports of waterborne outbreaks have appeared in the past few years (Table 4.11). Another massive waterborne outbreak was reported in Milwaukee,

Wis. Contamination of the public water supply during March and April 1993 resulted in approximately 300,000 infections. Infection during this outbreak appeared to be more severe than in previous reports of large case series. The risk of secondary infection in a household was low

^a Data from the CDC Surveillance for Waterborne-Disease Outbreaks—United States (usually provided on a 2-year cycle with a 2- to 3-year delay).

^b In June/July, 2004, approximately 50 people were infected with *C. cayetanensis* from the ingestion of snow peas (7).

(5%) when the index case involved an adult. Also, the recurrence of watery diarrhea after apparent recovery was a frequent occurrence among visitors with laboratory-confirmed cryptosporidiosis (39%) and among visitors and residents with clinical infection (21%).

This increase in the number of reported waterborne disease outbreaks associated with *Cryptosporidium* spp. can be attributed to improved techniques for oocyst recovery and identification. The use of high-volume filters, immunofluorescence, and molecular detection methods has resulted in the demonstration of oocysts in surface and drinking waters and in sewage effluents from many geographic regions (3, 12, 19, 20, 30, 42).

The immunofluorescence method can be used to examine large volumes of water, is relatively specific for *Giardia* and *Cryptosporidium* spp., and permits examination of the specimen by epifluorescence and phase-contrast or differential interference contrast microscopy (Figure 4.9). However, disadvantages of the method include low recovery percentages (5 to 25%), long processing times (1–2 days to 1–2 weeks), the need for highly trained per-

Figure 4.9 Procedure for water testing for the recovery of *Giardia* cysts and *Cryptosporidium* oocysts in water. (Adapted from J.B. Rose, J.T. Lisle, and M. LeChavalier, Waterborne cryptosporidiosis: incidence, outbreaks, and treatment strategies, p. 95–100, in R. Fayer (ed.), *Cryptosporidium and Cryptosporidiosis*, ASM Press, Washington, D.C., 1997.

- Water sample (example: 400 liters of surface water; 1,000 liters of groundwater)
- Filter through large polypropylene cartridge filter (pore size, 1 μm)
- Cut filter in half lengthwise
- Suspend fibers in 0.1% SDS–0.1% Tween 80 buffer
- Hand wash or homogenize with large stomacher (to release organisms from polypropylene filter fibers)
- Centrifuge and combine sedimented material into one pellet
- Select appropriate volume, sonicate for 10 min
- Underlay or overlay with Percoll-sucrose flotation medium (specific gravity, 1.10)
- Centrifuge at $1,050 \times g$ for 10 min
- Draw off top layer, dilute to 50 ml, centrifuge at $1,050 \times g$ for 10 min
- Layer flotation surface sample on 25-mm filter (pore size, 0.2 μm)
- Add monoclonal antiserum mixture (*Giardia* and *Cryptosporidium*)
- Wash
- Add labeling reagent
- Wash
- Dehydrate with alcohol series
- Clear filter with 2% DABCO–glycerol solution
- Examine using epifluorescence, phase-contrast, or differential interference contrast microscopy

sonnel, the high cost per sample (approximately \$300), the inability to identify viable or virulent organisms, and cross-reactivity with nonhuman *Cryptosporidium* organisms. Unfortunately, the more the specimen or water sample is manipulated during processing, the more likely it is that organisms will be lost in the process, thus accounting for the low recovery percentages.

Incorporation of the use of fluorogenic vital dyes to determine oocyst viability appears to offer some improvements; however, the positive relationship between vital-dye reactions and excystation may not always correlate directly with viability or infectivity. A number of other methods have been used in an effort to improve organism recovery and to determine the viability and infectivity of the oocysts recovered. These include the use of a fluorescence in situ hybridization technique for labeling of *Cryptosporidium* oocysts in water samples, species- and strain-specific typing of parasites in clinical and environmental samples, use of PCR for the detection of *Cryptosporidium* oocysts in municipal water samples, use of cell culture to determine the infectivity of *Cryptosporidium* oocysts, immunomagnetic separation coupled with immunofluorescence microscopy for oocyst detection, a combination of immunomagnetic separation and integrated cell culture-PCR, and use of β -tubulin mRNA as a marker of *Cryptosporidium* oocyst viability.

Data indicate that viable *Cryptosporidium* oocysts exposed to chlorine or other oxidizing conditions may lack identifying epitopes. This finding may be important for the water industry, where naturally occurring oxidizing conditions or sanitizing treatments could produce viable oocysts that are undetectable by standard protocols. Detailed knowledge of the structure and stability of the *Cryptosporidium* oocyst wall may ultimately contribute to the development of water treatment options that will reduce the viability of the intact oocyst and thus the waterborne dissemination of the parasite.

The importance of agricultural wastewater and runoff, particularly from lambs and calves, is also now recognized as a potential source of infective *Cryptosporidium* oocysts (42). It has been shown that in healthy adults with no serologic evidence of past infection with *Cryptosporidium*, a low dose of oocysts is sufficient to cause infection. With healthy human volunteers, the median infective dose was 132 oocysts and one-fifth of the volunteers became infected with a dose as low as 30 oocysts. Specific guidelines are available for the prevention of cryptosporidiosis, particularly where drinking water is involved. Information can be seen in Tables 4.12 to 4.14.

Various surveys indicate prevalence rates of 1 to 2% in Europe, 0.6 to 4.3% in North America, and 3 to 20% in other areas of the world (Asia, Australia, Africa, and

Central and South America). It has been suggested that the infection rate for individuals with diarrheal illness is 2.2% for persons living in industrialized countries and 8.5% for those residing in developing countries. Available data indicate that there are 250 million to 500 million *Cryptosporidium* infections annually among persons living in Asia, Africa, and Latin America. Generally, young children tend to have higher infection rates and all patients appear to have symptoms. Available serologic data support the prevalence rates, with figures from Europe and North America normally between 25 and 35% and those from South America indicating rates of up to 64%.

The epidemiologic considerations for cryptosporidiosis emphasize transmission by environmentally resistant oocysts, numerous potential reservoir hosts for zoonotic transmission, documentation of person-to-person transmission in day care centers, nosocomial transmission within the health care setting, occurrence of asymptomatic infections (infective, carrier state), widespread environmental distribution resulting in the probability of waterborne transmission, and the link between cryptosporidiosis and severe, life-threatening disease in individuals with impaired immune function. Prevalence data from the Centers for Disease Control and Prevention for patients with AIDS are thought to be an underestimate of the actual prevalence (2 to 5%), particularly when other figures indicate percentages of 15% (National Institutes of Health, Bethesda, Md.) and 11% (Great Britain). Surveillance systems currently under discussion can be seen in Table 4.15.

As our understanding of the epidemiology of cryptosporidiosis expands, it is obvious that there are numerous ways for the resistant oocysts to become disseminated. Some of these recent examples have generated enhanced interest in and concern about additional sources of infectious oocysts and the potential for accidental human consumption through contaminated food and/or water. Specific examples can be seen in Table 4.16 and Figures 4.6 and 4.10.

Cyclospora cayetanensis

In recent years, human cyclosporiasis has emerged as an important infection, with a number of outbreaks being reported in the United States and Canada. Prior to 1995, only one outbreak of cyclosporiasis had been reported in the United States; however, from May through August 1996, more than 1,400 cases were reported from 20 states, Washington, D.C., and two Canadian provinces (7, 22, 36). Understanding of the biology and epidemiology of *C. cayetanensis* is limited and has been complicated by a lack of information about the parasite's

Table 4.12 Prevention of cryptosporidiosis: recommendations (particularly important for patients who are immunocompromised)^a

Preventive measure	Comments
Handwashing	Prior to eating and food preparation; after touching children in diapers; after touching clothing, bedding, toilets, bed pans from anyone with diarrhea; after gardening; after touching pets or other animals; after touching or coming in contact with anything contaminated with human or animal stool (includes dirt); after removing gloves to perform any of the above activities.
Practicing safe sex	Always wash hands after touching partner's anal or rectal area.
Avoiding touching farm animals	Particularly important for contact with young animals; wash hands thoroughly; avoid touching stool of any animal; after potential exposure, clean shoes (HIV-infected persons should not perform this task).
Avoiding pets' stools	If HIV infected, avoid cleaning litter boxes or cages or stool disposal (very important if animals are younger than 6 months); have puppies or kittens (if younger than 6 months) tested for presence of <i>Cryptosporidium</i> before bringing them home; have any pet tested that has diarrhea.
Swimming	Avoid swallowing water when in lakes, rivers, pools, or hot tubs; organisms are not killed by routine chlorination; avoid swimming in polluted ocean water, since oocysts can survive for several days in salt water.
Washing and cooking food	Thoroughly wash all fruits and vegetables if eating uncooked; use safe water (see below) for washing food; peel fruit; avoid unpasteurized milk or dairy products. Cooking kills <i>Cryptosporidium</i> , so cooked or packaged food is safe unless handled by someone infected with the organism.
Drinking water	Do not drink directly from lakes, rivers, streams, or springs; may want to avoid tap water (including refrigerator ice-maker ice and chilled water); boil water (rolling boil for 1 min is sufficient to kill organisms); filter with appropriate filters (look for "reverse osmosis," "absolute 1 micron," "Standard 53," and the words "cyst reduction" or "cyst removal"); a home distiller can be used. Store filtered water as for boiled water.
Bottled water	Bottled water labels reading "well water," "artesian well water," "spring water," or "mineral water" do not guarantee that the water does not contain <i>Cryptosporidium</i> . However, water that comes from protected well or spring water sources is less likely to be contaminated than bottled water from rivers and lakes.
Drinks	Canned or bottled soda, seltzer, fruit drinks, and steaming hot tea and coffee are safe; fountain drinks, fruit drinks mixed with tap water from concentrate, and iced tea or coffee may not be safe.

Table 4.15 Possible surveillance approaches for the establishment of baseline data on the occurrence of cryptosporidiosis

Surveillance approach	Comments
Make cryptosporidiosis reportable to CDC	Applies to each state or city; provides legal authority for collecting information
Monitor sales of antidiarrheal medications	Local pharmacy computerized databases (provide historical as well as current diarrheal illness information)
Monitor logs maintained by HMOs and hospitals (complaints of diarrheal illness)	May be particularly useful if keyed to zip codes, particularly in case of waterborne transmission
Monitor incidence of diarrheal illness in nursing homes	Can monitor differences between use of municipal and bottled water; could also serve to establish baseline data
Monitor laboratory data for <i>Cryptosporidium</i> spp.	More likely to provide information on AIDS (or other immunocompromised) patients; may not be best way to obtain information on general public (excessive cost)
Monitor tap water in selected cities or locations	Intensive surveillance might be recommended in approximately 10 cities known to have <i>Cryptosporidium</i> spp. in their finished water, again to establish some baseline data
Establish methods of rapid reporting and communication among relevant agencies	Education of physicians, public, etc., vital to the understanding of epidemiology of cryptosporidiosis

origins, possible animal reservoir hosts, and relationship to other coccidia (28, 36).

During the past few years, there have been several outbreaks of diarrhea associated with *C. cayetanensis*; the distribution is worldwide (United States, Caribbean, Central and South America, Southeast Asia, Eastern Europe, Australia, Nepal). These organisms are acid-fast variable and have been found in the feces of immunocompetent travelers to developing countries, immunocompetent subjects with no travel history, and patients with AIDS. Patients reported symptoms of a “flu-like” illness with nausea, vomiting, anorexia, weight loss, and explosive diarrhea lasting 1 to 3 weeks. Cumulative evidence suggests that outbreaks in the United States and Canada during the spring months of 1996 and 1997 were related to the importation and ingestion of Guatemalan raspberries. It is quite likely that the outbreak reported from Florida in 1995 was also attributed to contaminated food. The cases reported in all three outbreaks probably represented only a small fraction of those that occurred.

Table 4.16 Potential sources for *Cryptosporidium* oocysts related to accidental human ingestion of contaminated food and/or water

Transmission agent	Comments
Eastern oysters (<i>Crassostrea virginica</i>)	Oysters collected from Maryland tributaries of the Chesapeake Bay contain infectious oocysts; 7 sites in Chesapeake Bay area are positive for infected oysters
Atlantic coast commercial shellfish	<i>Cryptosporidium</i> spp. found in commercial shellfish from 64.9% of sites examined along the Atlantic coast, using either microscopy or molecular testing
Clams (Italy, seawater)	Oocysts detected in 23 of 32 pools of clams
Clams (California, freshwater)	<i>C. parvum</i> DNA in clams from 3 different riverine ecosystems confirmed with PCR and DNA sequence analysis
Clams (<i>Tapes decussates</i> , Spain)	Oocysts found in siphons, gills, stomach, digestive diverticula, intestine; oocysts found in branchial mucus and in interfilamentary spaces suggest repeated filtrations and the possibility of infective oocysts
Bent mussels (<i>Ischadium recurvum</i>)	Mussels may be useful as biological indicator of water contamination with <i>Cryptosporidium</i> oocysts; found in same areas indicated above for oysters
Mussels (<i>Mytilus galloprovincialis</i>)	Oocysts survive in seawater for at least 1 year; filtered out by benthic mussels, retaining infectivity up to 14 days
Canada geese (migrating birds)	Infectious oocysts disseminated by migrating waterfowl
House flies (<i>Musca domestica</i>)	Adult and larval stages of house flies can mechanically carry oocysts in their digestive tracts and deposit them on external surfaces
Filth flies (Calliphoridae, Sarcophagidae, Muscidae)	Wild-caught flies (>90%) harbored <i>Cryptosporidium</i> oocysts; oocysts carried internally and externally—potential for mechanical transmission of infectious oocysts
Filth flies (Muscidae, Calliphoridae, Lauxaniidae, Anthomyiidae)	80% of all <i>Cryptosporidium</i> oocysts viable; >69% of <i>Giardia lamblia</i> cysts viable; potential for mechanical transmission of infectious oocysts high
Dung beetles (<i>Anoplotrupes stercorosus</i> , <i>Aphodius rufus</i> , <i>Onthophagus fracticornis</i>)	Although many oocysts pass safely through mouthparts and gastrointestinal tracts of the beetles, most are destroyed; however, coprophagous insects are considered important as agents of both control and dissemination
Free-living soil nematode (<i>Caenorhabditis elegans</i>)	<i>C. elegans</i> can ingest and excrete oocysts; the role of free-living nematodes in contamination requires further study

These organisms have now been identified as coccidia in the genus *Cyclospora* and were first discovered in the late 1880s but not connected with human infections.

Life Cycle and Morphology

The oocysts that had previously been recovered from human stool specimens were immature, so the structure of the mature oocyst was not seen in those specimens. It takes approximately 5 days or more for oocyst maturation, so the mature stage may not have been seen in human specimens. Evidence obtained from excystation experiments indicates that the oocyst contains two sporocysts, each containing two sporozoites, a pattern which places these organisms in the coccidian genus *Cyclospora*. Electron microscopy (EM) confirmed the presence of characteristic organelles for coccidian organisms of the phylum Apicomplexa. The name *Cyclospora cayetanensis* sp. nov. has been proposed for this newly described disease-producing coccidian organism from humans. The species name comes from the university where it was initially studied (Universidad Peruana Cayetano Heredia).

Two types of meronts and sexual stages have been seen in jejunal enterocytes in biopsy specimens from infected patients. These findings confirm that the entire life cycle can be completed within a single host (Figure 4.11). Unsporulated oocysts are passed in the stool, and sporulation occurs within approximately 7 to 13 days. Complete sporulation produces two sporocysts that rupture to reveal two crescent-shaped sporozoites measuring 1.2 by 9.0 μm .

The transmission of *Cyclospora* is thought to be fecal-oral, although direct person-to-person transmission has not been well documented and may not be a factor, since sporulation takes a number of days. Outbreaks linked to contaminated water and various types of fresh produce (raspberries, basil, baby lettuce leaves, and snow peas) have been reported (Table 4.17). Also, information on potential reservoir hosts has yet to be defined; however, it appears that in some areas the human is the only host.

Clinical Disease

Developmental stages of *C. cayetanensis* usually occur within epithelial cells of the jejunum and lower portion of the duodenum. *Cyclospora* infection reveals characteristics of a small bowel pathogen, including upper gastrointestinal symptoms, malabsorption of D-xylose, weight loss, and moderate to marked erythema of the distal duodenum. Histopathology in small bowel biopsy specimens reveals acute and chronic inflammation, partial villous atrophy, and crypt hyperplasia.

The incubation period is approximately 2 to 11 days after exposure. There is generally 1 day of malaise and

Figure 4.10 *Cryptosporidium* oocysts (arrows) detected by immunofluorescent antibodies in fecal spots and on the exoskeleton of house flies (*Musca domestica*) exposed to bovine diarrheal feces containing *Cryptosporidium* oocysts. (Photograph courtesy of T. K. Graczyk, with permission.)

low-grade fever, with rapid onset of diarrhea of up to seven stools per day. There may also be fatigue, anorexia, vomiting, myalgia, and weight loss with remission of self-limiting diarrhea in 3 to 4 days, followed by relapses lasting from 4 to 7 weeks. In patients with AIDS, symptoms may persist for as long as 12 weeks; biliary disease has also been detected in this group. Diarrhea alternating with constipation has also been reported; this is not uncommon in a number of protozoal gastrointestinal infections. Clinical clues include unexplained prolonged diarrheal

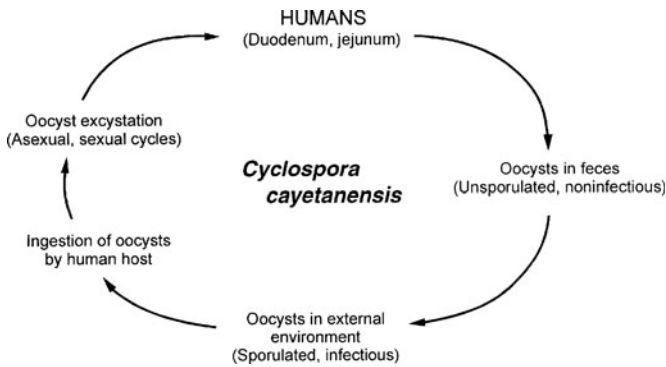

Figure 4.11 (Top) *Cyclospora cayetanensis* life cycle. (Middle and bottom) *C. cayetanensis* in wet preparation, phase contrast. M, mature oocyst; IM, immature oocyst. (Courtesy of Susan Novak [middle] and Charles R. Sterling [bottom].)

illness during the summer in any patient and in persons returning from tropical areas. The majority of infected individuals had intermittent diarrhea for 2 to 3 weeks, and many complained of intense fatigue, as well as anorexia and myalgia, during the illness. The clinical presentation of patients infected with this organism is similar to that of patients infected with *Cryptosporidium*.

Diagnosis

When examined in formalin-preserved human stool specimens and by EM, these organisms exhibited characteristics of a cyanobacterium. The organisms stained orange with safranin and were modified acid-fast variable, with some organisms staining deep red with a mottled appearance but no internal organization (38). Preliminary EM revealed internal structures that resembled those of the cyanobacteria. In clean wet mounts, the organisms are seen as nonrefractile spheres and are acid-fast variable with the modified acid-fast stain; those that are unstained appear as glassy, wrinkled spheres (Figures 4.11 to 4.14). Modified acid-fast stains stain the oocysts light pink to deep red, and some will contain granules or have a bubbly appearance. It is very important to be aware of these organisms when the modified acid-fast stain is used, because *Cryptosporidium* spp. and other similar but larger structures (approximately twice the size of *Cryptosporidium* oocysts) are seen in the stained smear. It is important for laboratories to measure all acid-fast oocysts, particularly if they appear to be somewhat larger than those of *Cryptosporidium*. The oocysts autofluoresce strong green (450 to 490 DM excitation filter) or intense blue (365 DM excitation filter) under UV epifluorescence. It is strongly recommended that during concentration (formalin-ethyl acetate) of stool specimens, the centrifugation be carried out for 10 min at $500 \times g$.

Although modified acid-fast stains are the most commonly used stains to identify the oocysts in stool, a safranin-based stain that tends to uniformly stain *Cyclospora* oocysts is also recommended (38).

Another diagnostic option involves the use of flow cytometry. This approach appears to be a useful alternative to microscopy, particularly for screening large numbers of clinical specimens for *Cyclospora* oocysts in an outbreak situation (11).

KEY POINTS—LABORATORY DIAGNOSIS

Cyclospora cayetanensis

1. Specimens may appear to be larger than normal *Cryptosporidium* oocysts; be sure to measure these organisms to confirm their size.
2. Fecal specimens should be concentrated prior to staining; centrifugation for 10 min at $500 \times g$ is recommended.
3. On wet smears, the oocysts appear as nonrefractile spheres and, depending on the filters used, autofluoresce green to blue with epifluorescence. Autofluorescence may be 2+ to 4+.
4. On modified acid-stained smears, the oocysts stain from light pink to deep red, and some contain

Table 4.17 Outbreaks of *Cyclospora cayetanensis* infection

Outbreak	Implicated cause	Comments
July 1990 (11 cases), Chicago hospital	Tap water from the physicians' dormitory was probably the source of the outbreak	This is the first reported outbreak of diarrhea associated with <i>Cyclospora</i> in the United States
1995 (14 cases), Florida	Fresh raspberries and strawberries	Given the cumulative evidence and the occurrence in 1996 and 1997 of outbreaks in North America associated with consumption of Guatemalan raspberries, food-borne transmission of <i>Cyclospora</i> was likely in 1995 in Florida as well
23 May 1996 (38 cases), South Carolina	Fresh raspberries	Imported from Guatemala
26 June 1996 (48–54 possible cases), Virginia	Basil-pesto pasta salad	No raspberries or mesclun lettuce was served at the luncheon
June and July 1996 (185 possible cases), 25 clusters in northern Virginia, Washington D.C., and Baltimore, Md.	Food containing fresh basil	All basil was associated with the same company
1996 (180 cases), Florida	Fresh raspberries	Imported from Guatemala
1996 (1,465 cases), 20 states	Fresh berries, berries with or without fresh raspberries	As few as five Guatemalan farms could have accounted for the 25 events; the raspberries could be traced to a single exporter per event
April and May 1997 (80 cases), California, Florida, Nevada, New York, and Texas	Fresh raspberries, mesclun (baby lettuce leaves, known as spring mix, field greens, or baby greens)	These 80 cases a part of the next listing for 1997 of a total of 1,450 cases
1997 (1,450 cases), United States and Canada	Fresh raspberries, mesclun	Most cases were linked to ingestion of raspberries from Guatemala; exportation of fresh raspberries from Guatemala was voluntarily suspended at the end of May 1997
1998 (94 cases), Boston, Mass.	Dessert containing raspberries, strawberries, blackberries, and blueberries	No specific commentary on source of fresh berries, but probably imported
July 1999 (62 cases), Missouri	Fresh basil	Chicken pasta salad and tomato basil salad; grown either in Mexico or United States
June 2000 (54 cases)	Fresh raspberries	Wedding cake, which had a cream filling that included raspberries imported from Guatemala
2001 (17 cases), British Columbia	Fresh Thai basil	Importation was traced from the United States
June and July 2004 (96 cases), Pennsylvania	Pasta salad containing raw snow peas	Snow peas imported from Guatemala

granules or have a bubbly appearance. Those that do not stain may appear wrinkled. A strong decolorizer should not be used; a 1% sulfuric acid solution is recommended and also works well for modified acid-fast stains for *Cryptosporidium* spp. and/or *Isospora belli*. The original 3 to 5% sulfuric acid is usually too strong for *Cyclospora* and removes too much color. Even with the 1% acid decolorizer, some oocysts may appear clear or very pale.

5. If the oocysts are seen in a regular trichrome-stained smear of stool, they may appear as clear, round, somewhat wrinkled objects that are larger than *Cryptosporidium* spp.
6. It is very important to measure these oocysts; *Cyclospora* oocysts measure 8 to 10 μm , and *Cryptosporidium* oocysts measure from 4 to 6 μm .
7. In the modified safranin technique, the oocysts uniformly stain a brilliant reddish orange if fecal smears

Figure 4.12 Human jejunal biopsy sections containing *Cyclospora cayetanensis* (courtesy of Ynes Ortega). Hematoxylin-and-eosin-stained sections. (Top) Low magnification ($\times 10$). Infected tissue showing villus atrophy and widening of villi. (Second from top) Magnification, $\times 100$. Multiple intracellular forms. (Third from top) Magnification, $\times 100$. Meront. (Bottom) Transmission electron microscopy. Meront with four merozoites.

Figure 4.13 (Upper) *Cyclospora cayetanensis* autofluorescence. (Lower) Modified acid-fast stain of *Cyclospora cayetanensis* (note that some oocysts stain quite dark, while some have not retained the stain; this is typical, and the organisms are described as “modified acid-fast variable”).

are heated in a microwave oven during staining. The stained slide can also be examined by epifluorescence microscopy first, and suspect oocysts can be confirmed by bright-field microscopy.

Treatment

Apparently, patients do not respond to conventional antimicrobial therapies. Some patients have been treated symptomatically with antidiarrheal preparations and have obtained some relief; however, the disease appears to be

Figure 4.14 Modified acid-fast stain (note the *Cryptosporidium* [4 to 6 μm] and *Cyclospora cayetanensis* [8 to 10 μm] oocysts); the *Cyclospora* oocyst has not retained the stain.

self-limiting within a few weeks. Trimethoprim-sulfamethoxazole (TMP-SMX) is currently the drug of choice (adults: 760/800 mg given orally twice daily for 7 days; children: 5 mg of TMP/kg plus 25 mg of SMX/kg given orally twice daily for 7 days); relief of symptoms has been seen by 1 to 3 days posttreatment. Patients with AIDS may need higher doses and long-term maintenance treatment. However, symptoms recur within 1 to 3 months posttreatment in over 40% of patients. In a study with TMP-SMX in Nepal, shedding of oocysts and symptoms disappeared after 7 days of treatment (28).

Epidemiology and Prevention

Published reports indicate that individuals of all ages, including both those who are immunocompetent and those who are immunosuppressed, can become infected. Travelers to areas with endemic *Cyclospora* infection should be aware of the increased risk of infection during the late spring and summer. Since this parasite, like *Cryptosporidium*, is not killed by routine chlorination, drinking water treated by halogenation may not be safe. Boiling is recommended. Hot drinks such as coffee or tea are recommended, rather than placing any reliance on iodine treatment of the water. Fresh fruits and vegetables should be thoroughly washed and/or peeled prior to eating. Although prophylaxis has not been adequately investigated and is not recommended, specific circumstances might warrant this approach (e.g., for human immunodeficiency virus [HIV]-positive individuals visiting these areas). In Peru, infections with this organism have shown

some seasonal variation, with peaks during April to June. This pattern is similar to that seen in *Cryptosporidium* infections in Peru. Preliminary data and extrapolation from what we currently know about cryptosporidiosis suggest that modes of transmission may be similar, particularly considering waterborne transmission (Table 4.11).

As our understanding of the epidemiology of cyclosporiasis expands, it is obvious that there may be numerous ways for the resistant oocysts to become disseminated. Some of these recent examples identified for *Cryptosporidium* spp. have generated enhanced interest in and concern about additional sources of infectious oocysts and the potential for accidental human consumption through contaminated food and/or water. These examples may be just as relevant for *Cyclospora*. Specific examples for *Cryptosporidium* can be seen in Table 4.16. Recovery of waterborne oocysts of *C. cayetanensis* in Asian freshwater clams (*Corbicula fluminea*) has been reported (28, 36).

Isospora (Cystoisospora) belli

Isospora belli was first described by Virchow in 1860 but not named until 1923. Molecular biology studies have demonstrated that *Isospora* spp., particularly those from primates and carnivores, are more closely related to the Sarcocystiidae than to the Eimeriidae. This has required the transfer of the species into the family Sarcocystiidae and the genus *Cystoisospora*. However, throughout the remainder of the chapter, the organism is referred to as *Isospora belli* and the disease as isosporiasis. Transition to the new genus name will probably occur during the next couple of years. Although isosporiasis has been found in various parts of the world, certain tropical areas in the Western hemisphere appear to contain some well-defined locations of endemic infections. These organisms can infect both adults and children, and intestinal involvement and symptoms are generally transient unless the patient is immunocompromised. *I. belli* has also been implicated in traveler's diarrhea (2). However, unlike *C. cayetanensis*, large outbreaks of isosporiasis have not been reported.

Life Cycle and Morphology

Schizogonic and sporogonic stages in the life cycle of *I. belli* have been found in human intestinal mucosal biopsy specimens. Development in the intestine usually occurs within the epithelial cells of the distal duodenum and proximal jejunum. Eventually, oocysts are passed in the stool; they are long and oval and measure 20 to 33 μm by 10 to 19 μm (Table 4.2). Usually the oocyst contains only one immature sporont, but two may be present (Figures 4.15 and 4.16). Continued development occurs outside the body with the development of two mature sporocysts,

Figure 4.15 (1) Immature oocyst of *Isospora belli*; (2) mature oocyst of *I. belli*. (Illustration by Nobuko Kitamura.)

each containing four sporozoites, which can be recovered from the fecal specimen (Figures 4.17 and 4.18). The sporulated oocyst is the infective stage that will excyst in the small intestine, releasing the sporozoites, which penetrate the mucosal cells and initiate the life cycle. The life cycle stages, i.e., schizonts, merozoites, gametocytes,

Figure 4.16 (Upper) Immature oocyst of *Isospora belli*, wet preparation. (Lower) Immature oocyst of *I. belli*, modified acid-fast stain (note that the entire oocyst has stained).

Figure 4.17 Life cycle of *Isospora belli*. (Illustration by Gwen Gloege.)

gametes, and oocysts, are structurally similar to those seen in the other coccidia.

The patent period is not known but may be as short as 15 days. Chronic infections develop in some patients, and oocysts can be shed for several months to years. In one particular case, an immunocompetent individual had symptoms for 26 years and *I. belli* was recovered in stool a number of times over a 10-year period.

Clinical Disease

Clinical symptoms include diarrhea, which may last for long periods (months to years), weight loss, abdominal colic, and fever; diarrhea is the main symptom. Bowel movements (usually 6 to 10 per day) are watery to soft, foamy, and offensive smelling, suggesting a malabsorption process. Eosinophilia is found in many patients, recurrences are quite common, and the disease is more severe in infants and young children.

Patients who are immunosuppressed, particularly those with AIDS, often present with profuse diarrhea associated with weakness, anorexia, and weight loss. In one patient with a well-documented infection of long standing, a series of biopsies showed a markedly abnormal mucosa with short villi, hypertrophied crypts, and

Figure 4.18 (Upper) Mature oocyst of *Isospora belli*, wet preparation. (Lower) Mature oocyst of *I. belli*, modified acid-fast stain.

infiltration of the lamina propria with eosinophils, neutrophils, and round cells. It has been recommended that physicians consider *I. belli* in AIDS patients with diarrhea who have immigrated from or traveled to Latin America, are Hispanics born in the United States, are young adults, or have not received prophylaxis with TMP-SMX for *Pneumocystis jiroveci*. It has also been recommended that AIDS patients traveling to Latin America and other developing countries be advised of the waterborne and food-borne transmission of *I. belli*, and they may want to consider chemoprophylaxis.

Extraintestinal infections in AIDS patients have been reported. One patient was a 38-year-old white man who presented with progressive dyspnea and fever; he also complained of dysphagia, nausea, vomiting, and brown watery diarrhea (eight or nine episodes daily) and had lost 20 lb in 2 months. He was diagnosed with *P. jiroveci* pneumonia and oropharyngeal candidiasis and was treated with TMP-SMX and pentamidine. His condition improved, and he was discharged; however, he was readmitted complaining of nausea, vomiting, and diarrhea; he was diagnosed with giardiasis and treated. Five months later he was diagnosed as having *I. belli* and *Entamoeba histolytica* infection and was treated. Three months later he presented with dyspnea, fever, diarrhea, and generalized wasting; he was diagnosed with cytomegalovirus pneumonia and died 2 weeks later. At autopsy,

microscopic findings associated with *I. belli* infection were seen in the lymph nodes and walls of both the small and large intestines. Intracellular zoites were seen in the cytoplasm of histiocytes. Each organism was surrounded by a thick eosinophilic cyst wall in routine histologic preparations with hematoxylin and eosin, and the cyst wall was periodic acid-Schiff (PAS) positive. Examination of the intestinal tissues revealed intraepithelial asexual and sexual stages of *I. belli*, as well as some merozoites that appeared to be in cells of the lamina propria.

The second case involved a 30-year-old black woman who was living in France but was originally from Burkina Faso. Initially she was symptomatic with fever, diarrhea, and weight loss. She was diagnosed with esophageal candidiasis and *I. belli* infection. She was treated with TMP-SMX and given maintenance therapy but suffered episodes of recurrent infection over the next 3 years. Examination of samples collected at autopsy revealed stages of *I. belli* in the intestine, mesenteric and mediastinal lymph nodes, liver, and spleen. The extraintestinal stages were always observed as single organisms that did not stain well with acid-fast stains. Massive infection with plasmacytosis and some eosinophils, but no granulomatous reaction, was observed.

In a third AIDS patient who presented with watery, nonbloody diarrhea and fever, examination of small intestine biopsy specimens revealed merozoites in the intestinal lumen, lamina propria, and lymphatic channels. Finding the merozoites within the lymphatic channels documents a means of dissemination to lymph nodes and other tissues. Additional studies of extraintestinal tissue cysts have identified early tissue cysts that lack a developed cyst wall, demonstrating that more than one tissue cyst can occupy a host cell, describing the distribution of micronemes and the shedding of zoite membranes, and identifying tubular structures in the inner tissue cyst wall and inner compartment.

Charcot-Leyden crystals derived from eosinophils have also been found in the stools of patients with *I. belli* infection. The diarrhea and other symptoms may continue in compromised patients, even those on immunosuppressive therapy, when the regimen of therapy is discontinued. This infection has been found in homosexual men, all of whom were immunosuppressed and had several months of diarrhea.

Diagnosis

Examination of a fecal specimen for the oocysts is recommended. However, wet-preparation examination of fresh material either as the direct smear or as concentrated material is recommended rather than the permanent stained smear (Figure 4.5; Table 4.3). The oocysts are very pale and transparent and can easily be overlooked.

Figure 4.19 *Isospora belli* immature oocyst photographed by phase-contrast microscopy.

They can also be very difficult to see if the concentration sediment is from polyvinyl alcohol-preserved stool. The light level should be reduced, and additional contrast should be obtained with the microscope for optimal examination conditions (Figures 4.16, 4.18, and 4.19). It is also quite possible to have a positive biopsy specimen but not recover the oocysts in the stool because of the small numbers of organisms present. These organisms are acid fast and can also be demonstrated by using auramine-rhodamine stains. Organisms tentatively identified by using auramine-rhodamine stains should be confirmed by wet smear examination or acid-fast stains, particularly if the stool contains other cells or excess artifact material (more normal stool consistency).

KEY POINTS—LABORATORY DIAGNOSIS

Isospora belli

1. The oocysts are more easily recovered and identified when wet preparations are examined (direct smear, concentration smear).
2. Oocysts recovered in a concentrated sediment from polyvinyl alcohol-preserved stool may be very difficult to detect (the oocyst wall is very difficult to see).
3. A biopsy can be positive while no organisms are seen in the stool. This is not necessarily due to poor-quality laboratory work but may reflect normal findings.
4. Although these organisms can be stained with auramine-rhodamine stains, they should be confirmed by wet smears or modified acid-fast stains.

Treatment

Effective eradication of the parasites has been achieved with co-trimoxazole, TMP-SMX, pyrimethamine-sulfadiazine, primaquine phosphate-nitrofurantoin, and primaquine phosphate-chloroquine phosphate (1, 2). Other drugs proven to be ineffective include dithiazanine,

tetracycline, metronidazole, phanquone, and quinacrine hydrochloride. The drug of choice is TMP-SMX, which is classified as an investigational drug for treatment of this infection. TMP (160 mg)-SMX (800 mg) is given every 6 h for 10 days and then twice a day for 3 weeks. Pyrimethamine alone (50 to 75 mg daily) has cured infections in patients allergic to sulfonamides. In immunosuppressed patients with recurrent or persistent infection, therapy must be continued indefinitely.

Epidemiology and Prevention

I. belli is thought to be the only species of *Isospora* that infects humans, and no other reservoir hosts are recognized for this infection. Transmission is through ingestion of water or food contaminated with mature, sporulated oocysts. Sexual transmission by direct oral contact with the anus or perineum has also been postulated, although this mode of transmission is probably much less common. The oocysts are very resistant to environmental conditions and may remain viable for months if kept cool and moist; oocysts usually mature within 48 h following stool evacuation and are then infectious. It has been speculated that diagnostic methods for laboratory examinations may tend to miss the organisms when they are present. Since transmission is via the infective oocysts, prevention centers on improved personal hygiene measures and sanitary conditions to eliminate possible fecal-oral transmission from contaminated food, water, and possibly environmental surfaces.

Sarcocystis spp.

The organism once known as *Isospora hominis* is now recognized as being a part of the life cycle of *Sarcocystis* spp. (Figure 4.20). Two well-described species are *Sarcocystis bovi-hominis* (cattle) and *S. sui-hominis* (pigs). Some publications refer to *S. bovi-hominis* as *S. hominis*. When uncooked meat from these infected animals is ingested by humans, gamogony can occur within the intestinal cells, with the eventual production of the sporocysts in stool. In this case, humans who have ingested meat containing the mature sarcocysts serve as the definitive hosts (2, 13, 34). There have been reports of fever, severe diarrhea, abdominal pain, and weight loss in immunocompromised hosts, although the number of patients with these symptoms has been quite small.

Life Cycle and Morphology

Species of *Sarcocystis* have an obligatory two-host life cycle. Intermediate hosts such as herbivores and omnivores become infected through ingestion of sporocysts excreted in the feces of the definitive hosts such as carnivores and omnivores. The definitive hosts become

Figure 4.20 Life cycle of *Sarcocystis* spp. (Illustration by Gwen Gloege.)

Table 4.18 *Sarcocystis* development and disease symptoms in humans^a

Topic	Muscle	Intestine
Infection source	Water or food contaminated with infected feces containing oocysts from unknown carnivore or omnivore	Raw or poorly cooked meat
Infective stage	Oocyst or free sporocysts	Sarcocyst containing bradyzoites
Developmental stages	Intravascular schizonts (not seen); intramuscular sarcocysts	Sexual stages found in lamina propria; oocysts excreted in feces
Incubation time from ingestion of infective stage to disease symptoms	Weeks to months, lasting months to years	3–6 h, lasting approximately 36 h
Disease symptoms	Musculoskeletal pain, fever, rash, cardiomyopathy, bronchospasm, subcutaneous swelling	Nausea, anorexia, vomiting, stomach ache, bloat, diarrhea, dyspnea, and tachycardia; may also include abdominal pain and eosinophilia; severe symptoms may include segmental necrotizing enteritis (rare and not well confirmed)
Diagnosis	Biopsy specimen(s) contains sarcocysts; antibodies to bradyzoites; routine histology on biopsy specimens; wall may be PAS positive, but stain variability is common	Oocysts or sporocysts in feces, beginning about 5–12 days after ingestion of raw or undercooked meat; <i>S. hominis</i> (beef) is excreted 14–18 days after meat ingestion, while <i>S. suihominis</i> (pork) is excreted 11–13 days after ingesting meat
Therapy	Co-trimoxazole, furazolidone, albendazole, anticoccidials, pyrimethamine, anti-inflammatories	None

^a Adapted from references 2, 13, and 34.

infected through ingestion of mature cysts found in muscles of the intermediate hosts. In some intermediate hosts, such as cattle and sheep, all adult animals may be infected.

The sporocysts that are recovered in the stool are broadly oval and slightly tapered at the ends, measure 9 to 16 μm , and contain four mature sporozoites and the residual body (Table 4.2). Normally, two sporocysts are contained within the oocyst (similar to that seen with *I. belli*); however, in *Sarcocystis* infections, the sporocysts are released from the oocyst and normally are seen singly (Figure 4.20). They tend to be larger than *Cryptosporidium* oocysts, which contain four sporozoites, so there should be no confusion between the two. The oocysts are fully sporulated when passed in the stool.

Clinical Disease

When humans accidentally ingest oocysts from other animal stool sources, the sarcocysts that develop in human muscle apparently do little if any harm (schizogony) (2, 34). The prepatent period in humans is from 9 to 10 days. There is essentially no inflammatory response to these stages in the muscle and no conclusive evidence of pathogenicity of the mature sarcocyst. However, symptoms have been seen in some patients, probably associated with disintegration of the sarcocysts (Table 4.18). Painful muscle swellings, measuring 1 to 3 cm in diameter, initially associated with erythema of the overlying skin in various parts of the body, occur periodically and last for 2 days to 2 weeks. Some patients also have fever, diffuse myalgia, muscle tenderness, weakness, eosinophilia, and bronchospasm. No apparent clinical manifestations have been found in patients in whom myocardial *Sarcocystis* infection was detected accidentally by autopsy. A number of different morphological types of skeletal and cardiac muscle sarcocysts have been recovered in humans. No specific therapy is known for this type of infection; however, corticosteroids should reduce the allergic inflammatory reactions occurring after cyst rupture.

Intact sarcocysts in skeletal or cardiac muscle of humans measure up to 100 by 325 μm and are usually not accompanied by an inflammatory reaction (Figure 4.21). Each sarcocyst contains many bradyzoites, approximately 7 to 16 μm long. Inflammation follows disintegration of the cysts and death of the intracystic bradyzoites. Vasculitis is seen in the muscle and subcutaneous tissues. Histologic findings include myositis with vasculitis and sometimes myonecrosis.

When humans serve as definitive hosts, prevention involves adequate cooking of beef and pork (34); when humans are intermediate hosts, preventive measures involve careful disposal of animal feces that may contain

Figure 4.21 (Upper) *Sarcocystis* spp. in human muscle. (Lower) Higher magnification showing individual elongate bradyzoites.

the infective sporocysts. This may be impossible in the wilderness areas, where wild animals may serve as reservoir hosts for many of the different types of organisms that have been grouped under the term *Sarcocystis* “*lindemanni*.” However, this name is no longer used. No specific therapy is known for the muscle stages of *Sarcocystis* spp. Various sizes of protozoan cysts, oocysts, and spores that occur in human stool specimens are given in Table 4.19.

Diagnosis

Presumptive diagnosis is often based on the patient symptoms, including a history of having ingested raw or poorly cooked meat. Confirmation of the diagnosis may depend on several stool examinations, some of which may reveal sporocysts. They are generally passed beginning 14 to 18 days after beef ingestion and about 11 to 13 days after pork ingestion. Some researchers think that the zinc sulfate fecal flotation method is preferred to the formalin-ethyl acetate sedimentation method for sporocyst and/or oocyst recovery (13). Sporocysts of *S. hominis* tend to be

Table 4.19 Protozoan cysts, oocysts, sporocysts, and spores seen in human feces^a

Organism	Shape	Size (µm)	Features	Comments
<i>Balantidium coli</i>	Spherical to oval	50–70	Large macronucleus, thick wall	Although cilia are within the cyst wall, they are more difficult to see than the cilia surrounding the trophozoite form
<i>Isospora belli</i>	Oval, more tapered ends	20–33 by 10–19	Generally immature oocysts passed, but some containing two sporocysts may be visible	Not infectious when passed; best diagnostic approach is wet mount of concentrated sediment; some recommend flotation rather than sedimentation concentration
<i>Sarcocystis hominis</i>				
Oocysts	Spherical	15–19 by 15–20	Contain 2 sporocysts, but oocyst wall appears to be missing	Generally infectious when passed
Sporocysts	Oval	15–19 by 8–10	Contain 4 sporozoites	Infectious
<i>Sarcocystis suihominis</i>				
Oocysts	Spherical	15–19 by 15–20	Contain 2 sporocysts, but oocyst wall appears to be missing	Generally infectious when passed
Sporocysts	Oval	15–19 by 8–10	Contain 4 sporozoites	Infectious
<i>Entamoeba histolytica/E. dispar</i>				
	Spherical	12–15		Precyst contains single nucleus (generally), while mature cyst contain 4 nuclei and possible chromatoidal bars with rounded ends
<i>Giardia lamblia</i>				
	Spherical to oval	11–14	Contains four nuclei, curved median bodies and linear axonemes	Some cysts appear to be found; important to focus up and down to see morphologic characteristics; infective when passed
<i>Cyclospora cayentanensis</i>				
	Spherical	8–10	May appear as “wrinkled cellophane”	Not infectious when passed
<i>Cryptosporidium hominis</i> and <i>C. parvum</i>				
	4–6	Nearly spherical	Sporozoites may be difficult to see; modified acid-fast stains recommended	Infectious when passed
<i>Encephalitozoon</i> spp. and <i>Enterocytozoon bieneusi</i>				
	1.5–3.5	Oval, mimic small yeast cells and/or bacteria	Horizontal or diagonal stripe (polar tubule) may be difficult to see in every spore	Infectious when passed

^a Other pathogenic protozoa, *Dientamoeba fragilis* (no cyst form) and *Blastocystis hominis*, may overlap *Giardia* and *Entamoeba* spp. in size and may appear spherical to somewhat oval.

more elongated than those of *S. suihominis*, but the two may be difficult to differentiate.

Intramuscular infection would be suspected based on symptoms, including persistent myalgia, episodic weakness, subcutaneous nodules, dermatomyositis, eosinophilia, and elevated muscle creatinine kinase levels. Often these symptoms, coupled with a history of travel to or living in tropical locations, suggest the next step, which would be a muscle biopsy. Sarcocysts in biopsy specimens can be identified by microscopy of routine histologic sections stained with hematoxylin and eosin. Stain variability is common, and PAS positivity of the sarcocyst wall is not always seen.

Sarcocystis can be detected in meat by using routine histologic methods. Most sarcocysts in humans have been identified in skeletal and cardiac muscle; however, muscles

in the larynx, pharynx, and upper esophagus have also been involved. Artificial digestion fluids can also be used on the meat source; after centrifugation, the sediment can be examined microscopically for the presence of bradyzoites.

KEY POINTS—LABORATORY DIAGNOSIS

Sarcocystis spp.

1. The oocysts are more easily recovered and identified in wet preparations (direct smear, concentration smear; flotation is recommended over sedimentation concentration methods).
2. The sporocysts are released from the oocyst and are seen singly (they are larger than *Cryptosporidium* oocysts).

3. Sarcocysts in muscle can be identified by routine histologic methods; however, there is a lot of staining variability (hematoxylin and eosin stains; PAS-positive sarcocyst walls may not be easily visible).

Treatment

Intestinal sarcocystosis is self-limiting and often asymptomatic and lasts for a short time. Although co-trimoxazole and furazolidone have been used, their effectiveness is still questionable. Currently, no therapy has been approved for treatment for myositis, vasculitis, or related lesions in humans. The efficacy of albendazole has not been demonstrated in controlled studies. Although drugs such as pyrimethamine and others used to treat toxoplasmosis have been considered, the efficacy of such drugs has not been documented. It is also unknown if immunosuppressives might be effective in reducing the inflammatory reactions seen in vasculitis or myositis. Without more definitive data, no recommended course of therapy is currently available.

Epidemiology and Prevention

Apparently, multiple ruminant species serve as intermediate hosts of *Sarcocystis* spp. and as sources of infection for humans, and humans serve as intermediate hosts for several species of *Sarcocystis*, perhaps by ingesting sporocysts excreted by predators of nonhuman primates. Humans, baboons, and rhesus monkeys serve as definitive hosts for *S. hominis*, and humans, chimpanzees, and rhesus and cynomolgus monkeys serve as definitive hosts for *S. suis*. *S. hominis* occurs worldwide in areas where cattle or buffalo have access to human feces and humans ingest raw or undercooked beef. *S. suis* probably occurs worldwide in areas where swine have access to human feces and humans ingest raw or undercooked pork.

Thoroughly cooking or freezing meat to kill bradyzoites within the sarcocysts will prevent intestinal sarcocystosis. Freezing at -4 and -20°C for 48 and 24 h, respectively, is sufficient to kill bradyzoites. It has been documented that rare roast beef and hamburger purchased from a supermarket contained bradyzoites infectious for dogs whereas cooked products were not infectious for dogs.

Prevention of infection in food animals depends on eliminating the sporocyst stage from human feces in contaminated water, feed, and bedding. Also, to prevent humans from serving as intermediate hosts, ingestion of sporocysts must be prevented; the most likely source is contaminated water for drinking or washing foods. Boiling is the best method to guarantee disinfection. Thorough washing or cooking of foods is also recommended.

Microsporidia

Although the microsporidia are true eukaryotes (i.e., they possess a typical eukaryotic nucleus, endomembrane system, and cytoskeleton), they also display molecular and cytological characteristics of prokaryotes, including features of the translational apparatus and genome size (range of bacteria), and lack recognizable mitochondria, peroxisomes, and typical Golgi membranes. Phylogenetic studies have confirmed that the microsporidia evolved from the fungi, being most closely related to the zygomycetes (28). Other features that are shared with fungi include the presence of chitin and trehalose, similarities in cell cycles, and certain gene organizations. Microsporidia are now considered to be highly derived fungi that underwent genetic and functional losses, thus resulting in one of the smallest eukaryotic genomes known. However, at this point, clinical and diagnostic issues and responsibilities may remain with the parasitologists, and these organisms will be maintained as a part of this parasitology text. We may be in a transition stage, similar to that seen with *Pneumocystis jiroveci* as it was moved from the parasites to fungi in terms of classification status.

During the early part of the 19th century, an epidemic disease was causing tremendous problems in the silkworm industry, particularly in Italy and France; the disease was called pébrine, which means “pepper disease.” In 1863 Louis Pasteur was asked to study this problem, and by 1870 he had published his findings, in which he described a method for controlling and preventing the disease. This work represents the first scientific study of a disease caused by a protozoan, a microsporidian parasite, which resulted in practical control measures. Nägeli named the agent *Nosema bombycis*; however, he placed it in the Schizomycetes (at that time consisting of yeast and bacteria). A similar infection is seen in honeybee hives and is caused by *Nosema apis*. In 1882, Balbiani suggested the order Microsporida to handle *N. bombycis*, the only microsporidian known at the time. It was not until 1976 that the phylum Microspora was created, and it was updated in 1992 to propose that Microsporidia Balbiani 1882 should be the acknowledged phylum name, as well as the correct author and date (2).

The microsporidia are obligate intracellular organisms that have been recognized in a variety of animals, particularly invertebrates. Typical sizes range from 1.5 to 5 μm wide and 2 to 7 μm long; unfortunately, the organisms found in humans tend to be quite small, ranging from 1.5 to 2 μm long. Until recently, awareness and understanding of human infections have been marginal; only with increased understanding of AIDS within the immunosuppressed population has attention been focused on these organisms. Limited availability of EM capability

has also played a role in the inability to recognize and diagnose these infections. However, with the introduction of newer diagnostic methods, the ability to identify these parasites has definitely improved. The organisms are characterized by having spores containing a polar tubule, which is an extrusion mechanism for injecting the infective spore contents into host cells. To date, seven genera have been recognized in humans: the more common, *Encephalitozoon* and *Enterocytozoon*, and the less common, *Brachiola*, *Pleistophora*, *Trachipleistophora*, *Vittaforma*, and “*Microsporidium*,” a catch-all genus for organisms that have not yet been classified (or may never be classified due to a lack of specimen). Classification criteria include spore size, configuration of the nuclei within the spores and developing forms, the number of polar tubule coils within the spore, and the relationship between the organism and host cell.

Microsporidiosis is an important emerging opportunistic infection in HIV-infected patients, and several hundred patients with chronic diarrhea have been seen worldwide. Patients infected with *Cryptosporidium* spp. may also have concurrent infections with microsporidia, and this number may approach 30%. These findings emphasize the importance of considering both organisms as potential causative agents of diarrhea in compromised patients, particularly those with HIV. However, with the current use of antiretroviral combination therapy, the same decrease seen with cryptosporidiosis in this patient group has also been seen with microsporidiosis. Microsporidia also cause disease in organ transplant recipients, children, travelers, contact lens wearers, and the elderly (35).

Life Cycle and Morphology

The spore is the only life cycle stage able to survive outside of the host cell and is the infective stage. The spore normally reaches the new host through ingestion, although other routes of transmission have been identified.

As seen in Figure 4.22, infection occurs with the introduction of infective sporoplasm through the polar tubule into the host cell. The microsporidia multiply extensively within the host cell cytoplasm; the life cycle includes repeated divisions by binary fission (merogony) or multiple fission (schizogony) and spore production (sporogony). Both merogony and sporogony can occur in the same cell at the same time. During sporogony, a thick spore wall is formed, providing environmental protection for this infectious stage of the parasite. An example of infection potential is illustrated by *Enterocytozoon bieneusi*, an intestinal pathogen. The spores are released into the intestinal lumen and are passed in the stool. These spores are environmentally resistant and can then be ingested by other hosts. There is also evidence for inhalation of spores and evidence in animals that suggests that

human microsporidiosis may also be transmitted via the rectal route (28).

Clinical Disease

Microsporidia have been recognized as causing disease in animals as early as the 1920s but were not recognized as agents of human disease until the AIDS pandemic began in the mid-1980s. Several earlier human cases had been reported but were thought to be very unusual. Currently, there are 7 genera and 13 species of microsporidia that have been implicated in human infection; with more than 1,000 species of microsporidia, one would expect confirmation of additional human parasites in the future (Table 4.20) (9, 28).

***Enterocytozoon bieneusi*.** Although currently there are seven genera, one of which is the catch-all genus “*Microsporidium*,” human infections are more common with some than with others. A number of cases of infection with *E. bieneusi* have been found in AIDS patients. Chronic intractable diarrhea, fever, malaise, and weight loss are symptoms of *E. bieneusi* infections and are similar to those seen in patients with cryptosporidiosis or isosporiasis. These patients have already been diagnosed with AIDS, and they tend to have four to eight watery, nonbloody stools each day, which can be accompanied

Figure 4.22 Life cycle of microsporidia. (From C.H. Gardiner, R. Fayer, and J.P. Dubey, *An Atlas of Protozoan Parasites in Animal Tissues*, U.S. Department of Agriculture handbook no. 651, U.S. Department of Agriculture, Washington, D.C., 1988.)

Table 4.20 Microsporidia causing human infection^a

Species	Nonhuman hosts	Sources of human infection	Sites of infection	Comments
Common				
<i>Enterocytozoon bieneusi</i>	Pigs, nonhuman primates, nonmammals (chickens, pigeons)	Fecal-oral; oral-oral, inhalation, ingestion, direct human-to-human; organ transplants	Small intestine, gallbladder, liver, disseminated (respiratory system)	Short-term culture only; 3 strains identified but not named; AIDS patients with chronic diarrhea, immunocompetent individuals; more than 50 genotypes described (17 infect humans); zoonotic and nonzoonotic genotypes
<i>Encephalitozoon cuniculi</i>				
Strain I (rabbit)	Rabbits, rodents, carnivores, monkeys	Probably ingestion	Cerebrospinal fluid, intestine, respiratory, kidneys, nasal epithelium, eyes	Definitely zoonotic; spores highly resistant in environment (months under humid conditions); waterborne infections feasible
Strain II (mouse)	Mice, wild rats, blue fox	Not relevant	Not relevant	Not identified in humans
Strain III (dog)	Dog, tamarins (may have been imported from United States)	Probably ingestion	Kidneys, adrenal glands, ovaries, brain, heart, spleen, lungs, lymph nodes	Case occurred in Italy; AIDS (may be first report of infection involving ovaries); identified in humans in United States (not confirmed in dogs related to cases)
<i>Encephalitozoon hellem</i>	Psittacine birds	No epidemiologic studies; surface waters not confirmed; probably ingestion, aerosols, or oral or ocular direct inoculation; for drug addicts, contaminated syringes suggested but not proven	Disseminated, ocular HIV-positive patients; patients with eye infections owned birds	Asymptomatic respiratory infections reported; bronchoalveolar lavage in HIV-seronegative patients; stools from travelers (coinfected with <i>E. bieneusi</i>); <i>E. hellem</i> isolates from the United States and Europe are different populations
<i>Encephalitozoon intestinalis</i>	Dogs, donkeys, pigs, cows, goats, free-ranging gorillas	Probably ingestion, inhalation, direct inoculation; waterborne transmission suspected	Small intestine, disseminated; immunocompromised and immunocompetent	Second most common species infecting humans; double infections with <i>E. bieneusi</i> occur
Uncommon				
<i>Brachiola algerae</i>	Mosquitoes	Possible arthropod-borne	Eyes, muscle; possible dissemination; immunocompromised and immunocompetent	Formerly <i>Nosema algerae</i>
<i>Brachiola connori</i>	None identified	Unknown	Disseminated	Formerly <i>Nosema connori</i> ; immunocompromised child (SCID)
<i>Brachiola vesicularum</i>	None identified	Unknown	Corneal stroma, skeletal muscle	Probably a <i>Nosema</i> -like species; non-HIV patient
<i>Microsporidium africanum</i>	None identified	Unknown	Corneal ulcer of African woman	Catch-all genus for organisms that could not be identified; HIV-seronegative individual at autopsy
<i>Microsporidium ceylonensis</i>	None identified	Unknown	Corneum	Boy gored by goat (injured eye), but may not be relevant
<i>Pleistophora ronneae</i>	Fish, reptiles; possible animal reservoir not defined	Unknown	Muscle	Non-HIV and HIV positive; <i>Pleistophora</i> spp. (2 cases) may actually be <i>Trachipleistophora</i> spp.
<i>Trachipleistophora anthropophthera</i>	None identified, but may be insects	Unknown	Brain, heart, kidneys, eyes	AIDS patients
<i>Trachipleistophora hominis</i>	None identified, but may be insects	Unknown, but probably direct inoculation	Muscle, nasal epithelium, conjunctiva, keratitis	AIDS patient (severe sinusitis, myositis); immunocompetent patient
<i>Vittaforma corneae</i>	Appear to be ubiquitous	Waterborne very likely; some intestinal infections may reflect intestinal passage of spores rather than infection	Eyes, corneal stroma; possible kidneys	First human isolate established in an in vitro culture; non-HIV patient; formerly <i>Nosema corneum</i>

^a Adapted from E. S. Didier and G. T. Bessinger, Host-parasite relationships in microsporidiosis: animal models and immunology, p. 225–229, in M. Wittner and L. M. Weiss (ed.), *The Microsporidia and Microsporidiosis*, ASM Press, Washington, D.C., 1999; additional data from references 5, 9, and 28.

by nausea and anorexia. There may be dehydration with mild hypokalemia and hypomagnesemia, as well as D-xylose and fat malabsorption. The patients tend to be severely immunodeficient, with a CD4 count always below 200 and often below 100. A dual infection with *E. bienewisi* and another microsporidian that infects the small intestine has also been reported. *E. bienewisi* infection has been implicated in AIDS-related sclerosing cholangitis. However, demonstration of *E. bienewisi* spores in extraepithelial tissues does not always appear to be associated with development of subsequent systemic infection.

E. bienewisi spores have been identified in the sputum and bronchoalveolar lavage fluid, as well as stool samples, from a patient with a 2-year history of intestinal microsporidiosis. Although no pulmonary pathology could be established in this or one other reported case, it is well established that *E. bienewisi* is capable of colonizing the respiratory tract, and these clinical specimens may reveal the presence of spores. Using transmission EM, multiorgan microsporidiosis due to *E. bienewisi* has been diagnosed in an HIV-infected patient; organisms were recovered in stools, duodenal biopsy specimens, nasal discharge, and sputum.

Infection with this organism has also been found in individuals with intact immune function; symptoms were self-limited, and the diarrheal disease resolved within 2 weeks. These cases suggest that *E. bienewisi* may be more commonly associated with sporadic diarrheal disease than was previously suspected and that the immune system may play a role in the control of this organism within the intestine. It is also quite possible that *E. bienewisi* may persist as an asymptomatic infection in immunocompetent individuals.

Encephalitozoon spp. Both *Encephalitozoon cuniculi* and *E. hellem* have been isolated from human infections, the first species from the central nervous system and the second from the eye. The first case occurred in a 9-year-old Japanese boy who presented with neurologic symptoms such as convulsions, vomiting, headaches, fever, and periods of unconsciousness. The spores were recovered in the cerebrospinal fluid and urine. This particular patient was treated with sulfisoxazole and recovered. Another case of *E. cuniculi* was in a 2-year-old child with a similar neurologic illness; the spores were recovered from the urine. A case of keratoconjunctivitis and chronic sinusitis due to infection with *E. cuniculi* in an AIDS patient has been reported; diagnosis was confirmed by EM. Currently, there are at least three *E. cuniculi* strains which may become more important in the epidemiology of human infections. As additional isolates are characterized, further classification changes will probably occur. Several eye infections with *E. hellem* have been found in

AIDS patients, including the first reported case of *E. hellem* infecting not only sinuses and conjunctivae but also the nasal epithelium. In the first case of disseminated *E. hellem* infection in an AIDS patient, a complete autopsy revealed organisms in the eyes, urinary tract, and respiratory tract. The presence of numerous organisms within the lining epithelium of almost the entire length of the tracheobronchial tree was very suggestive of respiratory acquisition. It is also interesting that although *E. cuniculi* and *E. hellem* differ biochemically and immunologically, their fine structure and development are indistinguishable. Some of the eye infections have also suggested a topical route rather than dissemination. Dual infection with *E. hellem* and *Vittaforma corneae* has also been found in an AIDS patient; this is the second isolation of *V. corneae* and the first description of urinary tract infection due to *V. corneae* in a patient with AIDS.

Encephalitozoon (Septata) intestinalis. *Encephalitozoon (Septata) intestinalis* infects primarily small intestinal enterocytes, but infection does not remain confined to epithelial cells. *E. intestinalis* is also found in lamina propria macrophages, fibroblasts, and endothelial cells. Dissemination to the kidneys, lower airways, and biliary tract appears to occur via infected macrophages (29). Fortunately, these infections tend to respond to therapy with albendazole, unlike the infections with *E. bienewisi*.

Brachiola (Nosema) spp. *Brachiola connori* (formerly referred to as *Nosema connori*) has been identified in human tissues, with the spores being oval and measuring approximately 2 by 4 μm . The polar tubule has about 11 coils. The single human case occurred in a 4-month-old infant with combined immunodeficiency disease with a disseminated, fatal infection. Parasites were found in the myocardium, diaphragm, arterial walls, kidney tubules, adrenal cortex, liver, and lungs. Concurrently, this patient also had *P. jiroveci* pneumonia.

B. algerae (formerly *N. algerae*) is apparently transmitted by mosquitoes. Infections have been found in the eye and muscle, possibly from a disseminated case. Both immunocompromised (HIV-negative, but receiving immunosuppressive therapy for rheumatoid arthritis) and immunocompetent patients have become infected. This organism has been known as an insect pathogen for some time. It appears that an initial infection of the eye allows the parasite to adapt to conditions within the mammalian host, thus spreading via macrophages to internal organs.

B. vesicularum is probably a *Nosema*-like species found in non-HIV-infected patients. Corneal stroma and skeletal muscle were involved in a case in an AIDS patient. Although it was thought that *B. algerae* and *B. vesicularum* might be identical, there are ultrastructural

differences between the two organisms. Thus, the designation of two species is currently accepted.

Microsporidium spp. *Microsporidium africanum* were identified in the histiocytes of a corneal ulcer. Although it was first thought to be a *Nosema* sp., electron micrographs confirmed the differences and it was designated *M. africanum*. No information on other hosts is available.

M. ceylonensis was found in an eye infection in a child who had been gored by a goat and suffered an eye injury. *Nosema helminthorum* was considered a possibility, since the organism is a parasite of goat tapeworms; however, since a generic classification could not be completed, it was assigned to the genus *Microsporidium*. Since no additional infections have been seen and there is no tissue left for further study, this genus name, *Microsporidium*, will probably remain. Since it is now accepted, you will see it written as *Microsporidium* rather than “*Microsporidium*.”

Pleistophora spp. Microsporidia of the genus *Pleistophora* have rarely been identified in humans; however, three cases in immunocompetent patients have been reported. In these cases, atrophic and degenerating muscle fibers were full of spores, which were seen in clusters of about 12 organisms, each cluster enclosed by an enveloping membrane, the pansporoblastic membrane. The spores were oval, measuring approximately 2.8 by 3.4 μm . The disease was characterized by a 7-month history of progressive generalized muscle weakness and contractions in addition to fever, generalized lymphadenopathy, and an 18-kg weight loss. Although the patient was diagnosed as having AIDS, the presence of HIV was never demonstrated. Early biopsies demonstrated atrophic and degenerating muscle fibers; later biopsies showed fibrosis and scarring. *Pleistophora* microsporidia have been identified in a confirmed AIDS patient. Ultrastructural studies of specimens from one of the cases led to the classification of *P. ronneafiei*; no information is available about possible animal reservoirs.

Trachipleistophora spp. *Trachipleistophora hominis* causes severe myositis and sinusitis and was first detected in an AIDS patient. To date, no natural hosts other than humans have been identified, although when inoculated intraperitoneally into athymic mice, the organisms infect the skeletal muscle, as seen in human infections. *T. anthropophthera* is the most recently described microsporidian in humans and has been found in brain tissue of two AIDS patients at autopsy; the organisms were also found in the kidneys and heart.

Vittaforma corneae. It has been recently proposed that the human microsporidian *Nosema corneum* be

reclassified in a new genus, *Vittaforma corneae*. This organism has been documented in both immunocompromised (urinary tract) and immunocompetent (ocular) patients. These organisms are found everywhere, but no specific natural common hosts have been identified. PCR and sequencing data from surface water studies suggest that these organisms may be present and that they can also be present in human feces; it has been suggested that this might represent intestinal passage of microsporidian spores, although these patients were symptomatic with diarrhea (29).

Infections in Immunocompetent Hosts. In studies of rabbits and mice, the majority of immunologically competent hosts that become infected with microsporidia develop chronic and persistent infections with few clinical signs or symptoms. Spore shedding has been described as sporadic, and parasite replication seems to be regulated by the host immune system. However, if these animals are intentionally immunosuppressed, more severe symptoms are seen. On the basis of serologic studies, it is very likely that immunocompetent humans have persistent or chronic infections with microsporidia. This is also supported by the fact that patients with microsporidiosis who are HIV-seronegative show clinical resolution of their infections after a few weeks. As improved diagnostic methods, such as PCR, are developed and used, verification of human subclinical microsporidian infections should become possible.

Infections in Immunocompromised Hosts. In the immunocompromised host, microsporidian infection may lead to overwhelming disease and death. The first cases of human microsporidiosis were identified in children with impaired immune systems, and infections have been widely recognized and studied in individuals with AIDS, primarily those with fewer than 100 CD4⁺ T lymphocytes. Infection has also been recognized in organ transplant recipients who are intentionally immunosuppressed before and after transplantation.

Diagnosis

Routine Histology. A number of techniques are available for recovery and identification of microsporidia in clinical specimens (Tables 4.21 and 4.22). Although the organisms have been identified in routine histologic preparations, they do not tend to stain predictably if at all (Figure 4.23). Occasionally, the spores take on a refractile gold appearance in formalin-fixed, paraffin-embedded, routine hematoxylin-and-eosin-stained sections. Some of the difficulty may be attributed to the use of formalin; alternative fixatives are currently being tried. Spores are occasionally seen very well by using PAS stain, silver stains,

Table 4.21 Microsporidia: general information

Genus	Body site	Diagnosis	Comments
<i>Brachiola</i> , <i>Encephalitozoon</i> , <i>Enterocytozoon</i> , <i>Microsporidium</i> , <i>Pleistophora</i> , <i>Trachipleistophora</i> , <i>Vittaforma</i> (<i>Enterocytozoon bieneusi</i> and <i>Encephalitozoon intestinalis</i> are the most common pathogenic species recovered in humans)	All body organs, including eyes	Routine histology with hematoxylin and eosin (fair); tissue Gram, acid fast, PAS, silver recommended (spores); other specimens (stool, urine, etc.), modified trichrome stains, optical brightening agents, poly- or monoclonal antibody-based kits (FA, EIA); animal inoculation not recommended—laboratory animals may carry occult infections; EM may be required; some can be cultured, but results are not consistent among the various genera and species	These organisms have been found as insect or other animal parasites; route of infection may be ingestion, inhalation, or direct inoculation (eye); well documented as emerging opportunistic infection in AIDS and other immunocompromised patients; name changes and reclassifications continue to occur; also refer to Table 4.20

Table 4.22 Microsporidia: recommended diagnostic techniques

Technique ^a	Use ^b	Comments ^a
Light microscopy		
Stool specimens (more artifacts)		
Modified trichrome	++	Reliable, available; light infections difficult to identify
Giemsa	–	Not recommended for routine use, hard to read
Optical brightening agents	++	Calcofluor, Fungi-Fluor, Uvitex 2B; sensitive but nonspecific
IF technique	++	Commercial availability limits use; products in development
Other body fluids (fewer artifacts)		
Modified trichrome	++	Reliable, available; light infections difficult to identify
Giemsa	+	Urine, conjunctival swab, BAL, CSF, duodenal aspirate
Optical brightening agents	++	Calcofluor, Fungi-Fluor, Uvitex 2B; sensitive but nonspecific
IF technique	++	Commercial availability limits use; products in development
Routine histology		
Hematoxylin and eosin	+	Sensitivity uncertain with small parasite numbers
PAS	+	Controversy over effectiveness
Modified Gram stains (Brown Brenn, Brown-Hopps)	++	Sensitive, generally recommended
Giemsa	+	Sensitivity uncertain with small parasite numbers
Warthin-Starry	+	Not standardized, may not be necessary
Modified trichrome	++	Reliable, sensitive
IF technique	++	Commercial availability limits use; products in development
Electron microscopy		
Body fluids	+	Specific, sensitivity unknown; used for identification to species level
Tissue sections	++	“Gold standard” for confirmation, but sensitivity lower than for detection of spores in stool or urine; used for identification to species level
Serologic antibody detection	–	Reagents not commercially available, preliminary results controversial
Cultures	–	Generally used in the research setting; continued advances in culture options and organism survival/growth
PCR	–	Availability limited to research laboratories; studies ongoing

^a IF, immunofluorescence detection procedure; BAL, bronchoalveolar lavage; CSF, cerebrospinal fluid.^b–, not available or recommended for routine use; +, reported; ++, techniques in general use (probably most widely used).

Figure 4.23 Spores in enterocyte. Note the position of the spores between the cell nucleus and the lumen of the intestine. Top photograph taken with a 40 \times objective; middle and bottom photographs taken with a 100 \times oil immersion lens. Note the dark-staining dot within the spores in the bottom photograph. The tissue was stained with Giemsa stain.

or acid-fast stains. Modified Gram stains have also been found to be sensitive although not always standardized. The spore has a small, PAS-positive posterior body, the spore coat stains with silver, and the spores are acid-fast variable (Figures 4.23 to 4.26). There is also evidence to indicate that specimens from plastic-embedded tissues are seen more easily, regardless of the fixative used. Tissue

examination by EM techniques is still considered the best approach (Figure 4.27); however, this option is not available to all laboratories, and the sensitivity of EM may not be equal to that of other methods when examining stool or urine.

Techniques that do not require tissue embedding are now becoming more popular. Touch preparations of fresh biopsy material that are air dried, methanol fixed, and Giemsa stained have been used; however, screening must be performed at $\times 1,000$ magnification. Another

Figure 4.26 Heart. Some *Nosema* spores are acid fast (photographed with green filter; Ziehl-Neelsen, $\times 1,080$). (Armed Forces Institute of Pathology photograph.)

Figure 4.27 Spores in cytoplasm of intact jejunal enterocyte of a man with intractable diarrhea and malabsorption; transmission electron micrograph of a jejunal suction biopsy specimen. Note the dark oval developing spores; at higher magnification, some of the elements of the polar tubules would be visible. (Courtesy of R. L. Owen; from M. J. G. Farthing and G. I. Keusch (ed.), *Enteric Infection: Mechanisms, Manifestations and Management*, Chapman & Hall, Ltd., London, 1987.)

study, using cytocentrifugation followed by Giemsa staining, found that 27% of 55 AIDS patients with chronic diarrhea were positive for *E. bienensis*; all results were confirmed by EM.

Routine Clinical Specimens. *Modified trichrome stains.* Other, more recent options recommend using modified trichrome stains in which the chromotrope 2R component added to the stain is 10 times the concentration normally used in the routine trichrome stain for stool (9, 23, 29). It is important to remember that the stool preparations must be very thin, the staining time must be 90 min, and the slide must be examined at $\times 1,000$ (or higher) magnification. Unfortunately, there are many objects within stool material that are oval, stain pinkish with trichrome, and measure approximately 1.5 to 3 μm .

If this stain is used for the identification of microsporidia in stool, positive control material should be available for comparison. Additional modifications of this method include the use of heat and a shorter staining time (23). There is also some evidence to indicate that pretreatment of fecal specimens (1:1) with 10% KOH may provide a better-quality smear to examine when using the modified trichrome stains (Figure 4.28). Unfortunately, there are always situations in which artifact material can be confused with actual spores (Figure 4.29).

Optical brightening agents. Another approach involves the use of chemofluorescent agents (optical brightening agents) such as calcofluor, Fungi-Fluor, or Uvitex 2B (Figure 4.28). These reagents are sensitive but nonspecific; objects other than microsporidial spores will also fluoresce. This is a particular problem when examining stool specimens; both false-positive and false-negative results have been seen. When these reagents are used

Figure 4.28 Microsporidian spores. (A) Spores stained with modified trichrome stain (Ryan blue) (note the diagonal or horizontal “stripes” that are evidence of the polar tubule); (B) calcofluor white staining of urine sediment (note the small oval intracellular and extracellular spores) (this is a nonspecific stain but is more likely to represent a true positive than when seen in a stool specimen containing many fluorescing artifacts).

Figure 4.29 Artifacts stained with a modified trichrome stain (Ryan blue). Note the shape and staining characteristics are not consistent with microsporidial spores; also note the lack of horizontal or diagonal “stripes” representing the polar tubule.

with other body fluids, particularly urine, the interpretation of results is much easier than when they are used with stool. There is now general agreement that this method is recommended as a simple, sensitive screening method for the detection of microsporidial spores in stool specimens.

Antigen detection. The newest approach for the identification of spores in clinical specimens uses antisera in an indirect FA procedure (Figure 4.30). Fluorescing microsporidial spores were distinguished by a darker cell wall and by internal visualization of the polar tubule as diagonal lines or cross lines within the cell. In another study with the same antiserum, 9 (30%) of 27 patients who

Figure 4.30 Microsporidian spores. This image shows a positive FA test using *Encephalitozoon*-specific reagent. Note the fluorescing spores, indicating the organisms are within the genus *Encephalitozoon*.

had already been diagnosed as having cryptosporidiosis (8 AIDS patients and 1 non-AIDS but immunodeficient patient) were found to have *Encephalitozoon* spp. in the stool. Although there is some cross-reactivity with bacteria, this technique offers a more sensitive approach than routine staining methods currently available for the examination of stool specimens. Very specific reagents are in various stages of development and clinical testing and should provide some additional, more sensitive methods than are currently available at this time. Some of these reagents are also being used in conjunction with flow cytometry. As clinicians begin to suspect these infections and laboratorians become more familiar with the diagnostic methods, the number of positive patients, particularly those who are immunocompromised, may increase dramatically. Current recommendations also suggest that multiple diagnostic methods may be necessary to diagnose microsporidiosis, particularly when examining fecal specimens (23).

Molecular Methods. Molecular studies of the microsporidia have been limited to date (33, 39). Few genes have been located, and DNA sequence studies have been reported for just a few of the identified human pathogens. Microsporidia have extremely small genomes, very similar to those seen in bacteria. This may be due to the early divergence of microsporidia or may be related to the highly adapted parasitic life-style of these organisms. Although PCR methods have been tried in the research setting, commercial products are not yet available. For HIV-infected patients suspected of having microsporidiosis but with negative stool and biopsy results, PCR testing of intestinal biopsy specimens may be helpful in diagnosing the infection. Application of molecular techniques to diagnosis, identification of isolates to the species level, and classification will certainly continue to expand during the next few years. These advances should include newer diagnostic reagent kits that will simplify molecular testing in the routine clinical laboratory setting, particularly tests applicable to the stool specimen.

Cell Culture. The use of *in vitro* culture methods continues to provide confirmatory as well as diagnostic information. This approach has been instrumental in the development of immunologic reagents for diagnosis and species differentiation. *In vitro* culture has also been used to assess the efficacy of antimicrobial agents on several microsporidian species including *Encephalitozoon cuniculi*, *E. hellem*, and *E. intestinalis* (29). However, the use of cell culture in routine clinical diagnosis is not practical and is generally reserved for research facilities. A number of cell lines have been used, including monkey

and rabbit kidney cells (Vero and RK13), human fetal lung fibroblasts (MRC-5), and MDCK cells. Although a number of the microsporidia have been cultured using these techniques, one of the most common human microsporidian pathogens, *Enterocytozoon bieneusi*, has been propagated only in short-term cultures (6 months). The inability to grow this organism in continuous culture may reflect additional nutritional requirements that have not yet been identified.

Serologic Testing. A variety of serologic tests (carbon immunoassay, indirect immunofluorescent-antibody test, enzyme-linked immunosorbent assay, counterimmunoelectrophoresis, and Western blotting) have been used to detect immunoglobulin G (IgG) and IgM antibodies to microsporidia, particularly to *E. cuniculi*. The indirect immunofluorescent-antibody test and the enzyme-linked immunosorbent assay have been the most useful because of the simplicity of the test methods; however, the actual sensitivity and specificity of all the available tests have not yet been defined. Antibodies to *E. cuniculi* and *E. intestinalis* have been found in humans both with and without HIV infection; whether this represents true infection, cross-reactivity with other species, or nonspecific reactions is not clear. Serologic surveys for antibodies to *E. cuniculi* appear to show a link between exposure to a tropical environment and microsporidiosis. Unfortunately, there are no serologic assays available for *E. bieneusi* due to the lack of success in long-term culture and development of available antigens. Whether antibodies to this organism will cross-react with those to *E. cuniculi* is not known. At present, the available serologic data are interesting but the tests are not useful as diagnostic tools for the diagnosis of microsporidiosis.

Although *E. bieneusi* appears to be the most common human microsporidian, serologic evidence is based primarily on results for *E. cuniculi* as the parasite antigen. Whether these surveys reveal actual infections with this organism or whether there is cross-reactivity with other microsporidia is unknown. However, the data are highly suggestive that latent infections with microsporidia occur in a number of groups, ranging from patients with other infections such as tuberculosis, typhoid fever, leprosy, malaria, schistosomiasis, toxoplasmosis, Chagas' disease, and toxocariasis to normal individuals and a group of homosexual men. Microsporidian infections in immunocompetent patients may result in a self-cure following mild symptoms over a short time frame, a situation similar to that seen with both cryptosporidiosis and isosporiasis. As awareness of this infection increases and more sensitive diagnostic techniques are developed, we may find that these infections are not uncommon in immunocompetent hosts.

KEY POINTS—LABORATORY DIAGNOSIS**Microsporidia**

1. Approximately 30% of AIDS patients and those with cryptosporidiosis may also have infections with microsporidia. Microsporidian infections must be considered for this group of patients with chronic diarrhea.
2. The modified trichrome staining procedure for stool may be difficult to interpret without positive controls to review. Make sure that the material on the slides is very thin, the smear is stained for the recommended time, and the smear is examined under oil immersion (total magnification of at least $\times 1,000$). When using various stains, optical brightening agents, or experimental immunoassay reagents where diagnosis is based on seeing the actual spores, it is recommended that the fecal specimen be concentrated and centrifuged at $500 \times g$ for 10 min. Personal experience in our laboratory has demonstrated a larger number of spores in the concentrated sediment than in the unconcentrated specimen *or in specimens that have been centrifuged at a lower speed or for a shorter time*.
3. The optical brightening agents (calcofluor, Fungi-Fluor, Uvitex 2B) provide a sensitive screening method, but the results are nonspecific. False-positive results have been reported because of fluorescent artifact material.
4. As immunoassay reagents become commercially available, we may see diagnostic procedures with greater specificity and sensitivity. Reagents are currently being used in a few institutions; these preparations are generally easier to read than are the routine stains.
5. Touch preparations can be methanol fixed and stained with Giemsa.
6. Plastic-embedded tissues stained with PAS, silver, acid-fast, and routine hematoxylin-eosin stains generally stain better than paraffin-embedded tissues. This finding may be related to the use of formalin as a tissue fixative. Tissue Gram stains (Brown Brenn, Brown-Hopps) are also highly recommended.
7. Be sure to gain some experience in examining these preparations before sending out patient specimen results. This work almost mandates the use of positive control material, regardless of which technique(s) is used. Once a laboratory has gained experience with these methods, it is appropriate to begin accepting clinical specimens.
8. EM is the “gold standard” (very specific) for confirming infection and for attempting to classify the organisms seen in tissues. However, EM procedures

may not be as sensitive as some of the other available methods.

9. It is recommended that more than one procedure be used when working with stool specimens (modified trichrome, optical brightening agent); this is primarily because of the large number of artifacts present in stool. Urine and other body fluid specimens are much easier to examine for the presence of microsporidian spores, since less artifact material is seen in these specimens than in stool.

Treatment

Although a number of drugs have been tried, results have been variable. Agents such as metronidazole, itraconazole, octreotide, primaquine, Lomotil, sulfasalazine, loperamide, and albendazole have been used in various patients. In some cases, the diarrhea subsided; however, biopsy specimens showed the continued presence of organisms, which were probably *Enterocytozoon bieneusi*. Over the past few years, confirmatory evidence indicates that a complete parasitological cure is possible with albendazole. However, these patients had disseminated infections with *Encephalitozoon (Septata) intestinalis*; albendazole, a benzimidazole that binds to β -tubulin, appears to be very effective in treating this particular organism (1). Currently, the recommended dose for ocular (*Encephalitozoon cuniculi*, *Vittaforma corneae*), intestinal (*Enterocytozoon bieneusi*, *Encephalitozoon [Septata] intestinalis*), and disseminated (*Encephalitozoon hellem*, *E. cuniculi*, *E. intestinalis*, *Pleistophora* spp., *Trachipleistophora* spp.) infections with albendazole is 400 mg orally twice a day. In vitro, albendazole has activity at concentrations of $<0.1 \mu\text{g/ml}$ against all of the Encephalitozoonidae. Although apparently static rather than cidal effects are seen with *E. bieneusi* infections, treatment with albendazole results in reduction of symptoms in as many as 50% of patients infected with this organism. Albendazole as a systemic agent is recommended when the organisms have been confirmed in urine or nasal smears.

Fumagillin (soluble salt Fumidil B) has activity against microsporidia, and solutions applied topically have been used in corneal infections. The effects of this drug are static rather than cidal, and relapses of infection occur when the treatment has been discontinued. In one study, the efficacy of fumagillin was measured by clearance of *E. bieneusi* from stools and intestinal biopsy specimens; four patients who received fumagillin remained free of *E. bieneusi* after a mean follow-up of 10 months.

Itraconazole can also be recommended to treat ocular, nasal, and paranasal sinus infection caused by *E. cuniculi* parasites when albendazole treatment fails. In a patient with sinusitis and keratoconjunctivitis, the symptoms

completely resolved with itraconazole treatment (200 mg/day for 8 weeks) after albendazole therapy (400 mg/day for 6 weeks) was unsuccessful.

Epidemiology and Prevention

The sources of human infections are not yet totally defined. From what we currently know, possibilities include human-to-human and animal-to-human transmission (29). Although there is some speculation that insect microsporidia can infect humans, this is still unknown. Many questions relating to reservoir hosts and possible congenital infections are still unanswered. Primary infection can occur by inhalation or ingestion of spores from environmental sources or by zoonotic transmission. There is serologic evidence to indicate widespread occurrence of antibodies to *E. cuniculi* in humans. Recent data indicate that the presence of *Encephalitozoon intestinalis* was confirmed in tertiary sewage effluent, surface water, and groundwater; *Enterocytozoon bieneusi* was confirmed in surface water; and *Vittaforma corneae* was confirmed in tertiary effluent. This study represents the first confirmation, to the species level, of human-pathogenic microsporidia in water, indicating that these parasites may be waterborne pathogens.

The presence of infective spores in human clinical specimens suggests that precautions when handling body fluids and personal hygiene measures such as hand washing may be important in preventing primary infections in the health care setting. However, comprehensive guidelines for disease prevention will require more definitive information regarding sources of infection and modes of transmission.

Algae (*Prototheca*)

Although algae are not parasites, it is important to know what they are and the relationship of opportunistic infections with these organisms to the compromised patient. The genus *Prototheca* contains several species, the most prevalent of which is *Prototheca wickerhamii*. These organisms are achlorophyllic algae found in the slime flux of trees and freshwater environments. Cutaneous infections were reported more than 30 years ago, and subsequent reports describe other manifestations including systemic disease. The other species implicated in human infections is *P. zopfii* (10, 37). Susceptibility to infection is not well defined but may involve the inability of neutrophils to effectively kill phagocytosed organisms. Approximately 100 cases have been reported throughout the temperate and tropical areas of all continents. Protothecosis is being reported with increasing frequency, and within the United States the majority of cases have been reported from the southeastern states (10).

Life Cycle and Morphology

Prototheca spp. are unicellular organisms that reproduce asexually by internal septation and cleavage; they then rupture, releasing endospores. The sporangium contains 2 to 16 sporangiospores, which develop into mature endosporulating cells. No sexual reproductive stages have been identified. These organisms are thought to be achlorophyllous mutants of green algae in the genus *Chlorella*.

Clinical Disease

The overall incubation time is not known but is generally considered to be about 2 weeks from the time of trauma and possible implantation of infectious organisms. The majority of infections involve the skin and underlying structures, such as the olecranon bursa (10, 37); however, disseminated infection may also occur. Cutaneous or bursal infection may result from accidental inoculation or from trauma, including surgical. One patient developed nasopharyngeal ulceration due to *P. wickerhamii* after prolonged endotracheal intubation. Bursal infection presents with indolent swelling and tenderness. Cutaneous lesions have been described as painless papules, papulonodules, diffuse erythema, plaques (may be verrucous), and eczematoid or ulcerated areas. Immunocompromised patients may have more severe lesions. In addition to disseminated infection, peritonitis has been found in patients undergoing chronic ambulatory peritoneal dialysis and in the blood of patients with central venous access infections. Infections have also been seen in the gallbladder, peritoneum, and liver in a patient presenting with symptoms consistent with sclerosing cholangitis.

One 80-year-old woman receiving 2 mg of dexamethasone daily presented with tenderness in an area of diffuse erythema of the right arm, forearm, and dorsum of the hand together with several 4- to 6-mm flesh-colored papules. Biopsy revealed granulomatous inflammation with many organisms present in the dermis (10, 37). These organisms stained with both PAS and Gomori's methenamine-silver (GMS) stain and were approximately 5 to 15 μm in diameter. They contained multiple internal septa. Another patient presented with recalcitrant ulcerated papules and plaques on both legs.

This infection has also been found in an HIV-positive patient (37). The patient presented with a nodule in the extensor face of the thumb. A routine excision was performed, and histology revealed numerous granulomas, some with central fibrinoid necrosis. Large numbers of prototheca were found in PAS and GMS stains, showing endosporulation with diagnostic morula- or daisy-like sporangia. On the basis of the relative number of polymorphonuclear leukocytes, lymphocytes, and plasma cells present, the cellular response was considered minimal. The organisms were found extracellularly or within macrophages and

giant cells. Protothecal meningitis has also been found in an AIDS patient. In general, these cases are seen in patients who are immunocompromised, either from other underlying diseases or from immunosuppressive therapy (10).

Diagnosis

These algae are easily recovered on routine culture media; however, they are inhibited by cycloheximide, which is present in many selective fungal media. The optimal temperature for growth is 30°C, and these algae grow as white to creamy yeast-like colonies on Sabouraud's medium. Microscopic examination of culture material reveals the same structures as seen in tissue, including spherical sporangia containing multiple sporangiospores (endospores) (Figures 4.31 to 4.33). The organisms have been described as looking like a spoked wheel. Macroscopically, the cells are variable in size and shape and do not bud or form hyphae. Asexual reproduction occurs through release of sporangiospores from sporangia. Sporangia of *P. zopfii* range from 14 to 16 µm in diameter,

Figure 4.31 Sporangia containing sporangiospores (endospores) of *Prototheca wickerhamii*. (Illustration by Sharon Belkin.)

Figure 4.32 Sporangia containing developing sporangiospores (endospores) of *Prototheca* spp.

Figure 4.33 *Prototheca zopfii*. Ruptured sporangia showing the released sporangiospores (oval to cylindrical).

and those of *P. wickerhamii* are 7 to 13 µm. Cells of *P. wickerhamii* tend to be round, while those of *P. zopfii* are oval or cylindrical. Both species assimilate glucose and galactose; *P. wickerhamii* also assimilates trehalose. These organisms are nonfermentative.

In histologic preparations, the typical tissue response includes a granulomatous inflammation with multinuclear giant cell formation. The organisms may be numerous or few and can be seen as single cells or clusters. The GMS stain is recommended. In tissue the sporangia are usually larger (30 µm) than those seen in culture (*P. wickerhamii*, 7 to 13 µm; *P. zopfii*, 14 to 16 µm).

Treatment

Most of the protothecal infections are indolent and very slow to heal. Although surgical debridement or excision may be necessary and effective, most infections are treated with antifungal agents. Combined therapy with tetracycline and amphotericin B appears to be effective. Infections that are multifocal or visceral or occur in an immunocompromised host require amphotericin B or combined therapy. Recent reports indicate that itraconazole is effective; however, healing may be gradual. Infections caused by *Prototheca* spp. tend to be resistant to 5-fluorocytosine.

Epidemiology and Prevention

Prototheca spp. have been isolated from a number of different environmental sites, including slime flux of trees, freshwater and seawater, soil, and sewage. Organisms have also been isolated from dogs, cats, cattle, sheep, deer, and some wild animals. *Prototheca* spp. have been recovered from human feces, sputum, skin scrapings,

and fingernails, even in cases with no true infectious process. Although infections caused by *Prototheca* spp. are relatively uncommon, the true incidence worldwide may be underestimated. These infections should always be suspected in cases where the skin and subcutaneous tissues are involved and/or olecranon bursitis is present with indolent swelling and tenderness. An awareness of the possibility of infection with these organisms is critical to accurate diagnosis and prompt treatment.

Free-Living Amebae

Naegleria fowleri

Acanthamoeba spp.

Balamuthia mandrillaris

Sappinia diploidea

Infections caused by small, free-living amebae belonging to the genera *Naegleria*, *Acanthamoeba*, *Balamuthia*, and *Sappinia* are generally not very well known or recognized clinically. Also, methods for laboratory diagnosis are unfamiliar and not routinely offered by most laboratories. However, infections caused by these organisms include primary amebic meningoencephalitis (PAM) caused by *Naegleria fowleri*; granulomatous amebic encephalitis (GAE) caused by *Acanthamoeba* spp. and *Balamuthia mandrillaris*; and amebic keratitis, cutaneous lesions, and sinusitis caused by *Acanthamoeba* spp. (Table 5.1). Another organism, recently identified, has been linked to encephalitis; *Sappinia diploidea* has been confirmed as a newly recognized human pathogen. Effective therapy remains a problem with these infections. When free-living, these organisms feed on bacteria and nutrients in moist soil and in freshwater and marine water. The development of diagnostic molecular methods represents a specific and potentially rapid method for the identification of some of these organisms soon after their primary isolation from the environment (6, 7, 18).

Although it is well known that both free-living and pathogenic protozoa harbor a variety of endosymbiotic bacteria, it is unclear what role these organisms play in terms of host survival, infectivity, and invasiveness. The study of parasites and symbionts of free-living amebae is relatively new, and many of the terms used to describe these relationships are listed in Table 5.2 (10, 15). Serologic evidence that some of the endosymbionts within the free-living amebae might be human pathogens has led to additional studies of these relationships. The ameba-resistant bacteria are varied; some are natural hosts of free-living amebae, some have been recovered by amebic coculture, and some are resistant to a particular amebic host in vitro. Some bacteria are obligate intracellular organisms, others are facultative intracellular bacteria, and some are extracellular. While some of these bacteria are established human pathogens, some are emerging potential pathogens which were formerly considered environmental species. The presence of intracellular bacteria has been detected in axenically grown *Acanthamoeba* isolates. *Legionella pneumophila* can infect, multiply within, and kill both *Naegleria* and *Acanthamoeba* amebae. These amebae may be natural hosts for *Legionella* organisms as well as for other bacteria such as *Campylobacter jejuni*, *Listeria monocytogenes*, *Vibrio cholerae*, *Mycobacterium leprae*, *Burkholderia cepacia*, *Burkholderia pickettii*, and *Pseudomonas aeruginosa* (3, 10, 15). Because of their well-known resistance to chlorine, the amebic cysts are considered to be vectors for these intracellular

Table 5.1 Free-living amebae causing disease in humans^a

Characteristic		<i>Acanthamoeba</i>		<i>Balamuthia</i>	<i>Naegleria</i>
Disease parameter	GAE	<i>Acanthamoeba</i> keratitis	Cutaneous lesions, sinusitis	GAE	PAM
General disease description	Chronic, protracted, slowly progressive CNS infection (may involve lungs); generally occurs in individuals with underlying diseases	Painful, progressive, sight-threatening corneal disease; patients generally immunocompetent	Most common in patients with AIDS, with or without CNS involvement, and in those receiving immunosuppressive therapy for organ transplantation	Chronic, protracted, slowly progressive CNS infection (may involve lungs); generally occurs in individuals with underlying diseases	Rare but nearly always fatal infection; migration of amebae to brain through olfactory nerve; symptoms can mimic bacterial meningitis; death usually occurs 3–7 days after onset of symptoms; clinical suspicion based on history critical
Entry into the body	Olfactory epithelium, respiratory tract, skin, sinuses	Corneal abrasion	Skin, sinuses, respiratory tract	Olfactory epithelium, skin, respiratory tract	Olfactory epithelium
Incubation	Weeks to months	Days	Weeks to months	Weeks to months	Days
Clinical symptoms	Confusion, headache, stiff neck, irritability	Blurred vision, photophobia, inflammation, corneal ring, pain	Skin lesions, nodules, sinus lesions, sinusitis	Slurred speech, muscle weakness, headache, nausea, seizures	Headache, nausea, vomiting, confusion, fever, stiff neck, seizures, coma
Disease pathology	Focal necrosis, granulomas	Corneal ulceration	Granulomatous reaction in skin, inflammation	Multiple necrotic foci, inflammation, cerebral edema	Hemorrhagic necrosis
Diagnostic methods ^b	Brain biopsy, CSF smear/wet prep, culture, indirect immunofluorescence of tissue, PCR	Corneal scrapings or biopsy, stain with calcofluor white, culture, confocal microscopy	Skin lesion biopsy, culture, indirect immunofluorescence of tissue	Brain biopsy, culture on mammalian cells, indirect immunofluorescence of tissue	Brain biopsy, CSF wet prep, culture, indirect immunofluorescence of tissue, PCR

^a Table information adapted from references 5, 12, 15, 17, 20, and 22.

^b Indirect immunofluorescence on tissue and PCR methods available from the Centers for Disease Control and Prevention.

Table 5.2 Definitions pertaining to the relationships among free-living amebae and other organisms^a

Description	Definition
Adaptation	Selection pressure = change in an organism
Ameba-resistant microorganisms	Microorganisms that evolved to resist destruction by amebae, but being neither internalized nor killed while within the amebae
Ameba-resistant bacteria	Bacteria that evolved to resist killing by amebae
Character	Phenotypic characteristics of an organism
Crib	“Baby bed”—free-living amebae that serve as a reservoir and incubator of new antibiotic-resistant bacteria = adaptation to human macrophages
Commensalism	Symbiosis—one organism benefits and the other neither is harmed nor benefits
Endosymbiont	Symbiont that lives within another organism
Endosymbiotic	During portion of life cycle or throughout; no lysis activity
Lytic	Lyses the host cell
Mutualism	Symbiosis in which both organisms benefit
Parasite	Benefits from an association but is harmful to the host
Symbiont	Lives in close contact with another organism during most of life cycle
Symbiosis	Two organisms living in close contact for most of their life spans
Symbiosis island	Gene cluster that confers symbiotic traits, which may be transferred horizontally
Trojan horse	Protozoan “horse” that may bring ameba-resistant organisms into the human host
Virulence	Pathogenicity

^a Adapted from references 10 and 15.

bacteria. This can have tremendous significance for any hospital where the water source is contaminated with free-living amoebae. There is also evidence to suggest that the presence of amoebae in domestic water supplies may provide growth conditions that enhance the pathogenicity of the organisms for the human host (23). These amoebae are also acceptable hosts for *Chlamydia pneumoniae*, echoviruses, and polioviruses (10).

Naegleria fowleri

Culbertson and his colleagues in 1958 were the first to develop the concept that free-living soil and water amoebae could cause disease in humans. A number of fatal cases of acute meningoencephalitis have been reported since that time (20, 21). Almost all patients whose cases were documented in the years immediately following this awareness of amoebic infections had a history of swimming in freshwater lakes or ponds a few days prior to the onset of symptoms.

Infections of the central nervous system (CNS) caused by free-living amoebae have been recognized only since the mid-1960s, and our understanding of this disease process is still incomplete. One type of meningoencephalitis (PAM) is a fulminant and rapidly fatal disease that affects mainly children and young adults. The disease closely resembles bacterial meningitis but is caused by *N. fowleri*, an organism found in moist soil and freshwater habitats. Close to 200 cases of PAM have occurred worldwide, and approximately 90 of those cases have been reported from the United States. Until recently, it was thought that this infection was limited to humans; however, infections have also been reported in other animals.

Life Cycle and Morphology

There are both trophozoite and cyst stages in the life cycle, with the stage primarily depending on environmental conditions (Figure 5.1). Trophozoites can be found in water or moist soil and can be maintained in tissue culture or other artificial media.

Morphology of Trophozoites. The trophozoites can occur in two forms, amoeboid and flagellate (Figures 5.2 through 5.4). Motility can be observed in hanging-drop preparations from cultures of cerebrospinal fluid (CSF); the amoeboid form (the only form recognized in humans) is elongate with a broad anterior end and tapered posterior end (Table 5.3). The size ranges from 7 to 35 μm . The diameter of the rounded forms is usually 15 μm . There is a large, central karyosome and no peripheral nuclear chromatin. The cytoplasm is somewhat granular and contains vacuoles (Figure 5.2). The amoeboid-form

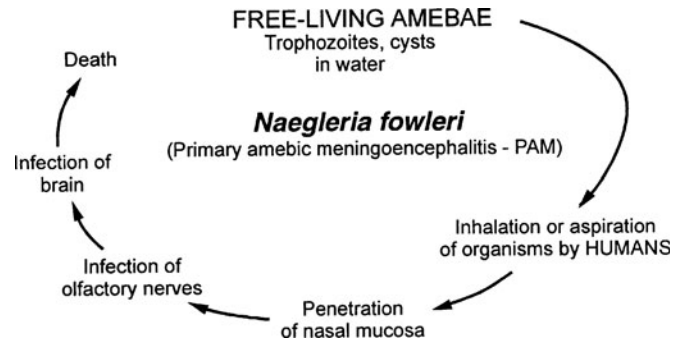

Figure 5.1 Life cycle of *Naegleria fowleri*.

organisms change to the transient, pear-shaped flagellate form when they are transferred from culture or teased from tissue into water and maintained at a temperature of 27 to 37°C. The change may occur very quickly (within a few hours) or may take as long as 20 h. The flagellate form has two flagella at the broad end. Motility is typical, with either spinning or jerky movements. These flagellate forms do not divide, but when the flagella are lost, the amoeboid forms resume reproduction.

Morphology of Cysts. Cysts from nature and from agar cultures look the same and have a single nucleus almost identical to that seen in the trophozoite. They are generally round, measuring from 7 to 15 μm , and there is a thick double wall (Figure 5.2; Table 5.3).

Figure 5.2 Diagram of trophozoite. (Upper row) Flagellate and cyst forms of *Naegleria fowleri*; (lower row) trophozoite and cyst of *Acanthamoeba* spp. (Illustration by Sharon Belkin.)

Figure 5.3 (Upper left) Scanning electronic micrograph (SEM) of *N. fowleri* (Lovell strain) ameboid cell with numerous blunt pseudopods. (Upper right) SEM of *N. fowleri* (Lovell strain) preflagellate, rounded and producing two short, blunt flagella. (Lower left) SEM of *N. fowleri* (Lovell strain) flagellate with two long, pointed flagella emerging from the anterior rostrum. (Lower right) SEM of *N. fowleri* (Lovell strain) reverting flagellate with two long, pointed flagella. (Photographs courtesy of D. T. John. Reprinted from B. L. Cable and D. T. John, Conditions for maximum enflagellation in *Naegleria fowleri*, *J. Protozool.* 33:467–472, 1986, with permission.)

Table 5.3 Comparison of *Naegleria fowleri* and *Acanthamoeba* spp.

Characteristic	<i>Naegleria fowleri</i>	<i>Acanthamoeba</i> spp.
Trophozoite	Biphasic (amebic) and flagellate forms; 8–15 (7–35) μm ; lobate pseudopodia (amebic form)	Large (15–25 μm); no flagella; filiform pseudopodia
Cysts	Not present in tissue; small, smooth, rounded; 7–15 μm	Present in tissue; large with wrinkled double wall
Growth on media	Require living cells (bacteria or cell culture); do not grow with >0.4% NaCl	May grow without bacteria; not affected by 0.85% NaCl
Appearance in tissue ^a	Smaller than <i>Acanthamoeba</i> spp.; dense endoplasm; less distinct nuclear staining	Large; rounded; less endoplasm; nucleus more distinct

^a *Entamoeba histolytica* has a delicate nuclear membrane and a small, pale-staining nucleolus. Freshwater amebae have a distinct nuclear membrane and a large, deep-staining nucleolus.

Figure 5.4 (Top) Three amoebae of the pathogenic free-living amoeba *N. fowleri* attacking and engulfing a fourth, presumably dead, amoeba. The amoebae are using sucker-like structures (amebostomes) in this novel form of phagocytosis. (Photograph courtesy of D. T. John. In D. T. John, T. B. Cole, Jr., and F. M. Marciano-Cabral, Sucker-like structures on the pathogenic amoeba *Naegleria fowleri*, *Appl. Environ. Microbiol.* 47:12–14, 1984). (Middle) *N. fowleri* trophozoites; (bottom) *N. fowleri* trophozoite ingesting starch granules. (Middle and bottom images courtesy of F. M. Marciano-Cabral.)

Clinical Disease

Amebic meningoencephalitis caused by *N. fowleri* is an acute, suppurative infection of the brain and meninges (Figure 5.5). With extremely rare exceptions, the disease is rapidly fatal in humans. The period between contact with the organism and onset of clinical symptoms such as fever, headache, and rhinitis may vary from 2 to 3 days to as long as 7 to 15 days.

The amoebae may enter the nasal cavity by inhalation or aspiration of water, dust, or aerosols containing the trophozoites or cysts. The organisms then penetrate the nasal mucosa, probably through phagocytosis of the olfactory epithelium cells, and migrate via the olfactory nerves to the brain (5, 20). Data suggest that *N. fowleri* directly ingests brain tissue by producing food cups or amebostomes, in addition to producing a contact-dependent cytolysis which is mediated by a heat-stable hemolytic protein, heat-labile cytolysis, and/or phospholipase enzymes (20). Cysts of *N. fowleri* are generally not seen in brain tissue.

Early symptoms include vague upper respiratory distress, headache, lethargy, and occasionally olfactory problems. The acute phase includes sore throat, stuffy blocked or discharging nose, and severe headache. Progressive symptoms include pyrexia, vomiting, and stiffness of the neck. Mental confusion and coma usually occur approximately 3 to 5 days prior to death. The cause of death is usually cardiorespiratory arrest and pulmonary edema.

PAM can resemble acute purulent bacterial meningitis, and these conditions may be difficult to differentiate, particularly in the early stages. The CSF may have a predominantly polymorphonuclear leukocytosis, increased protein concentrations, and decreased glucose concentration like those seen with bacterial meningitis. Unfortunately, if the CSF Gram stain is interpreted incorrectly (identification of bacteria as a false positive), the resulting antibacterial therapy has no impact on the amoebae and the patient will usually die within several days.

Extensive tissue damage occurs along the path of amebic invasion; the nasopharyngeal mucosa shows ulceration, and the olfactory nerves are inflamed and necrotic. Hemorrhagic necrosis is concentrated in the region of the olfactory bulbs and the base of the brain. Organisms can be found in the meninges, perivascular spaces, and sanguinopurulent exudates.

The first case of organ transplantation from a donor who had died of undiagnosed *N. fowleri* infection was reported in 1997 (20). While no subsequent amebic infections occurred in the three organ recipients, this report emphasizes the need for adequate evaluation of the benefits and risks of transplanting tissues from persons whose illness might have been caused by an infectious

Figure 5.5 *Naegleria fowleri* organisms in brain tissue from a human with PAM.

agent. Apparently, the Centers for Disease Control and Prevention are also aware of another instance in which kidneys were transplanted prior to determination that the donor was infected with *N. fowleri* (20). At present, the risk of transmission of *N. fowleri* by donor organs has not been clarified, and no practical test is available to ensure that donor organs are organism free. Also, no prophylactic drug regimen to treat transplant recipients has been established.

Diagnosis

Clinical and laboratory data usually cannot be used to differentiate pyogenic meningitis from PAM, and so the diagnosis may have to be reached by a process of elimination. A high index of suspicion is often mandatory for early diagnosis (20). Although most cases are associated with exposure to contaminated water through swimming or bathing, this is not always the case. The rapidly fatal course of 3 to 6 days after the beginning of symptoms (with an incubation period of 1 day to 2 weeks) requires early diagnosis and immediate chemotherapy if the patient is to survive.

Analysis of the CSF shows decreased glucose and increased protein concentrations. Leukocytes may range from several hundred to $>20,000$ cells/mm³. Gram stains and bacterial cultures of CSF are negative; however, the Gram stain background can incorrectly be identified as bacteria, thus leading to incorrect therapy for the patient.

A definite diagnosis could be made by demonstration of the amebae in the CSF or in biopsy specimens. Either CSF or sedimented CSF should be placed on a slide, under a coverslip, and observed for motile trophozoites; smears can also be stained with Wright's or Giemsa stain. CSF, exudate, or tissue fragments can be examined by light microscopy or phase-contrast microscopy. Care must be taken not to mistake leukocytes for actual organisms or vice versa. It is very easy to confuse leukocytes and amebae, particularly when one is examining CSF by using a counting chamber, hence the recommendation to use just a regular slide and coverslip. Motility may vary, and so the main differential characteristic is the spherical nucleus with a large karyosome.

Specimens should never be refrigerated prior to examination. When centrifuging the CSF, low speeds ($250 \times g$) should be used so that the trophozoites are not damaged. Although bright-field microscopy with reduced light is acceptable, phase microscopy, if available, is recommended. Use of smears stained with Giemsa or Wright's stain or a Giemsa-Wright's stain combination can also be helpful. If *N. fowleri* is the causative agent, trophozoites only are normally seen. If the infecting organism is *Acanthamoeba*, cysts may also be seen in specimens from patients with CNS infection. Unfortunately, most cases are diagnosed at

autopsy; confirmation of these tissue findings must include culture and/or special staining with monoclonal reagents in indirect fluorescent-antibody procedures. Organisms can also be cultured on nonnutrient agar plated with *Escherichia coli*.

In cases of presumptive pyogenic meningitis in which no bacteria are identified in the CSF, the computed tomography appearance of basal arachnoiditis (obliteration of basal cisterns in the precontrast scan with marked enhancement after the administration of intravenous contrast medium) should alert the staff to the possibility of acute PAM.

The amebae can be identified in histologic preparations by indirect immunofluorescence and immunoperoxidase techniques. The organism in tissue sections looks very much like an *Iodamoeba bütschlii* trophozoite, with a very large karyosome and no peripheral nuclear chromatin; the organisms can also be seen with routine histologic stains.

In infections possibly caused by *Acanthamoeba* spp., periodic acid-Schiff stains the cyst wall red and methenamine silver stains the cyst black; these stains may be helpful. Normally, *Naegleria* and *Acanthamoeba* isolates are identified to the species level by a reference laboratory, such as the Centers for Disease Control and Prevention, using indirect fluorescent-antibody procedures with a monoclonal or polyclonal antibody. The formalin stability of at least one of the epitopes may be useful in detecting *N. fowleri* in fixed biopsy specimens and in investigating the pathologic process (20).

In general, serologic tests have not been helpful in the diagnosis of this infection. The disease progresses so rapidly that the patient is unable to mount an immune response.

KEY POINTS—LABORATORY DIAGNOSIS

Naegleria fowleri

1. Never refrigerate the specimen(s) prior to examination.
2. Beware of the false-positive Gram stain, especially since PAM usually mimics bacterial meningitis (CSF contains increased numbers of leukocytes, increased protein concentrations, and decreased sugar concentrations).
3. The *Naegleria* trophozoites mimic leukocytes in a counting chamber. Motility is more likely to be seen if a drop of CSF is placed directly on a slide and a coverslip is added. Phase-contrast optics are recommended; however, if regular bright-field microscopy is used, the light level should be low. The slide can also be warmed to 35°C to stimulate trophozoite motility.

4. Organisms can be cultured on nonnutrient agar plated with *Escherichia coli*.
5. Low-speed centrifugation is recommended for CSF (150 × g for 5 min).
6. Incubate the plate in room air at 35 to 37°C for tissues from the CNS and at 30°C for tissues from other sites.
7. Using the low-power objective (10×), observe the plates daily for 7 days.
8. Remember that *B. mandrillaris* does not grow on agar plates seeded with bacteria.
9. Standard precautions should be used when handling these specimens and cultures. Procedures should be performed in a biological safety cabinet.

Treatment

Many antimicrobial and antiparasitic drugs have been screened for in vitro and in vivo activity against *N. fowleri*. Although *N. fowleri* is very sensitive to amphotericin B in vitro, only a few patients have recovered after receiving intrathecal and intravenous injections of this drug alone or in combination with miconazole (20). One case within California in which the patient was successfully treated with amphotericin B, miconazole, and rifampin has been documented. There was a synergistic effect with miconazole and amphotericin B in vitro; however, rifampin was ineffective. Dexamethasone and phenytoin were also given to this patient to decrease intracranial pressure and seizure, respectively. *Naegleria* infections have also been treated successfully with amphotericin B, rifampin, and chloramphenicol; amphotericin B, oral rifampin, and oral ketoconazole; and amphotericin B alone (1, 20, 21). Delay in diagnosis and the fulminant nature of PAM result in few survivors; this is unfortunate since *N. fowleri* is quite sensitive to the antifungal agent amphotericin B.

Epidemiology and Prevention

Nearly 200 presumptive or proven cases of PAM have been reported in the literature, including cases from the United States, Ireland, England, Belgium, Czechoslovakia, Australia, New Zealand, Brazil, and Zambia. Clinical patient histories indicate exposure to the organism via freshwater lakes or swimming pools shortly before onset; patients had been previously healthy with no specific underlying problems (20). Pathogenic *Naegleria* organisms have also been isolated from nasal passages of individuals with no history of water exposure, suggesting the possibility of airborne exposure.

The first isolations of the environmental strains of pathogenic *N. fowleri* were reported from water and soil

in Australia and from sewage sludge samples in India. Detection of *N. fowleri* in heated discharge water has been reported in Belgium and Poland. Since then, there have been additional reports describing isolations of virulent or avirulent strains of *N. fowleri* from the environment. Studies in Belgium have clearly indicated that *N. fowleri* strains are present in artificially heated waters (power plant warm discharge), and studies in the United States have indicated that virulent strains are also found in lakes in geographic latitudes with water temperatures of 14 to 35°C that are totally isolated from any source of thermal discharge (20). These data suggest that the presence of pathogenic or potentially pathogenic amebic strains may depend on both climate and modification of the natural environment. The ability of the cysts to survive under various environmental conditions has been investigated by several workers. These findings suggest that *N. fowleri* cysts produced in the warm summer months may survive the winter and are capable of growth during the following summer.

General preventive measures include public awareness of potential hazards of contaminated water. It has been recommended that warm discharge water not be used for sports and recreational purposes (20), particularly since DNA restriction fragment profiles of environmental strains and human isolates were homogeneous.

In more recent studies, 30 strains of *N. fowleri* were investigated by the randomly amplified polymorphic DNA (RAPD) method. The data confirmed earlier work indicating that RAPD variation is not correlated with geographic origin. In particular, Mexican strains belong to the variant previously detected in Asia, Europe, and the United States. In France, strains gave RAPD patterns identical to those of the Japanese strains. All of these strains, in addition to another strain from France, exhibited similarities to South Pacific strains. The results confirmed the presence of many variants in Europe, while only two variants were detected in the United States; these two variants were different from the South Pacific variants (20).

Acanthamoeba spp.

Formerly, the genus *Acanthamoeba* was included in the genus *Hartmanella*. In 1975, Sawyer and Griffin proposed a new family, Acanthamoebidae, for the spiny amebae, with *Acanthamoeba* as the type genus and *Acanthamoeba castellanii* as the type species (5). The most characteristic feature of this genus is the presence of spine-like pseudopods called acanthopodia. Several species of *Acanthamoeba* (*A. culbertsoni*, *A. castellanii*, *A. polyphaga*, *A. astronyxis*, *A. healyi*, and *A. divionensis*) cause GAE, primarily in immunosuppressed, chronically ill, or otherwise debilitated persons. These patients tend to have no relevant history involving

exposure to recreational freshwater. *Acanthamoeba* spp. also cause amebic keratitis, and it is estimated that to date approximately 1,000 cases of *Acanthamoeba* keratitis have been seen in the United States. Species of *Acanthamoeba* linked to keratitis include *A. castellanii*, *A. polyphaga*, *A. hatchetti*, *A. culbertsoni*, *A. rhyodes*, *A. griffini*, *A. quina*, and *A. lugdunensis* (15). The number of cases worldwide has also been increasing; apparently, the incidence of *Acanthamoeba* keratitis in the United Kingdom is 15 times that in the United States and 7 times that in Holland (13).

The pathogenesis of *Acanthamoeba* infection involves the ability of the organism to invade tissues. This capability depends on adherence to mucosal surfaces, migration through tissues, and the release of oxygen radicals and proteases that can destroy connective tissue. Studies have found that alkaline cysteine proteinases were more active in pathogenic strains whereas serine proteases were found in both pathogenic and nonpathogenic strains (15).

Humoral immunity and complement activation appear to be the primary defense mechanisms against *Acanthamoeba* infections; serum antibodies are mainly the immunoglobulin M (IgM) and IgG classes. Both antibody and complement promote recognition of the organisms by phagocytic cells. The amebae are destroyed by neutrophils, which are activated by lymphokines to accelerate the respiratory burst and to release lysosomal enzymes. Macrophages and neutrophils are the major inflammatory cell types found in tissues surrounding amebae. Although the cornea is infiltrated by neutrophils and there is a measurable humoral response, the disease will progress to corneal opacity or perforation without therapy in the immunocompetent patient. It has been suggested that the organisms mask their antigens from cellular immune responses, thus suppressing macrophage functions and/or preventing neutrophil activity. Total serum immunoglobulins do not differ significantly between healthy subjects and patients with *Acanthamoeba* keratitis, but levels of ameba-specific tear IgA were significantly lower in patients with keratitis (15). Although *Acanthamoeba* infections stimulate a granulomatous response, the response in AIDS patients is minimal or absent, findings which are consistent with the poor immune response in these patients.

Another type of meningoencephalitis, GAE, caused by freshwater amebae is less well defined and may occur as a subacute or chronic disease with focal granulomatous lesions in the brain (Table 5.4). The route of CNS invasion is thought to be hematogenous, with the primary site being the skin or lungs. In this infection, both trophozoites and cysts can be found in the CNS lesions. An acute-onset case of fever, headache, and pain in the neck preceded by 2 days of lethargy has also been documented (15). The causative organisms are probably *Acanthamoeba* spp. in

^a Adapted from J. P. Sison, C. A. Kemper, M. Loveless, D. McShane, G. S. Visvesvara, and S. C. Deresinski, Disseminated *Acanthamoeba* infection in patients with AIDS: case reports and review, *Clin. Infect. Dis.* 20:1207–1216, 1995.

most cases, but it is possible that other genera are involved (15, 20). In the acute case mentioned above, *A. culbertsoni* was repeatedly found in and cultured from the CSF. The patient responded dramatically to a combination therapy of penicillin and chloramphenicol. Cases of GAE have been reported in chronically ill or immunologically impaired hosts; however, some patients apparently have no definite predisposing factor or immunodeficiency. Conditions associated with GAE include malignancies, systemic lupus erythematosus, human immunodeficiency virus infection, Hodgkin's disease, skin ulcers, liver disease, pneumonitis, diabetes mellitus, renal failure, rhinitis, pharyngitis, and tuberculosis. Predisposing factors include alcoholism, drug abuse, steroid treatment, pregnancy, systemic lupus erythematosus, hematologic disorders, AIDS, cancer chemotherapy, radiation therapy, and organ transplantation. This infection has become more widely recognized in AIDS patients, particularly those with a low CD4⁺ cell count.

The *Acanthamoeba* group also causes keratitis and corneal ulceration. There are a number of published cases that emphasize the need for clinicians to consider acanthamoebic infection in the differential diagnosis of eye infections that fail to respond to bacterial, fungal, or viral therapy. These infections are often due to direct exposure

of the eyes to contaminated materials or solutions. It is now recognized that the wearing of contact lenses is the leading risk factor for keratitis. Conditions which are linked with disease include the use of homemade saline solutions, poor contact lens hygiene, and corneal abrasions.

Life Cycle and Morphology

Unlike *N. fowleri*, *Acanthamoeba* spp. do not have a flagellate stage in the life cycle, only the trophozoite and cyst (Figures 5.6 and 5.7) (Table 5.3).

Morphology of Trophozoites. Motile organisms have spine-like pseudopods; however, progressive movement is usually not very evident (Figures 5.2 and 5.8). There is a wide range (25 to 40 μm), with the average diameter of the trophozoites being 30 μm. The nucleus has the typical large karyosome, like that seen in *N. fowleri* (Figures 5.2 and 5.9 to 5.11). This morphology can be seen on a wet preparation. In the environment, these organisms feed on bacteria, algae, and yeast; however, they can also exist on liquid nutrients taken up through pinocytosis

(15). Organelles typically found in higher eukaryotic cells have been identified and include a Golgi complex, smooth and rough endoplasmic reticula, free ribosomes, digestive vacuoles, mitochondria, and microtubules.

Morphology of Cysts. The cysts are usually round with a single nucleus, also having the large karyosome seen in the trophozoite nucleus. The double wall is usually visible, with the slightly wrinkled outer cyst wall and what has been described as a polyhedral inner cyst wall (15) (Figures 5.2, 5.9, 5.12, and 5.13). This cyst morphology

can be seen in organisms cultured on agar plates. Cyst formation occurs under adverse environmental conditions; cysts are resistant to biocides, chlorination, and antibiotics and can also survive low temperatures (0 to 2°C).

Clinical Diseases

GAE. Meningoencephalitis caused by *Acanthamoeba* spp. may present as an acute suppurative inflammation of the brain and meninges like that seen with *N. fowleri* infection. However, *Acanthamoeba* spp. are generally reported to cause a more chronic protracted slowly progressive form of meningoencephalitis (GAE). Due to the confusion in the earlier literature regarding the nomenclature of *Acanthamoeba* and *Hartmanella* spp., these organisms have been referred to in the past as belonging to the *Hartmanella-Acanthamoeba* group. However, since no true *Hartmanella* species has been found to be pathogenic to humans, references to *Hartmanella* in human tissues should be revised to read *Acanthamoeba* or *Balamuthia* spp. (14, 15).

The incubation period of GAE is unknown; several weeks or months are probably necessary to establish the disease. The clinical course tends to be subacute or chronic and is usually associated with trauma or underlying disease, not swimming. GAE is characterized by confusion, dizziness, drowsiness, nausea, vomiting, headache, lethargy, stiff neck, seizures, and sometimes hemiparesis. Within the CNS, the cerebral hemispheres are the most likely tissue to be involved. There may be edema and hemorrhagic necrosis within the temporal, parietal, and occipital lobes. A chronic inflammatory exudate can be seen over the cortex, mainly of polymor-

phonuclear leukocytes and mononuclear cells. Unlike in PAM caused by *N. fowleri*, both trophozoites and cysts are found throughout the tissue. Granulomatous inflammation necrosis and thrombosed vessels are seen in the brain. Multinucleated giant cells forming granulomas can be seen in immunocompetent patients, while granuloma formation is generally poor or lacking in immunocompromised individuals. It is unknown whether brain necrosis is due to direct tissue destruction caused by the organisms, to inflammatory cytokines such as interleukin-1 or tumor necrosis factor, or both. Also, dissemination to other tissues such as the liver, kidneys, trachea, and adrenals can occur in immunocompromised individuals; more unusual sites also include the ears and necrotic bone from a bone graft of the mandible (15).

In the differential diagnosis, other space-occupying lesions of the CNS (tumor, abscess, fungal infection, etc.) must also be considered. Some of the predisposing factors have included Hodgkin's disease, diabetes, alcoholism, pregnancy, and steroid therapy. Organisms have also been found in the adrenal gland, brain, eyes, kidneys, liver, pancreas, skin, spleen, thyroid gland, and uterus.

Amebic meningoencephalitis can also be an unusual complication of bone marrow transplantation. A case has been reported in a patient with non-Hodgkin's lymphoma after autologous stem cell transplantation. Leg weakness, fever, and urinary retention developed 69 days after transplantation. The patient then developed fever, seizures, rapid deterioration of mental functions, and hypercapneic respiratory failure. Magnetic resonance imaging demonstrated a ring-enhancing lesion at the level of thoracic spines 11 and 12. Pleocytosis was seen in the CSF. On

autopsy, a subacute meningoencephalitis secondary to *A. culbertsoni* infection was seen (15).

AIDS Patients. Although the first case of an *Acanthamoeba* infection in a patient with AIDS was in 1986, many additional cases have been reported since that time. *Acanthamoeba* spp. are now well accepted as opportunistic pathogens in immunocompromised patients with AIDS. Unfortunately, most of the cases have resulted in death and have been confirmed postmortem. These individuals usually have advanced HIV disease with a very low CD4⁺ T-cell count, generally less than 200/mm³. Often the patients expire within a month after onset of CNS symptoms. Unfortunately, the diagnosis of this infection requires a high index of suspicion, since both clinical and histologic findings may mimic those of disseminated fungal or algal disease (Tables 5.4 and 5.5). The primary site of infection is thought to be the sinuses and lungs. The skin is also thought to be a possible portal of entry. Clinical manifestations of patients with AIDS and *Acanthamoeba* infection can be reviewed in Table 5.4. They may include general complaints such as fever and chills, nasal congestion or lesions, neurologic symptoms, and musculoskeletal and cutaneous lesions. Some patients, especially those with AIDS, can develop erythematous nodules, chronic ulcerative skin lesions, or abscesses. Although CSF lymphocytosis is seen in non-AIDS patients, the CSF may reveal no cells in HIV-positive patients. These patients also tend to exhibit chronic sinusitis, otitis, and cutaneous lesions (Figure 5.14). Patients with CNS symptoms and AIDS may be misdiagnosed with toxoplasmosis, although serologic tests for *Toxoplasma* may be negative. Other patients have been misdiagnosed with CNS vasculitis, squamous cell carcinoma, or bacterial meningitis.

Both PAM and GAE carry a grave prognosis and, although considered rare, should be considered in the differential diagnosis of patients who present with appropriate histories and imaging findings including nonspecific brain edema on computed tomography in PAM and focal

Figure 5.14 *Acanthamoeba* infection in a 28-year-old Mexican woman who had a skin lesion for 6 months. She developed CNS symptoms including headache and nausea. (From A Pictorial Presentation of Parasites: a cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of G. H. Healy.)

punctate enhancing lesions in the posterior cranial fossa on T1-weighted magnetic resonance imaging in GAE. The initial symptoms are commonly fever and headache. It is important to remember that in patients thought to have toxoplasmosis, review of the cranial computed tomogram could not distinguish between the two etiologic agents *Toxoplasma* and/or *Acanthamoeba*.

In patients with disseminated disease, the duration of infection from onset to death can range from 7 days to 5 months. Once neurologic symptoms became obvious, the survival time is generally about a month. Since early therapy can alter the clinical outcome, recognition of this disease as a potential cause of the patient's presentation is critical. It is important to initiate appropriate diagnostic testing for confirmation of the causative agent as soon as possible.

Keratitis. Keratitis, uveitis, and corneal ulceration have been associated with *Acanthamoeba* spp. Infections have been seen in both hard- and soft-lens wearers, and particular attention has been paid to soft-lens disinfection systems, including homemade saline solutions. Heat disinfection overall appears to be more effective than cold disinfection methods in killing *Acanthamoeba* trophozoites and cysts. Recent studies indicate that not all commercial contact lens disinfectant solutions are equal in their ability to kill *A. castellanii* (4). Solutions containing hydrogen peroxide or chlorhexidine-thimerosal were active against both trophozoites and cysts. A benzalkonium chloride-based solution was effective only against trophozoites, and solutions containing polyaminopropyl biguanide or polyquaternium 1 were completely ineffective. Unfortunately, a lack of standard methods for testing disinfection solutions may also complicate the issue, although the use of a more reproducible approach may be helpful (4). Obviously, the cyst form of the parasite is much more resistant, and the need to test any solution for both trophozoites and cysts is critical. In addition to the active ingredient(s), it is important to consider adequate exposure times. In general, products containing hydrogen peroxide were the most active, demonstrating the best minimum trophozoite amebicidal concentration for both trophozoites (3 min) and cysts (9 h). It is always important to remember that different products containing hydrogen peroxide at the same concentration may have different killing properties; one report indicated that when hydrogen peroxide was used according to the manufacturer's directions (30 min of contact time), it was not effective against *A. castellanii* trophozoites and cysts. An excellent discussion of the manufacturer's minimum recommended disinfection time for contact lens solutions can be found in reference 4. In order for a disinfectant to be cysticidal, it must be able to gain access to the trophozoite contained within the cyst wall. The most likely route would be the pores in the double cell wall; however, it is thought that these pores (ostioles)

are plugged with mucopolysaccharide. Thus, the disinfectant would need to be able to disrupt these "plugs" in order to reach the trophozoite.

The onset of corneal infection with *Acanthamoeba* spp. can vary tremendously; however, two factors often appear to be involved: trauma and contaminated water. When corneal abrasions occur, the disease process is usually more rapid, with ulceration, corneal infiltration, iritis, scleritis, severe pain, hypopyon (pus in the anterior chamber), and loss of vision. When this process occurs in an individual who wears contact lenses, the onset is more gradual but the results are often the same. A contact lens can act as a mechanical vector for transport of amebae present in the storage case onto the cornea. Subsequent multiplication and invasion of the tissue may occur. Another consideration involves the potential infection of the nasal cavity via lacrimal drainage, a condition that probably causes no problems in a healthy individual. However, it remains unknown whether the presence of these organisms in the nasopharynx of an immunocompromised individual increases the risk of GAE.

Decreased corneal sensation has contributed to the misdiagnosis of *Acanthamoeba* keratitis as herpes simplex keratitis; this mistake can also be attributed to the presence of irregular epithelial lesions, stromal infiltrative keratitis, and edema, which are commonly seen in herpes simplex keratitis. *Acanthamoeba* keratitis may be present as a secondary or opportunistic infection in patients with herpes simplex keratitis. Unfortunately, as a result, treatment can be delayed for 2 weeks to 3 months. The presence of nonhealing corneal ulcers and the presence of ring infiltrates are also clinical signs that alert the ophthalmologist to the possibility of amebic infection.

It is important to consider *Acanthamoeba* infection in the differential diagnosis of uveitis in patients with AIDS. It is also important to remember that incisional keratotomy may predispose the cornea to delayed-onset infectious keratitis; *Acanthamoeba* should always be considered as a possible cause of infection, and clinical specimens should be cultured in refractory cases.

One of the mechanisms of *Acanthamoeba* adhesion to the corneal surface may involve interactions between the mannose binding protein of *Acanthamoeba* and mannose-containing glycoproteins on the surface of the corneal epithelium (15, 20). It appears that enhanced growth is seen in surface-attached amebae and that cocontamination of lens systems with bacteria may be a prime factor in the development of amebic keratitis. Data also suggest that obligate bacterial endosymbionts are able to enhance the amebic pathogenic potential in vitro, although the exact mechanisms have not yet been identified (10). There are also data to show that monoclonal anti-*Acanthamoeba* IgA antibodies can protect against *Acanthamoeba* keratitis,

suggesting that this occurs by inhibiting adhesion of the amebae to the corneal epithelium (15).

Acanthamoeba spp. elaborate a variety of proteases, which may facilitate cytolysis of the corneal epithelium, invasion of the extracellular matrix, and dissolution of the corneal stromal matrix (20). *Acanthamoeba* spp. are also resistant to complement lysis. The ability of *Acanthamoeba* spp. to activate the alternative complement pathway but to resist complement-mediated cellular lysis can be attributed to both the release of a transport-dependent extracellular matrix and the presence of complement-inhibitory surface proteins.

Although previous studies have shown that early diagnosis and therapy are definitely related to outcome, differences among patients with and without contact lenses should also be considered. The mean time to diagnosis could be significantly longer in patients who are not contact lens users than in those who are, primarily due to the differences in the index of suspicion regarding the link between contact lens use and *Acanthamoeba* keratitis. These differences could be directly related to poor outcome, with patients who did not wear contact lenses having a very poor visual acuity or penetrating keratoplasty compared with patients who wore contact lenses. It is important to remember that all patients with unresponsive microbial keratitis, even those who do not wear contact lenses, should be evaluated for possible *Acanthamoeba* infection.

Cutaneous Lesions. Cutaneous infections are more common in patients with AIDS, regardless of the presence or absence of CNS involvement. The disease includes the presence of hard erythematous nodules or skin ulcers (Figures 5.14 and 5.15). The early lesions appear as

Figure 5.15 Microscopic view of *Acanthamoeba* amebae in skin. Note the typical large karyosome. (From A Pictorial Presentation of Parasites: a cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of G. H. Healy.)

firm papulonodules that drain purulent material; these lesions then develop into nonhealing indurated ulcers. Although disseminated skin lesions may be the first sign of *Acanthamoeba* infection, it is unclear whether the skin lesions represent a primary focus or may result from hematogenous spread from other body sites. Although the mortality rate for these individuals without CNS involvement is around 75%, it increases to 100% if cutaneous infection is accompanied by CNS disease (15).

Histology reveals necrosis surrounded by inflammatory cells, vasculitis, and the presence of trophozoites and cysts of the amebae. However, these findings can also mimic skin lesions caused by fungi, viruses, mycobacteria, or foreign-body reactions. The amebae can also resemble yeast forms of *Blastomyces dermatitidis*, sporangia of *Rhinosporidium seeberi*, *Cryptococcus neoformans*, or *Prototheca wickerhamii*. Because cutaneous acanthamoebiasis has been misdiagnosed as a number of different conditions, it is important to repeat the examination of biopsy material with a different specimen if the first results are negative and no amebae are seen.

Diagnosis

Laboratory examinations similar to those for *N. fowleri* can be used to recover and identify these organisms; the one exception is recovery by culture, which has not proven to be as effective with GAE patients infected with *B. mandrillaris*. The most effective approach uses nonnutrient agar plates with Page's saline and an overlay growth of *Escherichia coli* on which the amebae feed (15, 20) (Figure 5.16). There is also evidence that phosphate-buffered saline can be used. Specimens transported in ameba-saline (5.0 ml) and filtered through 13-mm, 0.22- μ m-pore-size cellulose acetate and nitrate filters (Millipore Corp., Bedford, Mass.) have also been acceptable for organism recovery. The filter is then placed in the center of the nonnutrient agar plate seeded with *E. coli*. Tissue stains are also effective, and cysts can be stained with Gomori's silver methenamine, periodic acid-Schiff, and calcofluor white (15, 20).

Various improved medium formulations have been developed and provide some additional options. *Acanthamoeba* isolates have been recovered from clinical specimens inoculated onto buffered charcoal-yeast extract agar (BCYE), nonnutrient agar with live or dead *E. coli*, and tryptic soy agar (TSA) with 5% horse or sheep blood. Good recovery of trophozoites has been obtained on BCYE, TSA with rabbit blood, TSA with horse blood, and Remel TSA with sheep blood. BBL TSA with horse blood or rabbit blood provided good recovery of cysts. All species of live or dead bacteria (*Enterobacter aerogenes*, *E. coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Serratia marcescens*, *Staphylococcus aureus*,

Figure 5.16 (Left) *Acanthamoeba* trophozoites in wet preparation (note the “spiky” pseudopods, called acanthopodia); (right) *Acanthamoeba* cyst in wet preparation (note the double-wall appearance).

and *Stenotrophomonas maltophilia*) yielded good recovery of trophozoites; however, only nonnutrient agar with live *P. aeruginosa*, live *E. aerogenes*, or live *S. maltophilia* gave good recovery of cysts. TSA with rabbit blood or horse blood, BCYE, and nonnutrient agar prepared with live *P. aeruginosa*, *E. aerogenes*, or *S. maltophilia* offered optimal recovery of *Acanthamoeba*. Filtration of specimens through cellulose membranes and cultivation on nonnutrient agar plates covered with *E. coli* was compared with culture of centrifuged specimens (15). Significantly higher parasite detection could be obtained with samples processed by filtration (100% of specimens containing 10 parasites and 65% of specimens containing 2 parasites compared with 8 and 0%, respectively, with centrifugation).

Cryopreservation studies have also found that the highest viability of trophozoites of *A. culbertsoni* occurs when dimethyl sulfoxide is used at a final concentration of 10% and an equilibrium temperature of 4°C. Gross cultural or morphological changes were not noted in trophozoites thawed from frozen suspension; the organisms were grown in serum-casein-glucose-yeast extract medium (2).

Identification of acanthamoebae in ocular and other tissues can be difficult, even for trained microscopists; in histologic preparations the organisms look much like keratoplasts, as well as neutrophils and monocytes. It has been estimated that up to 70% of clinical *Acanthamoeba* keratitis cases are misdiagnosed as viral keratitis. Also, the mean time to diagnosis of keratitis due to *Acanthamoeba* infection can average 2.5 weeks longer for non-contact lens wearers than for contact lens users. Certainly the availability of rapid, accurate, and relatively simple diagnostic tests would increase the timely application of appropriate chemotherapy. Genetic markers have also been developed and used to identify pathogenic *Acanthamoeba* strains associated with nonkeratitis infections (8).

Cutaneous lesion material can be inoculated onto various growth media, including nonnutrient agar plates

with a bacterial overlay. Inoculation of mammalian cell culture monolayers is also possible, as for GAE. Histologic stains such as hematoxylin and eosin, periodic acid-Schiff, or calcofluor white can be used. Also, DNA-based molecular methods such as restriction fragment length polymorphism and randomly amplified DNA analysis can be used.

CSF or bronchoalveolar lavage fluid cytospin preparations can be used to look for amebae in patients with GAE or respiratory symptoms. The characteristic morphology of the *Acanthamoeba* trophozoites, such as the prominent nucleolus, contractile vacuole, and cytoplasmic vacuoles, can be seen more easily using trichrome or hematoxylin and eosin stains on fixed preparations after cytocentrifugation.

Although detection of antibodies to *Acanthamoeba* spp. has been confirmed, the usefulness of serologic tests for the diagnosis of these infections has not been proven. Also, these procedures are not generally available. Further work related to the issue of false-positive and false-negative results and interpretive guidelines regarding past exposure or present infection must be performed before these diagnostic procedures can be routinely used.

KEY POINTS—LABORATORY DIAGNOSIS

Acanthamoeba spp.

1. As with *N. fowleri*, beware of a false-positive Gram stain (the leukocyte count in CSF may be elevated).
2. Examine clinical material on a slide with a coverslip; do not use a counting chamber (organisms in CSF look like leukocytes).
3. Nonnutrient agar with Page’s saline and an *E. coli* overlay can be tried for culture recovery.
4. Various other media containing different agar bases, some of which contain horse, sheep, or rabbit blood, are also available.

5. Tissue stains are also effective, and the use of calcofluor white to visualize the double-walled cyst is recommended.
6. Refer to chapter 32 for specific methods and recommendations.

Treatment

Disseminated Infections. Trophozoites and cysts of *Acanthamoeba* isolates vary in their sensitivity to antimicrobial agents. They are sensitive in vitro to ketoconazole, pentamidine, hydroxystilbamidine, paromomycin, 5-fluorocytosine, polymyxin, sulfadiazine, trimethoprim-sulfamethoxazole, azithromycin, and extracts of medicinal plants and, especially, to combinations of these drugs (15, 21). Increased awareness of these infections and early therapy play a large role in patient outcomes. Although steroids have been used in the past to treat cerebral edema and inflammation in CNS infections, this approach should not be used since the steroids tend to exacerbate the *Acanthamoeba* infection. Encephalitis has been treated, somewhat successfully, with antimicrobial combinations including sterol-targeting azoles (clotrimazole, miconazole, ketoconazole, fluconazole, and itraconazole), pentamidine isethionate, 5-fluorocytosine, and sulfadiazine. The use of drug combinations helps address resistance that may exist or occur during treatment. In vitro testing confirms strain and species differences in sensitivity, so that no single drug is effective against all amebae (16).

Amebic Keratitis. Because the infection may be misdiagnosed and/or therapy may be delayed, total blindness may result in the infected eye(s). However, if the infection is correctly diagnosed early and the epithelium alone is involved, debridement may be sufficient for cure. This approach not only removes organisms but also enhances the delivery of topical medications. However, if treatment is delayed and the organisms invade the cornea or tissues below the cornea, therapy may need to be continued for many months to a year or longer. These patients must be monitored continually because the cysts tend to be quite resistant to therapy; treatment failures tend to be fairly common. In vitro susceptibility testing may be very helpful in these cases (16).

Cutaneous Disease. Cutaneous infections with subsequent dissemination to other body sites have been found in patients who are immunocompromised due to HIV infection or preparation for organ transplantation. As with other disease manifestations, a number of drug combinations have been tried, some of which were successful.

Table 5.6 *Acanthamoeba* infections, treatment, and positive patient outcomes^a

Immunocompetent or underlying disease	Amebic disease involvement	Treatment ^b	Outcome
Immunocompetent	CNS (2 patients)	TMP/SMZ + KC + rifampin	Survived
AIDS	Cutaneous/sinusitis	Ketoconazole + i.v. FC	Resolution of lesions; no CNS involvement
AIDS	Cutaneous/sinusitis	Debridement of sinuses + pentam + topical chlorhexidine + 2% KC; pentam toxicity, maintenance on FC	Survived
AIDS	CNS lesion	Sulfadiazine + pyrimethamine, flucon + sulfadiazine; one localized brain lesion excised	Survived
AIDS	Rhinosinusitis	Removal of all diseased nasal mucosa, pentam, levofloxacin, FC, AmpB	Survived
HIV positive	Sinusitis	Debridement of sinuses, IT + gentamicin nasal wash	Resolution of lesions
HIV positive	Sinusitis/cutaneous, lobular panniculitis	Surgical debridement + IT, azithromycin, 5FC, rifampin	Survived
Renal transplant	Cutaneous lesions, IgA deficiency	Pentamidine + chlorhexidine + 2% KC cream; maintenance on oral IT	Resolution of lesions; no CNS involvement
Lung transplant	Cutaneous	AmpB + i.v. pentam + IT + chlorhex/KC cream + azithro + FC + pentam, maintenance FX + clarithromycin	Survived, but died 6 months after <i>Acanthamoeba</i> diagnosis

^a Based on references 1, 15, 16, 17, 20, and 21.

^b FC, fluorocytosine; IT, itraconazole; azithro, azithromycin; AmpB, amphotericin B; KC, ketoconazole; TMP/SMZ, trimethoprim-sulfamethoxazole; pentam, pentamidine; flucon, fluconazole; chlorhex, chlorhexidine; i.v., intravenous.

However, not all combinations are effective; toxicity with certain drugs also becomes a consideration (Table 5.6).

In a case of skin ulcers due to *Acanthamoeba* in an immunodeficient individual who had undergone kidney transplantation, the patient was successfully treated after extended therapy over a period of 8 months. He received topical as well as systemic administration of combination therapy. The skin ulcers were cleaned twice daily with chlorhexidine gluconate solution, and 2% ketoconazole cream was applied topically. He also received pentamidine isethionate intravenously for 1 month and was then given oral itraconazole therapy for 8 months. This resulted in complete healing of the ulcers (15).

Successful treatment of *Acanthamoeba* infections has been limited; specific examples of patients, disease manifestations, treatment, and outcomes are seen in Table 5.6.

Epidemiology and Prevention

General preventive measures are similar to those for *N. fowleri*. Several disinfectants have been tested against both *Naegleria* and *Acanthamoeba* spp. The conclusion is that *Naegleria* spp. are generally susceptible to swimming-pool levels of chlorine but *Acanthamoeba* spp. are more resistant (15). The recovery of *Acanthamoeba* spp. in nasal isolates and pharyngeal swabs may indicate human introduction of the organisms into swimming pools. With the increasing reports of infection in wearers of soft contact lenses, it will be important to carefully consider the effectiveness of various contact lens disinfection systems. A number of factors probably play a role in the increased incidence of infection: a large number of human immunodeficiency virus-infected individuals and more patients undergoing cancer chemotherapy or immunosuppressive therapy for organ transplantation.

Mitochondrial DNA fingerprinting of *Acanthamoeba* spp. from the American Type Culture Collection and environmental sources has confirmed that approximately half of the 35 isolates displayed fingerprints similar to those of clinical isolates. Comparisons with other published mitochondrial DNA fingerprints indicated that two groups have counterparts in Europe and Japan and in Europe and Australia. These data provide strong evidence that the most common clinical isolates do have counterparts that are geographically widespread and can be isolated from the environment.

Acanthamoeba cysts can remain viable in water at 4°C for 24 years. In animal studies, it has been shown that some of the isolates completely lost their virulence only after 8 years of *in vitro* cultivation. On the basis of these results, one can assume that cyst viability may be as long as 25 years and that these cysts can maintain their invasive properties (15, 20).

Both failure to disinfect daily-wear soft contact lenses and the use of chlorine-release lens disinfection systems,

which have little effect against the organism, are major risk factors for *Acanthamoeba* keratitis. These risks have been very common in disposable-lens use. Some investigators think that over 80% of cases of *Acanthamoeba* keratitis could be avoided by the use of lens disinfection systems that are effective against the organism.

Current recommendations for contact lens wearers include (i) regular scrubbing of contact lens case interiors to disrupt biofilms, (ii) exposure of the contact lens case to very hot water (at least 70°C) to kill *Acanthamoeba* contaminants, (iii) allowing the contact lens case to air dry between uses, (iv) use of a two-step system if hydrogen peroxide disinfection is preferred, and (v) regular replacement of the contact lens case. It has also been documented that some bottled waters contain large numbers of potential ocular pathogens and that, as a general recommendation, bottled water is not safe for routine use with contact lenses.

There have been a number of studies reviewing the potential for carriage of pathogenic bacteria within free-living amoebae. In one study in Germany, *Legionella*-contaminated hot water systems and moist sanitary areas in six hospitals were sampled for amoebae. Amoebae were detected in 29 of 56 hot-water samples and 23 of 49 swabs; six *Acanthamoeba* species isolated from the moist areas were considered potential pathogens (10). It has also been shown that *Acanthamoeba* species can produce vesicles containing live *Legionella pneumophila* cells. Such vesicles may be agents for the transmission of legionellosis associated with cooling towers, and the risk may be underestimated by plate count methods since each vesicle could contain several hundred bacteria. Data also demonstrate that obligate anaerobic bacteria can survive and multiply in *Acanthamoeba* spp. under aerobic conditions, thus suggesting a previously undescribed mechanism for the spread, replication, and persistence of obligate anaerobes in the environment (10). *E. coli* O157 also survives and replicates within *A. polyphaga*. These amoebae may serve as an important environmental reservoir for transmission of *E. coli* O157 and other pathogens (10).

Balamuthia mandrillaris

The free-living amoeba *Balamuthia mandrillaris* is relatively uncommon and was originally thought to be another harmless soil organism, unlikely or unable to infect mammals. However, since *B. mandrillaris* was first discovered in a pregnant mandrill at the San Diego Wild Animal Park that died of meningoencephalitis, a number of primates including gorillas, gibbons, baboons, orangutans, and monkeys, as well as a sheep and a horse, have died of CNS infection caused by this organism. Over 90 cases of human amoebic encephalitis worldwide have been

Figure 5.17 (A) Trophozoite and (B) cyst of *Balamuthia mandrillaris*. (Illustration by Sharon Belkin.)

identified, with about half of the cases diagnosed within the United States (19). Death can occur from 1 week to several months after the onset of stroke-like symptoms, which can mimic other conditions including brain stem glioma. Patients eventually die of a massive CNS infection. One individual who survived the infection was left with severe neurologic deficits.

Life Cycle and Morphology

The life cycle is similar to that seen with *Acanthamoeba* spp.; like *Acanthamoeba* spp., *Balamuthia* does not have a flagellated stage in its life cycle as do organisms classified as *N. fowleri* (Figure 5.7).

Morphology of Trophozoites. Trophozoites of *B. mandrillaris* are usually irregular in shape, and actively feeding amebae may measure from 12 to 60 μm in length (normal, 30 μm) (Figure 5.17). In tissue culture, broad pseudopodia are usually seen; however, as the monolayer cells are destroyed, the trophozoites develop fingerlike pseudopodia.

Morphology of Cysts. Cysts are usually spherical and measure from 6 to 30 μm in diameter (Figure 5.17). Under electron microscopy, the cysts are characterized by having three layers in the cyst wall: an outer wrinkled ectocyst, a middle structureless mesocyst, and an inner thin endocyst. Under light microscopy, they appear to have two walls, an outer irregular wall and an inner round wall.

Clinical Disease

The disease is very similar to GAE caused by *Acanthamoeba* spp. and has an unknown incubation period (Figures 5.18 to 5.21). The clinical course tends to be subacute or chronic and is usually not associated with swimming in freshwater. No characteristic clinical symptoms, laboratory findings, or radiologic indicators have been found to be diagnostic for GAE. The neuroimaging findings show heterogeneous, hyperdense, nonenhancing, space-occupying lesions. Whether single or multiple, they involve mainly the cerebral cortex and subcortical white matter. These findings suggest a CNS

Figure 5.18 *Balamuthia mandrillaris* trophozoites in brain (hematoxylin and eosin; magnification, $\times 74$). (Armed Forces Institute of Pathology photograph.)

neoplasm, tuberculoma, or septic infarcts. Patients complain of headaches, nausea, vomiting, fever, visual disturbances, dysphagias, seizures, and hemiparesis. There may also be a wide range in terms of the clinical course, from a few days to several months.

In immunocompetent hosts, an inflammatory response is mounted and amebae are surrounded by macrophages, lymphocytes, and neutrophils. However, with rare exceptions, these patients also tend to die of severe CNS disease.

Figure 5.19 *Balamuthia mandrillaris* trophozoites in neutrophilic exudate of brain (hematoxylin and eosin; magnification, $\times 112$). (Armed Forces Institute of Pathology photograph.)

Figure 5.20 *Balamuthia mandrillaris* trophozoites in brain (hematoxylin and eosin; magnification, $\times 742$). (Armed Forces Institute of Pathology photograph.)

Both trophozoites and cysts of *B. mandrillaris* are found in many of the same CNS tissues as are *Acanthamoeba* spp. Although differentiation of these two organisms in tissue by light microscopy is difficult, *B. mandrillaris* appears to have more than one nucleolus in the nucleus in some tissue sections (6). Generally, electron microscopy and histochemical methods are required for definitive identification of *B. mandrillaris*. An immunofluorescence test using species-specific sera is the most reliable means of distinguishing between *Acanthamoeba* and *Balamuthia* spp. (5).

Diagnosis

It is interesting that attempts to isolate the organisms from some humans with GAE have not been successful, and *B. mandrillaris* has also been shown not to grow well on *E. coli*-seeded nonnutrient agar plates. In the diagnostic laboratory, these organisms can be cultured in mammalian cell cultures; some success has been obtained with monkey kidney cells and with MRC, HEp-2, and diploid macrophage cell lines. Using human brain microvascular endothelial cells, investigators have cultured *B. mandrillaris* postmortem from brain and CSF from a case of granulomatous amebic meningoencephalitis (11). A cell-free growth medium is also now available (5). The trophozoites are characterized by extensive branching and a single nucleus (occasionally binucleate forms are seen) with a central karyosome. Occasionally, a few elongated forms with several contractile vacuoles are seen. The cysts have a single nucleus (occasionally, binucleate forms are seen) and have the typical double wall, with the outer wall being thick and irregular.

Figure 5.21 *Balamuthia mandrillaris* cyst with outer, wrinkled cyst wall in brain (hematoxylin and eosin; magnification, $\times 562$). (Armed Forces Institute of Pathology photograph.)

Serum antibodies to *B. mandrillaris* have been found in both adults and children; however, testing is not currently available for routine use. Although the mouse model is rarely used and is somewhat impractical, mice infected with *Acanthamoeba* spp. or *B. mandrillaris* may die of acute disease within 5 to 7 days or chronic disease after several weeks. In either case, amebae can be seen in the mouse brain after culture or histologic examination.

Based on sequence analysis of mitochondrial small-subunit rRNA genes, primers have been developed that amplify a *Balamuthia*-specific PCR product. These primers will be useful not only for retrospective analyses of preserved tissues but also for possible organism identification in vivo (7). Genotyping studies indicate that lethal infections caused by *B. mandrillaris* are due to a single species with a global distribution. Apparently, there is no correlation between a particular mitochondrial sequence and the genus of infected vertebrate. The mitochondrial sequence from the mandrill isolate is identical to that obtained from a human (6).

Treatment

In vitro studies indicate that *B. mandrillaris* is susceptible to pentamidine isethiocyanate and that patients with this infection may benefit from this treatment. Other studies indicate that ketoconazole, propamidine isethionate, clotrimazole, and certain biguanides have amebicidal activity (12, 21). In one immunocompetent patient who survived, treatment included combination antibiotics (pentamidine, 300 mg intravenously once a day; sulfadiazine, 1.5 g four times a day; fluconazole, 400 mg once a day; and clarithromycin, 500 mg three times a day) (14). As of April 2004, there have been no neurologic sequelae in this patient.

(Lower) Two trophozoites in brain tissue (note the trophozoite on the right has the two nuclei clearly visible). (Photographs courtesy of Govinda Visvesvara, Centers for Disease Control and Prevention.)

Epidemiology and Prevention

Current recommendations are similar to those for *Acanthamoeba* spp. Information on the environment of *B. mandrillaris* is scarce; however, it is assumed that its habitat is similar to that of other free-living amebae. Although attempts to isolate *B. mandrillaris* from soil samples related to previous encephalitis cases were unsuccessful, there was always some question regarding the designation “free-living” amebae. However, following the death of a 3-year-old Northern California resident from amebic encephalitis caused by *Balamuthia*, environmental samples were collected around the child’s home and outdoor play areas. An ameba, consistent with *Balamuthia*, was isolated from the soil found in a potted plant in the home (19). Thus, the isolation of *Balamuthia* amebae from soil affirms its status

Table 5.7 Summary of information on the newly recognized pathogenic free-living ameba, *Sappinia diploidea*^a

Characteristic	Comments
Patient	38-year-old man
Symptoms	Visual disturbances, headache, seizure
Brain scan	Solitary tumor-like mass in posterior left temporal lobe
Surgical excision	Necrotizing hemorrhagic inflammation
Histologic findings	Central necrotic and hemorrhagic inflammations; acute and chronic inflammatory cells without granulomas or eosinophils; trophozoites present in viable brain parenchyma on mass periphery without inflammatory response
Organisms present	Amebic trophozoites
Trophozoite characteristics	Large (40–70 μm), 2 nuclei per trophozoite
Stained trophozoites	Bright; Giemsa, periodic acid-Schiff stains
Cysts	Not found, but possibility not excluded
Therapy after surgery	Azithromycin, pentamidine, itraconazole, flucytosine

^a Information from reference 9.

as a free-living ameba; like *Acanthamoeba* and *Naegleria*, *Balamuthia* is also an opportunistic pathogen.

From the information presented above, it is clear that *B. mandrillaris*, formerly regarded as having no pathogenic potential, will continue to be identified as the etiologic agent of fatal meningoencephalitis in humans as well as animals (Figures 5.18 to 5.21). This opportunistic infection may also continue to cause disease in individuals with AIDS.

Sappinia diploidea

Sappinia diploidea is a newly recognized human pathogen, causing amebic encephalitis. The infection has been well documented in a single patient (9). Trophozoites measure from 40 to 70 μm and have a distinctive double nucleus (Figure 5.22). Transmission electron microscopy confirms that the trophozoites contain two nuclei attached to each other by connecting perpendicular filaments. The trophozoites ingested host blood cells and stained brightly with Giemsa and periodic acid-Schiff stains. Cysts were not seen, but their presence in the human host was not excluded. These and other morphologic characteristics led to the diagnosis of *S. diploidea*, a demonstrated human pathogen for the first time.

The patient was a 38-year-old man who complained of visual disturbances and headache; he also had a seizure.

Brain scans revealed a solitary tumor-like mass in the posterior left temporal lobe. On biopsy, the mass demonstrated necrotizing hemorrhagic inflammation, which contained free-living amoebae. Postoperatively, the patient was treated with a sequential regimen of antiamebic drugs, including azithromycin, pentamidine, itraconazole, and flucytosine. Characteristics of this case are summarized in Table 5.7.

Protozoa from Other Body Sites

Trichomonas vaginalis

Toxoplasma gondii

Trichomonas vaginalis

Trichomonas vaginalis was first isolated in 1836 from the purulent discharge from the female genital organs. The infection occurs worldwide and has been found in the population whenever the appropriate specimens have been examined for the presence of the organism. It is estimated that 5 million women and 1 million men in the United States have trichomoniasis, with the annual incidence of new cases estimated at 7.4 million (35). The annual incidence of trichomoniasis worldwide is estimated to be more than 170 million cases, which does not include the number of asymptomatic cases that are not treated. In North America, more than eight million new cases are reported yearly, with an estimated rate of asymptomatic cases being as high as 50% (35). Trichomoniasis is now the primary nonviral sexually transmitted disease worldwide. Infection with *T. vaginalis* has major health consequences for women, including complications in pregnancy, association with cervical cancer, and predisposition to human immunodeficiency virus (HIV) infection.

Life Cycle and Morphology

T. vaginalis has only the trophozoite stage in its life cycle, and it is very similar in morphology to other trichomonads (Figure 6.1; Table 6.1). The trophozoite is 7 to 23 μm long and 5 to 15 μm wide. The axostyle is usually extremely obvious, and the undulating membrane stops halfway down the side of the trophozoite (Figure 6.2). The nuclear chromatin is uniformly distributed, and there are many siderophil granules that are particularly evident along the axostyle. The axostyle is thought to anchor the parasite to vaginal epithelial cells. The cytoskeleton is composed of tubulin and actin fibers.

There are five flagella, with the fifth being incorporated within the undulating membrane. Different conditions alter the shape of the trophozoites; in axenic culture the trophozoite tends to be more pear shaped and oval, but it may appear more ameboid when attached to vaginal epithelial cells. When environmental conditions are unfavorable, the organisms may tend to round up and internalize the flagella. Although some workers have suggested that this may be a preliminary or pseudocyst form, it is probably just a degenerating trophozoite form.

The life cycle has been described but remains poorly understood. In growth phase culture, large, round forms of the organism are seen, some without

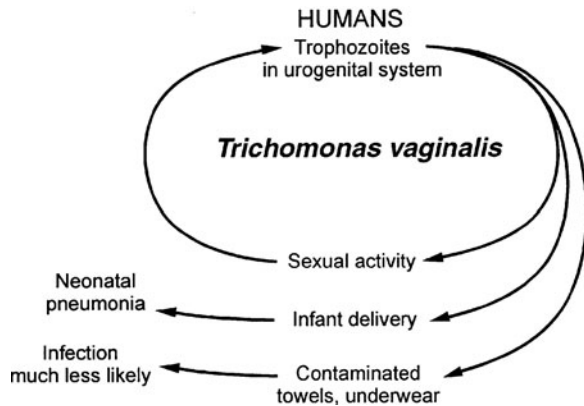

Figure 6.1 Life cycle of *Trichomonas vaginalis*.

flagella, some with flagella and a dividing nucleus, and some with flagella and multiple nuclei. Although there are different opinions about these forms, they are probably developmental stages that appear prior to the typical mononuclear flagellates that generally reproduce by longitudinal binary fission.

Glucose Metabolism. *T. vaginalis* is a primitive eukaryotic organism; however, its metabolism is similar to that of primitive anaerobic bacteria (33). Carbohydrate metabolism is described as being fermentative under both anaerobic and aerobic conditions because glucose is incompletely oxidized. Carbohydrate metabolism occurs in the cytoplasm and an organelle called the hydrogenosome, which is similar to the mitochondria of higher eukaryotes. Within the cytoplasm, glucose is converted to phosphoenolpyruvate and subsequently to pyruvate via the typical Embden-Meyerhoff-Parnas pathway. Pyruvate, which is generated

Figure 6.2 *Trichomonas vaginalis* trophozoite. (Illustration by Sharon Belkin.)

Table 6.1 Characteristics of *Trichomonas vaginalis*

Shape and size	Pear shaped; 7–23 μm long (avg, 13 μm), 5–15 μm wide
Motility	Jerky, rapid
No. of nuclei and visibility	1; not visible in unstained mounts
No. of flagella (usually difficult to see)	3–5 anterior, 1 posterior
Other features	Seen in urine, urethral discharges, and vaginal smears; undulating membrane extends half the length of the body; no free posterior flagellum; axostyle easily seen
Infective stage	Trophozoite
Usual location	Vagina (male, urethra)
Striking clinical findings	Leukorrhea, pruritus vulva (thin, white urethral discharge in male)
Other sites of infection	Urethra (prostate in male)
Stage usually recovered during clinical phase	Trophozoite only (no cyst)

through glycolysis, undergoes further metabolism in the hydrogenosome. The pyruvate:ferredoxin oxidoreductase has retained diversity in the usage of alternative keto acids for energy production by using a wide variety of substrates. Also, *T. vaginalis* has alternative enzymes that are active in metronidazole-resistant parasites; these alternative pathways are clearly important for the survival of the organism (33). Although *T. vaginalis* is not very energy efficient, it can adapt its metabolism to variable carbon sources. The organism has a high maintenance energy, expending up to half its carbon flow on maintaining internal homeostasis. This ability is critical since the vaginal environment is constantly changing in terms of pH, hormones, menses, and the nutrient supply (33).

Lipid Metabolism. *T. vaginalis* contains cholesterol, phosphatidylethanolamine, phosphatidylcholine, and sphingomyelin as its major phospholipids; apparently the organism is unable to synthesize fatty acids and sterols and must rely on exogenous sources of lipid moieties to survive. It has been postulated that de novo glycolipid and glycoposphosphingolipid synthesis occurs in trichomonads.

Amino Acid Metabolism. Although carbohydrates are the preferred source of nutrients, amino acids can sustain survival and growth. Under normal culture conditions, *T. vaginalis* consumes large amounts of arginine and smaller amounts of methionine for energy production. There appears to be some form of equilibrium that is maintained between the free amino acids within the cell and its external environment.

Nucleotide Metabolism. The organism is unable to synthesize purines and pyrimidines; adenine and guanine or their nucleosides are required for growth, as are thymidine, cytidine, uracil, and/or uridine (33). It also appears that there may be two nucleoside carriers, a characteristic that has also been found in *Leishmania donovani*.

Humans are the only natural host for *T. vaginalis*, and normal body sites for these organisms include the vagina and prostate. Apparently, the organisms feed on the mucosal surface of the vagina, where bacteria and leukocytes are found (35). The preferred pH for good growth in females is slightly alkaline or acidic (pH 6.0 to 6.3 optimal), not the normal pH of the healthy vagina. Although the organisms can be recovered in urine, in urethral discharge, or after prostatic massage, the pH preference of the organisms in the male has not been determined. Often, the organisms are recovered in the centrifuged urine sediment from both male and female patients.

Clinical Disease

T. vaginalis is site specific and usually cannot survive outside the urogenital system. Although the incubation period is not well defined, in vitro studies provide a range of 4 to 28 days. After introduction, proliferation begins, with resulting inflammation and large numbers of trophozoites in the tissues and the secretions. As the infection becomes more chronic, the purulent discharge diminishes, with a decrease in the number of organisms. The onset of symptoms such as vaginal or vulval pruritus and discharge is often sudden and occurs during or after menstruation as a result of the increased vaginal acidity. In acute infections, diffuse vulvitis is seen and is due to copious leukorrhea. The discharge is frothy, yellow or green, and mucopurulent; however, only about 10 to 12% of women exhibit this frothy discharge. Small punctate hemorrhagic spots can be seen on the vaginal and cervical mucosa; this has been called a "strawberry appearance" and is seen in about 2% of patients. In general, symptoms include vaginal discharge (42%), odor (50%), and edema or erythema (22 to 37%) (35). Other complaints include dysuria and lower abdominal pain.

In chronic infections, symptoms may be very mild with pruritus and some pain during sexual intercourse, while the vaginal secretion may be scanty and mixed with mucus. Individuals with these symptoms are the major source of transmission. From 25 to 50% of infected women may be asymptomatic and have a normal vaginal pH of 3.8 to 4.2 and normal vaginal flora. Although there is a carrier form, about 50% of these women will develop clinical symptoms during the following 6 months.

Although vaginitis is the most common finding in women with trichomoniasis, other complications include pyosalpinx (distention of a fallopian tube with pus),

endometritis, infertility, low birth weight, and cervical erosion. There is also an association with increased HIV transmission and cervical dysplasia (35, 36). In a study of Malawian men, there was no difference in the rate of HIV seropositivity in men with and without *T. vaginalis* infection. However, for HIV-positive men with symptomatic urethritis, the median HIV RNA concentration in seminal plasma was significantly higher in patients with trichomoniasis than in those without trichomoniasis (35).

About 20% of women with vaginal trichomoniasis have dysuria, a symptom that may occur before any additional symptoms appear. Infection in the male may be latent, with essentially no symptoms, or may be present as self-limited, persistent, or recurring urethritis. *T. vaginalis* has been detected in 10 to 20% of subjects with nonspecific urethritis and in 20 to 30% of those whose sexual partners had vaginitis. Once established, the infection persists for a long time in females but only for a short time (usually about 10 days or less) in males. *T. vaginalis* is the cause of 11% of all cases of nongonococcal urethritis in males (33).

Respiratory distress was found in a full-term, normal male infant with *T. vaginalis* who had severe respiratory difficulties after delivery. A wet preparation of thick, white sputum showed few leukocytes and motile flagellates, which were identified as *T. vaginalis*. This study supports previous data indicating that this organism may cause neonatal pneumonia (8, 33, 35).

Factors that impact the inflammatory response are not clearly defined but may include hormonal levels, co-existing vaginal flora, and the strain and concentration of the organisms present. Lymphocytes from patients with active trichomoniasis show a proliferative response when incubated in the presence of secretory and cellular products of *T. vaginalis*. This finding indicates that delayed hypersensitivity reactions may act to modify inflammatory responses.

Several mechanisms are used by *T. vaginalis* to maintain the infection in the female urogenital tract. Recognition and binding to vaginal epithelial cells by adhesins that resemble metabolic enzymes is the first step (Table 6.2). Immune responses are evaded by masking the organisms with host proteins, shedding of trichomonad proteins into the secretions, and degradation of all immunoglobulin subclasses and complement (33). Parasites undergo phenotypic variation between surface and cytoplasmic expression of a number of immunogenic proteins against which host antibody is directed. Phenotypic variation occurs in response to iron-regulated proteins, virus-induced and -repressed proteins, erythrocyte binding proteins and hemolysins, proteinases, and adhesins and contributes to the organism's overall antigenic diversity and complexity (40). Subpopulations of trichomonads express high- or low-iron-regulated proteins depending on

Table 6.2 Virulence factors associated with *Trichomonas vaginalis* pathogenesis^a

Capability	Virulence factor(s)
Nutrient acquisition and adherence	Receptors for nutrient acquisition Adhesin that is time, temperature, pH dependent Adhesin proteins, which are receptors to host extracellular matrix proteins Carbohydrates, which provide basis for ligand-receptor binding Presence of cysteine proteinases required Microfilaments concentrated on side of parasite that attaches Laminin may be target for adhesion
Cysteine proteinases	Enzymes that are lytic factors in hemolysis of erythrocytes Required for adherence to epithelial cells
Contact-independent mechanisms	Cell detaching factor (CDF) causes cytopathic effects in cell culture (not seen in nonpathogen <i>Pentatrichomonas hominis</i>) CDF levels correlate with severity of clinical disease
Damage of target cell plasma membrane	Pores created in erythrocyte membranes
Interaction with vaginal flora	Normal vaginal pH 4.5; <i>T. vaginalis</i> thrives in less acidic pH (pH > 5) Rise in pH produces concomitant reduction or loss of protective lactobacilli
Immune system evasion	Surface coating with host proteins Shedding of immunogens Cysteine proteinase degradation of IgG and IgA and complement Epitope phenotypic variation Continuous secretion of large amounts of highly immunogenic soluble antigens short-circuits antibody response
Regulation of virulence genes	General nutrient limitations Environmental factors (iron) Parasite factors (double-stranded RNA virus)

^a Adapted from references 34, 35, and 40.

the iron status of microenvironments within the vagina. Thus, the expression of virulence genes is controlled by both parasite and host environmental factors. Populations of *T. vaginalis* from fresh clinical isolates probably comprise a heterogeneous population, thus guaranteeing that some organisms will be able to infect the host. Based on current knowledge, it appears that interference with trichomonad mucin receptors and proteinases may be a strategy to prevent colonization with this parasite.

Diagnosis

Unfortunately, clinical manifestations are not reliable criteria for the diagnosis of trichomoniasis; demonstration of the parasite is required for accurate diagnosis of infection. It was demonstrated in the early 1980s that if the classic features such as “strawberry cervix” and frothy discharge were used alone in the diagnosis of trichomoniasis, 88% of infected women would not be diagnosed and 29% of uninfected women would be incorrectly diagnosed as having trichomoniasis (33).

Wet Mounts. The identification of *T. vaginalis* is usually based on the examination of wet preparations of vaginal and urethral discharges and prostatic secretions. This examination must be performed within 10 to 20 min of sample collection, or the organisms lose motility and

may be very difficult to see. Several specimens may have to be examined to detect the organisms, and the sensitivity of this technique may vary between 40 and >80%. The specimen should be diluted with a drop of saline and examined under low power with reduced illumination for the presence of actively moving organisms; urine sediment can be examined in the same way. As the jerky motility of the trophozoite diminishes, it may be possible to see the movement of the undulating membrane, particularly under high dry power. Specimens should never be refrigerated.

Since the morphology of nonpathogenic *Pentatrichomonas hominis* from stool samples is very similar to that of pathogenic *T. vaginalis*, it is important to ensure that the specimen is not contaminated with fecal material.

Stained Smears. Diagnostic tests other than wet preparations, such as permanent stains and fluorescent stains, can also be used. Organisms may be difficult to recognize in permanent stains; however, if a dry smear is submitted to the laboratory, Giemsa or Papanicolaou stain can be used. Chronic *Trichomonas* infections may cause atypical cellular changes that can be misinterpreted, particularly on the Papanicolaou smear. The organisms are routinely missed on Gram stains. Unfortunately, *T. vaginalis* does not always appear in its typical pear-shaped forms but instead may resemble polymorphonuclear leukocytes.

The number of false-positive and false-negative results reported on the basis of stained smears strongly suggests that the results should be confirmed by observation of motile organisms either from the direct wet mount or from appropriate culture media (35).

Culture. If culture techniques are used, it is mandatory that the specimen be collected correctly, immediately inoculated into the proper medium, and properly incubated. If these requirements are not met, the findings may represent a false-negative result. Although culture is more sensitive than wet mounts, this approach is not routinely used because of cost and inconvenience. To improve these parameters, a more convenient plastic envelope method has been developed (4) (Figure 6.3). This envelope approach allows both immediate examination and culture in one self-contained system. The system is commercially avail-

Figure 6.3 InPouch TV diagnostic system for culturing *Trichomonas vaginalis*. (A) The swab containing a specimen from the patient is being inserted into the liquid medium within the plastic pouch; (B) the top of the plastic pouch is folded over and sealed with the tabs; (C) the pouch is inserted into the plastic holder; (D) the pouch (in the holder) is placed onto the microscope stage for examination (organism motility). (Photographs courtesy of BIOMED Diagnostics.) See also chapter 32.

able as the InPouch TV (BIOMED Diagnostics, San Jose, Calif.), which serves as the specimen transport container, the growth chamber during incubation, and the “slide” during microscopy. Once it is inoculated, it requires no opening for examination, and positive growth occurs within 5 days. The sensitivity of this system is reported to be superior to that of other available culture methods (4, 33, 35). Also, no detectable differences were seen with the timing of the inoculation of the top or bottom pouch (4). This delayed-inoculation technique allows the initial reading of the wet mount and then inoculation of the culture pouch if the wet mount is negative.

Various studies have been published regarding newer medium formulations and comparisons, including the use of modified Columbia agar (37). Although the results of this study were excellent, the specimens were processed at bedside, an approach that is often not practical for specimen collection. Cell culture methods use a variety of cell lines to recover *T. vaginalis* from clinical specimens, and they include McCoy cells. This has been reported to detect the organism at a concentration as low as 3 organisms/ml (33). However, this approach is not as practical as other available culture options and is rarely used in the routine clinical laboratory setting. Similarities in the results of these various diagnostic methods, particularly culture methods, have to be reviewed within the context of delivery systems and compliance with the proper use of transport options.

Antigen Detection. Screening patients for the presence of *T. vaginalis* has been somewhat limited by the available tests, many of which tend to be insensitive or expensive or require delays before the result is reported. A rapid diagnostic test for *T. vaginalis* infection has been developed and has proven to be much more sensitive than the wet-mount examination (Table 6.3). When compared with culture (InPouch), the XenoStrip-Tv (Xenotope Diagnostics, Inc., San Antonio, Tex.) was 76.7% sensitive and 99.8% specific and 79.4% sensitive and 97.1% specific in two different studies (24). Rapid test performance did vary with the day of the culture-positive result, with a 71% decline in XenoStrip sensitivity for every additional day of delay until cultures were positive. This product is easy to use, is more sensitive than the wet mount, and should be considered as an alternative to the wet mount, particularly for point-of-care diagnosis when microscopy may be impractical (34).

Another rapid detection system for *T. vaginalis* uses an immunochromatographic capillary-flow (dipstick) assay, which provides results in 10 min. Compared with wet mount and culture, this system, OSOM *Trichomonas* Rapid Test (Genzyme Diagnostics, Cambridge, Mass.), showed 83.3% sensitivity and 98.8% specificity, while the wet mount has a sensitivity of 71.4% and a specificity of 100% (Figure 6.4). This test also detected *T. vaginalis* in

^b DFA, direct fluorescent antibody.

samples that required 48 to 72 h of incubation before becoming culture positive (17). Compared to culture alone, OSOM was 83.5% sensitive and 99.0% specific.

Antibody Detection. Various techniques have been used to demonstrate antibodies against *T. vaginalis*; they include agglutination, complement fixation, indirect hemagglutination, gel diffusion, fluorescent-antibody assay, and enzyme-linked immunosorbent assay (ELISA). However, there are a number of reasons why this approach has not been used routinely. In some cases, an antibody response is not seen, due to test sensitivity or the timing of the test procedure. Also, antitrichomonal

Figure 6.4 *Trichomonas vaginalis*, direct antigen detection strip used for rapid testing (OSOM Trichomonas Rapid Test). (Courtesy of Genzyme Diagnostics, Cambridge, Mass.)

antibodies persist for long periods after therapy, and so current and past infections cannot be differentiated.

Recombinant-DNA Techniques. The use of PCR methods has led to improvements in *T. vaginalis* detection; nonviable organisms and cells and target sequences can also be detected. In addition to various culture and transport options, there are currently several other products available, including the Affirm VPIII probe (Becton Dickinson, Cockeysville, Md.), the Quik-Tri/Can latex agglutination test (PanBio Integrated Diagnostics, Baltimore, Md.), and the T.VAG DFA (Light Diagnostics, Temecula, Calif.). The Affirm VP system uses synthetic oligonucleotide probes for the detection of both *Gardnerella vaginalis* and *T. vaginalis* from a single vaginal swab (33). A PCR-based ELISA with urine as the clinical specimen gave sensitivity and specificity data (compared with wet mount or culture) as 90.8 and 93.4%, respectively, in women and 92.7 and 88.6%, respectively, in men (21, 22). For clinical settings in which vaginal specimens are not available and culture is not an option, urine-based PCR-ELISA may be another option. In some settings, self-obtained vaginal swabs may be useful for PCR, and it appears that PCR may be more sensitive than culture for the diagnosis of *T. vaginalis* in males (35). Based on your patient population, client base, number of requests, and cost, these tests may be relevant for your laboratory test menu.

KEY POINTS—LABORATORY DIAGNOSIS

Trichomonas vaginalis

1. Wet-preparation (motile organisms) examination is recommended; the specimen should be examined immediately. If this is not possible, other methods should be considered.

2. Fluorescent stains and culture have also been recommended.
3. The newer rapid methods may not be as sensitive as culture or PCR, but organisms can be detected, often 48 to 72 h prior to cultures becoming positive for *T. vaginalis*.
4. If dry smears are submitted to the laboratory, they can be fixed with absolute methanol, allowed to dry, and stained like a thin blood smear (Giemsa stain).
5. Serologic tests are not routinely available.

Treatment

Metronidazole is recommended for the treatment of urogenital trichomoniasis, although resistance to both metronidazole and other 5-nitroimidazoles has been reported (1). It is also recommended that all sexual partners of the patient be treated simultaneously to avoid immediate reinfection. Metronidazole-resistant *T. vaginalis* has been implicated in an increased number of cases; unfortunately, metronidazole is currently the only drug approved for the treatment of trichomoniasis in the United States (8). Although vaginal metronidazole creams and pessaries are available, their cure rate compared with oral drug administration is poor. Metronidazole can be taken as a single or multiple doses, as well as being administered intravenously. Additional information on therapy can be found in chapter 25.

A recent review reported that metronidazole reduced the risk of persistent infection in women with *T. vaginalis* infection but increased the incidence of preterm birth (31). Neonatal infection depends on maternal estrogen levels, which wane after the third to sixth week of life; after this time, the infection may disappear. However, if required, treatment of neonates should be postponed until the sixth to eighth week of age and then given if the infant is symptomatic (33).

Although the cure rate is excellent, treatment failure can be due to several factors including noncompliance and reinfection. Published case reports of *T. vaginalis* strains that are clinically resistant to metronidazole are increasing; in the late 1990s, it was estimated that approximately 5 to 10% of all patient isolates demonstrated some level of resistance to metronidazole (13). Resistance can be linked to progressive decrease and eventual loss of the pyruvate:ferredoxin oxidoreductase, so that the drug-activating process is averted. The development of resistance in *T. vaginalis* is also accompanied by decreased expression of ferredoxin (8). Refractory cases are defined as cases in which two standard courses of therapy fail to cure the patient, and these cases can be very difficult to treat. Refractory cases are treated with higher (often double) doses of metronidazole for an extended period; this is effective approximately 80% of

the time. Treatment protocols are now available for marginal, low, moderate, and high levels of metronidazole resistance. Therefore, the need for metronidazole susceptibility testing has become more important for clinically relevant patient care. Different methods are used as pharmacological screening procedures for new drugs, including simple cell enumeration. However, this approach is highly subjective. Another approach, which involves determination of acid phosphatase activity as the screening procedure, has been recommended. Compared with microscopy procedures, there are some clear advantages to these newer colorimetric methods, including greater speed and efficiency and less subjectivity (28). Other metabolic routes of *T. vaginalis* have also been used to develop susceptibility testing methods for determining antitrichomonal activity (28).

Tinidazole, a 5-nitroimidazole, is currently being used outside of the United States; this drug is delivered more effectively to vaginal secretions at levels found in serum. However, potential cross-resistance among nitroimidazoles is a concern (8, 33). Other potential drugs include niridazole, nitazoxanide, sulfimidazole, nifuratel, berberine sulfate, furazolidone, mebendazole, butoconazole, benzoisothiazolinon, and gynalgin, most of which have shown some promise, but research is in the preliminary stages (8, 33).

Epidemiology and Prevention

Trichomoniasis has been found in every continent and climate, with no season variability. It has a cosmopolitan distribution within all racial groups and throughout all socioeconomic levels. The annual incidence of trichomoniasis is estimated to be more than 170 million cases worldwide. The incidence can exceed 50% in patients attending sexually transmitted disease clinics and depends on age, sexual activity, number of sexual partners, other sexually transmitted diseases, sexual customs, phase of the menstrual cycle, and sensitivity of patient examination and specimen collection and testing.

Humans are the only natural host for *T. vaginalis*. Risk factors for trichomoniasis have also been investigated. The associations between HIV and trichomoniasis may relate to increased shedding of HIV due to local inflammation produced by *T. vaginalis*, increased susceptibility to HIV as a result of breaks in the mucosal barriers, a higher prevalence of sexually transmitted diseases in HIV-infected individuals, and/or an increased susceptibility to HIV due to immunosuppression. Transmission of HIV is enhanced by coinfection with *T. vaginalis*, and treatment of trichomoniasis reduces the levels of HIV RNA (35).

A symbiotic relationship between *T. vaginalis* and *Mycoplasma hominis* has been documented; such a symbiosis may indicate a potential role of *T. vaginalis* in the transmission of bacterial infection (9). These findings

suggest that this relationship between the two organisms may provide the bacteria with the ability to resist the host defense mechanisms and therapy.

Infection is acquired primarily through sexual intercourse, hence the need to diagnose and treat asymptomatic males. The organism can survive for some time in a moist environment such as damp towels and underclothes; however, this mode of transmission is thought to be very rare. Evidence implicating *T. vaginalis* as a potential contributor to poor outcomes in both women and men continues to accumulate. In women, this infection may play a role in the development of cervical neoplasia, postoperative infections, and potential problems with pregnancy. It is also seen as a factor in atypical pelvic inflammatory disease and infertility. In men, trichomoniasis causes nongonococcal urethritis and contributes to male infertility. The importance of this infection needs to be recognized beyond the limits of the sexually transmitted disease clinics (36).

Vaccines. As with many sexually transmitted diseases, infection with *T. vaginalis* does not produce long-term immunity. Although the antibody response to this organism is well documented, the antibodies provide only limited protection, and antibody titers disappear after therapy. Vaccine development has shown some promise; potential targets include a 100-kDa protein that is immunogenic across a number of *T. vaginalis* isolates, as well as essential adherence molecules such as adhesins, mucinases, and cysteine proteinases (8). Although several vaccine trials were held during the 1960s and the late 1970s, subsequent studies led to doubts about the efficacy of the vaccines. Later studies using a murine model have shown promise, and a bovine *Tritrichomonas foetus* model in cattle has also yielded promising results. A whole-cell *T. foetus* vaccine is now commercially available for cattle and provides protection, as well as accelerating the eradication of infection.

Toxoplasma gondii

Toxoplasma gondii is worldwide in distribution, is closely related to other coccidia, and also has certain similarities to malarial parasites. The parasites were first discovered in 1908, by Charles Nicolle and Louis Manceaux at the Pasteur Institute, in the North African rodent called the gundi, hence the species name *gondii*. At the same time, Alfonso Splendore described the organism from laboratory rabbits at the Portuguese Hospital in São Paulo, Brazil. However, the complete life cycle was not determined until 1970 (5). Although serologic evidence indicates a high rate of human exposure to the organism, the disease itself is relatively rare. *T. gondii* can infect many vertebrates as

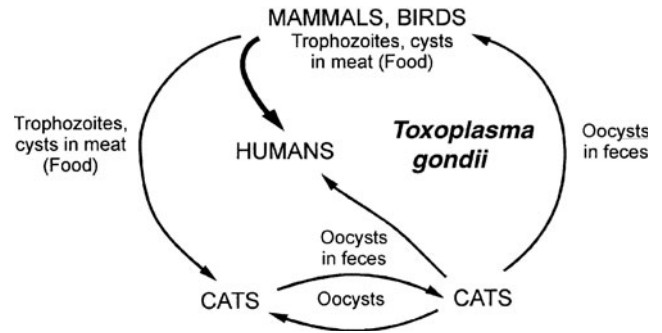

Figure 6.5 Life cycle of *Toxoplasma gondii*. The active forms (trophozoites) are also referred to as tachyzoites, while the resting stages within the cysts are called bradyzoites (very slow-growing trophozoites).

well as humans, but the definitive host is the house cat and other members of the Felidae family.

Life Cycle and Morphology

The life cycle is shown in Figure 6.5. Humans can acquire the infection in several ways, either by the accidental ingestion of oocysts shed in cat feces or by the ingestion of rare or raw meats, particularly pork, lamb, or venison. Transmission can also occur in utero, by transfusion, and during organ transplantation. Toxoplasmosis should be considered as a possible cause of multiorgan failure after liver transplantation. The inclusion of serologic testing should be considered in routine donor testing. The most common means of infection is probably through ingestion of rare or raw meats. The oocysts shed in cat feces are 9 to 11 μm wide by 11 to 14 μm long and contain two sporocysts, each containing four sporozoites (Figure 6.6). Cats shed oocysts after ingestion of any of the three infectious stages of *T. gondii*: tachyzoites in groups, bradyzoites in tissue cysts, and sporozoites in oocysts (11). Cats become infected from eating birds, small rodents, or other sources of raw meat. In the tachyzoite-induced life cycle of *T. gondii* in cats, the animals can shed up to 360 million oocysts per day and will shed for 4 to 6 days (11).

There are three infectious stages of *T. gondii*: the tachyzoites (in groups or clones), the bradyzoites (in tissue cysts), and the sporozoites (in oocysts). Tachyzoites rapidly multiply in any cell of the intermediate host (many other animals and humans) and in nonintestinal epithelial cells of the definitive host (cats). Bradyzoites are found within the tissue cysts and multiply very slowly; the cyst may contain few to hundreds of organisms, and intramuscular cysts may reach 100 μm in size. Although the tissue cysts may develop in visceral organs such as the lungs, liver, and kidneys, they are more prevalent in neural and muscular tissues, including the brain, eyes, and skeletal and cardiac

Figure 6.6 *Toxoplasma gondii* in the intestine of a cat. (A) Bradyzoites ($\times 1,000$); (B) gametocytes ($\times 1,000$); (C) oocyst containing two sporocysts with sporozoites ($\times 1,600$). (Courtesy of J. K. Frenkel, University of Kansas School of Medicine, Kansas City.)

muscle. Intact tissue cysts can persist for the life of the host and do not cause an inflammatory response (5).

The organisms are obligate intracellular parasites and are found in two forms in humans. The actively proliferating trophozoites or tachyzoites are usually seen in the early, more acute phases of the infection. The resting forms or cysts are found primarily in muscle and brain, probably as a result of the host immune response. The cysts contain the more slowly growing trophozoites or bradyzoites. Bradyzoites encyst approximately 8 to 10 days after entry into the host and differ from tachyzoites in being more resistant to pepsin, having a longer generation time, containing cytoplasmic vacuoles which may serve as carbohydrate stores, and being the only stage to initiate the enteroepithelial cycle and transform into oocysts in the feline intestine.

The trophozoites (tachyzoites) are crescent shaped and are 2 to 3 μm wide by 4 to 8 μm long (Figures 6.7 and 6.8). One end tends to be more rounded than the other.

Figure 6.7 Forms of *Toxoplasma gondii* found in humans. (A) Trophozoites (tachyzoites) seen within a cell; (B) cyst containing the bradyzoites (illustration by Sharon Belkin; based on illustration from H. H. Najarian, *Textbook of Medical Parasitology*, The Williams & Wilkins Co., Baltimore, Md., 1967); (C) tachyzoites recovered from mouse peritoneal fluid.

Figure 6.8 Forms of *Toxoplasma gondii* found in humans. (Upper) Tachyzoites seen within bone marrow. (Lower) Bradyzoites seen in human tissue.

Giemsa is the stain of choice; the cytoplasm stains pale blue and the nucleus stains red and is situated toward the broad end of the organism.

The cysts are formed in chronic infections, and the organisms within the cyst wall are strongly periodic acid-Schiff positive (Figure 6.7). During the acute phase, there may be groups of tachyzoites that appear to be cysts; however, they are not strongly periodic acid-Schiff positive and have been termed pseudocysts.

The cycle occurring in cats includes asexual multiplication and sexual reproduction in the small intestinal epithelial cells (5, 11). The final stage of the reproductive cycle is the oocyst, which is passed in the feces. After defecation, development of infective sporozoites inside the oocysts requires 1 to 5 days and depends on environmental conditions. The developmental cycle in the cat takes approximately 19 to 48 days after infection with the oocysts but only 3 to 10 days after the ingestion of meat infected with cysts, e.g., a mouse.

The number of cats in the United States is estimated at around 70 million, with the number of feral cats probably

being greater than that of domestic cats. Of the cats examined within the United States, <1% had *T. gondii* oocysts in their feces. However, this may be because the period of shedding is usually only 1 to 2 weeks during the life of the cat and the oocysts are quite small, measuring approximately 10 μm . Consequently, the use of routine fecal examinations to determine whether cats are positive for *T. gondii* is somewhat limited and is not particularly helpful in determining whether the animal is shedding oocysts.

Clinical Disease

When the tachyzoites are actively proliferating, they invade cells adjacent to the original infected cell as it ruptures. This process creates continually expanding focal lesions. Once the cysts are formed, the process becomes quiescent, with little or no multiplication and spread. In the immunocompromised or immunodeficient patient, a cyst rupture or primary exposure to the organisms often leads to lesions. The organisms can be disseminated via the lymphatics and the bloodstream to other tissues. Disintegration of cysts may give rise to clinical encephalitis in the presence of apparently adequate immunity.

The large number of people who are serologically positive for *T. gondii* suggests that the majority of infections are benign, with most people exhibiting few (e.g., cold or light case of the flu) or no symptoms. The most severe symptoms are seen with congenital, transplacental infections or infections in compromised patients (Table 6.4). Toxoplasmosis can be categorized into four groups: (i) disease acquired in immunocompetent patients, (ii) disease acquired or reactivated in immunosuppressed or immunodeficient patients, (iii) congenital disease, and (iv) ocular disease.

Acquired Infections in Immunocompetent Individuals.

In approximately 90% of cases, no clinical symptoms are seen during the acute infection. However, 10 to 20% of patients with acute infection may develop painless cervical lymphadenopathy. This presentation is benign and self-limited, with symptoms resolving within weeks to months. Acute visceral manifestations are seen in rare cases. In one study from French Guiana over a period of 6.5 years, 13

Table 6.4 People at risk for severe toxoplasmosis

Persons with severely weakened immune systems	Infection that occurred at any time during life can reactivate

of 16 patients had consumed game in the 2 weeks prior to the onset of symptoms and in 8 cases the game was undercooked (7). Although other cases have been reported during the last decade, very few were reported in detail. In reviewing the possible link between *T. gondii* and schizophrenia, it appears that some cases of acute toxoplasmosis in adults are associated with psychiatric symptoms such as delusions and hallucinations (39).

Infections in Immunocompromised Patients. Infections in immunocompromised patients can lead to severe complications; underlying conditions that may influence the course of the disease include various malignancies (such as Hodgkin's disease, non-Hodgkin's lymphomas, leukemias, and solid tumors), collagen vascular disease, organ transplantation, and AIDS. In immunocompromised patients, the central nervous system (CNS) is primarily involved, with diffuse encephalopathy, meningoencephalitis, or cerebral mass lesions. More than 50% of these patients show an altered mental state, motor impairment, seizures, abnormal reflexes, and other neurologic sequelae. Studies show that even in these groups, most patients receiving chemotherapy for toxoplasmosis will improve significantly or have complete remission. However, in those with AIDS, therapy must be continued for long periods to maintain a clinical response.

In genotyping studies, it appears that the type of *T. gondii* strain does not predominantly influence the pathogenesis of toxoplasmosis in immunocompromised patients. Thus, regardless of the strain genotype, there remains the need for specific prophylaxis in these patients infected by *T. gondii* (16).

Transplant recipients. In transplant recipients, disease severity depends on previous exposure to *T. gondii* by the donor and recipient, the type of organ transplanted, and the level of immunosuppression of the patient. Disease can be due to reactivation of a latent infection or an acute primary infection acquired directly from the transplanted organ (43). Stem cell transplant recipients are particularly susceptible to severe toxoplasmosis, primarily due to reactivation of a previously acquired latent infection. If stem cell transplant recipients have a positive serologic test prior to transplantation, they are known to be at risk for severe disseminated toxoplasmosis (29). All potential transplant recipients should be tested for *Toxoplasma*-specific immunoglobulin G (IgG) antibodies to determine their antibody status. An individual with acute acquired infection often produces detectable IgG and IgM antibodies, while those with reactivation may or may not have an increase in the levels of IgG antibodies and normally do not demonstrate an IgM response. Seronegative cardiac transplant recipients who receive an organ from a sero-

positive donor may develop toxoplasmic myocarditis; this disease presentation may also mimic organ rejection.

AIDS patients. Patients who become infected with *T. gondii* risk developing disease when their CD4⁺ T-lymphocyte count falls below 100,000/ml. Fever and malaise usually precede the first neurologic symptoms; headache, confusion, seizures, or other focal signs strongly suggest the diagnosis of toxoplasmosis.

Toxoplasma encephalitis (TE) was reported as a life-threatening opportunistic infection among patients with AIDS prior to the use of highly active antiretroviral therapies. This condition is fatal if untreated. Most AIDS patients with TE have detectable IgG antibodies to *T. gondii*; however, <5% may not have antibody in their serum. Psychiatric manifestations of *T. gondii* are also seen in immunocompromised individuals with AIDS in whom latent infections have become reactivated. Altered mental status occurs in approximately 60% of patients, with symptoms including delusions, auditory hallucinations, and thought disorders (39).

Disseminated toxoplasmosis should be considered in the differential diagnosis of immunocompromised patients with culture-negative sepsis, particularly if combined with neurologic, respiratory, or unexplained skin lesions. Examination of Wright's-stained peripheral blood smears or antitoxoplasma immunoperoxidase studies of skin biopsy specimens may be diagnostic (5).

In histologically confirmed cases of TE when the majority of the patients received some therapy, the overall prognosis has been poor, with the median survival following initiation of therapy being 4 months. No beneficial or harmful effects could be attributed to the use of corticosteroids, and toxicity attributed to pyrimethamine-sulfonamide therapy was reported for many patients. A clinical relapse of TE has been seen in approximately half of the patients discharged from the hospital.

Although an inflammatory process is observed during TE in HIV-positive patients, the major cause of CNS lesions is probably uncontrolled parasite multiplication rather than immunopathologic changes. Also, *T. gondii* is capable of enhancing HIV-1 replication within reservoir host cells and, simultaneously, HIV-1 itself undermines acquired immunity to the parasite, promoting reactivation of chronic toxoplasmosis.

Respiratory disease due to *T. gondii* has also been recognized in immunocompromised patients, and the few cases that have been found in HIV-positive patients have been in association with CNS disease. The finding of pulmonary toxoplasmosis in the absence of neurologic findings in HIV-positive patients emphasizes the importance of considering this organism as the cause of pulmonary disease in such patients with respiratory symptoms.

Congenital Infections. Congenital infections result from the transfer of parasites from the mother to the fetus when she acquires a primary infection during pregnancy. In 90% of patients, no clinical symptoms are apparent during acute infection. Congenital infections may be particularly severe if the mother acquires the infection during the first or second trimester of pregnancy. At birth or soon thereafter, symptoms in these infants may include retinochoroiditis, cerebral calcification, and occasionally hydrocephalus or microcephaly. Symptoms of congenital CNS involvement may not appear until several years later.

The risk of congenital toxoplasmosis depends on the timing of the mother's acute infection. Transmission to the fetus increases with gestation age: 15 to 25% in the first trimester, 30 to 45% in the second, and 60 to 65% in the third. However, the severity of congenital disease decreases with gestation age. Signs of infection at delivery are present in 21 to 28% of those infected in the second trimester and in $\leq 11\%$ of those infected in the third trimester. Overall, 10% are born with severe disease. Congenital transmission can occur even if the mother is immune, although this is rare; reinfection of the mother during pregnancy is possible, particularly if she comes in contact with large numbers of infective cysts and/or oocysts.

The characteristic symptoms of hydrocephalus, cerebral calcifications, and chorioretinitis resulting in mental retardation, epilepsy, and impaired vision represent the most severe form of the disease. Cerebral lesions may calcify, providing retrospective signs of congenital infection.

In the case of seroconversion by the mother during pregnancy, prenatal diagnosis is usually performed by analysis of amniotic fluid. However, it is important to remember that despite the use of advanced diagnostic methods, some cases of congenital toxoplasmosis cannot be detected early. This demonstrates the importance of careful follow-up of newborns who are at risk. Treatment of the mother may reduce the incidence of congenital infection; therefore, rapid and accurate diagnosis should be emphasized.

Ocular Infections. Chorioretinitis in immunocompetent patients is generally due to an earlier congenital infection. Patients may be asymptomatic until the second or third decade; at that point, cysts may rupture, with lesions then developing in the eye. The number of people who develop chorioretinitis later in life is unknown but may represent over two-thirds of the total. Also, up to 30% of patients relapse after treatment. Chorioretinitis is usually bilateral in patients with congenitally acquired infection and is generally unilateral in patients with recently acquired infection.

Diagnosis

Diagnosis is usually made by various serologic procedures. Other procedures include performing PCR, examining biopsy specimens, buffy coat cells, or cerebrospinal fluid, and isolating the organism in tissue culture or in laboratory animals (Tables 6.5 and 6.6). It is difficult to demonstrate the parasite in lymph node biopsy specimens, and while some authorities think the histologic appearance is very characteristic, others consider the histologic changes to be nonspecific. However, because many individuals have been exposed to *T. gondii* and may have cysts within the tissues, recovery of organisms from tissue culture or animal inoculation may be misleading, since the organisms may be isolated but may not be the etiologic agent of disease. For this reason, serologic tests are often recommended as the diagnostic approach of choice. However, two representative situations in which the detection of organisms may be very significant are (i) tachyzoite-positive smears and/or tissue cultures inoculated from cerebrospinal fluid and (ii) in patients with acute pulmonary disease, the demonstration of tachyzoites in Giemsa-stained smears of bronchoalveolar lavage fluid, with some tachyzoites being extracellular and some being intracellular.

Emphasis on pediatric patients, particularly neonates, is seen in the extensive literature on serologic testing. An algorithm for the diagnosis and treatment of neonatal toxoplasmosis is seen in Figure 6.9; a summary of risk management issues in pregnancy can be seen in Figure 6.10. An understanding of the difficulties in test interpretation is helpful. First, all newborns from mothers who are antibody positive will have passively transferred maternal IgG. These titers can be quite high but may not indicate infection in the baby. The detection of IgM antibodies, which do not cross the placental barrier, provides a much more accurate indication of infection in the newborn. There can still be situations in which a false-negative (IgG saturation of antigen receptors) or false-positive (presence of rheumatoid factor and antinuclear antibody) result is possible. There is evidence to indicate that in certain instances, the presence of IgM antibody titers in single serum specimens cannot be used to indicate recent exposure (14, 43). Interpretation of serologic tests for IgM can be seen in Figure 6.11.

The Sabin-Feldman dye test, one of the first methods used to diagnose toxoplasmosis, is based on the fact that in the presence of immune serum, *T. gondii* loses its affinity for methylene blue stain. Because this test uses live *Toxoplasma* trophozoites, however, most laboratories do not provide it routinely. A specific guide to the interpretation of serologic titers for toxoplasmosis is provided in Table 6.7.

The serologic diagnosis of toxoplasmosis is very complex and has been discussed extensively in the literature; a number of additional procedures, some of which are

Table 6.5 Clinical use of immunodiagnostic tests^a

Questions to answer	Tests to use	Interpretation	Comments
Is the patient currently infected?	IgG assays	If IgG positive = infected If IgG negative, retest in 3 weeks if acute infection suspected	A single specimen is satisfactory to determine antibody status Situations where baseline information is helpful: (i) women of childbearing age tested prior to conception (ii) before initiation of immunosuppressive therapy (iii) after determination of HIV-1-positive status (iv) organ donors prior to transplantation
Has the patient recently acquired the infection?	IgM and IgA assays	If IgG positive and IgM negative = infected for more than 6 months If IgG positive and IgM positive = infection within last 2 years, or false-positive IgM result	Specimens drawn 2 wk apart may or may not be helpful; often an increase in IgG or IgM titer is not possible; titers may already have reached a plateau when first sample is drawn
How recently was the infection acquired by the patient?	IgG avidity, differential agglutination	If IgG avidity high = infected at least 12 wk earlier If IgG avidity low = recent infection possible; some people have persistent low IgG avidity for months after infection	If IgG avidity low, draw second sample 3 weeks after first sample; send both specimens to <i>Toxoplasma</i> reference laboratory for confirmation of IgG, IgM, and IgG avidity results and possibly differential agglutination, IgA, and IgE testing
Is evidence of active infection present?	PCR, culture, antigen detection	<i>Toxoplasma</i> isolated from 95% of placentas of congenitally infected newborns when mother has not been treated and from approximately 81% when the mother has received therapy	Attempts should be made to isolate <i>T. gondii</i> from the placenta, amniotic fluid, and cord blood to confirm the diagnosis

^a Adapted from references 10 and 43.

automated, have been developed and reported in the last few years (32). These methods include enzyme immunoassays, some of which are automated (20), ELISAs (14, 30, 42, 43), direct agglutination (43), an immunosorbent agglutination assay (43), an indirect-immunofluorescence assay, immunocapture (43), and immunoblotting (15). Evaluations of various commercial assays have also been discussed (Table 6.7) (43).

A great deal of molecular biology-based work involving PCR for the diagnosis of toxoplasmosis and strain typing has also been done (2, 15, 19, 29, 38, 41, 43). This technology may be useful in situations where knowledge of recent infection is necessary. PCR has also been used to detect *T. gondii* in deparaffinized ocular tissue sections, cerebrospinal fluid, blood, and bronchoalveolar fluid; however, the absence of *Toxoplasma* DNA does not exclude toxoplasmosis. PCR can be very helpful in evaluating fetal infection; certainly the time needed to detect parasites is much shorter than when using mouse or tissue culture approaches. Sensitivity depends on the clinical presentation; it is higher when confirming congenital toxoplasmosis from amniotic fluid but lower in patients with infection reactivation such as HIV-positive patients.

Antigen detection has improved during the last few years; however, this approach still appears to lack sensitivity when used with human samples. Antigen detection may be helpful in diagnosing the compromised patient in whom antibody titers are low or absent. This serologic approach can also clarify low titers, i.e., those found in early acute infection or chronic infection. This test capability can also be very helpful in patients with monoclonal gammopathies, whose titers to *T. gondii* may be extremely high but may not be causing the clinical condition. See Algorithm 6.1.

KEY POINTS—LABORATORY DIAGNOSIS

Toxoplasma gondii

1. Serologic results are normally used to diagnose toxoplasmosis. Results of all other procedures must be interpreted in light of the serologic findings.
2. *T. gondii* identified in histologic preparations or isolated in animals or in tissue culture systems may or may not be the causative agent of the symptoms (many individuals harbor the organisms in their tissues but have no symptoms).

Table 6.6 General comments on the performance and interpretation of serologic results for the diagnosis of toxoplasmosis^a

1. Specific IgM normally develops early, within 1–2 wk after primary infection.
2. Specific IgG normally develops within 4 wk after primary infection.
3. Production and increase in titers usually peak within 4–8 wk, but in individual cases the increase in IgM may continue for some weeks and IgG for several months.
4. The antibody result from a single serum sample gives no clear indication of when the infection occurred.
5. A rise in titer (IgG) should be demonstrated between 2 or more samples tested in the same test run; a 4-tube antibody increase is required to support the diagnosis of acute febrile toxoplasmosis. If serum is taken during late infection or for the presence of lymphadenopathy, titers in excess of 1:1,000 should be present.
6. The presence of IgM does *not* confirm a very recent infection; a positive IgM result has low predictive value for identifying primary *T. gondii* infection.
7. The amount of specific IgM may decrease to below the detection level in less than 3 mo after infection; however, IgM may be detectable for many months after the primary infection (can be detected as long as a year or more after primary infection). IgM antibody can persist for 6 mo in the conventional test but as long as 6 yr in the capture test.
8. IgG avidity gradually increases after primary infection. Low or equivocal avidity results can persist for months to >1 yr after primary infection. High-avidity test results seen in individuals infected for at least 3 to 5 mo.
9. For congenital infections, an IgG titer of >1:1,000 indicates a tentative diagnosis, pending confirmation of a positive IgM test, the exclusion of rheumatoid factor and antinuclear antibody, and the isolation of *Toxoplasma*, if possible. Passively transferred antibody shows a 10-fold decay every 3 mo; during infection, high antibody titers are stable or will increase.
10. Specific IgA results are not particularly helpful. A negative result does not exclude, nor does a positive result confirm, a recent primary infection.
11. Termination of pregnancy may be offered to women who seroconvert in the first 8 wk of pregnancy and to those infected in the first 22 wk of pregnancy when fetal infection is confirmed. A more conservative approach is based on abortion only if there is ultrasonographic evidence of hydrocephalus.
12. In the context of recurrent pregnancy loss, intravenous immunoglobulin therapy can cause confusion in the interpretation of serologic results for the diagnosis of toxoplasmosis; the appearance of anti-*Toxoplasma* antibodies may lead to the conclusion that seroconversion has occurred. Also, if positive serologic results are seen, the woman may be incorrectly considered immune.

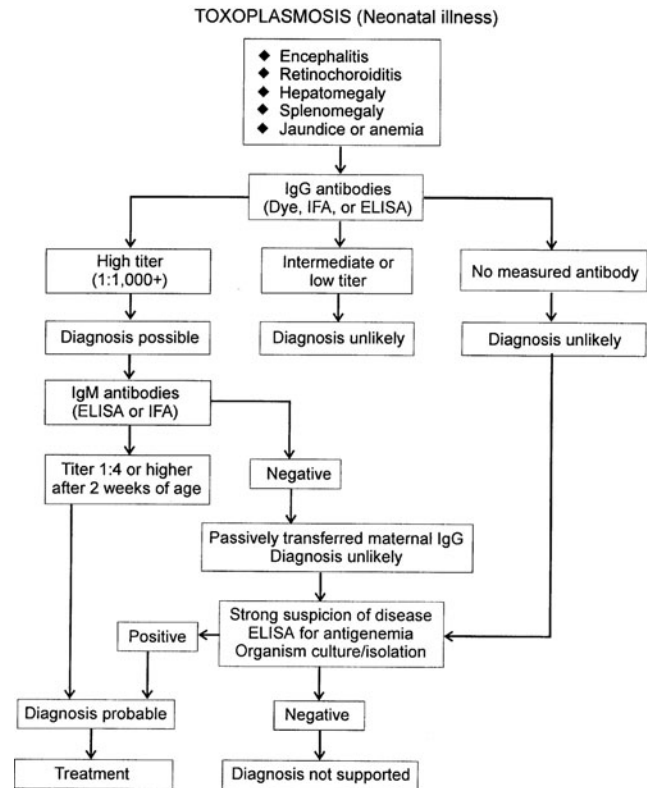

Figure 6.9 Chart for the diagnosis and treatment of neonatal toxoplasmosis. (Adapted from reference 14.)

Treatment

It is generally recommended that the following conditions be treated: clinically active disease, diagnosed congenital toxoplasmosis, and disease in symptomatic compromised patients. Therapy for pregnant patients who acquire the infection and for newborns with *Toxoplasma* antibody is somewhat controversial. However, prophylactic therapy is often recommended for the newborn until it can be demonstrated that IgM antibody is not present. Spiramycin has been used to treat women infected in pregnancy, since it is potentially less toxic for the fetus. Apparently this drug is concentrated in the placenta but does not cross the barrier freely, and drug levels in the neonate are low. Spiramycin has also been used to treat congenitally infected infants every other month, alternating with sulfadiazine-pyrimethamine treatment.

Drugs that have been found to be effective, either alone or in combination, include sulfonamides and pyrimethamine (actively multiplying tachyzoites). Clindamycin and spiramycin have also been used in certain circumstances.

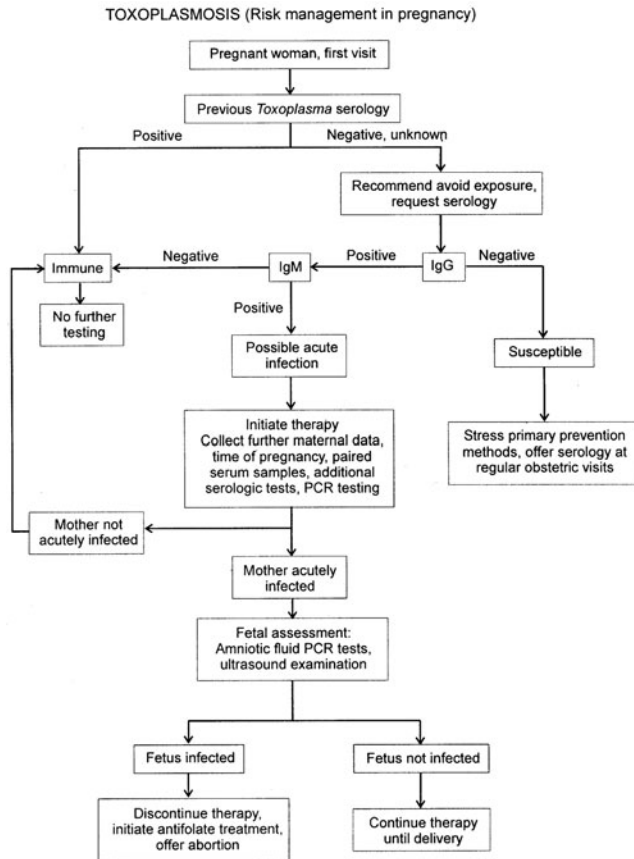

Figure 6.10 Toxoplasmosis: risk management in pregnancy.

Although a combination of pyrimethamine and a sulfonamide is the standard regimen for treating TE in AIDS patients, the use of these drugs can be contraindicated in patients with a history of bone marrow suppression and severe allergic reactions to sulfonamides. It is also important to realize the potential danger of using high doses of sulfadiazine, which may lead to the development of sulfadiazine-induced crystalluria; to prevent crystalluria, patients should be adequately hydrated and their urinary pH should be maintained above 7.5. The use of oral clindamycin and pyrimethamine is effective (1). Another combination regimen includes pyrimethamine-clarithromycin, which is comparable to the conventional therapeutic approach to acute TE in AIDS patients. Recent data also suggest that a combination of trimethoprim and sulfamethoxazole (TMP-SMX, co-trimoxazole) may be as effective as pyrimethamine-sulfadiazine in AIDS patients with TE. It is interesting that treatment of cerebral toxoplasmosis protects against *Pneumocystis* pneumonia in AIDS patients; the decreased risk is probably due to chronic suppressive treatment with pyrimethamine and sulfonamides.

Approximately 10 to 50% of patients who are seropositive for antibodies to *T. gondii* have CD4⁺ T-lymphocyte counts of <100/mm³. Detection of IgG antibodies indicates prior infection and possible presence of tissue cysts. Since TE may result from reactivation of tissue cysts, prophylaxis with TMP-SMX or dapsone plus pyrimethamine with leucovorin is recommended for these patients. HIV-infected persons who are seronegative for *Toxoplasma* IgG should be counseled to protect themselves from primary infection by eating well-cooked meats and washing their hands after possible soil contact. Cats kept as pets should be fed commercial or well-cooked food, should be kept indoors, and should have their litter box changed each day. An algorithm for prevention of TE can be seen in Figure 6.12. TE continues to occur among patients not receiving prophylaxis. It is estimated that at least half of the cases could be prevented by better motivation of physicians and increased compliance by patients.

The management of ocular toxoplasmosis depends on the severity of the clinical presentation. Most specialists treat patients whose visual acuity has progressed to worse than 20/200, who have lesions in the peripapillary, perifoveal, or maculopapillary bundle regions, or who have severe vitreous inflammation. However, most do not treat patients whose visual acuity is 20/20, who have lesions in the far peripheral retina, or who have trace to mild vitreous inflammation. Various therapeutic regimens are used; however, almost all specialists, when asked, indicated that they used corticosteroids in the initial treatment regimen. In general, most indicated that they would modify treatment during pregnancy, in newborns, and in AIDS patients. Additional information can be found in chapter 25.

Epidemiology and Prevention

Human infection can be acquired through ingestion or handling of infected meat or through ingestion of infective oocysts, which can remain viable within cool, moist soil for a year or longer (Table 6.8). Certainly, hand washing is highly recommended when there has been potential exposure to the oocysts. It is recommended that meat be cooked so that the internal temperature reaches 150°F (66°C). The question of the house cat always arises; indoor cats fed on dry, canned, or boiled food are unlikely to be infected. However, cats that go outside and have access to other infected animals (birds or mice) may shed oocysts in their feces; therefore, other preventive measures, including changing the litter box daily and disinfecting the pan with boiling water, have been recommended. Also, the feces should not be placed onto the soil but, rather, should be disposed of either in the toilet or within bags.

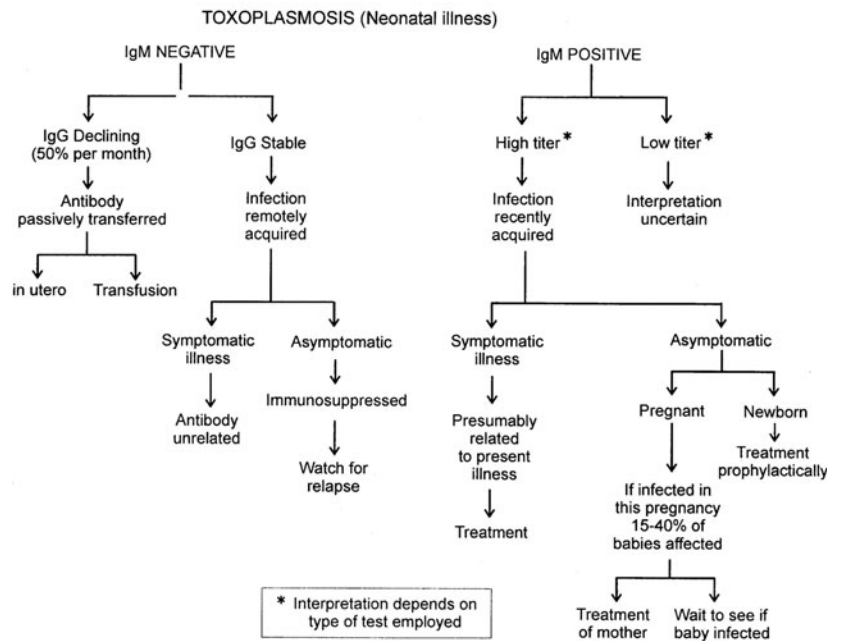

Figure 6.11 Chart for the analysis of conventional antibody tests for *Toxoplasma gondii* by the IgM technique. Interpretation depends on the type of test used. In the IgM-indirect immunofluorescence assay test, a titer of 1:64 would support a diagnosis of infection acquired 1 to 3 months earlier. In the double-sandwich IgM-ELISA (IgM capture), titers of 1:256 and higher should be expected in the first 4 months of infection. (Adapted from references 10, 14, and 43.)

Table 6.7 Guide to interpretation of serologic tests for the diagnosis of toxoplasmosis^a

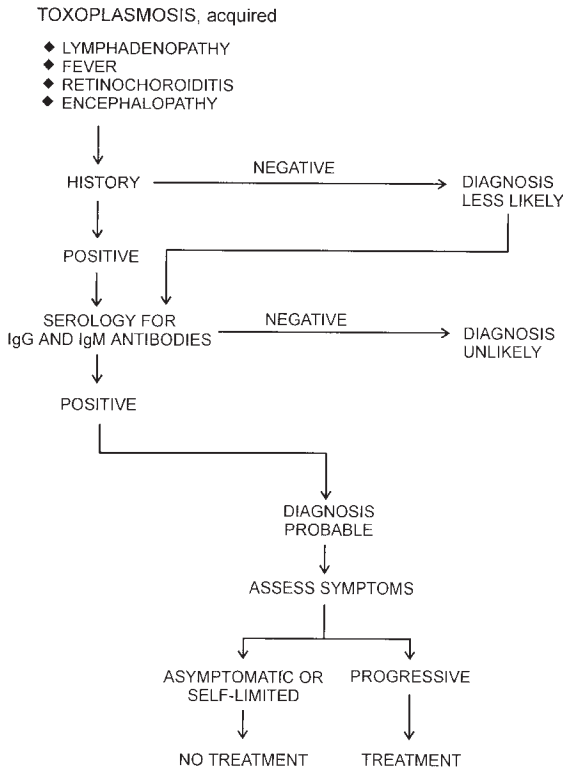

Clinical problem ^b	Infection status ^c of patients with titer ^d of:				
	0 (negative)	1:2–1:16	1:32–1:128	1:256–1:512	≥1:1,024
Asymptomatic	Susceptible to infection	Infection in the past, probably immune	Infection in the past, probably immune	Infection in the past, probably immune	Recent infection or reinfection
Pregnancy	Susceptible to infection	Infection in the past, probably immune	Infection in the past, probably immune	Infection in the past, probably immune	Need to monitor neonate for infection
Newborn, asymptomatic or with jaundice	No	No	Diagnosis unlikely	Diagnosis unlikely	Possible, perform testing for IgM
Newborn with encephalitis	No	No	No	Diagnosis unlikely	Diagnosis may be correct if titer is stable or rises; perform testing for IgM
Lymphadenopathy	No	No	No	Diagnosis unlikely	Diagnosis possible
Fever with pneumonia, myocarditis, or hepatitis	No	No	Diagnosis unlikely	Diagnosis unlikely	Diagnosis possible; perform testing for IgM
Retinochoroiditis	No	Diagnosis possible	Diagnosis possible	Diagnosis possible	Diagnosis possible
Encephalitis	No	No	Diagnosis unlikely	Diagnosis unlikely	Possible; perform testing for IgM
Encephalitis (immunosuppressed patient)	Nondiagnostic	Diagnosis unlikely (may be transfusion related)	Diagnosis possible	Diagnosis possible	Diagnosis likely; perform testing for IgM

^a Adapted from reference 14.

^b Patients are immunocompetent except where stated otherwise.

^c Susceptible to infection: the patient is not immune and is susceptible to a primary infection. No: with this antibody titer, toxoplasmosis should not be diagnosed. Diagnosis unlikely: these titers would be the lowest found in typical forms of the syndrome. Diagnosis possible: these titers would be characteristic but not necessarily diagnostic. Diagnosis likely: this titer would probably be diagnostic for toxoplasmosis. Perform testing for IgM: the presence of antibody may be informative.

^d Dye test or indirect fluorescent-antibody test for IgG.

Algorithm 6.1 Toxoplasmosis.

Figure 6.12 Chart for the prevention of TE in HIV-positive patients; the approach is based on results of the *Toxoplasma* IgG serology. (Adapted from references 10, 14, and 43.)

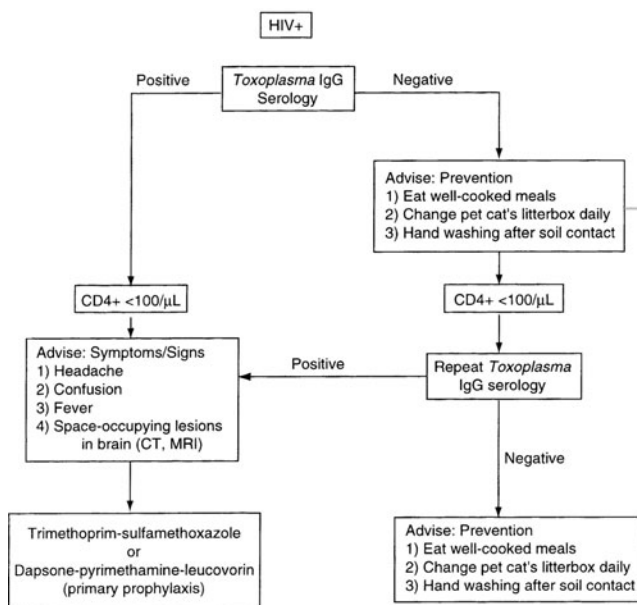

Table 6.8 Prevention of infection with *Toxoplasma gondii*

Prevention	Comments
Do not eat raw or undercooked meat or eggs	An example would be hollandaise sauce, prepared from raw eggs; pork, lamb, and venison particularly involved (6, 25, 27)
Cured and smoked meat and sausages are considered safe	As an additional precaution, freeze at -20°C for a minimum of 1 day; however, some sausages are eaten almost raw after adding salt and spices (incidence of <i>T. gondii</i> in certain populations can be very high)
Consume only pasteurized or ultra-heat-treated milk and dairy products	Remember to consider ingredients of dairy products
When handling raw meat, avoid contaminating face, other food, utensils, cutting boards, or countertops	Hand washing and cleaning utensils, sinks, cutting boards, and countertops sufficient
Wash or peel fruits prior to eating them uncooked	Washing of smooth fruits is much easier than of berries; irradiation at 0.5 kGy is effective in “killing” coccidian oocysts on fruits and vegetables (23)
Control insect pests and their access to food	Keep foods covered and/or refrigerated
Wear gloves when gardening or handling sand where cats usually defecate	Wash hands after removing gloves
If living with cats, change litter boxes every day and rinse them with boiling water	In one day, oocysts in cat feces will not have time to mature—extended periods in litter boxes will lead to fully infectious oocysts
Monitor and limit cat food sources	Infection in cats can be reduced by not allowing them to eat raw meat, birds, and rodents; use dry or canned cat food; in some areas of the world, ingestion of infected chicken viscera can lead to oocyst shedding and spread of <i>T. gondii</i> in the environment (12)
Avoid handling stray cats and kittens	May be outdoor cats or may have been fed raw meat
Administer feline <i>T. gondii</i> vaccine to farm cats on swine operations	Reduction of exposure of finishing pigs to <i>T. gondii</i> ; promising intervention to reduce risk of contaminating pork

Until recently, waterborne transmission of *T. gondii* was considered uncommon, but several large outbreaks linked to contaminated municipal water sources have led to a reassessment of this potential mode of transmission (3, 10). Considering the importance of using autofluorescence in environmental detection of oocysts, it has now been established that *T. gondii* oocysts fluoresce with the same pale blue color as can be seen with *Cyclospora*

cayetanensis and other organisms. Apparently, morphologic differences among coccidian oocysts provide fluorescent details sufficient for identification when testing environmental water samples (26).

Since primary infection with *T. gondii* leads to specific and definitive protection against reinfection, the feasibility of developing a vaccine is now being investigated. To protect humans, indirect procedures such as vaccination of the definitive host, i.e., the cat, or direct procedures by immunization with nonliving vaccines may be required.

Malaria and Babesiosis

Malaria

Babesiosis

Malaria

Malaria represents one of the oldest documented diseases of humans, and even today, organisms in the genus *Plasmodium* kill more people than do any other infectious microorganisms. Egyptian mummies more than 3,000 years old have been found with enlarged spleens, most probably due to malaria. Deadly periodic fevers and splenomegaly have been mentioned, dating from as early as 2700 B.C., in both Egyptian and Chinese writings.

Based on the lack of malaria records in the New World prior to the arrival of European explorers, conquistadors, and colonists, it is assumed that they imported *Plasmodium malariae* and *P. vivax* to the Americas. Apparently, the arrival of *P. falciparum* coincided with the importation of African slaves, and by the early 1800s malaria was found worldwide.

Malaria has probably had a greater impact on world history than any other infectious disease. It has been responsible for the outcome of wars, population movements, and the growth and development of various nations throughout the world. Before the American Civil War, malaria was found as far north as southern Canada; however, there has been a gradual decline, and by the early 1950s it was no longer an endemic disease within the United States. It is still a very common disease in many parts of the world, particularly in tropical and subtropical areas (Table 7.1).

Of the four most common species that infect humans, *P. vivax* and *P. falciparum* account for 95% of infections. Some estimates indicate that *P. vivax* may account for 80% of the infections. This species also has the widest distribution, extending throughout the tropics, subtropics, and temperate zones. *P. falciparum* is generally confined to the tropics, *P. malariae* is sporadically distributed, and *P. ovale* is confined mainly to central West Africa and some South Pacific islands.

We usually associate malaria with patients having a history of travel within an area where malaria is endemic. However, other situations that may result in infection involve the receipt of blood transfusions, use of hypodermic needles contaminated by prior use (as with, for example, drug addicts), possibly congenital infection, and transmission within the United States by indigenous mosquitoes that acquired the parasites from imported infections (27).

With the exception of tuberculosis, malaria kills more people than any other communicable disease in the world. More than 300 million to 500 million

Table 7.1 Countries reported by the Centers for Disease Control and Prevention to have areas of endemic malaria

Afghanistan	Guatemala	Panama
Algeria	Guinea	Papua New Guinea
Angola	Guinea-Bissau	Paraguay
Argentina	Guyana	Peru
Bangladesh	Haiti	Philippines
Belize	Honduras	Rwanda
Benin	India	São Tomé and Príncipe
Bhutan	Indonesia	Saudi Arabia
Bolivia	Iran	Senegal
Botswana	Iraq	Sierra Leone
Brazil	Jordan	Solomon Islands
Burkina Faso	Kenya	Somalia
Burundi	Lao People's Democratic Republic	South Africa
Cambodia	Liberia	Sri Lanka
Cameroon	Libyan Arab Jamahiriya (formerly Libyan Arab Republic)	Sudan
Central African Republic	Madagascar	Surinam
Chad	Malawi	Swaziland
China, People's Republic	Malaysia	Syrian Arab Republic
Colombia	Maldives	Tanzania
Comoros	Mali	Thailand
Congo	Mauritania	Togo
Costa Rica	Mauritius	Tunisia
Cote d'Ivoire (formerly Ivory Coast)	Mayotte	Turkey
Djibouti	Mexico	Uganda
Dominican Republic	Morocco	USSR (former) ^a
Ecuador	Mozambique	United Arab Emirates (formerly Trucial Sheikdoms)
Egypt	Myanmar (formerly Burma)	Vanuatu
El Salvador	Namibia	Venezuela
Equatorial Guinea	Nepal	Vietnam
Eritrea	Nicaragua	Yemen
Ethiopia	Niger	Yemen, Democratic
French Guiana	Nigeria	Zaire
Gabon	Oman	Zambia
Gambia	Pakistan	Zimbabwe (formerly Rhodesia)
Ghana		

^a Armenia, Azerbaijan, Belarus, Estonia, Georgia, Kazakstan, Kyrgyzstan, Latvia, Lithuania, Moldova, Russia, Tajikistan, Turkmenistan, Ukraine, Uzbekistan, and in a few areas adjacent to Afghanistan and Iran.

individuals throughout the world are infected with malaria, and 1.5 million to 2.7 million people a year, most of whom are children, are being killed by the disease. More people are dying from malaria today than 30 years ago. Malaria is endemic in over 90 countries in which 2,400 million people live; this is 40% of the world's population (66). The African countries, where 90% of the malaria deaths occur, are ravaged by warfare, and the richer nations that fund most malaria research are cutting budgets. Malaria prevention is difficult, and no drug is universally effective. Vaccine development studies are under way, but malarial vaccines are not yet in general use. Although over 1,000 cases of malaria are reported to the Centers

for Disease Control and Prevention each year, the actual number of cases may be much larger. There has also been a definite increase in the number of cases of *P. falciparum* malaria reported, which may be related to increased resistance to chloroquine.

It is important for both physicians and laboratorians within areas where malaria is not endemic to be aware of the difficulties related to malaria diagnosis and the fact that symptoms are often nonspecific and may mimic other problems. It is important for physicians to recognize that travelers are susceptible to malarial infection when they return to a country where malaria is endemic, and they should receive prophylactic medication. It is also

important to remember that 80% of the *P. falciparum* cases acquired by American civilians are contracted in sub-Saharan Africa; currently there are 40 cities in Africa with over 1 million inhabitants, and by 2025 over 800 million people will live in urban areas. Malaria has always been a rural disease in Africa; however, it appears that the urban poor are at a much higher risk of contracting malaria than was previously recognized. These changes also have the potential to affect travelers to Africa.

With the tremendous increase in the number of people traveling from the tropics to malaria-free areas, the number of imported malaria cases is also on the rise. There have been reports of imported infected mosquitoes transmitting the infection among people who live or work near international airports. It is also possible that mosquitoes can reach areas far removed from the airports (84). This situation has been termed “airport malaria,” i.e., malaria that is acquired through the bite of an infected anopheline mosquito by persons with apparently no risk factors for the disease. Unfortunately, unless a careful history is obtained, the diagnosis of malaria can be missed or delayed. Tests to exclude malaria should be considered for patients who work or live near an international airport and who present with an acute febrile illness. The potential danger of disseminating the mosquito vectors of malaria via aircraft is well recognized; however, modern disinfection procedures have not yet eliminated the risk of vector transportation. Not only can insects survive nonpressurized air travel, but also they may be transported further by car or other means after arriving at the airport. Contraction of airport malaria is certainly an unusual event, particularly considering that the number of air travelers is well over 1 billion annually. However, in addition to asking a patient, “Where have you been, and when were you there?” one should ask, “Where do you live?”

Potential contributing factors to malaria-related fatalities in U.S. travelers include (i) failure to seek pretravel advice, (ii) failure to prescribe correct chemoprophylaxis, (iii) failure to obtain prescribed chemoprophylaxis, (iv) failure to adhere to the chemoprophylaxis regimen, (v) failure to seek medical care promptly for their illness, (vi) failure to obtain an adequate patient history, (vii) delay in diagnosis of malaria, and (viii) delay in initiating treatment of malaria (78). One or more of these potential problems can lead to the death of the patient.

The most recent group of cases of imported malaria within the United States military has been reported to be in U.S. Army Rangers returning from Afghanistan. There were 38 cases represented in this group, with all diagnosed infections being due to *P. vivax*. It is interesting that the self-reported compliance rates were 52% for weekly chemoprophylaxis, 41% for postdeployment chemoprophylaxis, 31% for both weekly and postde-

ployment chemoprophylaxis, 82% for treating uniforms with permethrin, and 29% for application of insect repellent (58).

Life Cycle and Morphology

The vector for malaria is the female anopheline mosquito. When the vector takes a blood meal, sporozoites contained in the salivary glands of the mosquito are discharged into the puncture wound (Figures 7.1 and 7.2) (10). Within an hour, these infective stages are carried via the blood to the liver, where they penetrate hepatocytes and begin to grow, thus initiating the pre-erythrocytic or primary exoerythrocytic cycle. Detailed study of sporozoite entry into the hepatocytes indicates that the process involves parasite-encoded surface proteins and host molecules. The sporozoites become round or oval and begin dividing repeatedly. This schizogony results in large numbers of exoerythrocytic merozoites. Once these merozoites leave the liver, they invade the red blood cells (RBCs), thus initiating the erythrocytic cycle. It has been reported that a secondary or dormant schizogony may occur in *P. vivax* and *P. ovale* organisms, which remain quiescent in the liver until a later time. These resting stages have been termed hypnozoites (60). Delayed schizogony does not occur in *P. falciparum* and probably does not occur in *P. malariae*.

The situation in which the RBC infection is not eliminated by the immune system or by therapy and the numbers in the RBCs begin to increase again with subsequent clinical symptoms is called a recrudescence. All species may cause a recrudescence. The situation in which the erythrocytic infection is eliminated and a relapse occurs later because of a new invasion of the RBCs from liver merozoites, called a recurrence or true relapse, theoretically occurs only in *P. vivax* and *P. ovale* infection.

Once the RBCs and reticulocytes have been invaded, the parasites grow and feed on hemoglobin. Within the RBC, the merozoite (or young trophozoite) is vacuolated, ring shaped, more or less ameboid, and uninucleate. The excess protein, an iron porphyrin, and heme left over from the metabolism of hemoglobin combine to form malarial pigment (some workers use the term “hemozoin”; however, the term “malarial pigment” is used throughout this chapter).

Once the nucleus begins to divide, the trophozoite is called a developing schizont. The mature schizont contains merozoites (whose number depends on the species), which are released into the bloodstream. Many of the merozoites are destroyed by the immune system, but others invade RBCs, in which a new cycle of erythrocytic schizogony begins.

After several erythrocytic generations, some of the merozoites do not become schizonts but, rather, begin

Figure 7.1 Life cycle of *Plasmodium* spp. (Illustration by Nobuko Kitamura; adapted from Wilcox, A., *Manual for the Microscopical Diagnosis of Malaria in Man*, U.S. Public Health Service bulletin 180, National Institutes of Health, Bethesda, Md., 1951.)

to undergo development into the male and female gametocytes. Whether this development is predetermined genetically or as a response to some specific stimulus is unknown (8). It is likely that cells are committed to sexual development in the preceding round of asexual schizogony within the preerythrocytic schizont rather than differentiating following invasion of an RBC by uncommitted merozoites. Data also suggest that genetic and environmental factors may predispose *Plasmodium* spp. to switch from asexual to sexual development.

Apparently, sexual commitment is highest in merozoites derived directly from the liver schizont and there is a progressive loss of commitment with increasing numbers of asexual cycles. Environmental stimuli may relate directly to an increase in parasite density; there may also be some direct links between sublethal doses of chloroquine and an increase in gametocytogenesis, particularly in chloroquine-resistant parasites.

The asexual and sexual forms just described circulate in the bloodstream during infections by three

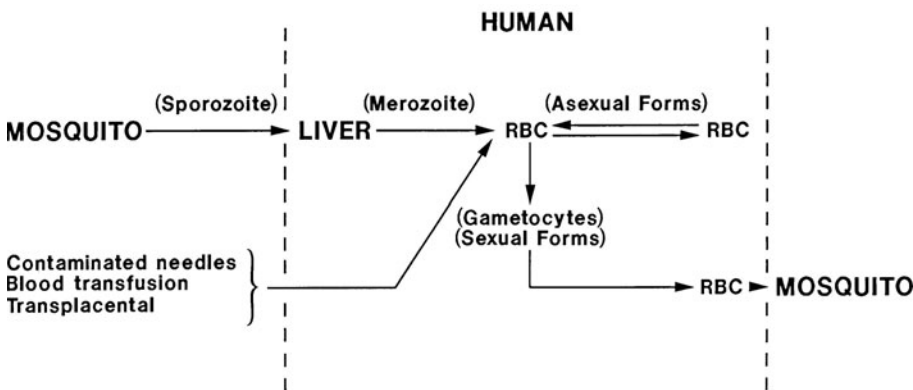

Figure 7.2 Life cycle of malaria.

of the *Plasmodium* species. However, in *P. falciparum* infections, as the parasite continues to grow, the RBC membrane becomes sticky and the cells tend to adhere to the endothelial lining of the capillaries of the internal organs. Thus, only the ring forms and the gametocytes (occasionally mature schizonts) normally appear in the peripheral blood.

If gametocytes are ingested when the mosquito takes a blood meal, they mature into gametes while in the mosquito gut. The male microgametes undergo nuclear division by a process called exflagellation, in which the microgametes break out of the RBC, become motile, and penetrate the female macrogamete, with the fertilized stage being called the zygote (Figure 7.3). This zygote then becomes elongate and motile and is called the ookinete. This stage migrates to the mosquito midgut, secretes a thin wall, and grows into the oocyst, which extends into the insect's hemocele. Within a few days to 2 weeks, the oocyst matures, with the formation of hundreds of sporozoites. When the oocyst ruptures, the sporozoites are released into the hemocele and dispersed throughout the body, and some make their way into the salivary glands. When the mosquito next takes a blood meal, the sporozoites are injected with saliva into the host. Unfortunately, when blood tubes are held at room temperature, especially with the cap removed, the process of exflagellation can occur within the blood. Subsequently, when the blood films are prepared, these microgametocytes can be confused with *Borrelia* spp. (11, 94).

Figure 7.3 Scanning electron micrograph of exflagellating male gametocyte. (Courtesy of Robert E. Sinden.)

Clinical Disease

From the time of the original mosquito bite until a week or more later, the patient remains asymptomatic. During this time, the organisms are undergoing multiplication (preerythrocytic cycle) in the liver. When the liver merozoites invade the RBCs, several broods begin to develop; however, one will eventually dominate and suppress the others, thus beginning the process of periodicity. Once the cycle is synchronized, the simultaneous rupture of a large number of RBCs and liberation of metabolic waste by-products into the bloodstream precipitate the paroxysms of malaria.

Clinical symptoms of malaria include anemia, splenomegaly, and the classic paroxysm, with its cold stage, fever, and sweats. Although the febrile paroxysms strongly suggest infection, many patients who are seen in medical facilities, particularly in the early stages of the infection, do not exhibit the typical fever pattern. They may have fever or several small, random peaks each day. Since the symptoms associated with malaria are so nonspecific, the diagnosis should be considered in any symptomatic patient with a history of travel to an area where malaria is endemic. During the primary infection in a nonimmune host, the early fever episodes can affect density-dependent regulation of the parasite population, maintaining cycles of parasitemia and promoting synchronous parasite growth. The typical paroxysm begins with the cold stage and rigors lasting 1 to 2 h. During the next few hours, the patient spikes a high fever and feels very hot, and the skin is warm and dry. The last several hours are characterized by marked sweating and a subsequent drop in body temperature to normal or subnormal.

Anemia seen in malarial infections can be caused by a number of mechanisms, including (i) direct RBC lysis as a function of the life cycle of the parasite, (ii) splenic removal of both infected and uninfected RBCs (coated with immune complexes), (iii) autoimmune lysis of coated infected and uninfected RBCs, (iv) decreased incorporation of iron into heme, (v) increased fragility of RBCs, and (vi) decreased RBC production from bone marrow suppression.

Malaria can mimic many other diseases, such as gastroenteritis, pneumonia, meningitis, encephalitis, or hepatitis. Other possible symptoms include lethargy, anorexia, nausea, vomiting, diarrhea, and headache. Leukopenia can also be seen in malaria, as can an occasional elevated white blood cell count with a left shift. Eosinophilia and thrombocytopenia may also be seen but are much less frequent. A clinical comparison of some of the features of the four different malarias is presented in Table 7.2. Information on the pathogenesis of malaria is provided in Figure 7.4 and Tables 7.3 to 7.5.

Plasmodium vivax. The primary clinical attack usually occurs 7 to 10 days after infection, although there are strain differences, with a much longer incubation period being possible. In some patients, symptoms such as headache, photophobia, muscle aches, anorexia, nausea, and sometimes vomiting occur before organisms can be detected in the bloodstream. In other patients, the parasites can be found in the bloodstream several days before symptoms appear.

During the first few days, the patient may not exhibit a typical paroxysm pattern but, rather, may have a steady low-grade fever or an irregular remittent fever pattern. Once the typical paroxysms begin, after an irregular periodicity, a regular 48-h cycle is established. An untreated primary attack may last from 3 weeks to 2 months or longer. The paroxysms become less severe and more irregular in frequency and then stop altogether. In 50% of patients, relapses occur after weeks, months, or up to 5 years (or more).

Severe complications are rare in *P. vivax* infections, although coma and sudden death or other symptoms of

cerebral involvement have been reported. These patients can exhibit cerebral malaria, renal failure, circulatory collapse, severe anemia, hemoglobinuria, abnormal bleeding, acute respiratory distress syndrome, and jaundice (57, 94). Studies have confirmed that these were not mixed infections with *P. falciparum* but single-species infections with *P. vivax*.

Since *P. vivax* infects only the reticulocytes, the parasitemia is usually limited to around 2 to 5% of the available RBCs. Splenomegaly occurs during the first few weeks of infection, and the spleen progresses from being soft and palpable to hard, with continued enlargement during a chronic infection. If the infection is treated during the early phases, the spleen returns to its normal size.

Leukopenia is usually present; however, leukocytosis may be present during the febrile episodes. Concentrations of total plasma proteins are unchanged, although the albumin level may be low and the globulin fraction may be elevated. The increase in the concentration of gamma globulins is caused by the development of antibodies. The level of potassium in serum may also be increased as a result of RBC lysis.

Table 7.2 *Plasmodium* spp.: clinical characteristics of the four infections^a

Infection parameter	<i>P. vivax</i>	<i>P. ovale</i>	<i>P. malariae</i>	<i>P. falciparum</i>	Comments
Incubation period	8–17 days	10–17 days	18–40 days	8–11 days	May be extended for months to years
Prodromal symptoms					In all 4 species, may mimic symptoms seen with influenza
Severity	Mild to moderate	Mild	Mild to moderate	Mild	
Initial fever pattern	Irregular (48 h)	Irregular (48 h)	Regular (72 h)	Continuous-remittent (48 h)	Lack of regular periodicity may not suggest malaria as a potential diagnosis, particularly in patients who present to the emergency room early in the course of the infection
Symptom periodicity	48 h	48 h	72 h	36–48 h	
Initial paroxysm					
Severity	Moderate to severe	Mild	Moderate to severe	Severe	
Mean duration	10 h	10 h	11 h	16–36 h	
Duration of untreated primary attack	3–8+ wk	2–3 wk	3–24 wk	2–3 wk	
Duration of untreated infection	5–7 yr	12 mo	20+ yr	6–17 mo	
Parasitemia limitations	Young RBCs	Young RBCs	Old RBCs	All RBCs	
Anemia	Mild to moderate	Mild	Mild to moderate	Severe	
CNS involvement	Rare	Possible	Rare	Very common	
Nephrotic syndrome	Possible	Rare	Very common	Rare

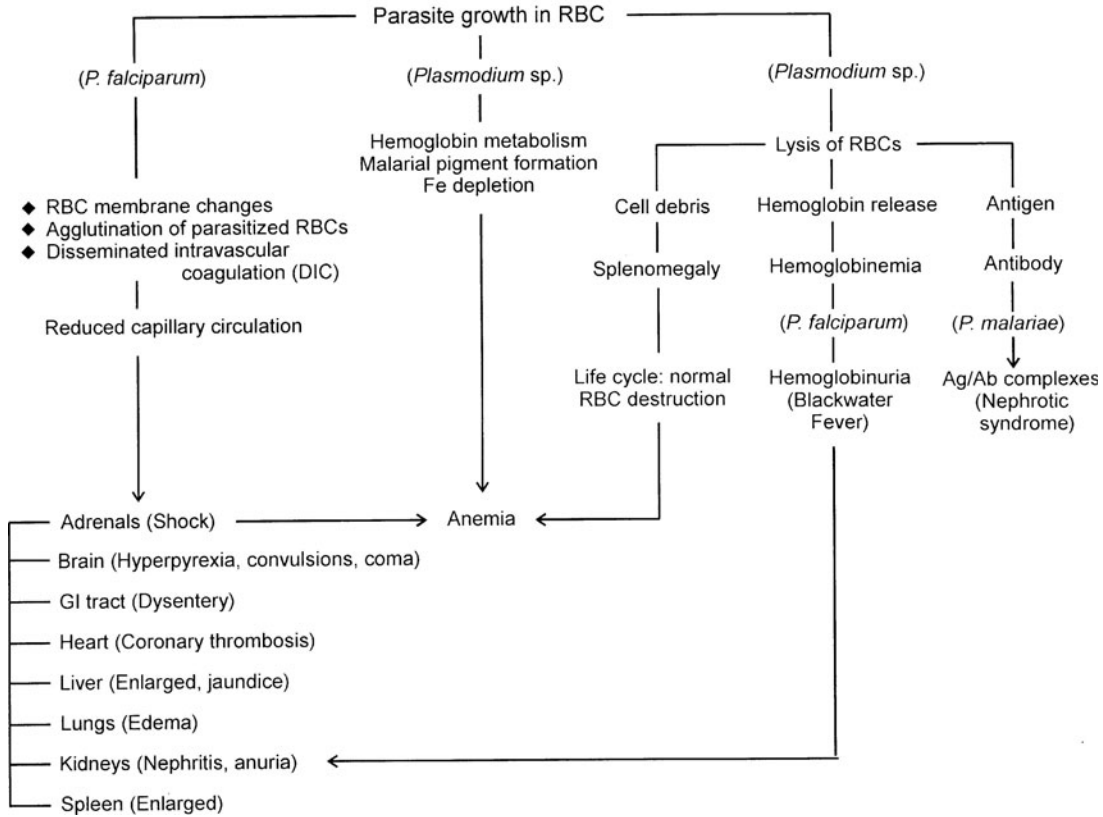

Figure 7.4 Pathogenesis of malaria. (Adapted from E. K. Markell and M. Voge, *Medical Parasitology*, 5th ed., The W. B. Saunders Co., Philadelphia, Pa., 1981.)

Table 7.3 Malaria pathophysiology^a

Factor	Comments ^b
Parasite virulence factors	Multiplication capacity: rapidly expanding biomass outstrips host defenses; immunity reduces multiplication RBC selectivity: age of RBC determines level of parasitemia; less so for <i>P. falciparum</i> Cytoadherence, rosetting: all four species can induce rosetting; <i>P. falciparum</i> causes cytoadherence Cytokine release: <i>P. falciparum</i> varies in ability to induce TNF release, even those derived from single genotype Antigenicity: in areas of endemic infection, parasites not recognized by the host will have relative growth advantage Drug resistance: antimalarial drugs widely available, self-medication common, selective pressure against drug-sensitive parasites
Parasite multiplication	At the onset of fever, approximately 10 ⁸ parasites in the body; corresponds to 20–20,000 parasites/μl of blood; in areas of endemic infection, patients may tolerate parasitemias up to 10,000 / μl of blood without feeling ill; only <i>P. falciparum</i> has ability to infect all RBCs and may exceed 50%
Parasite biomass	Loose positive correlation between parasitemia and prognosis in <i>P. falciparum</i> malaria; positive correlation between number of sequestered parasitized RBCs and severity of <i>P. falciparum</i> malaria
Toxicity and cytokines	Question of true toxin vs paroxysmal cytokine release due to nonspecific reaction to amount of particulate debris released into the circulation at schizont rupture; high concentrations of cytokines appear to be harmful, while lower levels probably benefit the patient; they are responsible for the typical symptoms of fever and malaise
RBC deformability	As the parasite grows, the normally flexible biconcave disk becomes more spherical and rigid, and the surface becomes irregular and covered with small protrusions; reduction in deformability results from reduced membrane fluidity, increasing sphericity, and enlarging, viscous intraerythrocytic parasite; also occurs in uninfected RBCs in acute malaria

(continued)

Table 7.3 (continued)

Factor	Comments ^b
Sequestration and pathology	RBCs adhere to microvascular endothelium (cytoadherence) and disappear from peripheral circulation (i.e., sequestration); greatest involvement is in brain, heart, kidney, intestines, and adipose tissue, least prominent is in skin; consequences of microcirculatory obstruction are reduced oxygen/substrate supply (anaerobic glycolysis and lactic acidosis)
Coma	Coma associated with 15–20% mortality; however, both adults and children recover without sequelae; thought to be metabolic or anesthetic encephalopathy (may involve neurotransmitter abnormalities and NO)
Intracranial pressure	Mild generalized increase in systemic vascular permeability in severe malaria; majority of patients with cerebral malaria do not have cerebral edema; all children with cerebral malaria (at some time) have elevated ICP; background rise in ICP probably results from increase in cerebral blood volume, independent of permeability
Immunological factors	Unlikely that cerebral malaria is due to immune-mediated damage; fatal falciparum malaria has lack of extravascular pathology; in cases of hypergammaglobulinemia, most antibody is not directed against malaria antigens; description suggests a “smoke screen” with broad-spectrum and nonspecific activation that interferes with the development of a specific cellular immune response; exception may be nephrotic syndrome caused by <i>P. malariae</i> and antigen-antibody immune complex formation in the kidneys
Renal failure	Basic pathology is acute tubular necrosis; urine sediment unremarkable, sodium level in urine low, blood pressure normal; no proof, but renal microvascular obstruction due to sequestration in kidneys may be responsible; glomerulonephritis is very rare in acute malaria, and renal necrosis does not occur
Pulmonary edema	Pulmonary function usually normal; pregnant women with severe falciparum malaria at risk for sudden, acute pulmonary edema (resulting from a sudden increase in pulmonary capillary permeability); cause not known
Cardiovascular function	Pump function not a problem in severe malaria; may be autonomic dysfunction in acute malaria (postural hypotension associated with impaired cardioacceleration), but may be common to all febrile infections
Fluid space; electrolyte changes	Patients may be dehydrated; mild hyponatremia and hypochloremia are common, but potassium levels are usually normal (in spite of hemolysis); after rehydration, total body water and extracellular volume are normal
Anemia	In general, degree of anemia corresponds to duration and severity of infection; obligatory destruction of RBCs due to life cycle; accelerated destruction of nonparasitized RBCs correlates with disease severity; condition is compounded by bone marrow dysfunction; factors that trigger removal of nonparasitized RBCs not fully explained; RBC survival reduced in malaria (not impacted by corticosteroids); reduced oxygen carriage; past explanation of death due to congestive cardiac failure may be due to tissue hypoxia and severe metabolic acidosis
Coagulopathy and thrombocytopenia	Accelerated coagulation cascade activity with accelerated fibrinogen turnover; moderate thrombocytopenia common in <i>P. falciparum</i> and <i>P. vivax</i> malaria, caused by splenic clearance; DIC no longer considered important in pathogenesis of malaria
Blackwater fever	Massive intravascular hemolysis and passage of dark red, brown, or usually black urine; occurs when patients with G6PD deficiency take oxidant drugs (whether or not they have malaria), when G6PD-deficient patients have malaria and receive treatment with quinine or artemisinin derivatives, and when some patients with normal G6PD levels are treated with quinine or artemisinin derivatives; blackwater fever is not usually accompanied by renal failure, although renal impairment is common
Spleen	Rapid splenic enlargement for removal of parasitized RBCs; may also modulate cytoadherence, but mechanism is not known
Gastrointestinal tract	Minor ulceration of stomach and duodenum common in severe malaria; may be reduced splanchnic perfusion (malabsorption of sugars, fats, and amino acids); may be increased gut permeability
Liver	Hepatic dysfunction usually seen in severe malaria; jaundice common (hemolytic, hepatic, cholestatic components); reduced clotting factor synthesis, metabolic drug clearance, and biliary excretion; failure of glyconeogenesis (lactic acidosis and hypoglycemia); liver blood flow may be reduced or may be elevated
Acidosis	Consistent feature; arterial, capillary, venous, and CSF lactate concentrations rise in direct proportion to disease severity; majority of lactic acid produced in malaria derives from host rather than parasite
Hypoglycemia	Closely associated with hyperlactatemia; hypoglycemia leads to nervous system dysfunction, and is associated with residual neurological deficit in survivors of cerebral malaria
Placenta	Pregnancy increases susceptibility to malaria (suppression of systemic and placental cell-mediated immune responses); intense sequestration of <i>P. falciparum</i> -infected RBCs in placenta and maternal anemia; leads to placental insufficiency and fetal retarded growth; maternal mortality approaches 50%, and fetal death usual; high incidence of cerebral malaria, hypoglycemia, and pulmonary edema; <i>P. vivax</i> also linked to reductions in birth weight, suggesting that systemic effects of malaria may be more important than previously recognized
Coincident infections	Patients vulnerable to other infections, including other species of malaria; relationship to HIV also questionable; chronic hepatitis B virus carriage also associated with increased risk of severe malaria

^a Adapted from references 18, 66, and 107.^b TNF, tumor necrosis factor; ICP, intracranial pressure; G6PD, glucose-6-phosphate dehydrogenase; NO, nitric oxide; DIC, disseminated intravascular coagulopathy; CSF, cerebrospinal fluid.

Table 7.4 *Plasmodium* pathogenesis and sequelae

Clinical situation and condition	Comments ^a	Reference(s)
Chronic malaria in West Africa	West Africa; SLVL and hyperreactive malarial splenomegaly have clinical and immunological features in common. Dysregulated immune response to repeated malaria infections results in a stimulated, proliferating pool of B cells; environmental and other factors promote the development of SLVL. Several infectious agents have been associated with B-cell non-Hodgkin's lymphomas.	7
Clinically severe malaria; 489 patients in Zimbabwe	Malaria and blood group A patients had lower hemoglobin levels; also at more risk of coma than patients in other blood groups.	31
64 <i>P. falciparum</i> patients in eastern Sudan; plasma samples and seasonal agglutination of infected RBCs	First demonstration of marked seasonal fluctuations in capacity of sera to agglutinate parasitized RBCs; may reflect drop in levels of agglutinating antibodies between seasons or shifts in antigens being recognized from one transmitting season to the next.	34
Cerebral malaria (<i>P. falciparum</i>); 250,000 Vietnam veterans	Cerebral malaria results in multiple, major, substantially underappreciated neuropsychiatric symptoms in Vietnam veterans (poor dichotic listening, "personality changes," depression, and, in some cases, partial seizure-like symptoms). History of malaria needs to be assessed in workup of any Vietnam veteran; positive response could dramatically change diagnosis and therapy.	105
Bone marrow transplantation in recipient of multiple blood transfusions	<i>P. falciparum</i> trophozoites and gametocytes found on peripheral blood smears.	99
Problem with donors living in high-risk areas	11/420 patients (2.6%) positive for <i>P. falciparum</i> (mean time 22 + 44 days).	103
Both donor and recipient checked prior to BMT	Recommendation for treatment prior to harvest, conditioning of cells, regardless of smear results.	64
Case of unrelated donor	Case of <i>P. vivax</i> infection, donor asymptomatic 11 months prior to donation.	76
Relapse of primary unidentified infection	Case of <i>P. vivax</i> infection after BMT.	87
Case of pancytopenia after 70 days	Case of <i>P. vivax</i> infection after BMT; always consider malaria in the differential.	82
Severe <i>P. falciparum</i> malaria; 24 adults (NO)	No support for the hypothesis that excessive NO production contributes to the pathogenesis of severe falciparum malaria. However, local changes in NO production (CNS) might not be reflected in total production or levels in the CSF.	24, 26
NO production varies throughout childhood (African children)	NO levels high in infancy, decrease after first year of life, then increase again after 5 yr of age. Elevated NO in both infants and older children may be related to age and malaria infection, respectively, and may be one of the mediators of anti-disease immunity in these two age groups.	3
NO production related to anemia (Tanzania)	NO production was inversely associated with hemoglobin concentration; thus, it is not a predictor of anemia after correction of age/gender data.	2
Cerebral malaria (<i>P. falciparum</i>)	Identification of rare <i>P. falciparum</i> parasites expressing a panadhesive phenotype linked to RBC rosetting (correlate of cerebral malaria).	30
	Parasitized RBCs may bind integrin $\alpha_v\beta_3$ on microvascular endothelial cells; sequestration leads to cerebral malaria.	92
	Binding of parasitized RBCs to cerebral endothelial cells lead to functional changes in the blood-brain barrier in cerebral malaria.	15
Adhesion phenomena (<i>P. falciparum</i>)	Cytoadherence begins at 12 h and peaks at 28 h; rosette formation (16–20 h); rosette formation and immunoglobulin binding rate of about 50% (24–36 h).	100
Molecular mechanisms of cytoadherence (<i>P. falciparum</i>)	Cytoadherence may activate intracellular signaling pathways in both endothelial cells and infected RBCs, leading to gene expression of mediators such as cytokines, which could modify the outcome of the infection.	47, 85
RBC deformability (<i>P. falciparum</i>)	Reduced deformability of uninfected RBCs at high shear stresses and subsequent splenic removal of these cells may be an important contributor to anemia of severe malaria.	24
Eosinophil activity (<i>P. falciparum</i>)	Appears that low eosinophil counts may be due to tissue sequestration and destruction rather than decreased production; levels of eosinophilia granule proteins in plasma correlated with levels of TNF and soluble IL-2 receptor, implicating inflammatory responses and T-cell activation as causes of eosinophil activation.	62

(continued)

Table 7.4 (continued)

Clinical situation and condition	Comments ^a	Reference(s)
Fatal malaria (<i>P. falciparum</i>) in African children	Three clinical syndromes: severe anemia, cerebral malaria, malaria-associated hyperpnea (increased rate and depth of breathing); “respiratory distress” may be misleading, malaria hyperpneic syndrome (severe systemic acidosis) may not be recognized in conscious children.	75
Frequent parasitemias with <i>P. falciparum</i> (asymptomatic); children in Tanzania	Asymptomatic (especially polyclonal) <i>P. falciparum</i> infection protects against clinical disease due to new parasites.	28
Maternal and infant mortality/ (<i>P. falciparum</i>)	Accumulation of large numbers of infected RBCs in maternal blood spaces of placenta may be mediated by adhesion of infected RBCs to molecules on the syncytiotrophoblast surface. Parasites infecting pregnant women may be antigenically distinct from those common in childhood disease.	9
<i>P. vivax</i> malaria	Although <i>P. vivax</i> is seldom fatal, it is a major cause of morbidity. <i>P. vivax</i> -infected RBCs form rosettes, like those seen in <i>P. falciparum</i> infections.	19

^b Ag, antigen; Ab, antibody; IL, interleukin; TNF, tumor necrosis factor.

Plasmodium ovale. Although *P. ovale* and *P. vivax* infections are clinically similar, *P. ovale* malaria is usually less severe, tends to relapse less frequently, and usually ends with spontaneous recovery, often after no more than 6 to 10 paroxysms. The incubation period is similar to that seen in *P. vivax* malaria, but the frequency and severity of the symptoms are much lower, with a lower fever and a lack of typical rigors. *P. ovale* infects only the reticulocytes (as does *P. vivax*), so that the parasitemia is generally limited to around 2 to 5% of the available RBCs (21). The geographic range has been thought to be limited to tropical Africa, the Middle East, Papua New Guinea, and Irian Jaya in Indonesia. However, infections with *P. ovale* in Southeast Asia may be the cause of benign and relapsing malaria in this region. In both Southeast Asia and Africa, two different types of *P. ovale* circulate in humans. Human infections with variant-type *P. ovale* are associated with higher parasitemias and thus have possible clinical relevance (109).

Plasmodium malariae. *P. malariae* invades primarily the older RBCs, so that the number of infected cells is somewhat limited. The incubation period between infection and symptoms may be much longer than that seen with *P. vivax* or *P. ovale* malaria, ranging from about 27 to 40 days. Parasites can be found in the bloodstream several days before the initial attack, and the prodromal symptoms may resemble those of *P. vivax* malaria. A regular periodicity is seen from the beginning, with a more severe paroxysm, including a longer cold stage and more severe symptoms during the hot stage. Collapse during the sweating phase is not uncommon.

Proteinuria is common in patients with *P. malariae* infection; in children it may be associated with clinical signs of the nephrotic syndrome. It has been suggested

that kidney problems may result from deposition within the glomeruli of circulating antigen-antibody complexes in an antigen excess situation seen with a chronic infection. Apparently, the nephrotic syndrome associated with *P. malariae* infections is unaffected by the administration of steroids. A membranoproliferative type of glomerulonephritis with relatively sparse proliferation of endothelial and mesangial cells is the most common type of lesion seen in *P. malariae* infection. Granular deposits of immunoglobulin M (IgM), IgG, and C3 are seen in immunofluorescence assays (104). Since chronic glomerular disease associated with *P. malariae* infections is usually not reversible with therapy, genetic and environmental factors may play a role in the nephrotic syndrome.

The infection may end with spontaneous recovery, or there may be a recrudescence or series of recrudescences over many years. These patients are left with a latent infection and persisting low-grade parasitemia for many, many years.

Plasmodium falciparum. *P. falciparum* tends to invade all ages of RBCs, and the proportion of infected cells may exceed 50%. Schizogony occurs in the internal organs (spleen, liver, bone marrow, etc.) rather than in the circulating blood. Ischemia caused by the plugging of vessels within these organs by masses of parasitized RBCs produces various symptoms, depending on the organ involved (Figure 7.5). It has been suggested that a decrease in the ability of the RBCs to change shape when passing through capillaries or the splenic filter may lead to plugging of the vessels.

Figure 7.5 *Plasmodium falciparum*-parasitized blood cells plugging the capillaries in brain tissue. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

The onset of a *P. falciparum* malaria attack occurs 8 to 12 days after infection and is preceded by 3 to 4 days of vague symptoms such as aches, pains, headache, fatigue, anorexia, or nausea. The onset is characterized by fever, a more severe headache, and nausea and vomiting, with occasional severe epigastric pain. There may be only a feeling of chilliness at the onset of fever. Periodicity of the cycle is not established during the early stages, and the presumptive diagnosis may be totally unrelated to a possible malaria infection. If the fever does develop a synchronous cycle, it is usually a cycle of somewhat less than 48 h.

An untreated primary attack of *P. falciparum* malaria usually ends within 2 to 3 weeks. True relapses from the liver do not occur, and after a year, recrudescences are rare.

Severe or fatal complications of *P. falciparum* malaria can occur at any time during the infection and are related to the plugging of vessels in the internal organs, with the symptoms depending on the organ(s) involved (Table 7.3). The severity of the complications in a malaria infection may not correlate with the parasitemia seen in the peripheral blood, particularly in *P. falciparum* infections. Acute lung injury is more likely to occur in patients with very severe, multisystemic *P. falciparum* malaria than in other malaria patients. When patients present with acute lung injury and septic shock, bacterial coinfection should be suspected and treated empirically.

Disseminated intravascular coagulation is a rare complication of malaria; it is associated with a high parasite burden, pulmonary edema, rapidly developing anemia, and cerebral and renal complications. Vascular endothelial damage from endotoxins and bound parasitized blood cells may lead to clot formation in small vessels.

Cerebral malaria is most often seen in *P. falciparum* malaria, although it can occur in the other types as well. If the onset is gradual, the patient may become disoriented or violent or may develop severe headaches and pass into coma. Some patients, even those who exhibit no prior symptoms, may suddenly become comatose. Physical signs of central nervous system (CNS) involvement are quite variable, and there is no real correlation between the severity of the symptoms and the peripheral blood parasitemia. It has been shown that patients with cerebral malaria were infected with RBC rosette-forming *P. falciparum* and that plasma from these patients generally had no antirosetting activity. A rosette usually consists of a parasitized RBC surrounded by three or more uninfected RBCs (Figure 7.6A). Interaction with adjacent uninfected RBCs in rosettes appears to be mediated by knobs seen on the parasitized RBC (Figure 7.6B) (56). In contrast, *P. falciparum* parasites from patients with mild malaria lacked the rosetting phenotype or had a much lower rosetting

Figure 7.6 (A) Scanning electron micrograph of a rosette consisting of a central parasitized RBC surrounded by several attached uninfected RBCs (original magnification, $\times 19,000$; bar, $1\ \mu\text{m}$). (B) Scanning electron micrograph of the interaction of a parasitized RBC with an uninfected RBC that appears to be mediated by protrusion of knobs (original magnification, $\times 53,000$; bar, $0.5\ \mu\text{m}$). (From reference 86 with permission.)

rate. Also, antirosetting activity has been detected in the plasma of these patients. These findings strongly support the idea that RBC rosetting contributes to the pathogenesis of cerebral malaria while antirosetting antibodies offer protection against these clinical sequelae.

Interplay among many factors, including free oxygen radicals and other mediators of inflammation, is likely to be involved in the pathogenesis of cerebral malaria (20, 66). Sequestration often predisposes to cerebral symptoms but in ways not necessarily restricted to obstruction of blood flow. Tumor necrosis factor alpha

and other pyrogenic cytokines play a role in the regulation of parasite density in the host; cerebral malaria is also thought to be related to excessive tumor necrosis factor alpha.

Magnetic resonance imaging of the brains of patients with cerebral malaria shows that the volume of the brain is increased. This increased volume probably results from sequestration of parasitized RBCs and compensatory vasodilatation rather than from edema. Brain stem herniation may occur, but its temporal relation to brain death in patients with cerebral malaria is still unclear. Ultrastructural study of the brain in patients with fatal *P. falciparum* infections reveals that sequestration of parasitized RBCs in cerebral microvessels is much higher in the brains of patients with cerebral malaria (cerebrum, cerebellum, and medulla oblongata) than in the brains of patients with noncerebral malaria. There were 26.6 times more parasitized RBCs in the brain microvasculature than in the peripheral blood (66).

Extreme fevers, 107°F (ca. 41.7°C) or higher, may develop in a relatively uncomplicated attack of malaria or may develop as another manifestation of cerebral malaria. Without vigorous therapy, the patient usually dies. Cerebral malaria is considered to be the most serious complication and the major cause of death from infection with *P. falciparum*; this complication accounts for up to 10% of all *P. falciparum*-infected patients admitted to the hospital and for 80% of fatal cases.

Bilious remittent fever involves the liver, with symptoms including abdominal pain, nausea, and severe and persistent vomiting, with the vomitus containing evidence of bile or fresh blood. There may also be severe diarrhea or dysentery with resulting dehydration. The liver is large and tender, the skin becomes icteric, and the urine contains bile.

Diarrhea or dysentery without liver involvement or jaundice is also seen, with malabsorption characterized by decreased absorption of D-xylose and vitamin B₁₂ and a low carotene level. Jejunal biopsy reveals edema, round cell infiltration of the lamina propria, and blunting of villi, which have also been found on postmortem examinations.

Algid malaria symptoms include circulatory collapse; low blood pressure; hypothermia; rapid, thready pulse; and pale, cold, clammy skin. There may be severe abdominal pain, vomiting and diarrhea, and muscular cramps. At postmortem examination, the adrenal glands are congested, necrotic, and hemorrhagic. In the subacute stage and after recovery, some patients develop signs resembling Addison's disease.

Although infrequent, blackwater fever is most often associated with *P. falciparum* malaria. Usually, there is a history of previous malarial attacks. Sudden, intravascular

hemolysis results in a dramatic color change in the urine (acidic urine with a high methemoglobin content). Since the hemoglobinuria does not necessarily give rise to symptoms, the onset may be missed. Quinine sensitivity has been postulated as one possible factor leading to blackwater fever. Another has been the presence of antibodies acting as hemolysins against RBC antigens. The parasitemia may be relatively low in patients with blackwater fever. With the increased use of quinine to treat chloroquine-resistant patients who live in areas with malaria, more cases of blackwater fever may be seen in the future.

Acute renal failure may also occur unassociated with blackwater fever and hemolytic anemia. Renal anoxia is thought to lead to tubular necrosis. The nephrotic syndrome, caused by acute glomerulonephritis, has also been found in some patients with *P. falciparum* malaria.

Independent risk factors contributing to anemia in falciparum malaria in patients presenting with anemia on admission include age younger than 5 years, a palpable spleen, a palpable liver, recrudescence infections, being female, a history of prolonged history of illness (>2 days) before admission, and pure *P. falciparum* infections rather than mixed infections with *P. falciparum* and *P. vivax*. It appears that coinfection with *P. vivax* can modify the severity of the disease.

In African children with malaria, the presence of impaired consciousness or respiratory distress can identify those at high risk of death. Biochemical evidence of hepatic and renal dysfunction also suggests a poor prognosis; however, in contrast to adults with malaria, children with severe malaria do not always have acute renal failure.

Using several different approaches, it is estimated that approximately 100,000 infant deaths in Africa could be attributed to malaria during pregnancy, resulting in low-birth-weight babies (38). Antimalarial intermittent preventive treatment during pregnancy has been estimated to prevent the death of 22,000 children younger than 5 years through reduced numbers of preterm deliveries. However, if one assumes an efficacy rate of 80% in preventing placental malaria, the number of deaths prevented may be closer to 80,000.

Mixed Infections. Coincident infection with more than one species of malaria is more common than previously suspected. As an example, in Thailand, up to 30% of patients who present with severe *P. falciparum* malaria also are infected with *P. vivax*. Based on overlapping geographic areas where both *P. falciparum* and *P. vivax* are found, it is not surprising that dual infections occur. In Africa, dual infections with *P. falciparum* and *P. malariae* have also been found. Although the

figures may be underestimates, in Gambian children the prevalence of mixed-species infection varies from <1% to >60%. There has even been a report of a rare quadruple malaria infection in a remote area in the western half of New Guinea Island (Irian Jaya Province, Indonesia), and this infection was confirmed using nested PCR and species-specific primer pairs (81). In Africa, *P. ovale* occurs commonly in areas with Duffy-negative populations who are refractory to *P. vivax*, thus appearing to prevent the natural coexistence of the two species. However, the Duffy blood group-negative trait that protects many African populations from *P. vivax* infection is considered very rare or nonexistent in New Guinea. Since *P. ovale* is considered a very unusual finding outside of Africa, the natural occurrence of *P. ovale* and *P. vivax* together in the same patient is considered a very rare finding.

Although antagonism and predominance of one *Plasmodium* species over the other in the human host has been described, differences in the methods and sensitivity of detection may have complicated the interpretation of results. It is generally accepted that *P. falciparum* predominates over *P. vivax* in mixed infections. *P. ovale* has been found in mixed infections and has been established in persons carrying *P. falciparum*, *P. vivax*, and *P. malariae* at the same time. Simultaneous patent infections with three or four *Plasmodium* species are not entirely rare findings in the blood of healthy carriers in regions of hyperendemic infection.

Interaction between *P. falciparum* and *P. vivax* is often reported to be suppressive. There are reciprocal seasonal changes in the prevalence of the two species that cannot be explained by changes in vector behavior, anti-malarial drug use, or age. Changes may be due to competition for host cells, since *P. falciparum* causes dyserythropoiesis, leading to a decreased number of reticulocytes available for invasion by *P. vivax*. It is possible that some cross-species immunity may be involved. Also, patients with a mixed *P. falciparum*-*P. vivax* infection were four times less likely to exhibit patent gametocytemia than were those with a *P. falciparum* infection alone. Thus, coinfection with *P. vivax* may attenuate infections with *P. falciparum*. Also, there appear to be no limitations to vector infections with multiple species of malaria, and transmission of more than one species to humans has been documented.

Detection of mixed infections can be difficult due to different levels of parasitemia, low organism densities, and confusion among various morphologic criteria for identification to the species level; these problems have been well documented. Using PCR methods, it is likely that a higher detection rate of chronic and mixed malarial species will be possible (81).

Diagnosis

Although malaria is no longer endemic within the United States, it is considered to be life-threatening, and laboratory requests for blood smear examination and organism identification should be treated as “STAT” requests. Malaria is usually associated with patients having a history of travel within an area where malaria is endemic, although other routes of infection are well documented (Algorithm 7.1).

Frequently, for a number of different reasons, organism recovery and subsequent identification are more difficult than the textbooks imply. It is very important that this fact be recognized, particularly when one is dealing with a possibly fatal infection with *P. falciparum*.

Patient Information. When requests for malarial smears are received in the laboratory, some patient history information should be made available to the laboratorian. This information should include the following.

1. Where has the patient been, and what was the date of return to the United States? (“Where do you live?”)
2. Has malaria ever been diagnosed in the patient before? If so, what species was identified?
3. What medication (prophylaxis or otherwise) has the patient received, and how often? When was the last dose taken?
4. Has the patient ever received a blood transfusion? Is there a possibility of other needle transmission (drug user)?

5. When was the blood specimen drawn, and was the patient symptomatic at the time? Is there any evidence of a fever periodicity?

Answers to such questions may help eliminate the possibility of infection with *P. falciparum*, usually the only species that can rapidly lead to death.

Conventional Microscopy. Often, when the diagnosis of malaria is considered, only a single blood specimen is submitted to the laboratory for examination; however, single films or specimens cannot be relied on to exclude the diagnosis, especially when partial prophylactic medication or therapy is used. Partial use of antimalarial agents may be responsible for reducing the numbers of organisms in the peripheral blood, thus leading to a blood smear that contains few organisms, which then reflects a low parasitemia when in fact serious disease is present. Patients with a relapse case or an early primary case may also have few organisms in the blood smear (Table 7.6).

It is recommended that both thick and thin blood films be prepared on admission of the patient, and at least 200 to 300 oil immersion fields should be examined on both films before a negative report is issued (74). Since one set of negative films will not rule out malaria, additional blood specimens should be examined over a 36-h time frame. Although Giemsa stain is recommended for all parasitic blood work, the organisms can also be seen if other blood stains, such as Wright’s stain, are used (Tables

Algorithm 7.1 Malaria.

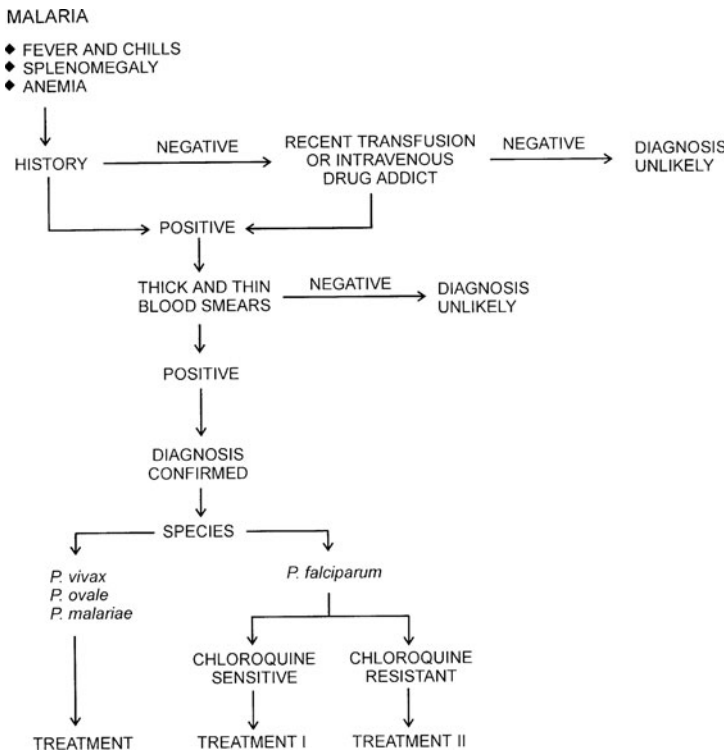

Table 7.6 Parasitemia determined from conventional light microscopy: clinical correlation^a

Parasitemia (%)	No. of parasites/ μ l	Clinical correlation ^b
0.0001–0.0004	5–20	Number of organisms that are required for a positive TBF (sensitivity) Note (TBF): Examination of 100 TBF fields (0.25 μ l) may miss up to 20% of infections (sensitivity, 80–90%); at least 300 TBF fields should be examined before reporting a negative result Note (THBF): Examination of 100 THBF fields (0.005 μ l); at least 300 THBF fields should be examined before reporting a negative result; <i>both</i> TBF and THBF should be examined for every specimen submitted for a suspect malaria case. One set (TBF + THBF) of negative blood films does not rule out a malaria infection.
0.002	100	Patients may be symptomatic below this level
0.2	10,000	Level above which immune patients will exhibit symptoms
2	100,000	Maximum parasitemia of <i>P. vivax</i> and <i>P. ovale</i> (infect young RBCs only) (rarely may exceed 2%)
2–5	100,000–250,000	Hyperparasitemia, severe malaria, ^c increased mortality
10	500,000	Exchange transfusion may be considered, high mortality

^a Adapted from references 39 and 108.

^b TBF, thick blood film; THBF, thin blood film.

^c WHO criteria for severe malaria are parasitemia of >10,000/ μ l and severe anemia (hemoglobin, <5 g/liter). Prognosis is poor if >20% of parasites are pigment-containing trophozoites and schizonts and/or if >5% of neutrophils contain visible pigment.

7.7 and 7.8; Figures 7.7 to 7.11). Blood collected with the use of EDTA anticoagulant is acceptable; however, if the blood remains in the tube for any length of time, true stippling may not be visible within the infected RBCs (*P. vivax*, as an example). Also, when using anticoagulants, it is important to remember that the proper ratio between blood and anticoagulant is necessary for good organism morphology. Heparin can also be used, but EDTA is preferred. Finger stick blood is recommended, particularly when the volume of blood required is minimal (i.e., when no other hematologic procedures have been ordered). The blood should be free flowing when taken for smear preparation and should not be contaminated with alcohol used to clean the finger prior to the stick.

Accurate species diagnosis is essential for good patient management, since identification to the species level may determine which drug or combination of drugs will be indicated. Some patients with *P. falciparum* infections may not yet have the crescent-shaped gametocytes in the blood. Low parasitemias with the delicate ring forms may be missed; consequently, oil immersion examination at $\times 1,000$ is mandatory.

Parasite density generally correlates with disease severity, but peripheral parasitemia does not always reflect the number of sequestered organisms. Malaria pigment may serve as a peripheral indicator of parasite biomass, since the pigment can be seen within monocytes and polymorphonuclear leukocytes during light microscopy examination. The presence of pigment has been strongly associated with more severe disease than occurs with uncomplicated cases of malaria (Figure 7.12). Pigmented neutrophils (polymorphonuclear leukocytes, monocytes) have been associated with cerebral malaria and with death in children with severe malaria (67).

Table 7.7 Malaria characteristics

Organism	Characteristics
<i>Plasmodium vivax</i> (benign tertian malaria)	<ol style="list-style-type: none"> 48-h cycle Tends to infect young cells Enlarged RBCs Schüffner's dots after 8–10 h Delicate ring Very ameboid trophozoite Mature schizont contains 12–24 merozoites
<i>Plasmodium malariae</i> (quartan malaria)	<ol style="list-style-type: none"> 72-h cycle (long incubation period) Tends to infect old cells Normal-size RBCs No stippling Thick ring, large nucleus Trophozoite tends to form “bands” across the cell Mature schizont contains 6–12 merozoites
<i>Plasmodium ovale</i>	<ol style="list-style-type: none"> 48-h cycle Tends to infect young cells Enlarged RBCs with fimbriated edges (oval) Schüffner's dots appear in the beginning (in RBCs with very young ring forms, in contrast to <i>P. vivax</i>) Smaller ring than <i>P. vivax</i>) Trophozoite less ameboid than that of <i>P. vivax</i> Mature schizont contains avg of 8 merozoites
<i>Plasmodium falciparum</i> (malignant tertian malaria)	<ol style="list-style-type: none"> 36–48-h cycle Tends to infect any cell regardless of age; thus, very heavy infection may result All sizes of RBCs No Schüffner's dots (Maurer's dots: may be larger, bluish, single dots) Multiple rings/cell (only young rings, gametocytes, and occasional mature schizonts seen in peripheral blood) Delicate rings; may have two dots of chromatin/ring, appliqué or accolé forms Crescent-shaped gametocytes

Table 7.8 Plasmodia in Giemsa-stained thin blood films

Characteristic	<i>Plasmodium vivax</i>	<i>Plasmodium malariae</i>	<i>Plasmodium falciparum</i>	<i>Plasmodium ovale</i>
Persistence of exoerythrocytic cycle	Yes	No	No	Yes
Relapses	Yes	No, but long-term recrudescences are recognized	No long-term relapses	Possible, but usually spontaneous recovery
Time of cycle (h)	44–48	72	36–48	48
Appearance of parasitized RBC (size and shape)	1.5 to 2 times larger than normal; oval to normal; may be normal size until ring fills half of cell	Normal shape; size may be normal or slightly smaller	Both normal	60% of cells larger than normal and oval; 20% have irregular, frayed edges
Schüffner's dots (eosinophilic stippling)	Usually present in all cells except early ring forms	None	None; comma-like red dots (Maurer's dots) occasionally present	Present in all stages including early ring forms; dots may be larger and darker than in <i>P. vivax</i>
Color of cytoplasm	Decolorized, pale	Normal	Normal, bluish tinge at times	Decolorized, pale
Multiple rings/cell	Occasional	Rare	Common	Occasional
All developmental stages present in peripheral blood	All stages present	Ring forms few, as ring stage brief; mostly growing and mature trophozoites and schizonts	Young ring forms and no older stages; few gametocytes	All stages present
Appearance of young trophozoite (early ring form)	Ring 1/3 diameter of cell; cytoplasmic circle around vacuole; heavy chromatin dot	Ring often smaller than in <i>P. vivax</i> , occupying 1/8 of cell; heavy chromatin dot; vacuole at times "filled in"; pigment forms early	Delicate, small ring with small chromatin dot (frequently 2); scanty cytoplasm around small vacuoles; sometimes at edge of red cell (appliqué form) or filamentous slender form; may have multiple rings per cell	Ring larger and more ameboid than in <i>P. vivax</i> ; otherwise similar to <i>P. vivax</i>
Appearance of growing trophozoite	Multishaped irregular ameboid parasite; streamers of cytoplasm close to large chromatin dot; vacuole retained until close to maturity; increasing amounts of brown pigment	Nonameboid rounded or band-shaped solid forms; chromatin may be hidden by coarse dark brown pigment	Heavy ring forms; fine pigment grains	Ring shape maintained until late in development; nonameboid compared with <i>P. vivax</i>

(continued)

Table 7.8 Plasmodia in Giemsa-stained thin blood films (*continued*)

Characteristic	<i>Plasmodium vivax</i>	<i>Plasmodium malariae</i>	<i>Plasmodium falciparum</i>	<i>Plasmodium ovale</i>
Appearance of mature trophozoite	Irregular ameboid mass; 1 or more small vacuoles retained until schizont stage; fills almost entire cell; fine brown pigment	Vacuoles disappear early; cytoplasm compact, oval, band shaped, or nearly round, almost filling cell; chromatin may be hidden by peripheral coarse dark brown pigment	Not seen in peripheral blood (except in severe infections); development of all phases following ring form occurs in capillaries of viscera	Compact; vacuoles disappear; pigment dark brown, less abundant than in <i>P. malariae</i>
Appearance of schizont (presegmenter)	Progressive chromatin division; cytoplasmic bands containing clumps of brown pigment	Similar to <i>P. vivax</i> except smaller; darker, larger pigment granules peripheral or central	Not seen in peripheral blood (see above)	Smaller and more compact than <i>P. vivax</i>
Appearance of mature schizont	Merozoites, 16 (12–24), each with chromatin and cytoplasm, filling entire RBC, which can hardly be seen	8 (6–12) merozoites in rosettes or irregular clusters filling normal-size cells, which can hardly be seen; central arrangement of brown-green pigment	Not seen in peripheral blood (see above)	3/4 of cells occupied by 8 (8–12) merozoites in rosettes or irregular clusters
Appearance of macrogametocyte	Rounded or oval homogeneous cytoplasm; diffuse delicate light brown pigment throughout parasite; eccentric compact chromatin	Similar to <i>P. vivax</i> , but fewer; pigment darker and more coarse	Sex differentiation difficult; “crescent” or “sausage” shapes characteristic; may appear in “showers,” black pigment near chromatin dot, which is often central	Smaller than <i>P. vivax</i>
Appearance of microgametocyte	Large pink to purple chromatin mass surrounded by pale or colorless halo; evenly distributed pigment	Similar to <i>P. vivax</i> , but fewer; pigment darker and more coarse	Same as macrogametocyte (described above)	Smaller than <i>P. vivax</i>
Main criteria	Large RBC; trophozoite irregular; pigment usually present; Schüffner’s dots not always present; several phases of growth seen in one smear; gametocytes appear as early as day 3	RBCs normal in size and color; trophozoites compact, stain usually intense, band forms not always seen; coarse pigment; no stippling of RBCs; gametocytes appear after a few weeks	Development following ring stage takes place in blood vessels of internal organs; delicate ring forms and crescent-shaped gametocytes are the only forms normally seen in peripheral blood; gametocytes appear after 7–10 days	RBC enlarged, oval, with fimbriated edges; Schüffner’s dots seen in all stages; gametocytes appear after 4 days or as late as 18 days

Malaria is one of the few parasitic infections considered to be immediately life-threatening, and a patient with the diagnosis of P. falciparum malaria should be considered a medical emergency because the disease can be rapidly fatal. Any laboratory providing the expertise to identify malarial parasites should do so on a 24-h basis, 7 days per week.

Patients with malaria may appear for diagnostic blood work when least expected. Laboratory personnel should be aware of the “STAT” nature of such requests and the importance of obtaining some specific patient history information. The typical textbook presentation of the blood smears may not be seen by the technologist. It is very important that the smears be examined at length and under oil immersion. The most important thing to remember is that even though a low parasitemia may be present on the blood smears, the patient may still be faced with a serious, life-threatening disease. See Algorithm 7.1 for additional information.

Alternative Methods. Giemsa-stained thick and thin blood films have been used to diagnose malaria for many years and have always been considered the “gold standard.” However, a number of alternative methods have been developed, including different approaches to microscopy, flow cytometry, biochemical methods, immunoassay, and molecular methods (Table 7.9). The aim of these procedures has been to reduce cost, reduce requirements for expensive equipment, increase sensitivity, and provide simple, rapid methods that do not require conventional microscopy (22, 32, 37, 39, 51–53, 72, 77, 79).

Microhematocrit centrifugation, using the QBC tube (glass capillary tube and closely fitting plastic insert [QBC malaria blood tubes; Becton Dickinson, Sparks, Md.]), has been used for the detection of blood parasites. At the end of centrifugation of 50 to 110 μ l of capillary or venous blood (5 min in a QBC centrifuge [14,387 \times g]), parasites or RBCs containing parasites are concentrated into a small, 1- to 2-mm region near the top of the RBC column and are held close to the wall of the tube by the plastic float, thereby making them readily visible by microscopy. Tubes precoated with acridine orange provide a stain that induces fluorescence in the parasites. This method automatically prepares a concentrated smear that represents the distance between the float and the walls of the tube. The tube is placed into a plastic holder, a drop of oil is applied to the top of the hematocrit tube, a coverslip is added, and the tube is examined with a 40 \times to 60 \times oil immersion objective (the objective must have a working distance of 0.3 mm or greater).

Note. Although a malaria infection can be detected by the microhematocrit centrifugation method (which is more sensitive than use of the thick or thin blood smear), *appropriate thick and thin blood films must be examined to accurately identify the species causing the infection.*

Another approach uses the fluorescent dye benzothio-carboxypurine (Becton Dickinson, Mountain View, Calif.), which intensely stains nucleic acid. In fresh blood, the dye easily penetrates the RBC membrane and stains malarial parasites, with the asexual forms staining more intensely than the gametocytes. Under these circumstances, the white blood cell nuclei do not stain. However, when fixed, the dye penetrates and stains both malarial parasites and white blood cells. The advantages of this alternative to Giemsa-stained blood films, particularly in field laboratories, are the speed of staining and evaluation and the relatively low level of training necessary to provide consistent results. Another fluorescent dye that is used is 4',6-diamidine-2-phenylindole-propidium iodide. However, the one disadvantage for field work is the requirement for a fluorescence microscope. Additional work is continuing on the use of benzothio-carboxypurine, and a stable prestained slide system that eliminates the need for liquid-stain application is now available.

With the increase in drug-resistant *P. falciparum* cases in the tropics, it is no longer feasible to treat febrile patients empirically with inexpensive yet effective antimalarial agents. The substitution of newer, more expensive drugs mandates rapid, accurate, and inexpensive diagnostic procedures so that directed therapy can be provided. A *P. falciparum* antigen detection system, the ParaSight-F test (Becton Dickinson Europe), has been very effective in field trials and detected the histidine-rich protein 2 (HRP-2). This procedure is based on an antigen capture approach and has been incorporated in a dipstick format; the entire test takes approximately 10 min (Figure 7.13). Another test that detects HRP-2, also in the dipstick format, is the ICT Malaria Pf (AMRAD ICT). This test appears to perform well and is comparable to the ParaSight-F test; however, the false-positive rate appears to be lower in this procedure. The third dipstick format procedure, OptiMAL (Flow Inc.), uses monoclonal antibodies against species-specific parasite lactate dehydrogenase (pLDH). Its sensitivity and specificity appear to be similar to those of the HRP-2 assays, with similar limitations at lower parasitemias. An advantage of this method is its use in follow-up for posttherapy patients to confirm a cure; the test detects only viable parasites.

Other methods that have been developed include a dot blot assay that provides significant improvements over previously reported DNA-based procedures for the diagnosis of malaria. Another method permits direct detection of *P. falciparum* by using a specific DNA probe after PCR amplification of target DNA sequences. For PCR amplification, blood samples were lysed and filtered onto filter paper, and after being dried, a portion of the filter paper was added directly to the PCR mixture. PCR products were detected by using a nonisotopically labeled probe. Monoclonal antibodies have also been used with good specificity and relatively good sensitivity.

S. BELKIN

A number of recent studies have reported on the benefits of using PCR for detection of malaria; the high sensitivity, rapidity, and simplicity of some of the methods should be applicable to large-scale epidemiology studies, follow-up of drug treatment, and immunization trials. Detection is possible with as few as 5 or 10 parasites per μl of blood, confirming that PCR detects many more cases of low-level parasitemia than do thick blood films (12, 89).

Note. Potential diagnostic problems with the use of automated differential instruments have been reported (33, 106). Some cases of malaria, as well as *Babesia* infection, have been completely missed by these methods. The number of fields scanned by a technologist on instrument-read smears is quite small; thus, failure to detect a light parasitemia is almost guaranteed. In both cases, after diagnosis had been made on the basis of smears submitted to the parasitology division of the laboratory, all previous smears examined by the automated system were reviewed and found to be positive for parasites. Failure to make the diagnosis resulted in delayed therapy. Although these instruments are not designed to detect intracellular blood parasites, the inability of the automated systems to discriminate between uninfected RBCs and those infected with parasites may pose serious diagnostic problems in situations where the parasitemia is $\geq 0.5\%$.

Microscopic examination of a peripheral blood smear occasionally reveals ookinetes of *P. vivax* (or another of the *Plasmodium* species); this represents a potential “artifact” that could lead to the incorrect diagnosis of *P. falciparum* infection (Figure 7.11). The ookinetes tend to resemble the crescent-shaped gametocytes seen in infections with *P. falciparum*. The appearance of these stages in the peripheral blood, rather than the mosquito gut, was probably due to the delay between blood collection and smear preparation. It has been documented that some gametocytes (*P. falciparum*) exflagellate at room temperature (pH 7.4). In this case, the microgametes could resemble spirochetes (94).

KEY POINTS—LABORATORY DIAGNOSIS

Malaria

1. Blood films should be prepared on admission of the patient. A fever pattern may not be apparent early in the course of the infection.
2. Both thick and thin blood films should be prepared. At least 200 to 300 oil immersion fields on both thick and thin films should be examined before the specimen is considered negative.
3. Wright's, Wright-Giemsa, Giemsa, or a rapid stain can be used, although Giemsa is the stain of choice for blood parasites; the majority of the original organism descriptions were based on Giemsa stain. However, if the white blood cells appear to be well stained, any blood parasites present will also be well stained.
4. Malarial parasites may be missed with the use of automated differential instruments. Even with technologist review of the smears, a light parasitemia is very likely to be missed.
5. The number of oil immersion fields examined may have to be increased if the patient has had any prophylactic medication during the past 48 h (the number of infected cells may be decreased).
6. *One negative set of blood smears does not rule out malaria. Quantitate organisms from every positive blood specimen.*
7. In spite of new technology, serial thick-film parasite counts are a simple, cheap, rapid, and reliable method for identifying patients at high risk of recrudescence due to drug resistance and treatment failure.
8. If you are using any of the alternative methods, make sure you thoroughly understand the pros and cons of each compared with the thick and thin blood film methods; see chapter 31 for additional information on diagnostic methods for blood parasites.

Figure 7.7 Morphology of malaria parasites. *Plasmodium vivax*: (1) early trophozoite (ring form); (2) late trophozoite with Schüffner's dots (note enlarged RBC); (3) late trophozoite with ameboid cytoplasm (very typical of *P. vivax*); (4) late trophozoite with ameboid cytoplasm; (5) mature schizont with 18 merozoites and clumped pigment; (6) microgametocyte with dispersed chromatin; (7) macrogametocyte with compact chromatin. *Plasmodium malariae*: (1) early trophozoite (ring form); (2) early trophozoite with thick cytoplasm; (3) early trophozoite (band form); (4) late trophozoite (band form) with heavy pigment; (5) mature schizont with nine merozoites arranged in a rosette; (6) microgametocyte with dispersed chromatin; (7) macrogametocyte with compact chromatin. *Plasmodium ovale*: (1) early trophozoite (ring form) with Schüffner's dots; (2) early trophozoite (note enlarged RBC); (3) late trophozoite in RBC with fimbriated edges; (4) developing schizont with irregularly shaped RBC; (5) mature schizont with eight merozoites arranged irregularly; (6) microgametocyte with dispersed chromatin; (7) macrogametocyte with compact chromatin. *Plasmodium falciparum*: (1) early trophozoite (accolé or appliqué form); (2) early trophozoite (one ring is in the headphone configuration with double chromatin dots); (3) early trophozoite with Maurer's dots; (4) late trophozoite with larger ring and Maurer's dots; (5) mature schizont with 24 merozoites; (6) microgametocyte with dispersed chromatin; (7) macrogametocyte with compact chromatin. *Note:* Without the appliqué form, Schüffner's dots, multiple rings per cell, and other developing stages, differentiation among the species can be very difficult. It is obvious that the early rings of all four species can mimic one another very easily. *Remember: One set of negative blood films cannot rule out a malaria infection.*

Figure 7.8 *Plasmodium vivax*. (Top row) Ring forms (note that double rings are not limited to *P. falciparum* and that the RBC is beginning to enlarge as the rings grow). (Second row) Growing trophozoites (note the amoeboid nature of the trophozoites and the presence of Schüffner's dots). (Third row) Developing schizonts (note the number of merozoites). (Bottom row) Mature schizonts, female gametocytes, male gametocyte.

Figure 7.9 *Plasmodium malariae*. (Top row and second row) Band form developing trophozoites (note that the RBC is normal or slightly smaller than normal). (Third row) Developing schizonts (note the small number of merozoites). (Bottom row) Mature schizonts in a thick blood film.

Figure 7.10 *Plasmodium ovale*. (Top three rows) Developing trophozoites (note the nonameboid trophozoites, presence of Schüffner's dots, oval RBCs, and fimbriated edges of infected red cells). (Bottom row) Developing schizonts and gametocytes.

Figure 7.11 *Plasmodium falciparum* and *Babesia* spp. (Top row) *P. falciparum* ring forms (note the double rings per cell, appliqué or accolé form, and head-phone appearance of some rings). (Second row) Ring forms and gametocyte (note Maurer's clefts and crescent-shaped gametocyte). (Third row) Gametocyte, exflagellation of male gametocyte, and developing ookinete. (Bottom row) *Babesia* spp. (note the Maltese cross configuration of rings; these are not seen in every species of *Babesia*).

Treatment

Malaria has become a more common health problem during the last few years, both in residents of areas where the disease is endemic and in travelers returning to areas where it is not endemic. Therapy has become more complex because of the increase in resistance of *P. falciparum* to a variety of drugs and because of advances in treatment of severe disease complications (Tables 7.10 to 7.12). Antimalarial drugs are classified by the stage of malaria against which they are effective. These drugs are often referred to as tissue schizonticides (which kill tissue schizonts), blood schizonticides (which kill blood schizonts), gametocytocides (which kill gametocytes), and sporonticides (which prevent formation of sporozoites within the mosquito). To ensure that proper therapy is given, it is important for the clinician to know what species of *Plasmodium* is involved, the estimated parasitemia, and the geographic and travel history of the patient to determine the area where infection was probably acquired and the possibility of drug resistance related to that geographic area. The use of oral or parenteral therapy will be determined by the clinical status of the patient. A number of studies related to the molecular genetics of drug resistance, particularly in *P. falciparum* malaria and modeling of the development of resistance of *P. falciparum* to anti-malarial drugs, are ongoing (Tables 7.13 to 7.15).

Development of resistance to the inexpensive antimalarials, such as chloroquine and Fansidar (pyrimethamine in combination with sulfadoxine), has had a tremendous financial and public health impact on developing countries. In the late 1980s, chloroquine-resistant *P. falciparum* completely covered Africa. Resistance to pyrimethamine has also spread rapidly since the introduction of this drug. Fansidar is no longer effective in many areas of Indochina, Brazil, and Africa; also, severe allergic reactions have limited its use for chemoprophylaxis.

Although chloroquine-resistant *P. falciparum* is well recognized, chloroquine has generally been effective for both chemoprophylaxis and treatment of *P. vivax*, *P. ovale*, and *P. malariae* infections. Cases of chloroquine-resistant *P. vivax* (CRPV) malaria have now been identified in Papua New Guinea, Indonesia, Malaysia, Vietnam, and Myanmar. CRPV is now endemic in Malaysia, Myanmar, and Vietnam. However, there is no evidence of CRPV from Thailand, Cambodia, Laos, China, the Korean Peninsula, or the Philippine archipelago (Baird). Although CRPV has been documented in a few areas within South America (Guyana, Colombia, Brazil, Peru), it is present at a very low frequency, with a risk of infection at <5%. Population-based epidemiologic studies are necessary to define the geographic range and prevalence of CRPV. It is not clear whether this development represents a newly emerging public health problem; however, clinicians need

Figure 7.12 Intracytoplasmic malaria pigment seen within a polymorphonuclear leukocyte in a specimen from a patient with malaria. (Courtesy of Loyda Oduber, Jaime LaRoche, Pitágoras Ureña, and Cinthia Batista, Clinical Hospital San Fernando, Panama.)

to be aware that possible therapeutic or prophylactic failures may result when chloroquine is used for *P. vivax* infections in people who have been in Indonesia or Oceania.

Suppressive Therapy. Chemoprophylactic agents to prevent clinical symptoms are given to individuals who are going into areas where malaria is endemic (78). These

Table 7.9 Alternative approaches to malaria diagnosis^a

Principle of the method	Method	Comments	Pros	Cons
Giemsa-stained blood films, light microscopy	TBF and THBF, after cytocentrifugation (100 µl of lysed blood centrifuged onto slide, stained with Giemsa)	Traditional method; commercially available (used in histopathology labs)	TBF used to screen larger amount of blood; THBF allows visualization of parasite within RBC; generally thought to be more sensitive than rapid antigen tests, particularly for ID to the species level	TBF unable to see parasite within RBC; THBF provides less blood per exam
Fluorescent DNA-RNA stains	TBF and THBF films (e.g., acridine orange)	Commercially available	Sensitivity good	Requires expertise in reading
	After centrifugation (QBC)		Saves time, fairly sensitive	Expensive, species ID may be difficult
Molecular methods	Flow cytometry	Commercially available; low sensitivity	Automated counts	Low sensitivity due to “background noise”
	DNA-RNA hybridization	Poor sensitivity	“New approach”	Low sensitivity, cumbersome procedures
	PCR	Sensitive	Detect small numbers; species ID with mixed infections; used with blood spot collection	Lengthy procedure; automation may solve this problem
	Real-time PCR (QT-PCR)	Sensitive	Sensitivity of 20 parasites/ml of blood	Requires 500 µl of blood; takes 12 h longer than QT-NASBA
Malaria pigment detection	Real-time nucleic acid sequence-based amplification (QT-NASBA)	Sensitive	Sensitivity of 20 parasites/ml of blood	Requires 50 µl of blood; takes 12 h less than QT-PCR; lends itself to testing large numbers of samples
	Dark-field microscopy	Inferior to TBF	Pigment in WBCs sensitive indicator of prognosis	Not as sensitive as TBF
	Automated blood cell analyzers	Commercially available; detection of cases in patients not suspected as having malaria	Detects malaria pigment (WBCs, schizonts, gametocytes)	Nonspecific findings per species and parasitemia
	Depolarizing monocytes containing malarial pigment	Related to duration of symptoms before testing	Malarial pigment in monocytes	More obvious if parasitemia is ≥0.5%
Antigen detection	Pseudoreticulocytosis	Related to <i>P. falciparum</i>	Nuclear material from intraerythrocytic parasites	More obvious if parasitemia is ≥0.5%
	HRP-2 assays: ParaSight-F	Commercially available	Simple, rapid dipstick format; good correlation with conventional microscopy; may detect <i>P. falciparum</i> (chloroquine resistant) after patient treated for <i>P. vivax</i> (mixed infections)	<i>P. falciparum</i> only; drop in sensitivity at low levels of parasitemia (<100/µl); misses cases of only mature gametocytes (no HRP-2); false positives seen
	ICT Malaria Pf	Commercially available	Simple, rapid dipstick format; lower false-positive rate; good sensitivity, especially when coupled with microscopy	Some reagents must be stored at 2–8°C; cost may be a factor; more sensitive for placental malaria than microscopy
	MAKROmed	Commercially available	Antigen capture immunochromatographic strip format; more sensitive than conventional microscopy	Highly sensitive in detecting placental malaria, lower than expected specificity
	pLDH OptiMAL	Commercially available; test positive only with viable organisms	Simple, rapid dipstick format; also picks up <i>P. vivax</i> ; few false positives; good test of cure (picks up viable parasites only)	Similar limitations at low parasitemias (<0.01%); mixed-infection ID difficult; cannot replace microscopy

^a Adapted from references 22, 32, 37, 39, 51–53, 69, 71, 72, 77, 79, 89, and 106.^b HRP-2, histidine-rich protein 2; ID, identification; pLDH, parasite lactate dehydrogenase; RBC, red blood cell; TBF, thick blood film; THBF, thin blood film; WBCs, white blood cells.

Table 7.10 Antimalarial drugs and their actions^{a,b}

Stage affected	Antimalarial action by interference with:					
	Folic acid synthesis	Folic acid metabolism	Nucleic acid metabolism	Iron-dependent free-radical generation	Parasite components	Unknown
Erythrocytic cycle (schizonts)	Sulfonamides Sulfones	Proguanil Pyrimethamine	Quinine ^c Amodiaquine ^e	Artemisinins	Chloroquine ^d (food vacuole function) Atovaquone (acts on mitochondria)	
Erythrocytic cycle (gametocytes)		Proguanil	Proguanil			Primaquine ^f
Exoerythrocytic cycle		Pyrimethamine	Pyrimethamine			Primaquine

^a Format adapted from E. K. Markell and M. Voge, *Medical Parasitology*, 5th ed., The W. B. Saunders Co., Philadelphia, Pa., 1981; information updated from references 97 and 110.

^b Not every drug is included in this table; however, additional information can be seen in the references mentioned above.

^c Affects the formation of malarial pigment; may also block ion transport to the parasite; inhibits production of tumor necrosis factor.

^d Interferes with the normal function of the food vacuole and hence with maturation through the trophozoite stage; specific mechanisms include (i) binding to free heme to prevent its incorporation into malaria pigment, (ii) inhibiting aspartic and cysteine protease activity, and (iii) raising vacuolar pH above the pH optima of the aspartic and cysteine proteases in the food vacuole. Inhibition of DNA synthesis is no longer considered a likely mechanism for chloroquine action against the parasite.

^e Amodiaquine binds heme and inhibits heme polymerization; this is an action similar to that seen with chloroquine.

^f Primaquine is effective against gametocytes of all four species, unlike some of the other drugs which are partially effective; following administration of primaquine, documented swelling of mitochondria in malarial parasites.

Table 7.11 *Plasmodium falciparum* drugs and therapeutic use^a

Drug	Mechanisms of resistance	Clinical pharmacokinetics	Therapeutic use	Adverse effects and drug interactions
4-Aminoquinolones				
Chloroquine	Reduced cellular accumulation of drug; drug efflux mechanism; <i>pfcr</i> major chloroquine resistance gene	Rapidly absorbed after oral, intramuscular, or subcutaneous administration; half cleared by kidneys; terminal elimination half-life, 1–2 mo	<i>P. vivax</i> , <i>P. ovale</i> , <i>P. malariae</i> ; uncomplicated <i>P. falciparum</i> in semi-immune patients; nonimmune patients require other drugs due to risks of drug failure	Well tolerated; >250 µg/ml causes dizziness, headache, diplopia, nausea, and exacerbation of epilepsy; cumulative dose of >100 g over time leads to irreversible retinopathy
Amodiaquine	Cross-resistance between this and chloroquine; may also be <i>pfcr</i> gene	In contrast to chloroquine, extensively converted to metabolite	Higher efficacy in much of Africa; used alone or in combination with sulfadoxine-pyrimethamine	Hepatitis and agranulocytosis during prophylaxis; no longer recommended; metabolic antigen-generated immune response may occur
Antifolate drugs and combinations				Severe allergic reactions to sulfa drugs well known; dapsone has concentration-related problems (allergy, problems with G6PD deficiency); pyrimethamine, proguanil, chlorproguanil have little serious toxicity other than folate deficiency
Sulfadoxine-pyrimethamine	Both long elimination half-lives, causing selective pressure for resistance; mutations in <i>dhfr</i> and <i>dhps</i> genes	Pyrimethamine well absorbed after oral or intramuscular administration; sulfa drugs given for synergistic effects with pyrimethamine or chlorproguanil	Used to treat chloroquine-resistant infections in Africa; severe skin reactions mean that it has no prophylaxis use	
Proguanil	Prophylaxis, but deteriorating clinical response; short half-life		Alone for prophylaxis; fixed-ratio combination with atovaquone (Malarone) (see below)	
Chlorproguanil and dapsone	Used for treatment; short half-life			

(continued)

Table 7.11 (continued)

Drug	Mechanisms of resistance	Clinical pharmacokinetics	Therapeutic use	Adverse effects and drug interactions
Quinine	Less potent than chloroquine, small therapeutic range; resistance rare in Africa; not major clinical problem	Oral bioavailability high; intramuscular half-life varies at 10 to 40 min; extensive hepatic biotransformation	Used in combination with antibiotics (tetracycline) in Southeast Asia; parenteral first choice for severe malaria	Tinnitus, deafness, headache, nausea, visual disturbances in the majority of patients receiving therapeutic levels; however, dose reduction not recommended; more serious sequelae can be seen
Artemisinin group	Artemether, artesunate, dihydroartemisinin semi-synthetic derivatives of plant extract; high-cost drugs	Rapidly hydrolyzed in vivo to dihydroartemisinin; short elimination half-lives; artemether absorption slower, more variable if administered intramuscularly or intravenously	Used to treat severe malaria and as combination therapy	Generally safe and well tolerated; main concern is reproductive safety (long-bone shortening); cannot be used in first trimester (WHO)

^a Adapted from references 97, 110, and 112.

Table 7.12 Antimalarial drugs and associated problems^a

Drug	Associated problems ^b
Artemisinin (qinghaosu)	Recrudescence, neurotoxicity; short half-life
Atovaquone (Mepron)	Limited experience; rapid development of resistance when used alone; recrudescence common
Azithromycin	Limited use; efficacy to be determined
Chloroquine (Aralen)	Resistance worldwide except in Central America; appears to increase <i>P. falciparum</i> gametocytogenesis
Doxycycline	Phototoxicity; not used in pregnant women and children; gastrointestinal intolerance
Fansidar	Severe allergic reactions; resistance worldwide
Halofantrine (Halfan)	Cardiotoxicity, poor absorption, sporadic resistance
Mefloquine (Lariam)	Psychoses; resistance in Indochina and Africa
Primaquine	Narrow therapeutic index; not used in G6PD-deficient patients; resistance may be a problem
Proguanil (Paludrine)	Mouth ulcers; resistance worldwide
Quinine sulfate	Tinnitus; resistance in Brazil and Indochina
Quinidine gluconate	Limited availability; requires cardiac monitoring

^a Adapted from references 16, 70, and 83.

^b G6PD, glucose-6-phosphate dehydrogenase.

Table 7.13 Malaria resistance^a

Resistance definition	Comments
Sensitive	From initiation of therapy, asexual parasites are cleared by day 6; no evidence of recrudescence up to day 28 Peripheral blood films appear to go from positive to negative very quickly (can be a change from one draw to the second draw 6 h later)
Resistance type I (RI)	From initiation of therapy, asexual parasites have cleared for at least 2 consecutive days (the latest day being day 6); recrudescence follows Parasite count initially drops and blood films appear to be negative; patient should be monitored for a period of days, particularly if drug-resistant <i>P. falciparum</i> suspected
Resistance type II (RII)	Within 48 h of initiation of therapy, marked reduction of asexual parasitemia to <25% of pretreatment count; however, no subsequent disappearance of parasitemia (smear positive on day 6) Patient appears to be improving; parasite count drops, but blood films always appear positive
Resistance type III (RIII)	Modest reduction in parasitemia may be seen; no change or increase in parasitemia seen during first 48 h after treatment; no clearing of asexual parasites In some cases, parasite count continues to increase with no visible decrease at any time; blood films show overall parasite increase

^a Adapted from references 49 and 70.

Africa	Asia
Angola	Afghanistan (May–Nov)
Benin	Bhutan (southern areas)
Botswana (Nov–June, northern areas)	Cambodia ^b
Burkina Faso	China (Hainan Island and southern provinces)
Burundi	Indonesia ^c
Cameroon	Iran (Mar–Nov)
Central African Republic	Lao People's Democratic Republic ^d
Chad	Malaysia
Comoros	Myanmar (formerly Burma)
Congo	Nepal (areas other than Kathmandu, northern high-altitude areas)
Cote d'Ivoire	Oman
Djibouti	Philippines (Luzon, Basilan, Mindoro Palawan, and Mindanao islands; Sulu Archipelago)
Equatorial Guinea	Saudi Arabia (some areas)
Ethiopia (some areas)	Sri Lanka (some areas)
Gabon	Thailand
Gambia	Vietnam
Ghana	Yemen (Sept–Feb, some areas)
Guinea	
Guinea-Bissau	
Kenya	
Liberia	
Madagascar	Oceania
Malawi	Papua New Guinea
Mali	Solomon Islands
Mauritania (some areas)	Vanuatu
Mozambique	
Namibia (Nov–June, northern rural areas)	Indian subcontinent ^b
Niger	Bangladesh (north and east)
Nigeria	India
Rwanda	Pakistan (Rawalpindi)
São Tomé and Príncipe	
Senegal	
Sierra Leone	South America
Somalia	Bolivia
South Africa (northern and eastern Transvaal)	Brazil ^e
Sudan	Colombia
Swaziland (northern and eastern plains)	Ecuador ^f
Tanzania (some areas)	French Guiana
Togo	Guyana
Uganda	Panama (east of the Canal Zone including the San Blas Islands)
Zaire	Peru (northern provinces)
Zambia (all year in Zambezi valley, Nov–June rest of country below 1,200 m)	Suriname (some areas)
Zimbabwe	Venezuela (some areas)

^a There is no malaria risk in urban areas unless otherwise indicated. This table should be used in conjunction with the text in determining appropriate prophylaxis. (From *Morb. Mortal. Wkly. Rep.* 34[14], 1985.) Also see reference 14.

^b Malaria risk exists in most urban areas.

^c Malaria risk exists in urban areas of Timor and Kalimantan provinces. Irian Jaya should be considered as Oceania.

^d Malaria risk exists in all urban areas except Vientiane.

^e Malaria risk exists in urban areas of interior Amazon River region.

^f Malaria risk exists in urban areas of Esmeralda, Manabi, El Oro, and Guayas provinces (including the city of Guayaquil). From J. S. Seidel (ed.), *The Pediatric Clinics of North America: Pediatric Infections* 32:4, 1985.

Table 7.15 Drugs available in the United States for treatment of malaria^a

Tablets for oral use

Atovaquone-proguanil (Malarone), 250 mg of atovaquone/100 mg of proguanil
Chloroquine phosphate (Aralen and generics), 500 mg (300-mg base), 1,000 mg (600-mg base)
Hydroxychloroquine sulfate (Plaquenil), 400 mg (310-mg base)
Mefloquine (Lariam and generics), 500 mg (456-mg base), 750 mg (684-mg base)
Primaquine phosphate, 52.6 mg (30-mg base)
Pyrimethamine (Daraprim), 25 mg
Quinine, 180 mg, 325 mg
Quinine sulfate, 650 mg (542-mg base)

Ampoules for parenteral use

Chloroquine hydrochloride (200-mg chloroquine base, 5-ml vial) and quinine dihydrochloride
Quinidine gluconate, 800 mg (500 mg of quinidine) in 10 ml of sterile water

^aAdapted from CDC *Guidelines for Treatment of Malaria in the United States* (23 March 2005) (www.cdc.gov/malaria/pdf/treatmenttable.pdf). Also see Table 7.17 and chapter 25.

drugs are effective only against the erythrocytic forms and do not prevent the person from getting malaria; i.e., they do not prevent sporozoites from entering the liver and beginning the preerythrocytic cycle of development. The most commonly used drugs for this purpose are quinine, chloroquine, hydroxychloroquine, and amodiaquine, all of which are effective when the organisms enter the RBCs from the liver and begin the erythrocytic cycle. Fansidar is recommended for prophylaxis only for travelers who are staying for a long time in high-transmission areas where chloroquine-resistant malaria is endemic. This recommendation was based on revisions in response to increased numbers of adverse reactions to Fansidar prophylaxis, including severe mucocutaneous reactions, some of which were fatal (Table 7.12). In general, chloroquine is still the choice for prophylaxis against *P. falciparum*, but it is not totally effective against *P. vivax*. Resistance to Fansidar was reported in Thailand as early as 1981. Quinine is normally used in these situations; however, quinine-resistant *P. falciparum* has been reported in Africa, with little to no information on previous chloroquine intake. A combination of quinine and tetracycline is recommended for chloroquine- and Fansidar-resistant *P. falciparum*. Areas with chloroquine-resistant *P. falciparum* are listed in Table 7.14, and drug information is presented in Tables 7.15 and 7.16; specific dosage information is given in chapter 25.

Summary of Prophylaxis. With the introduction of chloroquine, with its high potency, long half-life, and low toxicity, continued research into the chemoprophylactic potential of other antimalarial agents such as primaquine was drastically reduced. Resistance to the newer chemoprophylactic drugs such as chloroquine, sulfadoxine/pyrimethamine (Fansidar), proguanil, mefloquine, and doxycycline continues to increase, with many of these agents now becoming clinically useless. Other antimalarial agents such as quinine, halofantrine, or the artemisinin deriva-

tives are too toxic or have too short a half-life to be used for prophylaxis. A summary of antimalarial drugs used for prophylaxis and their activity on different life cycle stages of the malaria parasite can be seen in Table 7.10.

Perhaps the most common approach to chemoprophylaxis in travelers to areas with multidrug-resistant *P. falciparum* is the use of doxycycline. However, this tetracycline derivative must be taken daily, and its use must be continued for 4 weeks after the patient has left the area. Potential side effects include diarrhea, upper gastrointestinal upset, and phototoxicity. Patients may also be predisposed to oral or vaginal candidiasis, and the drug cannot be given during pregnancy or to young children. Also, breakthrough can occur in individuals who have missed only a single dose.

Radical Cure. The radical-cure approach to therapy eradicates all malarial organisms, both the liver and the RBC stages, from the body. Therapy is usually given to individuals who have returned from areas where malaria is endemic; it prevents relapses with *P. vivax* or *P. ovale* infection, although relapses with both *P. vivax* and *P. ovale* infections occasionally occur after treatment with primaquine (8). The gametocytes are also eliminated, thus stopping the chain of transmission to the mosquito vector. The drugs used are primaquine and other 8-aminoquinolones. Treatment with primaquine is usually not necessary for malarial cases acquired by transfusion or contaminated needles or passed from mother to child as a congenital infection. More specific information can be found in chapter 25.

An increase in the incidence of malaria caused by *P. falciparum* is well recognized, and delays in diagnosis and subsequent therapy may result in complicated or fatal cases, particularly in nonimmune hosts. Some of the complications of *P. falciparum* malaria that have been discussed include cerebral malaria, renal failure,

TABLE 7.16 Drugs used for the prevention of malaria^a

Drug	Usage	Adult dosage	Pediatric dosage	Comments
Atovaquone/proguanil ^b (Malarone)	Primary prophylaxis in areas with chloroquine-resistant or mefloquine-resistant <i>Plasmodium falciparum</i>	250 mg of atovaquone/100 mg of proguanil hydrochloride; 1 adult tablet orally daily	62.5 mg of atovaquone/25 mg of proguanil hydrochloride 11–20 kg: 1 tablet 21–30 kg: 2 tablets 31–40 kg: 3 tablets ≥40 kg: 1 adult tablet daily	Contraindicated in persons with severe renal impairment; should be taken with food or a milky drink; not recommended for children <11 kg, pregnant women, or women breast-feeding infants weighing <11 kg.
Chloroquine phosphate (Aralen and generic) ^c	Primary prophylaxis in areas where chloroquine-sensitive <i>P. falciparum</i> is endemic	300 mg of base (500 mg of salt) orally once/week	5 mg/kg (base), 8.3 mg/kg (salt) orally once/week, up to maximum adult dose of 300 mg of base	Safe to take during pregnancy, including first trimester; may exacerbate psoriasis.
Doxycycline (many brand names and generic) ^d	Primary prophylaxis in areas with chloroquine-resistant or mefloquine-resistant <i>P. falciparum</i>	100 mg orally once/day	>8 years of age: 2 mg/kg orally/day up to maximum adult dose of 100 mg/day	Contraindicated in children <8 years of age; teeth may become permanently stained; may cause photosensitivity; contraindicated during pregnancy.
Hydroxychloroquine sulfate (Plaquenil) ^e	Alternative to chloroquine for primary prophylaxis only in areas with chloroquine-sensitive <i>P. falciparum</i>	310 mg of base (400 mg of salt) orally once/week	5 mg/kg (base), 6.5 mg/kg (salt) orally once/week, up to maximum adult dose of 310 mg of base	May be better tolerated than chloroquine; see chloroquine comment.
Mefloquine (Lariam and generic) ^a	Primary prophylaxis in areas with chloroquine-resistant <i>P. falciparum</i>	228 mg of base (250 mg of salt) orally once/week (tablet = 250 mg of salt)	5–10 kg: 1/8 tablet orally once/week 10–20 kg: 1/4 tablet once/week 20–30 kg: 1/2 tablet once/week 30–45 kg: 3/4 tablet once/week >45 kg: 1 tablet once/week The recommended dose of mefloquine is 5 mg/kg of body weight once weekly. Approximate tablet fraction is based on this dosage. Exact doses for children weighing less than 10 kg should be prepared by a pharmacist.	Contraindicated in persons allergic to mefloquine and in those with active depression or a previous history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures. Not recommended for persons with cardiac conduction abnormalities.
Primaquine (for primary prophylaxis)	An option for primary prophylaxis in special circumstances. Call Malaria Hotline (770-488-7788) for additional information.	30 mg base (52.6 mg salt) orally daily	0.6 mg/kg base (1.0 mg/kg salt) up to adult dose orally daily	Contraindicated in persons with G6PD ^f deficiency. Also contraindicated during pregnancy and lactation unless the infant being breast-fed has a documented normal G6PD level. Use in consultation with malaria experts.
Primaquine (for terminal prophylaxis)	Used for terminal prophylaxis to decrease the risk of relapses of <i>P. vivax</i> and <i>P. ovale</i> infection	30 mg of base (52.6 mg of salt) orally once/day for 14 days after departure from the malarious area Note: The recommended dose of primaquine for terminal prophylaxis has been increased from 15 mg to 30 mg for adults	0.6 mg/kg base (1.0 mg/kg salt) up to adult dose orally once/day for 14 days after departure from the malarious area Note: The recommended dose of primaquine for terminal prophylaxis has been increased from 0.3 mg/kg to 0.6 mg/kg for children	Indicated for persons who have had prolonged exposure to <i>P. vivax</i> and <i>P. ovale</i> or both. Contraindicated in persons with G6PD deficiency. Also contraindicated during pregnancy and lactation unless the infant being breast-fed has a documented normal G6PD level.

Atovaquone-proguanil (Malarone); self-treatment drug	Self-treatment drug to be used if professional medical care is not available within 24 h; medical care should be sought <i>immediately</i> after treatment	4 tablets (each dose contains 1,000 mg of atovaquone and 400 mg of proguanil) orally as a single daily dose for 3 consecutive days Seek medical care immediately after treatment	Daily dose to be taken for 3 consecutive days using adult-strength tablets : 11–20 kg: 1 tablet 21–30 kg: 2 tablets 31–40 kg: 3 tablets ≥41 kg: 4 tablets Seek medical care immediately after treatment	Contraindicated in persons with severe renal impairment (creatinine clearance, <30 ml/min). Not recommended for self-treatment in persons on atovaquone-proguanil prophylaxis. Not currently recommended for children weighing <11 kg, pregnant women, or women breast-feeding infants <11 kg. Malaria can be fatal; if a traveler develops a fever or other flu-like symptoms and professional medical care is not available within 24 h, a self-treatment dose of atovaquone-proguanil is recommended.
--	--	--	--	---

^a From Centers for Disease Control and Prevention, Travel Information (<http://www.cdc.gov/travel/malariadrugs2.htm>).

^b Take the first dose 1 to 2 days before travel to malarious areas; take doses daily, at the same time each day, while in the malarious area; take doses daily for 7 days after leaving such areas. Mefloquine should be taken on a full stomach, such as after dinner; most travelers have few, if any, side effects. However, side effects can include abdominal pain, nausea, vomiting, and headache.

^c Take the first dose 1 to 2 weeks prior to arrival in the malarious area; continue once a week on the same day of the week during travel to malarious areas and for 4 weeks after leaving such areas. Side effects could include gastrointestinal disturbance, headache, dizziness, blurred vision, insomnia, and pruritus, but these symptoms usually do not require discontinuation of the drug.

^d Doxycycline should be taken on a full stomach, such as after dinner; do not lie down for 1 h to minimize reflux; can predispose women to vaginal yeast infections; should *not* be used in pregnancy, by children younger than 8 years, or by persons allergic to tetracyclines. Doxycycline can also cause sun sensitivity, usually manifested as an exaggerated sunburn reaction. Persons taking this drug should use sunscreen that absorbs long-wave UVA radiation.

^e Used for travelers to Africa who cannot take the more effective drugs mefloquine or doxycycline; less-effective combination than taking mefloquine or doxycycline and may put them at higher risk for malaria (see also comments under footnote *c*).
/ G6PD, glucose-6-phosphate dehydrogenase.

respiratory problems, disseminated intravascular coagulation, blackwater fever, and hepatic dysfunction. Death is directly related to the level of parasitemia and onset of complications, with significant mortality related to >5% parasitemia in spite of appropriate parenteral therapy and supportive care. In these situations, the role of exchange blood transfusion may be appropriate for the following reasons: (i) rapid reduction of the parasitemia, (ii) decreased risk of severe intravascular hemolysis, (iii) improved blood flow, and (iv) improved oxygen-carrying capacity. Powell and Grima have published an excellent review of the use of exchange transfusion for treatment of malaria (80).

Exposure to both placental malaria and maternal human immunodeficiency virus (HIV) infection increases postnatal mortality to a greater degree than does the independent risk associated with exposure to either maternal HIV or placental malaria infection alone. Therefore, malaria chemoprophylaxis during pregnancy could decrease the impact of HIV transmission from mother to infant (Table 7.17).

New Drug Development. Past approaches used to identify potential new antimalarials involved empirical screening of many natural plant extracts, as well as synthesis of new analogs of compounds known to have activity against microbes, tumors, and/or malarial parasites. Primary studies involve in vitro cultures and animal models; secondary and tertiary screening is then undertaken. Very few compounds are selected for clinical evaluation due to financial, compound formulation, stability, toxicity, or efficacy problems encountered in preliminary testing. New approaches involving computerized structure-based drug design and molecular modeling represent significant improvements. Molecular biology methods have become very important and widely used in this development process.

Drug candidates are currently being identified and developed for further testing. With the continued increase in the number of multiple-drug-resistant strains of *P. falciparum*, these drug development efforts have resulted from renewed commitment and have been moved up the priority list. However, the process of antimalarial drug discovery, design, and testing is very long and complex, not to mention expensive. In the United States, a national average of 12 to 15 years and an investment of 200 million to 500 million dollars per licensed drug are expended.

There seem to be inconsistencies between malaria control initiatives and actual policy development and implementation. Current consensus seems to be that a policy change is urgent when high-level resistance occurs in 40% or more of treated patients, when parasitological

Table 7.17 Current issues related to maternal malaria, transmission, pathogenesis, and therapy options

Issue	Comments	Reference(s)
Naturally acquired <i>Plasmodium knowlesi</i> in human (Thailand)	The occurrence of simian malaria in humans emphasizes the possible importance of wild primate populations in malaria-endemic and disease transmission areas.	55
Perinatal mother-to-child transmission (MTCT) of HIV	Placental malaria controlled at low density may cause increase in immune responses that protect against MTCT. Uncontrolled, high-density malaria may disrupt placenta structure and generate antigen stimulus to HIV replication, thus increasing the risk for MTCT.	4
Chloroquine resistance in <i>P. vivax</i>	Chloroquine has been the drug of choice for <i>P. vivax</i> since 1946. No genetic mutations have been linked to chloroquine resistance in <i>P. vivax</i> infections. Some recommend mefloquine as alternative; daily doxycycline is also an option when combined with chloroquine. Malarone plus primaquine is the only available therapy with proven efficacy (>90%).	5
Chloroquine resistance in <i>P. falciparum</i>	By 1973 in Thailand, chloroquine replaced by a combination of sulfadoxine and pyrimethamine (SP); >10 African countries also switched their first-line drug to SP. In 1985 SP was replaced by mefloquine; resistance to mefloquine led to introduction of artemisinin as combination drug in the mid-1990s. New drugs cost more, have more side effects, take longer time for cure, and have more compliance problems than chloroquine. Another option would be to combine SP (better parasitologic response than chloroquine) with chloroquine (more rapid clinical response).	29, 50
Atovaquone-proguanil resistance in nonimmune North American traveler to West Africa (<i>P. falciparum</i>)	Atovaquone-proguanil is a useful agent for treating uncomplicated <i>P. falciparum</i> malaria (oral, short course, low side effects). PCR and sequence analysis confirmed the acquisition of a point mutation in the cytochrome <i>b</i> gene of the recrudescence isolate (known to confer high-level resistance to atovaquone by reducing the binding affinity of atovaquone). Also, in this case, suboptimal therapy may have played a role in the emergence of resistance.	61
Rapid elimination of asexual forms of <i>P. falciparum</i> (most effective way to prevent development of gametocytes)	Primaquine (mefloquine-primaquine) is not effective in the eradication of gametocytes in the primary infection and in the prevention of subsequent gametocytemia compared with artesunate therapy (mefloquine-artesunate). Recrudescence infections lead to subsequent gametocytemia, which drives drug resistance.	95
Distinguishing <i>P. falciparum</i> treatment failures from reinfections: PCR genotyping	Study in Tanzania: all samples contained multiple <i>P. falciparum</i> infections; primary and recrudescence parasites analyzed by PCR; some of the recrudescence parasites originated from new infections.	68
Fake antimalarials in Southeast Asia (major impediment to malaria control)	Myanmar, Lao People's Democratic Republic, Vietnam, Cambodia, Thailand: 53% of tablet packs labeled as "artesunate" contained no artesunate; 9% of mefloquine samples contained <10% of the expected amount of active ingredient.	25
Recrudescence in artesunate-treated <i>P. falciparum</i> cases (depends on parasite burden, not on parasite factors)	Artemisinin derivatives are first-line drugs in Thailand; no documented resistance to artemisinin. Patients with admission parasitemias of >10,000/μl had a 9-fold higher likelihood of recrudescence than did patients with lower parasitemias; recrudescence not due to resistance but to admission parasitemia.	54

response is poor, and when the costs of treatment failures are higher than those of treatments with a newer drug. Improved cooperation is needed between the private and public sectors regarding overall delivery of health care relevant to malaria control issues (73).

Overall Patient Care. It is very important to remember that patients who present to a medical clinic, office, etc., that does not have expertise in tropical medicine tend to receive suboptimal treatment. Malaria may not

be recognized, and the diagnosis may be delayed until it is no longer possible to save the patient. Improvements in obtaining the patient history, symptom recognition, presumptive diagnosis development, and treatment of malaria are mandatory to prevent severe illness and death among travelers.

Epidemiology and Prevention

Malaria is primarily a rural disease and is transmitted by the female anopheline mosquito. There are great

Table 7.18 Malaria epidemics in recent years: climatic change, population displacement, control policy failures, drug resistance^a

Geographic area	Comments
Central America	Agricultural development, irrigation changes, colonization, insecticide resistance have led to overall increase in malaria
South America	
Amazon rain forest	New settlement and mining has led to >500,000 cases/year in Brazil (>50% of malaria cases in the Americas) and 6,000–10,000 deaths
Peru	Prolonged rains, abnormally high temperatures, and long, humid summers have led to an increase in malaria
Africa	
Savanna and forest	Increasing chloroquine resistance; >50% of population is infected; and malaria is main cause of death in children, killing 1 in 20 younger than 5 yr.
Dry savanna and desert fringe	Increased rains and population movements have led to epidemics
Cities	Severe increased drug resistance, inadequate sanitation, overextended services, and increasing deaths in young adults are all factors
Burundi, Rwanda, neighboring countries	Mass refugee problem has led to worsening overall malaria situation
Botswana, Namibia, Swaziland, Zimbabwe	Exceptional rains and population movements have led to an overall increase in malaria
East African highlands and Madagascar	Cyclical epidemics related to meteorological changes, complicated by agriculture changes, deforestation, and population movements
Ethiopia	Repeated epidemics in highlands due to degradation of environment, drought and famine, and large-scale resettlement approaches
Azerbaijan, Iraq, Tajikistan, Turkey	Civil disturbances, population displacement, and intensified agricultural activities have led to an epidemic resurgence of malaria
Afghanistan	Interruption of control and displacement of populations due to war are responsible for 2 million to 3 million cases annually
South Asia: middle	Increased epidemics in tribal, forest, and hill areas; periodic epidemics in dry lands of northwestern India and Sri Lanka (pooling of river sources, environment conducive to vector breeding); over 2.5 million cases/yr
Cambodia, Lao People's Democratic Republic, Myanmar, Thailand, Vietnam	500,000 cases/yr; rapidly increasing risk in frontier areas of economic activity, often including illicit mining and civil unrest; most severe drug resistance in the world
Papua New Guinea, Philippines; Solomon Islands, Vanuatu	300,000 cases/yr, released to colonization of new areas

^a Adapted from the WHO/CTD Health Map, 1997, and reference 101.

variations in vector susceptibility to infection with the parasite, with many variations being related to differences in parasite strain. Even when the vector is present in an area, an average number of bites per person per day must be sustained or the infection gradually dies out. This critical level can be influenced by a number of factors, including the vector preference for human blood and habitation and the duration of infection in a specific area. Once an area is clear of the infection, there may also be a drop in population immunity, a situation that may lead to a severe epidemic if the infection is reintroduced into the population (101) (Table 7.18).

Immunity. There are some genetic alterations in the RBCs that confer natural immunity to malaria. Changes in the RBC surface interfere with attachment and invasion of merozoites. Changes in hemoglobin or intracellular enzymes interfere with parasite growth and multiplication (Table 7.19).

Duffy antigen-negative RBCs lack surface receptors for *P. vivax* invasion. Many West Africans and some American blacks are Duffy antigen negative, which may explain the low incidence of *P. vivax* in West Africa. In other areas of Africa, *P. vivax* is much more prevalent.

Partial resistance is seen in individuals with the sickle cell trait and in those with sickle cell anemia. Resistance is

Table 7.19 Host genetic factors in resistance to malaria^a

Factor ^b	Comments
Hemoglobin disorders	
Sickling disorders	Includes sickle cell disease (SS), heterozygous states for sickle cell gene and those for hemoglobin C (SC) or β -thalassemia (S-thal); carrier state for sickle cell gene is AS; widely distributed throughout tropical Africa, parts of the Mediterranean, the Middle East, and central India; hemoglobin S confers protection against <i>P. falciparum</i> malaria (the parasite cannot complete life cycle due to cell sickling and destruction; reduced oxygen levels result in diminished parasite growth; reduced rosetting of RBCs in sickle carriers; protection also related to hemoglobin structure and parasite inability to metabolize)
Hemoglobins C and E	Data relating to selective advantage against malaria less convincing than for hemoglobin S; reduced parasite invasion and impaired growth have been documented; data for hemoglobin E have shown inconsistent results
Hemoglobin F	Growth of <i>P. falciparum</i> reduced in presence of hemoglobin F, thought to be due to hemoglobin itself rather than RBC properties; higher levels of hemoglobin F during first year of life might offer protection (newborn infants and adults with persistent fetal hemoglobin production)
Thalassemia (α and β)	Distribution of β -thalassemia coincides with that of malaria; 70% reduction in clinical malaria and 50% reduction in risk; although not seen in all geographic areas, in Papua New Guinea high protective effect of homozygous state for α -thalassemia against complications of <i>P. falciparum</i> malaria; babies under 2 yr (homozygous for α^+ -thalassemia) had higher frequency of both <i>P. vivax</i> and <i>P. falciparum</i> but were resistant from 2 yr of age
Erythrocyte polymorphisms	
Glucose-6-phosphate dehydrogenase deficiency	Both female heterozygotes and male hemizygotes have reduced risk (around 50%) of developing severe malaria
Duffy-negative RBCs	Resistant to invasion by <i>P. vivax</i>
Ovalocytosis	Patients subject to severe malarial infection with high parasitemias; however, there is strong protection against cerebral malaria; structural change in RBC membrane interferes with binding of infected RBCs to vascular endothelium
Immunogenetic variants	
HLA genes	Each protective HLA type associated with 40–50% decrease in risk; these HLA types are common
HLA class I	HLA-A, -B, -C determine specificities of CD8 ⁺ T cells (cytotoxic, major role in defense against intracellular pathogens); HLA-B35 frequency reduced in children with cerebral malaria and those with severe malarial anemia
HLA class II	HLA-DR, -DQ, -DP determine specificities of CD4 ⁺ T cells that secrete cytokines and provide T-cell help for antibody production and action of other T cells; HLA-DRB1*1302–HLA-DQB1*1501 frequently reduced in children with severe malarial anemia
Cytokine, other immune response genes	
TNF	Major mediator of malaria fever; TNF is increased in children with cerebral malaria and markedly so in children with fatal cerebral malaria
MBL	Deficiency may be associated with increased susceptibility to infectious diseases; effect on malaria may be small to none
CD35	Also called complement receptor 1 (CR1); plays a role in rosetting; African variant of CR1 may protect against severe malaria

^a Adapted from reference 45.

^b HLA, human leukocyte antigen; TNF, tumor necrosis factor; MBL, mannose-binding lectin.

related to the sickling of hemoglobin S (HbS)-containing RBCs. Other factors include the formation of deoxyhemoglobin aggregates within the cells, the loss of potassium from sickled cells, and the fact that the parasites actually cause HbS cells to sickle.

Resistance to *P. falciparum* is also seen in glucose-6-phosphate dehydrogenase-deficient cells. Partial immunity to malarial infection is seen in areas where malaria is endemic when HbC, HbE, β -thalassemia, and pyruvate kinase deficiencies exist.

Figure 7.14 Bed nets used in malaria prevention. (A) Nets being dipped in a suspension of insecticide following purchase. For people to appreciate the value of the insecticide treatment, it is important for them to see the process. The nets are wrung out, placed in a plastic bag, and returned to the owner. Later, in the house, the net is laid directly on the bed and allowed to dry out. This must be done indoors to avoid direct exposure to the sun, which degrades the insecticide. (B) Net in place in the home. The occupant of the house in the Bagamoyo BedNet Project, Tanzania, is preparing for rest. The net is a rectangular design, which provides a better ventilating effect than the conical variety. (C) Rectangular bed net being set up outdoors to enable the collection of mosquitoes by the Centers for Disease Control and Prevention Light Trap suspended on the left. Nets for this use are not treated with insecticide. Mosquitoes attracted to the person sleeping under the net are attracted to the light and enter the trap. In the morning, the trap is removed and the collection will indicate which mosquito species are hunting outdoors for blood meals. Similar collections can be made indoors. (Courtesy of Clive Shiff, Johns Hopkins University, with permission.)

Infants are also relatively immune to malarial infections during the first year of life as a result of the presence of a large percentage of HbF, passive immunity from maternal antibodies, and diets deficient in *p*-aminobenzoic acid.

Both cellular and humoral immunities play a part in protection. However, immunity is species specific and in some cases even strain specific. It has also been noted that acute malarial infections can cause immunosuppression. Actual impairment of immune responses to vaccination after acute malaria has been documented.

Insecticide-Impregnated Bed Nets and Clothing.

Insecticide-impregnated bed nets have been widely used with various degrees of success. Important factors for the success of any bed net program include insect susceptibility to the particular insecticide used (often pyrethroids), high coverage with impregnated bed nets, high malaria incidence, good community participation at an acceptable sustained level, high mosquito densities when people go to bed, and a high proportion of *P. falciparum*. Bed net impregnation appeared to be somewhat more effective than DDT spraying (Figure 7.14) (65, 90, 111).

The use of permethrin-impregnated clothing has also been evaluated and has been found to reduce the incidence of both malaria and leishmaniasis by a large percentage in the absence of any other interventions. In addition to use by the military (93), permethrin-impregnated clothing for travelers has a number of advantages. First, this insecticide is not a repellent but actually kills mosquitoes, flies, and ticks on contact. Also, impregnated clothing fibers remain effective even after 3 months of repeated machine washing. Apparently, this approach, in which the clothing is soaked with the appropriate solutions, works better than use of an aerosol spray. It is recommended that travelers treat two sets of clothing to wear in high-risk situations. Permethrin liquid is available in the United States as Permanone.

Vaccines. The development of techniques for in vitro culture of *P. falciparum* has enhanced the ability to study parasite metabolism and mechanisms of attachment and invasion. Other studies involving genetic engineering techniques and serologic immunofluorescence tests have led to the development of genetic manipulation of *Escherichia coli* to produce proteins that are identical to the receptor protein on the parasite necessary for RBC attachment. With the use of these and other, newer techniques, progress toward vaccine production may lead to effective protection against malarial infections (6, 35, 36, 40, 63, 98).

Recently, increased funding through private and public partnerships has led the industrial sector to become more involved in vaccine research. There are now at least three vaccine candidates being studied in pediatric populations in field settings.

The Perfect Vaccine. A perfect malaria vaccine will induce immune responses to every stage of the complicated life cycle of *Plasmodium*. Different and distinct immune mechanisms operate against these different stages in the life cycle. Therefore, a multistage vaccine must be a multi-immune response vaccine. Development of these types of vaccines is required to reduce significantly the increasing numbers of malaria infections and deaths seen each year (35).

Pre-erythrocytic stage as vaccine target. A pre-erythrocytic-stage vaccine would prevent sporozoites from invading the liver or prevent liver-stage parasites from developing to maturity and releasing infective merozoites, or both. This type of vaccine would prevent disease (absence of RBC cycle and clinical symptoms) and the transmission of malaria (no gametocyte formation).

Erythrocytic stage as vaccine target. The asexual RBC stage vaccine would prevent or reduce morbidity or mortality by parasite load reduction. Neutralizing antibodies to parasite products (released during schizont rupture) or

inhibiting cytoadherence of infected RBCs in severe forms of malaria would thus reduce morbidity and mortality.

Sexual stage as vaccine target. A vaccine designed to induce immune responses to the sexual-stage antigens would provide no protection to the infected patient but would dramatically limit or eliminate transmission of the parasite within the community (it would destroy gametocytes, prevent fertilization, and prevent development of the parasite within the mosquito).

Multistage, multivalent, multi-immune response vaccine. One of the main advantages of the multistage vaccine is its ability to combat parasite variation. Organism variants that evade the immune mechanisms operating at one of the early stages in the life cycle would most probably be susceptible to one of the later-stage immune mechanisms. Antigenic characteristics of the parasite vary with the life cycle stages, and most antigens are not expressed during all stages but may be present only during a single stage. This mandates either total removal of the parasite in one form within the life cycle or partial removal of various stages, with the overall result being parasite elimination (40).

For a malaria vaccine to induce optimal and sustainable protection, both cellular and humoral responses will have to be elicited against multiple targets from the different life cycle stages. It appears that global malaria vaccine development will move forward on several fronts, hopefully leading to effective products available for clinical use (35, 40).

Overall Control of Malaria. The major determinants related to malaria transmission include (i) the parasite, with its many biological options and genetic diversity; (ii) the vector, with tremendous differences in behavior and transmission capability; (iii) the human host, with biological, behavioral, political, and social ramifications; and (iv) the environment, with tremendous changes such as altitude, temperature, rainfall, and global warming (Table 7.20). Relevant concepts for the control of mosquito transmission of human malaria parasites are listed in Table 7.21; examination of this aspect of malarial transmission control provides an excellent example of the complexities that exist.

Another critical aspect of control involves the safety of the blood supply. A number of factors impact the blood supply worldwide, including government policies and regulations, professional society standards, the donor pool (voluntary and/or paid), the ability of health care personnel to order blood when necessary, infectious-disease screening, posttransfusion adverse effects monitoring, and product-related side effects (88). A number of constraints will continue to impact the development of a global strategy for the control of malaria (Table 7.22).

Table 7.20 Epidemiology of malaria^a

Characteristic	Stable malaria	Unstable malaria
Transmission pattern	Occurs throughout the year; uniform intensity; pattern repeated yearly	Seasonal transmission intensity variable; dramatic epidemics likely
Community immunity	Strong resistance due to intense transmission	Reduced resistance due to low-level and variable transmission intensity
Age group affected	Mainly young children	All age groups
Control	Difficult	Easier
Major determinants relevant to malarial transmission	Parasite—different biology, genetic diversity Vector—air temperature, relative humidity, breeding sites, density, feeding times, resting places, life cycle Human host—genetic factors, acquired immunity, general health status, behavior patterns, political/social factors Environment—altitude, temperature, rainfall, flow rate of rivers and streams, global warming, colonization, group migrations, agricultural and building projects, deforestation	

^a Adapted from reference 49.

Table 7.21 Relevant concepts for the control of mosquito transmission of human malaria parasites^a

Concept	Discussion	Control relevance
Only mosquitoes in the genus <i>Anopheles</i> support the sporogonic development of human malaria parasites	A high degree of specificity exists between mosquito species and malaria parasites. Approximately 50 of the 500 <i>Anopheles</i> species mosquitoes are competent vectors of human malaria.	It is important to correctly identify vector species in nature and to target vector control to coincide with blood-feeding and resting behaviors of the vector species.
Infected humans carrying gametocyte-stage parasites are the “reservoir of infection”	The probability that mosquitoes will become infected depends on the number and quality of gametocytes present and ingested during blood-feeding.	Most antimalarials have no direct effects on gametocytes; thus, treated individuals may remain infectious for the mosquito vectors.
The rate of <i>Plasmodium</i> development in the mosquito depends primarily on temperature	The rate of development from ingested gametocytes to sporozoites in the salivary glands depends on temperature. Temperature also determines mosquito survival and the probability of mosquito infection.	These relationships play a large role in parasite survival and parasite growth, impacting both the probability and intensity of transmission.
A female mosquito can remain infective for life	The female anopheline mosquito is capable of transmitting sporozoites during each consecutive blood-feeding instance, occasionally to multiple individuals during each feeding cycle.	Mosquito control has multiple parameters for consideration.
Epidemiology of human infection associated with vector populations	Worldwide patterns of epidemics are associated with environmental and climatic factors that impact vector distribution, abundance, and blood-feeding behavior.	Personnel knowledgeable about environmental issues and the relationship between the environment and vector control are vital.
Parasite transmission intensity depends on both the numbers of biting vectors and the proportion of vectors carrying sporozoites in the salivary glands	Intensity of transmission depends on the entomological inoculation rate (EIR), which is the product of the biting rate and the proportion of mosquitoes with sporozoites. EIRs are expressed in terms of average numbers of infective bites per person per unit of time.	EIRs in Africa range from 1 to >1,000 infective bites/yr. EIRs of >5 bites/year are associated with malaria prevalence rates of >70% in human populations.
Both the frequency of sporozoite inoculation and dose per infectious bite are important determinants of human infection	Sporozoites inoculated by only a single mosquito can cause human malaria and serious illness, even death.	In areas of Africa where residents are exposed to <5 bites/year, some of the highest incidences of severe disease can be seen.
Marked reduction in transmission intensity is required to lower the prevalence of human malarial infection	An infection acquired by a single individual can be transmitted via mosquitoes to many uninfected individuals in a short time.	In some areas, EIR reductions of >95% are required before the malaria prevalence drops.
From a public health point of view, there are no acceptable levels of malaria transmission	Multiple factors are required for control efforts to be successful, including an integrated approach: drug therapy, vector control, and public health education at the community level.	Future efforts will include vaccines, new antimalarial drugs, and better vector control means. Public health will emphasize “control” rather than “eradication.”

^a Adapted from reference 10.

Table 7.22 Global strategy for malaria control: constraints^a

Problem	Comments
Misleading assumptions Malaria control is a vertical program Existing tools will not allow impact on morbidity and mortality Malarial control is sole responsibility of health sector Malaria in Africa is uniform and can be controlled by “magic bullet”	Misconceptions have led to reduced political and financial commitment at local, national, and international levels. Accelerated control programs have not been achieved due to lack of funding.
Shortage of people with appropriate knowledge	Little knowledge and understanding of malaria epidemiology and planning/management of control efforts. Peripheral health services not equipped for correct and adequate diagnosis and treatment. Very few countries have operational training programs in place.
Drug resistance; shortage of antimalarial drugs	Complicates the development of national antimalarial drug policies and provision of adequate disease management. Poor-quality antimalarial drugs; no mechanisms to ensure quality, availability, and rational use of affordable and effective drugs.
Poor collaboration	Inter- and intracollaborative efforts within and among countries poor. Surveillance systems and information exchange mechanisms limited; improvement is required for successful implementation.
Limited commitment from private sector	New links between research and development and malaria control needs are minimal; limited commitment to development of new tools for control. However, various initiatives aiming to develop malaria clinical research have recently been launched. Donators are public or international (Global Fund, Roll Back Malaria Initiative, National Institutes of Health [NIH], European Developing Countries Clinical Trial Partnership [EDCTP] program), as well as private (Bill & Melinda Gates Foundation). These substantial funds should enhance the research of new antimalarial drugs and large-scale, adequately designed trials.

^a Adapted from reference 101.

Babesiosis

When blood parasites are discussed, malaria is usually considered the most important and well-known infection. However, there is another organism that also causes human infection. Recognition of the spectrum of disease caused by organisms of the genus *Babesia* has recently resulted in an increase in the number of cases reported. Increased interest has also been generated because the infection can be transmitted via transfusion, can cause serious illness, particularly in compromised patients, and is difficult to treat (48).

The *Babesia* blood parasite was first discovered in cattle in 1888, and in 1893 it was recognized as the cause of Texas cattle fever transmitted by ticks (8). Cases of babesiosis have been documented worldwide, and several outbreaks in humans have occurred in the northeastern United States, particularly in Long Island, Cape Cod, and the islands off the East Coast (48). Although there are many species of *Babesia*, *Babesia microti* is the cause of most human infections in the United States.

A case reported from California occurred in a 24-year-old man who had been splenectomized in 1985 for an immune system-mediated thrombocytopenia and who was a U.S. Army officer stationed at Fort Ord in Monterey County. This is the third reported case of presumed indigenous transmission of babesiosis in patients in California, all of whom had been previously splenectomized.

Over the past few years, one patient from Washington and four from California were identified as being infected with a similar protozoal parasite, very similar in morphology to *Babesia* species; the Washington isolate was designated WA1. All four patients had undergone splenectomy, two as a result of trauma and two for medical reasons. Two of the four patients had complications, and one died. Piroplasm-specific nuclear small-subunit ribosomal DNA was recovered from the blood of the four patients by PCR amplification. Genetic sequence analysis showed that the organisms were almost identical. Phylogenetic analysis showed that this strain is more closely related to a known canine pathogen (*B. gibsoni*) and to *Theileria* species than to most members of the genus *Babesia*. Serum from three of the patients was reactive to WA1 but not to *B. microti* antigen. It now appears that there is a newly identified *Babesia*-like organism which causes clinical infections in the western United States. The spectrum of illness ranges from asymptomatic infection to fulminant, fatal disease (48). The first case of transfusion-transmitted babesiosis with the WA1 type has been reported from Washington state.

Studies in New York state indicate evidence of exposure to five tick-borne pathogens, including *B. microti*, in a high-risk population in the northeastern United States. There was also evidence of possible dual infection in some patients (46). In the same area, a cluster of transfusion-associated babesiosis cases was traced to a single asymptom-

atic donor; six patients were exposed, and three of these developed parasitemia (23). Environmental conditions necessary for the transmission of *B. microti* now appear to be present in areas of New Jersey, and physicians in central New Jersey should be aware of this potential threat.

A total of 10 cases of babesiosis have been reviewed, most of which were probably acquired in northwestern Wisconsin. Of 10 cases, 3 were fatal and occurred in elderly patients, who died after experiencing complications (44). These cases also serve to emphasize the importance of this potentially fatal zoonosis, which is not limited to the northeastern United States. In another case from western Wisconsin, a woman who had not traveled outside of Wisconsin was hospitalized and found to be infected with both *B. microti* and *Borrelia burgdorferi* (96).

Babesia spp. are grouped into the small *Babesia* spp. (1.0 to 2.5 μm), which include *B. gibsoni*, *B. microti*, and *B. rodhaini*, and the large *Babesia* spp. (2.5 to 5.0 μm) which include *B. bovis*, *B. caballi*, and *B. canis*. These phenotypic classifications are, for the most part, consistent with genetic characterization based on nuclear small-subunit ribosomal DNA sequences. The small *Babesia* spp. are more closely related to *Theileria* spp. than are the larger organisms. The one exception is *B. divergens*, which appears small on blood smears but is genetically related to the large *Babesia* spp. The two primary pathogens of humans are *B. microti* and *B. divergens*, along with the unnamed species WA1 (Washington), CA1 (California), and MO1 (Missouri) (42).

Life Cycle and Morphology

These organisms have at least three stages of reproduction within the life cycle: (i) gamogony (formation and fusion of gametes inside the tick gut), (ii) sporogony (asexual reproduction in salivary glands), and (iii) merogony (asexual reproduction in the vertebrate host). Infection is transmitted by several species of ticks in which the sexual multiplication cycle occurs. Several thousand sporozoites can be found in the dermis surrounding the tick's mouth during the final hours of attachment and subsequent feeding. When a tick takes a blood meal, the infective forms are introduced into the human host (Figure 7.15). The organisms infect the RBCs, in which they appear as pleomorphic, ringlike structures (Figure 7.16). They resemble the early trophozoite (ring) forms of malarial parasites, particularly *P. falciparum*. The organisms measure 1.0 to 5.0 μm , the RBCs are not enlarged or pale, and the cells do not contain stippling. Malarial pigment is never seen. The early form contains very little cytoplasm and has a very small nucleus. In mature forms, two or more chromatin dots may be seen. Occasionally, a tetrad formation, referred to as a Maltese cross, is seen (Figure 7.16).

Clinical Disease

It is suspected that the frequency of *B. microti* and WA1 infection in the United States is greater than the number of cases reported. Between 1970 and 1991, 136 cases were reported in New York, while between 1969 and 1998, 160 cases were reported in Nantucket. Babesiosis

Figure 7.15 Life cycle of *Babesia* spp. (Illustration by Gwen Gloege.)

Figure 7.16 Six examples of blood films containing the ringlike forms of *Babesia* spp. (A) Thick blood film containing numerous *Babesia* rings; (B to F) various ring forms, multiple rings per cell, some rings present outside of the red blood cells, and the typical image of the “Maltese cross” configuration of the four rings.

is usually a self-limiting disease; there are probably also asymptomatic and undiagnosed carriers. The mortality rate has been reported at about 5% (48).

However, infections caused by *B. divergens* in Europe are far more serious, with a mortality rate of 42%. Fatal cases of *B. divergens* have been reported in France, Britain, Ireland, Spain, Sweden, Switzerland, the former Yugoslavia, and the former USSR (113) (Table 7.23). In two patients from Austria and Italy, the DNA sequences were identical; however, in phylogenetic analysis, the organism clusters with *B. odocoilei*, a parasite of white-tailed deer that is related to *B. divergens* (41). Although human babesiosis is relatively new to Japan, it appears that a new type of *B. microti*-like parasite, the Hobetsu type, is the major type among Japanese wild rodents. Seroepidemiologic surveys of humans are under way to estimate the prevalence of *Babesia* infection among Japanese (102).

In the first four human cases (before 1969) within the United States, the patients had been splenectomized and three died as a result of the infection. Since then, other cases have been found in patients with intact spleens. In the patients from Nantucket Island, Mass., who were not splenectomized, symptoms began 10 to 20 days after a tick bite and continued for several weeks. The symptoms started with general malaise, which was followed by fever, shaking chills, profuse sweating, arthralgias, myalgias, fatigue, and weakness. Hepatosplenomegaly was present, and five patients had slightly elevated serum bilirubin and transaminase levels as a result of hemolytic anemia.

During the summer of 1980, six patients from Shelter Island and eastern Long Island were diagnosed as having

babesiosis caused by *B. microti*. Symptoms lasted for 19 to 24 days in five patients and included fever, shaking chills, dark urine, and headache, as well as anorexia, malaise, and lethargy. The one patient in the group who had been splenectomized also had the most severe illness. The parasitemia could not be detected in one patient, was 5% in four of the six, and was 80 to 90% in the splenectomized patient. Hamster inoculation produced a patent parasitemia in all cases.

By the end of 1991, 13 cases of babesiosis had been reported in Connecticut, this being the largest number of human cases reported on the mainland United States (1). Information from the patients suggests that 12 infections were acquired via tick bites and 1 was acquired from a blood transfusion. The ages of the patients ranged from 61 to 95 years for those with tick-acquired infections. Two patients died of active infections, and one died of chronic obstructive pulmonary disease. Indirect fluorescent-antibody titers ranged from 11,024 to 14,096, and five of eight patients had significant IgG or IgM titers (1,640 to 15,120) to *Borrelia burgdorferi*. *Babesia microti* from the blood of 7 of 12 patients tested was isolated in Syrian hamsters. It is now clear that babesiosis is endemic in New Jersey, as well as other areas of the northeast (43).

Babesia infections described in California and in other parts of the world are quite different from those seen in the northeastern United States, where the infection is most often subclinical. Infections in California and Europe tend to present as a fulminant, febrile, hemolytic disease affecting splenectomized or immunosuppressed individuals.

Table 7.23 Similarities and differences in *Babesia* spp.^a

Species ^b	Geographic location	Vector	Incubation period	Disease	Comments
<i>Babesia divergens</i>	Europe; relatively rare, but 42% mortality	<i>Ixodes ricinus</i>	1–3 wk	Sudden appearance, hemoglobinuria followed by jaundice; shock-like picture	Most patients splenectomized (frequent contact with cattle); bovine pathogen; same vector for Lyme disease
EU1 (<i>B. divergens</i> -like)	Italy, Austria	Not known, but probably <i>I. ricinus</i>	One patient had possible tick exposure 2 wk prior to symptoms	Fever, chills, confusion, jaundice	Both patients splenectomized; organism most closely related to <i>B. odocoilei</i> (infects white-tailed deer)
<i>Babesia microti</i>	United States: north-eastern and Great Lakes regions; range probably expanding to include as far south as New Jersey, parts of Europe, and Japan; mortality rate for clinically apparent infections 5%	<i>Ixodes scapularis</i> (<i>I. dammini</i>)	1–6 wk; up to 3 mo	Most cases are mild and resolve on their own; most severe cases have fulminating malaria-like infection; malaise, chills, myalgia, anemia, fatigue, fever; hepatomegaly and splenomegaly may be present; hemolytic anemia several days to few months (more common in elderly or asplenic individuals)	Age range 3 wk to 86 yr; most within 50–60 yr; most are normosplenic; Japanese strains appear to be <i>B. microti</i> -like
WA1	Washington	Not known, but <i>Dermacentor variabilis</i> , <i>Ornithodoros coriaceus</i> , and <i>Ixodes pacificus</i> found in areas where WA1 found	Not known	Splenectomized patients	Related to canine pathogen, <i>B. gibsoni</i> , but WA1 does not seem to infect dogs; highly virulent in hamsters
<i>Babesia divergens</i> -like	Washington	Not known	Not known	Asplenic 82-year-old male with high parasitemia (41.4%) and multiorgan dysfunction including renal failure; survived	Patient's serum reacted to <i>B. divergens</i> but not to <i>B. microti</i> or WA1
CA1	California	Not known	Not known	Splenectomized patient; 2 patients had complicated courses, and 1 died	This strain is more closely related to <i>B. gibsoni</i> and to <i>Theileria</i> species
MO1	Missouri	Not known	Not known	Parasitemia in 3–4%; systemic lupus erythematosus, diagnosed in 1979, taking prednisone; splenectomy in 1979	<i>B. divergens</i> -like; 72-year-old asplenic male
PB-1	Baboon colonies	Not known	Not known	Potential problems with organ xenotransplantation to human recipients	Most closely related to <i>B. microti</i> ; may be organism previously described as <i>Entopolypoides</i> ; issues include prevention of potential zoonotic transmission

Work suggests that species other than *B. microti* or the bovine parasites were involved (17).

The serum of an 82-year-old splenectomized man from Washington reacted to *B. divergens* but not to *B. microti* or WA1 antigens. This case emphasizes the point that unusual parasites may be detectable by blood film examination but

not by serologic or molecular testing for *B. microti* or WA1-type parasites (42). This is important to remember, since new organisms similar but not identical to a number of the well-known *Babesia* spp. may be identified in patients in different parts of the world. Without the manual examination of blood films, these organisms may be missed.

A case of transfusion-induced babesiosis accompanied by disseminated intravascular coagulopathy in an elderly patient was reported in 1982. Symptoms included fever, chills, nausea, arthralgias, and lethargy, which began after the patient received 2 units of packed RBCs during surgery. One of the donors had a high indirect fluorescent-antibody titer against *B. microti*, but the infection was confirmed only by hamster inoculation.

Diagnosis

Most documented human patients have had a low parasitemia; thus, both thick and thin blood films stained with Giemsa stain must be examined. When the organisms cannot be demonstrated in a suspected patient, blood can be inoculated intraperitoneally into a hamster or gerbil. The organisms can usually be demonstrated within a few days, with the same morphology as that seen in humans.

Serologic studies have been reported; however, cross-reactivity has been seen among different species of *Babesia* and several species of *Plasmodium*. False-positive results have been seen in patients with connective tissue disorders such as systemic lupus erythematosus and rheumatoid arthritis. Titers of 1:128 to 1:256 rarely represent false positives; however, blood donor screening at a 1:64 titer may result in occasional false positives. False-negative results can be seen in immunosuppressed patients or in patients from whom blood specimens are drawn early in the course of the infection. Use of the indirect fluorescent-antibody test is helpful in the diagnosis of *B. microti* infections, particularly chronic infections. This test is specific and sensitive and is the currently recommended serologic method. Antibody can usually be detected when patients are first diagnosed; titers can remain elevated for 13 months to 6 years.

Note. Potential diagnostic problems with the use of automated differential instruments have been reported. Cases of babesiosis and malaria have been missed when blood smears were examined by these methods. The number of fields scanned by a technologist on instrument-read smears is quite small; therefore, a light parasitemia will almost surely be missed. Failure to make the diagnosis results in a delay of a number of days before therapy is instituted. Although the majority of these instruments are not designed to detect intracellular blood parasites, routine use of the automated systems may pose serious diagnostic problems, particularly if the suspected diagnosis is not conveyed to the laboratory.

KEY POINTS—LABORATORY DIAGNOSIS

Babesiosis

1. Blood films should be prepared on admission of the patient. Travel history and/or possible exposure

to tick-infested areas, recent blood transfusion, or splenectomy information is very important.

2. Both thick and thin blood films should be prepared. At least 200 to 300 oil immersion fields should be examined before the smears are considered negative.
3. Wright's, Wright-Giemsa, Giemsa, or rapid stain can be used, although Giemsa is the stain of choice for blood parasites.
4. *Babesia* parasites may be missed by automated differential instruments. Even with technologist review of the smears, a light parasitemia is very likely to be missed.
5. There does not have to be any significant history of travel outside the United States. If organisms are seen, they mimic *P. falciparum* rings.
6. No morphological stages other than ring forms will be seen. The classic arrangement of the four rings (Maltese cross) is not always seen.
7. *One negative set of blood smears does not rule out a Babesia infection.*
8. The quantitative buffy coat system can also be used and has shown 100% correlation with Giemsa-stained peripheral blood smears for the detection of parasitemia in patients with babesiosis. However, confirmation of morphologic differences between *Babesia* and malarial rings might require examination of Giemsa-stained blood films.
9. The indirect fluorescent-antibody test and possibly PCR are recommended. Hamster inoculation is helpful but is neither realistic nor practical for most diagnostic laboratories.

Treatment

Often, babesiosis can be effectively managed with supportive care. Currently, the combination of clindamycin plus quinine has been recommended as the standard regimen for human babesial infection. However, failure to eliminate the organisms in some immunocompromised and HIV-infected persons has been reported (91). Based on recent findings, the use of azithromycin in combination with quinine may be considered as an alternative therapy for human babesiosis, especially in a situation of failure to respond to standard regimens (91). It also appears that azithromycin combined with atovaquone is another possibility (86).

Any person with babesiosis acquired in Europe should be treated on an emergency basis. Such patients should receive prompt specific therapy to reduce parasitemia and to prevent the extensive hemolysis and renal failure that may follow. Massive exchange transfusion may be required due to the rapidly increasing parasitemia characteristic

of the disease with *B. divergens*. The element of time becomes critical; with the onset of hemoglobinuria, rapidly increasing intravascular hemolysis leads to renal failure. Treatment for these seriously ill patients can include exchange transfusion, intravenous clindamycin, and oral quinine. Atovaquone has been suggested as an option, as have chloroquine, tetracycline, primaquine, sulfadiazine, and pyrimethamine, with variable results.

Epidemiology and Prevention

The public health notice that was distributed to the Nantucket Board of Health indicated that *Babesia* parasites are transmitted from mice to humans primarily by the bite of the deer tick *Ixodes scapularis* and that individuals with the infection may be asymptomatic. The notice indicated that prevention still relies on the avoidance of ticks or their prompt removal once detected, since there are apparently no fully effective tick repellents. If symptoms appear 1 to 2 weeks after a tick bite, a physician should be consulted. In a study of Block Island, R.I., from 1991 through 2000, the incidence of babesial infection appeared to be at least 10-fold greater than previously recognized elsewhere (59).

Another problem is related to blood donors. The duration of parasitemia following asymptomatic or symptomatic infection is not known. In areas where the infection is endemic, exclusion of blood donors who are febrile, who are known to have had babesiosis, or who have an anti-*Babesia* titer of 116 or higher may reduce the risk. However, until a practical, effective, and sensitive screening method is developed, cases of transfusion-induced babesiosis will probably continue to occur.

It is now well established that under blood-banking conditions (4°C for 30 days), *B. microti* can remain infective and that transfusion-acquired infection with this parasite could occur during the normal storage time for blood.

The most common and accepted approach used to protect humans from infection involves methods to reduce the tick density. A number of methods have been used, including spraying acaricidal emulsions on vegetation. Repellents are useful for personal protection; however, daily examination of the body surface of a person who may have come in contact with ticks is critical. If ticks are found, they should be removed immediately to take advantage of the time lag between attachment to the human and transmission of infection (usually 50 to 60 h).

Leishmaniasis

Old World leishmaniasis

Cutaneous

Visceral

New World leishmaniasis

Cutaneous

Visceral

Leishmania spp. are protozoa belonging to the family Trypanosomatidae (Table 8.1). They are obligate intracellular parasites that are transmitted to the mammalian host by the bites of infected sand flies. On the basis of development in sand flies, the genus *Leishmania* has been divided into two subgenera. In the subgenus *Leishmania*, the development of organisms is restricted to the anterior portion of the alimentary tract of the sand fly, while in the subgenus *Viannia*, the parasites develop in the midgut and hindgut of the sand fly.

Leishmaniasis is mainly a zoonosis, although in certain areas of the world there is primarily human-vector-human transmission. The World Health Organization estimates that 1.5 million cases of cutaneous leishmaniasis (CL) and 500,000 cases of visceral leishmaniasis (VL) occur every year in 88 countries. Estimates indicate that there are approximately 350 million people at risk for acquiring leishmaniasis, with 12 million currently infected (25).

Leishmaniasis refers to a diverse group of diseases, with the spectrum of disease depending on the infecting species. Disease syndromes range from self-healing cutaneous lesions to debilitating mucocutaneous infections, subclinical viscerotropic dissemination, and fatal visceral involvement. Since disease presentations vary considerably, a well-defined classification system based on clinical findings is difficult and sometimes confusing (6, 14, 16, 20, 30, 39, 59–61, 82). With recent outbreaks in many areas of the world, including Brazil, India, Italy, Spain, Sudan, and Kenya, leishmaniasis has become more widely recognized as an important emerging infectious disease in many developed as well as underdeveloped countries.

Cases of leishmaniasis are diagnosed each year in the United States and can be attributed to immigrants from countries with endemic infection, military personnel, and American travelers. Another concern is the potential for more infections occurring in areas of endemic infection in Texas and Arizona (37, 50). Organisms can remain latent for years, and even when the potential exposure history is in the past, leishmaniasis should be considered, particularly in immunocompromised patients such as those infected with human immunodeficiency virus (HIV) (19, 21, 53, 58, 61, 72, 76).

The taxonomy of the *Leishmania* spp. is controversial and reflects the development of multiple parameters on which classification is based. Previously, organisms were classified based on the clinical disease picture and geographic

Table 8.1 Taxonomic classification of *Leishmania* parasites pathogenic for humans^a

Taxon	Old World ^b				New World ^c			
Family	Trypanosomatidae							
Genus	<i>Leishmania</i>							
Subgenus	<i>Leishmania</i>				<i>Leishmania</i>		<i>Viannia</i>	
Complex	<i>L. major</i>	<i>L. tropica</i>	<i>L. aethiopica</i>	<i>L. donovani</i>	<i>L. donovani</i>	<i>L. mexicana</i>	<i>L. braziliensis</i>	<i>L. guyanensis</i>
Species	<i>L. major</i>	<i>L. tropica</i>	<i>L. aethiopica</i>	<i>L. donovani</i> <i>L. infantum</i>	<i>L. chagasi</i>	<i>L. mexicana</i> <i>L. venezuelensis</i> <i>L. garnhami</i> <i>L. amazonensis</i> <i>L. pifanoi</i>	<i>L. braziliensis</i> <i>L. peruviana</i> <i>L. colombiensis</i> <i>L. lainsoni</i> <i>L. shawi</i> <i>L. naiffi</i>	<i>L. guyanensis</i> <i>L. panamensis</i>
Hybrid species ^d							<i>L. braziliensis/L. panamensis</i> <i>L. braziliensis/L. guyanensis</i>	

^a The classification scheme is based on biochemical and molecular characteristics.

^b Animal parasites of the Old World (*L. arabica*, *L. turanica*, and *L. gerbilli*) are not listed.

^c Animal parasites of the New World (*L. aristedesi*, *L. enrietti*, *L. forattinii*, *L. deanei*, *L. equatorensis*, and *L. bertigi*) are not shown; although human infection with these species has not yet been identified, there is often a time lag between the discovery of new animal genera and confirmation of human infection. In many cases, the relevant vectors have been found to bite humans as well as the normal animal hosts.

^d Strains with phenotypic and genotypic characters of two species have been recorded in different geographic areas of Latin America; either they represent strains that originated from a common ancestor or they are the result of genetic exchange.

locations; with the development of criteria based on biochemical and genetic data, the taxonomic groupings no longer coincide with recognized disease entities.

Old World Leishmaniasis: Cutaneous Leishmaniasis

Leishmania major, *L. tropica*, *L. aethiopica*, and, rarely, *L. infantum* cause cutaneous disease in the Old World; disease manifestations include nodular and ulcerative skin lesions (Table 8.2; Figure 8.1). Local geographic names for CL include Oriental sore, Baghdad boil, Delhi boil, Biskra button, and Aleppo evil. Although Wright was credited with the first detailed description of the cutaneous form of the disease, it had already been described by Borovsky in 1898 in an obscure military medical journal.

Life Cycle and Morphology

The life cycle can be seen in Figure 8.2. The parasite is found in two morphologic forms in the life cycle, the amastigotes and the promastigotes. The amastigotes are small (3 to 5 μm in diameter), ovoid, nonmotile intracellular forms, while the promastigotes are elongated, motile, extracellular stages (1.5 to 3.5 by 15 to 20 μm with a single free flagellum 15 to 28 μm long) (Figure 8.3). The form introduced into the skin of the mammalian host by the sand fly is

the promastigote. The organism is engulfed by reticulo-endothelial cells (RE cells) of the mammalian host, where the parasite transforms into the intracellular amastigote form (Leishman-Donovan body). Apparently, this process takes approximately 12 to 24 h. The large nucleus and small kinetoplast in the amastigotes can be seen in tissue after staining with Giemsa or Wright's stain. The short intracytoplasmic portion of the flagellum can also be seen within some of the amastigotes. The amastigotes multiply by binary fission within the macrophage until the cell is destroyed, and the released parasites are phagocytized by other RE cells or ingested by sand flies. This phase is chronic and can last from months to years, even a lifetime, depending on the species involved. In CL, the amastigotes remain confined to the skin, usually as skin lesions such as raised papules or ulcers. Lesions usually occur on exposed parts of the body such as the face, hands, feet, arms, and legs; uncommon sites include the ears, tongue, and eyelids.

During a blood meal taken by the sand fly (genus *Phlebotomus*), amastigotes are ingested and transform into the promastigote stage. Promastigotes multiply by longitudinal fission in the insect gut. Stages found in the sand fly vary from rounded or stumpy forms to elongated, highly motile metacyclic promastigotes. The metacyclic promastigotes migrate to the hypostome of the sand fly, where they are inoculated into humans when the sand fly

Species and sand fly vector	Human disease and lesion	Geographic distribution	Important hosts	Comments
<i>L. major</i> : <i>Phlebotomus papatasi</i> , <i>P. duboscqi</i> , <i>P. salehi</i>	Cutaneous leishmaniasis (Oriental sore; rural, zoonotic); lesions may number >100; wet lesion with crusting; necrotic and exudative	North Africa, sub-Saharan Africa, Central and West Asia	Great gerbil (<i>Rhombomys opimus</i>), fat sand rat (<i>Psammomys obesus</i>)	Primarily an infection of desert rodents; gerbil infection rate may reach 30%; village inhabitants near gerbil burrows may have infection prevalence rates of 100%; major problem for rural settlers in Israel, military personnel in the Sinai Desert, Israel, Iraq, and Iran
<i>L. tropica</i> : <i>Phlebotomus sergenti</i> , <i>P. papatasi</i> , <i>P. chaudi</i>	Cutaneous leishmaniasis (Oriental sore; urban, anthroponotic); lesions usually ~2; lesions more swollen, less necrotic; less exudate than with <i>L. major</i> ; leishmaniasis recidivans also seen (chronic lesions on face or other exposed areas, persist for years)	Middle East, Mediterranean littoral, India, Pakistan, Central Asia, Iran, Iraq	Dogs and humans	Major epidemic of anthroponotic CL has occurred in war-ravaged Kabul, Afghanistan, with thousands of cases identified; responsible for viscerotropic syndrome in a small group of American military personnel infected in the Persian Gulf War; extensive scarring can lead to disfigurement; can last for up to 40 years
<i>L. aethiopica</i> : <i>Phlebotomus longipes</i> , <i>P. pedifer</i>	Cutaneous leishmaniasis, diffuse cutaneous leishmaniasis; lesions more swollen, less necrotic; barely exudative	Ethiopia, Kenya, bordering countries	Rock hyraxes (<i>Heterohyrax brucei</i> , <i>Procavia</i> spp.)	Human disease usually self-healing, small number develop nonhealing disseminated CL

takes its next blood meal. Various surface molecules on the promastigote, such as gp63 and lipophosphoglycans, help bind the parasite to the host macrophage receptors, thus allowing it to be phagocytized. Depending on the species, the duration of the life cycle in the sand fly varies from 4 to 18 days.

Sand flies are pool feeders and possess cutting mouthparts that slice into the skin, allowing a small pool of blood to form. Thus, although they are small flies (2 to 3 mm), the bite can be painful. In most endemic foci, the vast majority of sand flies are uninfected; however, those that are infected are very efficient vectors. Infected flies probably remain so for life, although this is just a matter of weeks. Under optimal conditions, transformation of the amastigotes to promastigotes generally takes 5 to 7 days; by that time, the female phlebotomine fly is ready to take her next blood meal.

Leishmaniavirus is a double-stranded RNA virus that persistently infects some strains of *Leishmania*. There is a great deal of interest in the possibility that the presence of this virus may be able to alter the parasite phenotype and may affect disease pathogenesis. The virus has been detected

in cultured parasites and has also been detected in human biopsy samples prior to manipulation in culture (68).

Clinical Disease

The incubation period of CL is usually 2 to 8 weeks but can be as long as several years. The first sign of cutaneous disease is a lesion (generally a firm, painless papule) at the bite site. Although a single lesion may appear insignificant, multiple lesions of *L. major* or disfiguring facial lesions of *L. tropica* may be psychologically or physically devastating. In general, all lesions on a patient have a similar appearance and progress at the same speed.

The original lesion may remain as a flattened plaque or may progress, with the surface becoming covered with fine, papery scales. These scales are dry at first but later become moist and adherent, covering a shallow ulcer. As the ulcer enlarges, it produces exudate and may develop a crust. The edge of the lesion is usually raised. Depending on the species, satellite lesions are common and merge with the original lesion (Figure 8.4).

***L. major* (Rural Disease).** *L. major* causes rural disease, a variety of CL. Multiple lesions are present and are

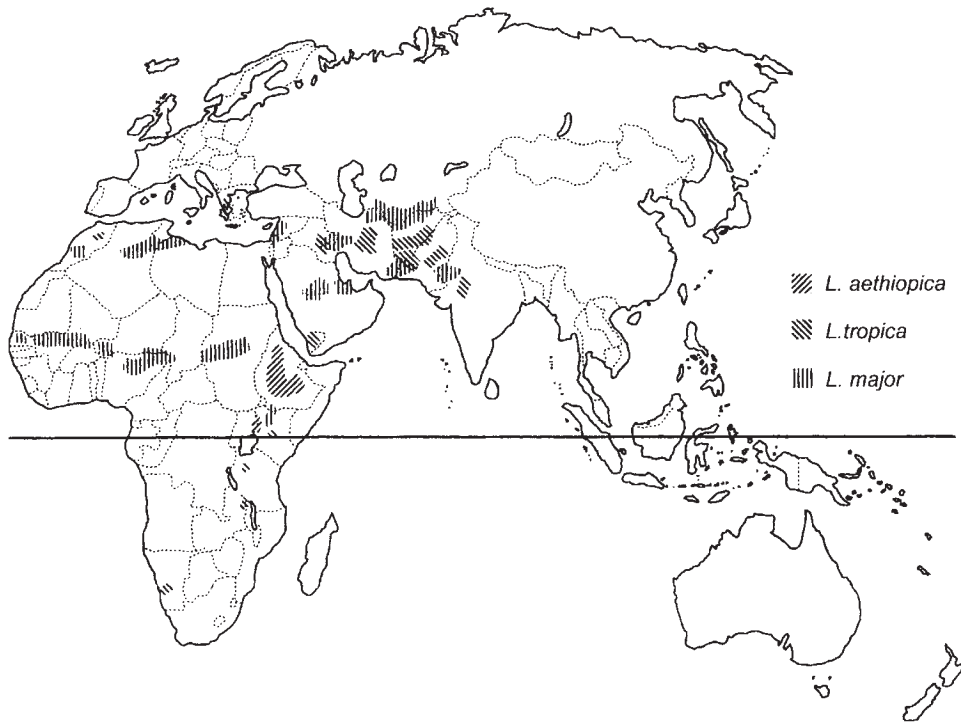

Figure 8.1 Geographic distribution of the agents of Old World cutaneous leishmaniasis.

accompanied by marked inflammation and crusting. The center of the lesion tends to be necrotic and exudative, forming a loose crust. The lesions tend to mature and heal relatively quickly, often lasting only a few months. Lymphatic spread may occur in *L. major* infections, with subcutaneous nodules in a linear distribution and regional lymphadenopathy; if the initial lesion is on the hand, this clinical presentation may resemble sporotrichosis. *L. major* infections may result in severe scarring.

From August 2002 to February 2004, over 500 cases of parasitologically confirmed cases of CL were found in U.S. military personnel serving in Afghanistan, Iraq, and Kuwait. The majority of these cases were probably acquired in Iraq, with *L. major* being confirmed for most of the cases through isoenzyme electrophoresis of cultured

parasites (16, 83). Based on the data from Fort Campbell, Ky., approximately 1% of troops returning from Iraq were diagnosed with CL, most by laboratory confirmation, including PCR.

***L. tropica* (Urban Disease).** The lesions of urban disease (a type of CL) caused by *L. tropica* occur singly or two at a time, develop more slowly than those caused by *L. major*, and can take a year or more to heal. They tend to be more swollen and less necrotic, with less exudate and a thicker crust.

***L. tropica* (Leishmaniasis Recidivans).** Leishmaniasis recidivans is generally associated with *L. tropica*. Small, nonulcerating lesions begin to appear, mainly on the

Figure 8.2 *Leishmania* life cycle.

Figure 8.3 *Leishmania* stages found in human and insect hosts. (Illustration by Nobuko Kitamura.)

margins of healed lesions, and continue to expand the limits of the original scar. Disfigurement due to extensive scarring can develop. This condition is thought to be associated with a strong cell-mediated immune response and tends to occur primarily in Iran and Iraq. Although there is a strong immune response on the part of the host, not all amastigotes are eliminated, and the infection can last for up to 40 years. The patient's physical appearance, as well as histologic sections, resembles cutaneous tuberculosis; therefore, the name "lupoid leishmaniasis" has also been used. Parasites may be very difficult to demonstrate; however, culture or animal inoculation has been successful. The leishmanin skin test (LST) (Montenegro test) is strongly positive in these patients.

***L. aethiopica* (Cutaneous Leishmaniasis).** Lesions of CL caused by *L. aethiopica* are the least inflamed but are more swollen. There may be very little exudate, but scaling and exfoliation of the dermis occur. These lesions tend to remain for years prior to complete healing.

***L. aethiopica* (Diffuse Cutaneous Leishmaniasis).** Diffuse "disseminated" CL (DCL) is an anergic form of CL in which neither humoral nor cell-mediated immune responses are functional; however, delayed hypersensitivity to tuberculin appears to be normal. DCL is caused by *L. aethiopica* and is seen in Ethiopia and Kenya; approximately 100 cases have been reported. The parasites are found in the skin, and the disease is characterized by the formation of thickened skin in plaques, papules, or multiple nodules. This condition is similar to that associated with the specific anergy in lepromatous leprosy, and DCL was originally confused with and thought to be leprosy. Although lesions are usually seen on the face, nose, limbs, and buttocks, they can occur over the entire body. The nodules are often described as soft and fleshy, while those of leprosy are generally more indurated. Although organisms have rarely been recovered from blood or bone marrow, there are no visceral lesions associated with this form of leishmaniasis. Treatment is difficult,

Figure 8.4 (Top) Cutaneous leishmaniasis facial lesion. (Armed Forces Institute of Pathology photograph.) (Middle) Examples of cutaneous lesions on the hand and arm. (Bottom) Extensive cutaneous lesion on the hand.

and the infection may last for the life of the patient. The LST remains negative unless treatment is effective and recovery occurs.

Diagnosis

In areas of the world where physicians are very familiar with leishmaniasis, the diagnosis may be made on clinical grounds. However, in other areas of the world, where the disease is rare, the condition may not be recognized. Definitive diagnosis depends on demonstrating the amastigotes in tissue specimens or the promastigotes in culture (Table 8.3). CL may have to be differentiated from a number of other lesions and diseases, including basal cell carcinoma, tuberculosis, various mycoses, cheloid, and lepromatous leprosy.

Specimen Collection. CL normally presents with no visceral involvement or systemic disease. The ability to detect parasites in aspirates, scrapings, or biopsy specimens depends on the number of amastigotes present, the level of the host immune response, the absence or presence of bacterial and/or fungal contamination within the lesion, and whether the specimen is collected from an active or healing lesion. If the patient has multiple lesions, specimens should be collected from the more recent or active lesions. These lesions should be thoroughly cleaned with 70% alcohol, and necrotic debris should be removed to prevent the risk of bacterial and/or fungal contamination of the specimen. This is mandatory if cultures are to be used for isolation and growth of the parasites; excess bacterial or fungal contamination prevents development of the promastigote forms. Also, the

specimen should be taken from the advancing margin of the lesion; the central portion of the ulcer contains nothing but necrotic debris.

If specimens are collected by aspiration, scraping, or biopsy, local anesthesia may be used to reduce patient discomfort. The specimen of choice would be a collection of several punch biopsy specimens taken from the most active lesion areas. Biopsy specimens can be divided and used for cultures and touch preparations; some material should always be saved and submitted for routine histology. If biopsy specimens need to be divided, material for culture should be obtained by using sterile techniques and instruments. The biopsy specimen can be used to make impression smears (touch preparations); these smears should be prepared after portions of the specimen have been placed in culture media by using a sterile technique. After any excess blood is cleaned off, a horizontal cut is made through the biopsy core and the cut surface is gently touched to glass slides; multiple slides should be prepared. Once material has been set up for culture and touch preparations have been made, the remainder of the tissue can be sent to the pathology laboratory for routine processing. It is important to remember that the amastigotes are more difficult to identify in tissue sections than in touch preparations; they appear smaller and may be cut at different angles.

Another option involving sterile techniques is to make a perpendicular slit in the margin of the lesion. After blood is removed with sterile gauze, the blade can be used to scrape the inner walls of the slit. Material can be inoculated into culture media and can be smeared onto several glass slides; the use of multiple slides is recommended to increase the chances of seeing the

^a For culture, specimens must be collected aseptically, and in older lesions the parasites may be scant and difficult to recover. Animal isolation involves hamsters and culture media (Novy-MacNeal-Nicolle medium and Schneider's *Drosophila* medium with 30% fetal bovine serum). Serologic testing is most suitable for VL, has little value for CL, and has limited value for MCL. The Montenegro test (LST) is a delayed-hypersensitivity reaction to intradermal injection of cultured parasites.

^b Additional information on relevant diagnostic methods can be found in chapters 31 and 32.

parasites. Fine-needle aspiration can also be performed with a sterile syringe containing sterile saline (0.1 ml) and a 26-gauge needle. The needle is inserted into the outer border of the lesion and rotated several times, after which saline is injected and tissue fluid is aspirated back into the needle. Material can be submitted for culture, and/or smears can then be prepared for staining. Additional techniques and specific methods can be found in chapters 30 to 32.

Specimen Staining. All smears to be Giemsa stained should be air dried and fixed with 100% methanol prior to staining. Other blood stains can also be used. The amastigotes are found within the macrophages or close to disrupted cells. Although this intracellular form may mimic other intracellular parasites (*Histoplasma capsulatum* and some of the microsporidia), the presence of the intracytoplasmic kinetoplast confirms the identification. After staining, the cytoplasm appears light blue and the nucleus and kinetoplast appear red to purple. In very early and older lesions, very few organisms may be present, so that prolonged examination of the slide may be required.

Culture Media. Media used for the growth of *Leishmania* spp. will also support the growth of bacteria and fungi, hence the need for aseptic techniques in collecting the clinical specimen. If cultures become overgrown with contaminating organisms, the parasites will not survive. It is also important to release the organisms from tissue prior to culture; mincing is recommended. However, tissue grinders are not recommended because of possible damage to the organisms. Culture media that have been used for the recovery and growth of leishmaniae include Novy-MacNeal-Nicolle medium and Schneider's *Drosophila* medium supplemented with 30% fetal bovine serum (see chapter 32). A number of newer medium formulations have also been developed and may prove very useful. These include a completely defined medium without serum and macromolecules (52), a semisynthetic fetal calf serum-free liquid medium (2), a new liquid medium with less expensive chemicals (40), and a sensitive new microculture method involving microcapillary tubes (3). Patient cultures should not be set unless the laboratory maintains specific organism strains for quality control checks. Both the control and patient cultures should be examined twice a week for the first 2 weeks and once a week thereafter for up to 4 weeks before they are reported as negative. Promastigote stages can be detected microscopically in wet mounts taken from centrifuged culture fluid. This material can also be stained with Giemsa stain to facilitate observation at a higher magnification. A number of molecular methods have been developed for species identification of the promastigotes, including the use of

DNA probes, isoenzyme analysis, PCR, and monoclonal antibodies (18, 46, 62, 84).

Animal Inoculation. Animal inoculation can be helpful when only a small number of organisms is present; however, most laboratories no longer consider this approach practical. Golden hamsters are inoculated intranasally, and the major argument against this approach is that it may take several months before the animal gives positive responses. A combination of tissue smears, culture, animal inoculation, and histopathology may be required for optimal diagnosis.

Skin Test. The LST (Montenegro test) is useful for epidemiologic population surveys to detect groups at risk for infection. However, the test is not species specific and must be interpreted with caution, particularly since some patients may have more than one type of leishmaniasis. Apparently, cross-reactions do not occur with African or American trypanosomiasis. The LST involves a delayed-hypersensitivity reaction to a suspension of killed promastigotes. The reaction is read at 48 and 72 h after injection. Positive reactions are generally seen in patients with cutaneous lesions; however, those with DCL give negative reactions.

Serologic Tests. Although available for epidemiology and/or research studies, serologic tests are not very useful for the diagnosis of cutaneous leishmaniasis. Reagent availability is usually limited to areas of endemic infection. Antibody detection is variable in patients with CL; if antibody is present, titers are usually low, and cross-reactions have been seen in patients with leprosy. Patients infected with the viscerotropic form of *L. tropica* seen during Operation Desert Storm have had low or undetectable antibody titers (26).

KEY POINTS—LABORATORY DIAGNOSIS

Old World Leishmaniasis: Cutaneous Leishmaniasis

1. For a complete laboratory diagnosis, microscopic examination of Giemsa-stained touch preparations and cultures is recommended.
2. Aspirates or biopsy specimens should be taken from the margin or base of the most active lesion (papule or ulcer). The lesion should be cleaned before the sample is collected, to reduce the chances of contamination with fungi or bacteria.
3. Multiple slides should be prepared for examination.
4. Tissue imprints or smears should be stained with Giemsa stain (or one of the stains commonly used for blood smears) (see chapter 31).

5. Amastigote stages should be found within macrophages or close to disrupted cells.
6. If cultures are to be performed, specimens must be taken aseptically and control organism cultures should be set up at the same time (see chapter 32).
7. Cultures should be checked weekly for 4 weeks before they are declared negative.

Treatment

Most Old World CL lesions are self-healing over a period of a few months to several years. This healing process confers immunity to individuals living within the immediate area of endemic infection; therefore, treatment is not recommended unless disfiguring scarring is a possibility. Chemotherapy should be given to patients with lesions on the face, particularly if the lesions are multiple or large. Pentavalent antimonials (sodium stibogluconate [Pentostam] and meglumine antimoniate [Glucantime]) are usually effective but must be given in adequate doses for the complete recommended time frame, often weeks or months (see chapter 25). Toxicity does not usually present a problem. Specific chemotherapy, including systemic administration, is used much less frequently for Old World leishmaniasis than for the New World disease presentations. The lesions of leishmaniasis recidivans respond to Pentostam at doses used for treatment of VL, and local heat therapy and intralesional injections are commonly used in the Middle East. In treating DCL, pentamidine, given as a single weekly injection for at least 4 months longer than it takes to eliminate parasites from slit skin smears, seems to be a good compromise between efficacy and toxicity. Cutaneous lesions, whether treated or not, should always be cleaned and covered to prevent secondary infections and vector access to the lesion.

In addition to chemotherapy, other more local treatment options have included cryotherapy, heat, and surgical excision of lesions (83). Organisms within the *L. tropica* group do not survive in temperatures above 37°C, and local heat therapy has proven to be effective. The temperature within the lesion should reach 40 to 42°C for 12 h at a time; this can be accomplished by using an infrared heat lamp. The use of hot water in baths or saunas has been helpful in cases of DCL, particularly since the response to chemotherapy is poor.

The administration of Pentostam as direct injections into the lesion has also been used. The dose is divided into four parts and injected into four different quadrants of the lesion (59). Another approach involves the application of a topical formulation of 15% paromomycin–12% methylbenzethonium chloride in soft white paraffin (P ointment or the “El-On” preparation), which decreases the healing time by half. Since this preparation causes

multiple local reactions, a number of other preparations have been tried, some effective and some no better than the placebo. The exact formula and optimal dose have not yet been finalized; however, formulations containing paromomycin appear to be very promising (73).

Epidemiology and Prevention

L. major, the cause of rural Oriental sore, is a zoonotic parasite and is found primarily in desert rodents such as gerbils that live in the dry desert areas of central Asia, in southern Russia, throughout Iran and Pakistan, in parts of Iraq, and in northwestern India and China. In areas of Libya, Saudi Arabia, and Israel, the rat is an important host. The infection is maintained in the reservoir population by sand flies that frequent rodent burrows. Human disease is maintained through the vectors *Phlebotomus papatasi* in Sudan and *P. duboscqi* elsewhere.

L. tropica, the cause of urban CL, has been isolated from dogs and rats; however, the human is considered to be the primary reservoir and source of infection. Various phlebotomine sand flies (*P. sergenti* and *P. papatasi*) transmit the infection, depending on the specific geographic area; areas of endemic infection include southern France, Italy, some Mediterranean islands, the Middle East, Greece, Pakistan, and northwestern India. In the first half of the 20th century, 40 to 70% of Europeans living in Delhi became infected. A major epidemic of CL due to *L. tropica* has occurred in war-ravaged Kabul, Afghanistan, with thousands of cases identified in the displaced population.

L. aethiopicum is also a zoonotic parasite, primarily involving the rock hyrax (*Procapra habessinica*) and the tree hyrax (*Heterohyrax brucei*). The organism is found in the Rift Valley in Ethiopia and Kenya. As human habitation moves into deforested mountain areas, exposure to the hyrax becomes much greater and coincides with the vector, *P. longipes*, while *P. pedifer* is implicated in Kenya.

Preventive measures involve vector control; residual spraying with DDT as a means of malaria control was very helpful. However, with the decline and total cessation of spraying in many areas, the leishmaniasis has returned. The infection can also be transmitted by direct contact with infected lesions and mechanically through bites by the stable or dog fly (*Stomoxys* spp.); lesions should be kept covered to prevent this type of transmission by primary or secondary vectors. Application of insect repellents to the skin has also been effective. Although reservoir control has been unsuccessful in most areas, disease incidence has been reduced by poisoning or deep plowing gerbil burrows.

In areas of Russia, Israel, Iran, Iraq, and Jordan where CL is endemic, vaccination has been used for many years. Exudate from a naturally acquired lesion can be

inoculated onto an inconspicuous area of the body of a nonimmune person. Another approach is to use live, attenuated *L. major* promastigotes, which are inoculated intracutaneously. The infection is allowed to develop and is usually limited to a single lesion; self-cure proceeds as in a natural infection. The immunized individual will become a carrier and source of infection until the lesion heals; a very small percentage of those vaccinated will develop lesions requiring treatment. Lifelong immunity to the homologous species develops and is comparable to that following a natural infection.

Old World Leishmaniasis: Visceral Leishmaniasis

VL (kala azar or dum dum fever) is caused by *L. donovani* and *L. infantum* in the Old World (Figure 8.5). *L. tropica* also causes classical kala azar in India and causes viscerotropic leishmaniasis in the Middle East. The two main species tend to cause similar diseases, although *L. infantum* mainly affects young children and has a greater tendency to cause lymph node enlargement. The course of the disease and outcome depend on the general health status of the patient at the time of infection; apparently malnutrition exacerbates *L. infantum* infection (9). Dermotropic strains of *L. infantum* are known to cause visceral infection in immunocompromised patients with AIDS. VL is very prevalent among AIDS patients in certain geographic areas (e.g., southern

Spain), with a high proportion of cases being subclinical. Like other opportunistic infections, subclinical VL can be found at any stage of HIV-1 infection, but symptomatic cases appear mainly when severe immunosuppression is present. HIV-*Leishmania* coinfection is being seen more and more frequently in the Mediterranean basin, especially in Spain, France, and Italy.

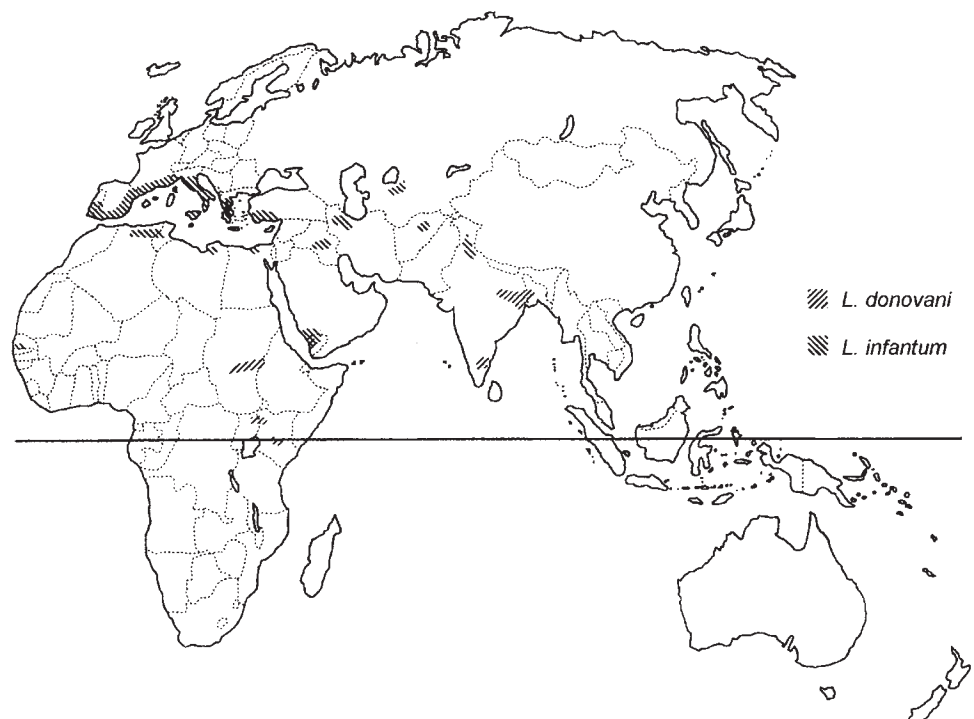

Life Cycle and Morphology

The life cycle and morphology of the organisms are essentially the same as for those causing Old World CL (Figure 8.2). However, amastigotes can be found throughout the body and are not confined to the macrophages of the skin. Organisms inoculated into the bite site by the sand fly are engulfed by tissue macrophages, which then enter the bloodstream and are carried to RE centers such as the bone marrow, spleen, and liver (Figures 8.6 and 8.7).

Clinical Disease

Visceral Leishmaniasis. Once the organisms have been carried to the bone marrow, spleen, and liver, a granulomatous cell-mediated immune response occurs that can result in subclinical disease and self-cure or in the clinical syndrome of VL (Table 8.4). The incubation period usually ranges from 2 to 6 months; however, it can take a few days or weeks to several years. When giving a history, many patients do not remember having a primary skin lesion. In areas of endemic infection, the onset may be gradual, with vague symptoms and a general feeling of ill health. The

Figure 8.5 Geographic distribution of the agents of Old World visceral leishmaniasis.

Figure 8.6 (Upper) *Leishmania donovani* amastigotes in a macrophage. (Lower) The nucleus and kinetoplast are visible within many of the amastigotes (arrows). (Courtesy of the Centers for Disease Control and Prevention.)

onset in naïve patients (migrants, soldiers, or travelers to areas of endemic infection) may be acute, with high fever, chills, anorexia, malaise, weight loss, and, frequently, diarrhea. This syndrome can easily be confused with typhoid fever, malaria, or other febrile illnesses caused by bacteria or viruses. Death may occur after a few weeks or several years. Generally, untreated VL leads to death; secondary bacterial and viral infections are also common in these patients.

In areas where VL is endemic, many people develop a positive LST with no history of actual clinical disease; these individuals appear to be resistant to infection with *L. donovani*. The difference between an asymptomatic

Table 8.4 Old World visceral leishmaniasis

Species and sand fly vector	Human disease and lesion	Geographic distribution	Important hosts	Comments
<i>L. donovani</i> : <i>P. argentipes</i> , <i>P. orientalis</i> , <i>P. martini</i>	Visceral leishmaniasis, kala azar, post-kala azar dermal leishmaniasis	Indian subcontinent, East Africa	Humans	Characterized by irregular fever, splenomegaly, hepatomegaly, weight loss, pancytopenia, and hypergammaglobulinemia; statistically significant differences between number of organisms in peripheral blood taken during the evening and during the day (66 and 46%, respectively), which coincides with biting habit of sand fly vector (night biting) (69)
<i>L. infantum</i> : <i>P. ariasi</i> , <i>P. perniciosus</i>	Infantile visceral leishmaniasis, cutaneous leishmaniasis (rare)	Mediterranean basin, central and western Asia	Domestic dogs	Mainly affects young children and tends to cause lymph node enlargement; poor nutrition exacerbates infection

infection and subclinical disease is difficult to establish, particularly since many of these patients do not seek medical care. However, “viscerotropic” leishmaniasis may be more common than was previously thought and should be considered in individuals with unexplained mild symptoms (cough, malaise, chronic fatigue, abdominal pain, intermittent fevers, and diarrhea) in areas of endemic infection or in travelers with a history of exposure.

Immunology. With parasitization of RE cells, there is a hyperplasia of RE cells from the liver, spleen, bone marrow, lymph nodes, mucosa of the small intestine, and other lymphoid tissues. Hematopoiesis is initially normal and then becomes depressed, with a reduction in the life span of erythrocytes and leukocytes, causing anemia and granulocytopenia. RE cell proliferation may lead to massive hypertrophy of the liver and spleen, both of which may return to normal size after successful treatment. In response to infection, there are decreases in T-cell blastogenesis production of interleukin-1 and -2, gamma interferon, and tumor necrosis factor. With successful therapy, these responses return to normal (27). Infection results in suppression of cell-mediated immunity, leading to uncontrolled reproduction of the parasite and dissemination. There is increased production of globulins, with high levels of immunoglobulin G (IgG) and IgM. The major target for the humoral immune response is heat shock proteins; Hsp70 was recognized in 92% of persons with VL (59). Circulating immune complexes involving IgA, IgG, and IgM can be found in the serum. Delayed-hypersensitivity responses to skin test antigens are suppressed or absent. With resolution of infection, the delayed-hypersensitivity reaction returns, and patients recovering from infection are considered immune to reinfection.

Clinical signs. Fever may occur at irregular intervals and, once established, may be seen as a double (dromedary) or triple fever peak each day. The patient is often weak and appears emaciated (Figure 8.8). Common clinical signs include a nontender enlarged liver with Kupffer cells containing many amastigotes and little or no cellular reaction, a markedly enlarged spleen, femoral and inguinal lymphadenopathy, and occasional acute abdominal pain or vague abdominal discomfort. In progressive disease, splenic infarcts are common; in acute cases, the spleen is smooth and friable; while in more chronic cases, the spleen is firm. Hair changes (thinning, dryness, hypopigmentation, and loss of curl) may be seen. Edema of the legs, jaundice, petechiae, and purpura have also occasionally been seen.

Skin. Skin changes are often seen on the face, hands, feet, and abdomen, particularly in India, where patients acquire an earth-gray color; this darkening of the skin apparently gave rise to the name kala azar (black sickness). In Africa, skin lesions often accompany VL and may appear very different from one patient to another. Some lesions are diffuse, warty, and nonulcerated and contain variable numbers of amastigotes.

Mouth and nasopharynx. Patients with VL in the Sudan and sometimes in East Africa and India have mucosal lesions in the mouth and nasopharynx. The lesions may appear as nodules or ulcers; the gums, palate, tongue, or lips can be involved. Lesions in the nasal mucosa can result in perforation of the septum, while nasopharyngeal and laryngeal lesions are characterized by mucosal swelling and subsequent hoarseness. Parasites tend to be more numerous in oral than in nasopharyngeal lesions;

however, they can be demonstrated in nasal and pharyngeal fluids.

Laboratory findings. Patients generally have anemia (normocytic and normochromic, assuming that there is no underlying iron deficiency), neutropenia, relative lymphocytosis, an almost complete absence of eosinophils, thrombocytopenia, and hypergammaglobulinemia (polyclonal B-cell activation). Liver enzyme levels may be mildly elevated, but elevations of bilirubin levels are uncommon. Malabsorption may be a severe problem in children with VL and can lead to complications or death.

Infections in immunocompromised individuals. During the last decade, leishmaniasis has emerged as one of the first and most important opportunistic infections in HIV-infected patients. Over 1,600 coinfection cases have been recorded, the majority from Europe, where 7 to 17% of HIV-positive individuals with fever have amastigotes. This finding strongly suggests that individuals infected with *Leishmania* spp. without symptoms will express symptoms of leishmaniasis if they become immunosuppressed. Based on the patient's general health status and prior exposure to the infection, leishmaniasis may be seen as an early opportunistic infection or as a complication late in the course of AIDS. In HIV-infected patients, VL occurs in late stages of HIV disease and often has a relapsing course (58). Secondary prophylaxis reduces the risk of relapse. VL in the HIV-infected population should be included in the Centers for Disease Control and Prevention clinical category C for the definition of AIDS in the same way that other geographically specific opportunistic infections are included. The majority of AIDS patients present with the classical picture of VL, but asymptomatic CL, mucocutaneous leishmaniasis, DCL, and post-kala-azar dermal leishmaniasis can be seen (these are usually caused by *L. infantum*). Cutaneous lesions of VL are being found increasingly frequently in patients with HIV infection, and their significance is still somewhat unclear. Lesions often

do not present a uniform or specific appearance and have been seen as erythematous papules and hypopigmented macules on the dorsa of the hands, feet, and elbows; small subcutaneous nodules on the thighs; and erythematoviolaceous, scaly plaques on the face. Also, the digestive and respiratory tracts are often parasitized (5), as well as the pleura and peritoneum. Lesions can also be coinfecting with other organisms, as evidenced by a case in which VL and *Mycobacterium avium-intracellulare* were seen in the same specimens from bone marrow and duodenal mucosa.

CD4 T-lymphocyte counts are usually $<50/\text{mm}^3$ and are almost always $<200/\text{mm}^3$ (64). However, many physicians think that VL does not cause severe symptoms in these patients but is just one of several opportunistic infections that may coinfect AIDS patients. However, VL can manifest atypical aspects in HIV-positive patients depending on the degree of immunosuppression and should therefore be listed among AIDS-defining conditions. The most common symptoms are fever, splenomegaly, hepatomegaly, and pancytopenia.

Data from Spain provide some interesting outcome figures regarding coinfection compared with leishmanial infections in non-HIV-infected persons. In spite of a good initial response to treatment for VL, 60.6% of the HIV-coinfected patients had relapsed by the end of 1 year. Mortality from the first episode was 18.5%, and 24% died in the first month after diagnosis of any VL episode. The mean survival of the 29 patients who died was 10.27 months. Survival in patients with and without AIDS at the time of the first episode of VL was compared at 30 months and found to be 53.7 and 30.5%, respectively. A diagnosis of AIDS at the time of the first episode of VL and thrombocytopenia were the only risk factors found to be related to survival. Certainly in AIDS patients, VL is a recurrent disease that is highly prevalent and whose clinical course is modified by HIV (41). VL is very prevalent among HIV-1-infected patients in southern Spain, with a high proportion of cases being subclinical. Symptomatic cases appear mainly when severe immunosuppression is

Figure 8.8 Cachexia (wasting) seen in severe visceral leishmaniasis. (Courtesy of Richard D. Pearson.)

present. There is also an association between VL, the male sex, and intravenous drug use.

In HIV-1-infected patients with active VL, the sensitivity of a peripheral blood smear is about 50%, due to a high parasitemia in these patients. However, in patients with HIV-1 and subclinical VL, the sensitivity of a routine blood smear is <10% (23). Unfortunately, in these patients serology and *Leishmania* skin tests have low sensitivities and are not very helpful (51). Cultures have proven to be effective in diagnosing VL in patients who are coinfecting with HIV-1 (24).

Post-Kala Azar Dermal Leishmaniasis. Post-kala azar dermal leishmaniasis (PKDL) was first detected in patients with VL in India, occurs in up to 20% of these patients, has been called dermal leishmanoid, and is associated with *L. donovani* only. PKDL has also been seen in >50% of Sudanese VL patients treated in the current epidemic. In India, skin lesions may appear 2 to 10 years after successful therapy for VL; in East Africa, lesions appear within a few months; and in the Sudan, onset also occurs in about 2 months. Macules and papules usually appear first around the mouth and spread to the face and then to the extensor surfaces of the arms, the trunk, and sometimes the legs. In the beginning they look like small hypopigmented patches; these then enlarge and may progress to nodules that often resemble leprosy. The lesions are somewhat delicate but do not tend to ulcerate unless traumatized. In some cases, PKDL is seen in patients with no history of visceral disease. Some patients with past or concomitant PKDL also have ocular lesions including conjunctivitis, blepharitis, and anterior uveitis; these conditions all respond to antimonial therapy, including steroid and atropine eyedrops.

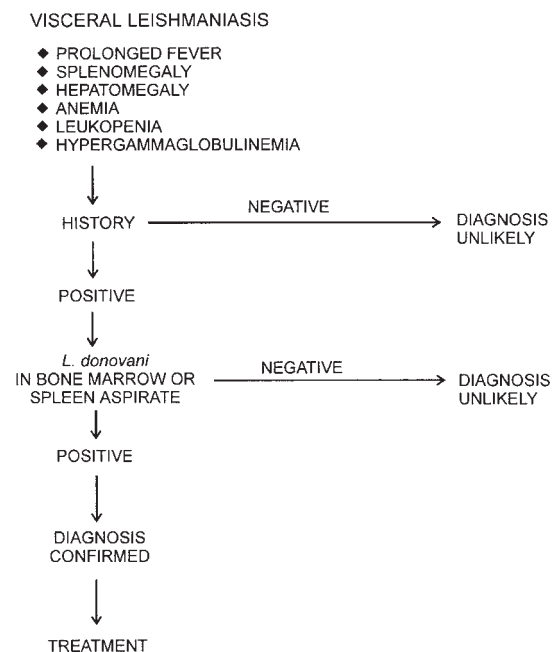

Treatment of PKDL with antimonials usually brings improvement; however, the skin changes persist indefinitely. The course of therapy is generally longer than that required for VL and may require 120 days. In Africa, patients with PKDL may self-cure. It is important to remember that these patients may serve as reservoirs of infection during interendemic cycles, since some patients with PKDL tend to have large numbers of parasites in the skin. Persistent lesions currently require daily injections of sodium stibogluconate for 2 to 4 months, and even then the treatment may not be successful. Treatment with liposomal amphotericin B (AmBisome) has been found effective and is considered less nephrotoxic than nonliposomal amphotericin B because it specifically targets the macrophages in which the *Leishmania* parasites develop. Apparently, there are also intrinsic differences in the antibodies generated in the sera from patients with PKDL and VL (54). Diagnostic methods would be identical to those used for the isolation and identification of amastigotes found in CL.

Diagnosis

A clinical diagnosis of Old World VL is often made based on clinical findings and local epidemiologic factors. However, confirmation of the diagnosis requires demonstration of the amastigotes in tissues or clinical specimens or the promastigotes in culture (Algorithm 8.1). Detection of parasite genetic material or antigen detection also suffices for confirmation. Leishmaniasis should be suspected in individuals who have resided in or traveled to areas where the disease is endemic. The diagnosis would be supported by findings of remittent fevers, hypergammaglobulinemia with anemia, circulating immune complexes, rheumatoid factors, weight loss, leukemia, and splenomegaly. The differential diagnosis of late-stage VL is limited to hematologic and lymphatic malignancies. The diagnosis of early disease is more difficult, and the differential would include malaria, African trypanosomiasis, brucellosis, enteric fevers, bacterial endocarditis, generalized histoplasmosis, chronic myelocytic leukemia, Hodgkin's disease and other lymphomas, sarcoidosis, hepatic cirrhosis, and tuberculosis. Also, patients with multiple myeloma and Waldenström's macroglobulinemia have monoclonal hypergammaglobulinemia. Mixed cryoglobulinemia secondary to VL has also been documented.

Blood. Examination of buffy coat smears shows that there is a significant difference in recovery between samples collected during the day (46%) and those collected

Algorithm 8.1 Visceral leishmaniasis.

during the night (66%) (69). Prior to an invasive procedure, blood specimens should be collected, keeping in mind the amastigote diurnal periodicity.

Tissue Aspirates. Although splenic puncture yields the highest rate of organism detection (98%), it carries a high degree of risk for the patient. Certainly deaths have occurred after this procedure, probably due to splenic laceration. Patients with coagulation disorders should not undergo splenic puncture. Other specimens include lymph node aspirates, liver biopsy specimens, sternal or iliac crest bone marrow, and buffy coat preparations of venous blood. Bone marrow aspirate is generally used in lieu of splenic puncture; however, smears from bone marrow usually contain fewer organisms, with a positivity rate of 80 to 85%. As discussed earlier in this chapter, it is important to prepare multiple smears for examination. Although amastigotes can be seen in buffy coat smears in Indian and Kenyan patients with VL, it is unusual to make the diagnosis by this method.

Culture and Animal Inoculation. Culture and animal inoculation studies are also helpful. Culture requirements, including specimen collection by an aseptic technique and the use of quality control strains, were discussed earlier in this chapter and are also addressed in chapter 32. A method for rapidly isolating promastigotes from the culture fluid has been developed using the stain acridine orange. This type of vital staining combines the advantages of direct microscopic examination with more accurate morphological imaging of the stained parasites. If available, hamsters should be inoculated intraperitoneally and killed after 2 to 3 months, and the liver and spleen should be checked for parasites (microscopic examination and/or cultures).

PCR and Other Antigen Detection Methods. PCR methods have excellent sensitivity and specificity for direct detection, for identification of causative species, and for assessment of treatment efficacy (18, 47, 48, 67, 70, 71, 84). A rapid immunochromatographic dipstick test using the recombinant RK39 antigen has become available for the qualitative detection of total anti-*Leishmania* immunoglobulins. The test uses antigen-impregnated nitrocellulose paper strips. Results from one study were very promising, with 100% sensitivity and 98% specificity (78). The RK39 strip test is ideal for rapid reliable field diagnosis of visceral leishmaniasis (80). The test has high sensitivity and specificity; however, it remains positive long after treatment (up to 3 years).

Formol-Gel Test (Hypergammaglobulinemia). In patients with kala azar, there is a characteristic hypergammaglobulinemia, including both IgG and IgM. This

fact has been used as the basis for a diagnostic procedure called the formol-gel test, which is used in areas of endemic infection. The test can be used as a screen; most patients with active disease are positive. A drop of formaldehyde is added to a test tube containing 1 ml of patient serum, which is observed for opacity and a stiff jelly consistency within 3 min to 24 h. Results also indicate that a specific IgE response is useful in the diagnosis of active VL and may be used to evaluate the response to treatment (10).

Skin Test. The Montenegro (LST) skin test is described above. In patients with active VL, this delayed-hypersensitivity test is negative. However, within several months to a year after recovery, the skin test reverts to positive. It is of limited value because it becomes positive late in the course of disease, and false-positive results are common.

Serologic Tests. A number of serologic diagnostic methods have been developed worldwide, although they are not widely available. In general, sensitivities are >90% but specificities are lower. False-positive results can be seen in patients with other infectious diseases, in patients treated for VL (in whom antibodies persist for months), and in some asymptomatic VL patients. There are currently four tests in use, the direct agglutination test (DAT), the indirect fluorescent-antibody test, counterimmunoelectrophoresis, and enzyme-linked immunosorbent assay (ELISA). DAT appears to be the best choice as a diagnostic tool since it is very specific and does not require expensive equipment or reagents (11). However, patients may still have positive sera 1.5 to 5 years after treatment (56). DAT has also been adapted to filter paper sampling, and the filter paper eluates compared well with their homologous sera and correlated strongly with respect to antibody titers (63). DAT based on axenic amastigote antigen provided 100% sensitivity and specificity, making it particularly useful for diagnosis of macular PKDL cases, which are often missed by the RK39 strip test. Thus, DAT provides a simple, reliable, and inexpensive test for PKDL diagnosis with potential applicability under field conditions (74). However, newer studies using ELISA formats indicate excellent sensitivity and specificity and may be very helpful in diagnosis of early infections (17, 66).

KEY POINTS—LABORATORY DIAGNOSIS

Old World Leishmaniasis: Visceral Leishmaniasis

1. For a complete laboratory diagnosis, microscopic examination of Giemsa-stained touch preparations and cultures are recommended, as well as PCR and animal inoculation if available.

2. Due to potential problems with splenic puncture, bone marrow specimens may be recommended. Although not that productive, examination of buffy coat preparations is recommended prior to a more invasive procedure. When collecting blood specimens, remember the diurnal periodicity.
3. Multiple slides should be prepared for examination from aspirates and/or biopsy specimens.
4. Tissue imprints or smears should be stained with Giemsa stain (or one of the stains commonly used for blood smears) (see chapter 31).
5. Amastigote stages should be found within RE cells or close to disrupted cells.
6. If cultures are to be performed, specimens must be collected aseptically and control organism cultures should be set up at the same time (see chapter 32).
7. Cultures should be checked weekly for 4 weeks before they are declared negative.
8. Patients with kala azar have hypergammaglobulinemia; the formol-gel procedure may be helpful.
9. Serologic tests are helpful, and newer procedures demonstrate increased sensitivity and specificity; this should be considered if parasites cannot be detected in clinical specimens.

Treatment

Patients should receive supportive care, especially if they are malnourished or have other infections such as pneumonia, tuberculosis, or other chronic conditions. Since the mid-1930s, pentavalent antimony compounds have been the drugs of choice for the treatment of VL. However, with the first reports of primary treatment failures in the mid-1990s, additional drugs have been used and include lipid-associated amphotericin B for Mediterranean and Indian VL (54). VL in renal transplant recipients has been successfully treated with liposomal amphotericin B (AmBisome). The disadvantages of using Pentostam and Glucantime include the need for intravenous administration and hospitalization, cardiotoxicity, pancreatitis, treatment failures, and increasing resistance (79). The dosing regimen for treating VL is also associated with a high rate of serious side effects in HIV-infected patients (22). Therapy combining either paromomycin or allupurinol with pentavalent antimonials has also been used with some success.

There is no effective orally administered medication for any *Leishmania* infection. However, studies with miltefosine appear very promising. This drug is a phosphocholine analogue that affects cell-signaling pathways and membrane synthesis. When 100 mg of miltefosine was given per day (approximately 2.5 mg/kg of body weight/day) for 4 weeks, 29 (97%) of 30 patients with at least moderate (2+) *Leishmania* in their splenic aspirates were cured. Gastrointestinal side effects were frequent but were only

mild to moderate in severity, and no patient discontinued therapy. The use of orally administered miltefosine appears to be an effective treatment for Indian VL (35, 77).

Epidemiology and Prevention

The epidemiology of VL depends on a number of factors including the interaction between sand flies, reservoir hosts, and susceptible humans. In the two main areas of endemicity, the Ganges river basin and the southern Sudan, high infection rates and many deaths have been documented during the last 10 years. Factors which affect the number of infections and the transmission include population movements, often related to forced migration, poor general health, and poverty, all of which are seen in both geographic areas. The disease is a zoonosis, with the exception of India, where humans serve as the major reservoir host and the relevant vector is *P. argentipes*. Dogs serve as the main reservoir host around the Mediterranean, and the infection is transmitted through bites of infected sand flies such as *P. perniciosus*, *P. major*, *P. simici*, and *P. longicuspis*. Disease in this area is usually found in infants and children; young dogs are very susceptible to *L. infantum* and often die of the disease. Dogs are also important reservoirs in certain parts of China. In southern France and central Italy, infected foxes appear to be the reservoir, with *P. ariasi* and *P. perfiliewi* serving as vectors. Jackals also probably serve as reservoir hosts in the Middle East and central Asia. The epidemiology of VL in Africa is somewhat confusing, since the presence of epidemics suggests a human reservoir but dogs have also been found to be infected. The main vector in Kenya appears to be *P. martini*, and in the Sudan the vector is *P. orientalis*.

L. donovani occurs in Africa and Asia, and in areas where transmission is somewhat sporadic, wild canids and various rodents are natural reservoirs of the disease. *L. infantum* is seen in Africa, Europe, the Mediterranean area, and southwest Asia. Humans are accidental hosts, with dogs and other members of the Canidae acting as natural reservoirs (28).

Although the usual route of transmission is through the bite of infected sand flies, parasites can be transmitted in other ways including blood transfusion, sexual contact, congenital transmission, and occupational exposure. However, for the most part, transmission is through the normal vector cycle. Apparently, *L. infantum* can circulate intermittently and at low density in the blood of healthy seropositive individuals, who appear to be asymptomatic carriers; this certainly has implications for the safety of the blood supply in certain areas of the world, including southern France.

In areas where humans serve as the main reservoir host, treatment of active cases is likely to interrupt the cycle of transmission. Reservoir control has proven to be somewhat sporadic, and there is little indication that it

has any impact on overall infection rates. Residual insecticide spraying, primarily for malaria vector control, was relatively successful; however, when spraying of DDT was discontinued, the incidence of VL began to increase again. Vaccines hold a great deal of promise, but currently no commercial products are available (33).

New World Leishmaniasis: Cutaneous Leishmaniasis

New World CL extends from southern Texas and Arizona to Latin and South America and the Caribbean islands (37). As seen in Old World leishmaniasis, there is a wide range of disease presentation, and separation based on clinical signs and symptoms is not possible (Figures 8.9 and 8.10). Organisms in this group belong to the subgenera *Leishmania* and *Viannia* (Table 8.1). Within the subgenus *Leishmania* is the *L. mexicana* complex (Table 8.5), and within the subgenus *Viannia* are the *L. braziliensis* complex (Table 8.6) and the *L. guyanensis* complex (Table 8.7). It is very likely that taxonomy will continue to change as molecular methods reveal genetic differences and similarities among the various genera and species. Common names for New World CL include uta (Peru), dicera de Baurid (Brazil), chiclero ulcer or bay sore (Mexico), and pian bois or forest yaws (Guyana). Collectively, this group has also been called American CL. This disease is quite old and has even been depicted on pottery from Peru and Ecuador that has been dated ca. AD 400 to 900.

Life Cycle and Morphology

The life cycle and organism morphology are essentially the same as for Old World CL (Figure 8.2). However, in some cases, destructive oral, nasal, or pharyngeal lesions may develop, causing mucocutaneous disease. In New World leishmaniasis, the sand fly vector is in the genus *Lutzomyia* or *Psychodopygus* rather than *Phlebotomus*. The genus *Leishmania* is divided into its two subgenera, *Leishmania* and *Viannia*, depending on the location of the development of the promastigote within the sand fly. Promastigotes from the subgenus *Viannia* develop in the midgut and hindgut of sand flies, while promastigotes from the subgenus *Leishmania* develop in the anterior portion of the alimentary tract of the sand fly (31).

Clinical Disease

Cutaneous Leishmaniasis. The lesions of New World CL are very similar to those seen with Old World cutaneous disease. Weeks to months after infection, an erythematous, often pruritic papule develops at the bite site. This papule may become scaly and enlarge, developing a central ulcer surrounded by a raised margin. Disease progression at this point will vary depending on the species involved. Lesions may be single or multiple and usually occur on exposed areas

Figure 8.9 *Leishmania*. Healed facial scar, “Seal of the Forest” (Costa Rica). (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

of the body. Many lesions may self-heal over a period of approximately 6 months (Figure 8.9); however, lesions on the ear occur in 40% of the patients and are chronic, lasting many years. Ulcerations on the ears may be quite destructive but cause the patient few problems. *L. mexicana* lesions are usually single, self-limiting

Figure 8.10 Facial lesion on a 9-month-old girl. (Courtesy of Yoshihisa Hashiguchi.)

Table 8.5 New World cutaneous leishmaniasis subgenus *Leishmania*, complex *Leishmania mexicana*

Species and sand fly vector	Human disease and lesion	Geographic distribution	Important hosts	Comments
<i>L. mexicana</i> : <i>Lutzomyia olmeca</i> , <i>L. anthophora</i> (Texas and Arizona)	Cutaneous leishmaniasis, chiclero ulcer	Belize, Guatemala, Honduras, Costa Rica, Mexico, Texas, Arizona (Panama, South America questionable); Southern Plains of Texas (wood rat [<i>Neotoma micropus</i>]); Arizona (white-throated wood rat [<i>Neotoma albigula</i>])	Forest rodents	Prolonged exposure of “chicleros,” who live in forest collecting chewing gum latex from chicle trees (30% infected during first year); timber cutters, road builders, agricultural workers
<i>L. venezuelensis</i> : <i>Lutzomyia olmeca bicolor</i>	Cutaneous leishmaniasis	Venezuela (humans only)	Humans	Poor long-term growth in blood agar medium; wild mammalian host not yet discovered; found in horses and the domestic car
<i>L. garnhami</i> : <i>Lutzomyia youngi</i> (not confirmed)	Cutaneous leishmaniasis	Venezuelan Andes	Humans, marsupial (<i>Didelphis marsupialis</i>)	Identical to <i>L. amazonensis</i> by isoenzyme profiles, but clear differences between nontranscribed rDNA intergenic spacer sequences; still difference of opinion regarding validity of species designation
<i>L. amazonensis</i> : <i>Lutzomyia flaviscutellata</i>	Cutaneous leishmaniasis, diffuse cutaneous leishmaniasis	Amazon region of Brazil, Bolivia, Colombia, French Guyana, Paraguay	Forest rodents (primary); marsupials, foxes (secondary)	Human disease uncommon; vector nocturnal and not very anthrophilic, lives in swampy areas with few inhabitants; DCL similar to that seen in Ethiopia (Old World); specific anergy to leishmanin skin test
<i>L. pifanoi</i> : <i>Lutzomyia flaviscutellata</i>	Diffuse cutaneous leishmaniasis	Venezuela (states of Yaracuy, Lara, and Miranda)	Humans	Some confusion regarding actual taxonomy; wild mammalian host not yet discovered; DCL similar to that seen in Ethiopia (Old World); specific anergy to leishmanin skin test

cutaneous papules, nodules, or ulcers that are painless and are found on the face and ears (Figures 8.10 and 8.11). Other infections that are usually associated with single cutaneous lesions include those due to *L. colombiensis*, *L. amazonensis*, *L. garnhami*, *L. lainsoni*, *L. peruviana*, and *L. venezuelensis*. Multiple lesions caused by spread along lymphatics are common with *L. guyanensis* infections, and subcutaneous lymphatic nodules can be seen with *L. panamensis*; the lesions can mimic those seen in sporotrichosis. The differential diagnosis of New World CL includes sporotrichosis, blastomycosis, yaws, syphilis, cutaneous tuberculosis, *Mycobacterium marinum* infection, and dermatologic cancers.

Mucocutaneous Leishmaniasis. Cutaneous lesions caused by *L. braziliensis* usually require a longer period for self-cure, taking up to 18 months or longer, and they

can begin with lymphadenopathy. Approximately 1 to 3% of patients infected with *L. braziliensis* develop metastatic spread of the organisms to the nasal, pharyngeal, and buccal mucosa (mucocutaneous leishmaniasis [ML]). ML, also known as espundia, may occur months to years after the initial cutaneous lesion has healed partially or completely. However, in many cases, mild mucosal lesions are present concomitantly with active cutaneous lesions. Mucosal disease tends to occur more frequently in males than females, and the patients are usually 10 to 30 years of age.

ML may begin with erythema and edema of the involved mucosal tissues, along with nasal inflammation, stuffiness, difficulty in breathing through the nose, and occasional bleeding. Following the early symptoms, ulcerations covered with a mucopurulent exudate may develop (Figure 8.12). There is often severe erosion and destruction of the soft tissues and cartilage, leading to loss of the

Table 8.6 New World cutaneous leishmaniasis, subgenus *Viannia*, complex *L. braziliensis*

Species and sand fly vector	Human disease and lesion	Geographic distribution	Important hosts	Comments
<i>L. braziliensis</i> : <i>Lutzomyia wellcomei</i> , <i>L. intermedius</i> , <i>L. pessoai</i>	Cutaneous leishmaniasis, mucocutaneous leishmaniasis	Brazil, Guatemala, Belize, Honduras, Nicaragua, Peru, Ecuador, Bolivia, Costa Rica, Panama, Colombia, Venezuela, Paraguay, Argentina	Forest rodents, humans	Vector feeds primarily during daylight hours; common in farming communities in newly cleared forest areas and in road construction and mining workers; also known as nariz de anta (tapir nose) and espundia
<i>L. peruviana</i> : <i>Lutzomyia peruensis</i> , <i>L. verrucarum</i>	Cutaneous leishmaniasis	Peru, western slopes of the Andes, inter-Andean valleys; 900–3000 m above sea level	Humans, dogs	Frequent in school children, commonly resulting in extensive facial scars; ulcers self-healing; known as uta; in some villages 90% of people are infected or scarred
<i>L. colombiense</i> : <i>Lutzomyia hartmanni</i> , <i>L. gomezi</i> , <i>Psychodopygus panamensis</i>	Cutaneous leishmaniasis	Colombia, Panama, Venezuela, probably into Brazil, Peruvian lowlands	Humans, single isolate from the sloth (<i>Choloepus hoffmanni</i>)	Single to multiple ulcerating skin lesions; ML has not been seen
<i>L. lainsoni</i> : <i>Lutzomyia ubiquitatis</i>	Cutaneous leishmaniasis	Amazon region of northern Brazil, probably elsewhere	Humans, rodent (<i>Agouti paca</i>)	Multiple lesions have also been seen; ML has not been seen
<i>L. shawi</i> : <i>Lutzomyia whitmani</i>	Cutaneous leishmaniasis	Amazon region of northern Brazil, south of the Amazon River	Humans, monkeys, sloths, coatimundi	Multiple lesions have also been seen; ML has not been seen
<i>L. naiffi</i> : <i>Psychodopygus ayrozai</i>	Cutaneous leishmaniasis	Brazilian states of Pará and Amazonas	Humans, nine-banded armadillo (<i>Dasyopus novemcinctus</i>)	Multiple lesions have also been seen; ML has not been seen

Table 8.7 New World cutaneous leishmaniasis, subgenus *Viannia*, complex *Leishmania guyanensis*

Species and sand fly vector	Human disease and lesion	Geographic distribution	Important hosts	Comments
<i>L. guyanensis</i> : <i>Lutzomyia umbratilis</i> (high infection rate, up to 7%)	Cutaneous leishmaniasis	Brazil north of Amazon River, Guyanas; range extends into Ecuador, Venezuela, lowland forests of Peru	Humans, two-toed sloth, lesser anteater, rodents, opossums	Reservoir infections inapparent, organisms in normal skin and viscera; vector lives in forest canopy and tree trunks; timing right for deforestation (early-morning biting); Brazil nut and fruit collectors, topographers, visiting botanists, zoologists, tourists affected; also known as pian bois or forest yaws
<i>L. panamensis</i> : <i>Lutzomyia trapidoi</i> , <i>L. ylephiletor</i> , <i>L. gomezi</i> , <i>Psychodopygus panamensis</i>	Cutaneous leishmaniasis	Panama and the Canal Zone, western and central Colombia, Ecuador, Venezuela, Costa Rica, Honduras, Nicaragua	Humans, sloths (two-toed and three-toed), occasionally other animals	Frequent in American military personnel; rare cases of ML

lips, soft parts of the nose, and soft palate. The lesions are chronic and progressive and can lead to death due to secondary infection or aspiration pneumonia. In the non-ulcerative form, there may be hypertrophy of the tissues of

the upper lip and nose, leading to the development of the “tapir nose.” Unfortunately for diagnosis, parasites are few and difficult to find in tissues involved in ML. Although this disease can be extremely disfiguring, the mortality rate

Figure 8.11 Large erythematous nodule with early ulceration on the right wrist, due to *Leishmania mexicana*. (Courtesy of Bonnie B. Furner.)

is low. New World ML mimics paracoccidioidomycosis, histoplasmosis, tuberculosis, syphilis, malignant tumors, and lethal midline granuloma.

Diffuse Cutaneous Leishmaniasis. Disseminated DCL is an anergic form of CL in which neither humoral nor cell-mediated immune responses are functional but in which delayed hypersensitivity to tuberculin appears to be normal. DCL is seen most frequently in Venezuela, Brazil, Mexico, and the Dominican Republic. Individuals infected with *L. pifanoi* and 30% of those infected with *L. amazonensis* are likely to develop DCL (Figure 8.13).

The parasites are found in the skin, and the disease is characterized by the formation of thickened skin in plaques, papules, or multiple nodules. Although lesions are usually seen on the face, nose, limbs, and buttocks, they can occur over the entire body (Figure 8.14). The nodules are often described as soft and fleshy, while those of leprosy are generally more indurated. Although organisms have rarely been recovered from blood or bone marrow, there are no visceral lesions associated with this form of leishmaniasis. Treatment is difficult, and the infection may last for the life of the patient. The LST remains negative unless treatment is effective and recovery occurs. Nodular DCL will have to be differentiated from lepromatous leprosy.

Diagnosis

In areas of the world where physicians are very familiar with leishmaniasis, the diagnosis may be made on clinical grounds. However, in areas of the world where the disease is rare, the condition may not be recognized as leishmaniasis. Definitive diagnosis depends on demonstrating the amastigotes in tissue specimens or the promastigotes in culture (Table 8.8). More recent results suggest that PCR is a valuable tool for the diagnosis of leishmaniasis on a routine basis and can provide valuable epidemiologic informa-

Figure 8.12 Mucocutaneous lesions on a 7-year-old girl with disseminated leishmaniasis. (Courtesy of Yoshihisa Hashiguchi.)

tion in areas of endemic infection (15, 43, 64, 65). CL may have to be differentiated from a number of other lesions and diseases, including basal cell carcinoma, tuberculosis, various mycoses, cheloid, and lepromatous leprosy.

Specimen Collection

CL normally presents with no visceral involvement or systemic disease. The ability to detect parasites in aspirates, scrapings, or biopsy specimens depends on the number of amastigotes present, the level of the host immune response, the absence or presence of bacterial and/or fungal contamination within the lesion, and whether the specimen is collected from an active or healing lesion. If the patient has multiple lesions, specimens should be collected from the more recent or active lesions. These lesions should be thoroughly cleaned with 70% alcohol, and necrotic debris should be removed to prevent the risk of bacterial and/or fungal contamination of the specimen. Also, the specimen should be taken from the advancing margin of the lesion; the central portion of the ulcer contains nothing but necrotic debris unless portions of the lesion are taken below the crater area.

The specimen of choice would be a collection of several punch biopsy specimens taken from the most active lesion areas. Biopsy specimens can be divided and used for cultures and touch preparations; some material should always be saved and submitted for routine histologic testing. The biopsy specimen can be used to make impression smears (touch preparations); these smears should be prepared after portions of the specimen have been placed in culture media by using a sterile technique. After any excess blood is cleaned off, a horizontal cut is made through the biopsy specimen core and the cut surface is gently touched

Figure 8.13 Two erythematous facial lesions on the right cheek of a 5-month-old boy infected with *Leishmania pifanoi*. (Courtesy of Yoshihisa Hashiguchi.)

Figure 8.14 Diffuse anergic cutaneous leishmaniasis due to *Leishmania mexicana* in a patient of Dr. Convit (Venezuela). (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

to glass slides; multiple slides should be prepared. Once material has been set up for culture and touch preparations have been made, the remainder of the tissue can be sent to the pathology laboratory for routine processing.

Another option involving sterile techniques is to make a perpendicular slit in the margin of the lesion. After blood is removed using sterile gauze, the blade can be used to scrape the inner walls of the slit. Material can be inoculated into culture media and can be smeared onto several glass slides; multiple slides are recommended to increase the chances of seeing the parasites. Fine-needle aspiration can also be performed with a sterile syringe containing sterile saline (0.1 ml)

and a 26-gauge needle. The needle is inserted into the outer border of the lesion and rotated several times, after which saline is injected and tissue fluid is aspirated back into the needle. Material can be submitted for culture, and/or smears can be prepared for staining. Additional techniques and specific methods can be found in chapters 30 to 32.

Table 8.8 Features of New World human leishmanial infections related to demonstration of the parasite^a

Organism	Disease type ^b	Humoral antibodies	Delayed hypersensitivity to leishmanin	Parasite present in clinical specimen	Self-cure	Recommended biopsy specimen
New World CL						
<i>L. mexicana</i> complex	CL	Present	Present	Present	Yes	Skin
	DCL	Variable	Absent	Abundant	No	Skin
<i>L. braziliensis</i> complex	CL	Present	Present	Present	Yes	Skin
	ML	Variable	Present	Few	No	Skin, mucous membranes
<i>L. guyanensis</i> complex	CL	Present	Present	Present	Slow	Skin
New World VL						
<i>L. chagasi</i>	VL	Abundant	Absent	Present	Possible	Bone marrow, spleen

^a For culture, specimens must be collected aseptically, and in older lesions the parasites may be scant and difficult to recover. Animal isolation involves hamsters and culture media (Novy-MacNeal-Nicolle medium and Schneider's *Drosophila* medium with 30% fetal bovine serum). Serologic testing is most suitable for VL, has little value for CL, and has limited value for MCL. The Montenegro test (LST) is a delayed-hypersensitivity reaction to intradermal injection of cultured parasites.

^b Additional information on relevant diagnostic methods can be found in chapters 31 and 32.

Specimen Staining. All smears to be Giemsa stained should be air dried and fixed with 100% methanol prior to staining. The amastigotes will be found within the macrophages or close to disrupted cells. In very early and older lesions, very few organisms may be present, so that prolonged examination of the slide may be required.

Culture Media. It is important to release the organisms from tissue prior to culture; mincing is recommended. However, tissue grinders are not recommended because of possible damage to the organisms. Culture media that have been used for the recovery and growth of the leishmaniae include Novy-MacNeal-Nicolle medium and Schneider's *Drosophila* medium supplemented with 30% fetal bovine serum (see chapter 32). Patient cultures should not be set unless the laboratory maintains specific organism strains for quality control checks. Both the control and patient cultures should be examined twice a week for the first 2 weeks and once a week thereafter for up to 4 weeks before they are reported as negative. Promastigote stages can be detected microscopically in wet mounts taken from centrifuged culture fluid. This material can also be stained with Giemsa stain to facilitate observation at a higher magnification.

Animal Inoculation. Animal inoculation can be helpful when only a small number of organisms are present; however, most laboratories no longer consider this approach practical. Golden hamsters are inoculated intranasally, and the major argument against this approach is that it may take several months before the animals give positive responses. A combination of tissue smears, culture, animal inoculation, and histopathology may be required for optimal diagnosis.

Skin Test. The LST (Montenegro test) is not species specific and must be interpreted with caution, particularly since some patients may have more than one type of leishmaniasis. Positive reactions are generally seen in patients with cutaneous lesions; however, those with DCL give negative reactions.

Serologic Tests. Standard serologic tests are not particularly useful for the diagnosis of New World CL or ML. Low titers are seen, tests are likely to be negative in early disease, and overall interpretation is difficult at best. However, if a patient is positive, serial measurement of antibody titers may be helpful in tracking the outcome of therapy. The development and use of recombinant antigens for specific and sensitive serodiagnosis of CL have led to improved diagnostic results (34).

Treatment

In contrast to Old World CL, systemic chemotherapy is recommended for New World CL. Differences between the two types of CL tend to justify this recommendation and include cases with multiple lesions; the long-term, chronic nature of some infections; and the tendency for disease progression and mucosal involvement in the absence of

chemotherapy. Time to healing has been improved in studies in which recombinant human granulocyte-macrophage colony-stimulating factor coupled with stibogluconate has been used (4). Studies also show that the combination of allopurinol and stibogluconate is superior to stibogluconate alone and can be used as an adjunct to stibogluconate or other oral agents in the treatment of CL (45). However, a combination of allopurinol and stibogluconate used for the treatment of ML provided no clinical benefit. It also appears that low-dose CL therapy using an antimony regimen (5 mg/kg/day for 30 days) may work just as well as the larger recommended dose (20 mg/kg/day for 3 to 4 weeks), particularly for children and the elderly (55).

The most promising drug found so far is an anticancer compound, miltefosine, which has undergone experimental and clinical trials and is 94 to 97% effective. However, the drug is contraindicated during pregnancy and may cause severe gastrointestinal side effects. Also, the cost is another limiting factor. Other drugs such as paromomycin, allopurinol, and sitamaquine have been reported to have variable cure rates. Because of these limitations, a combination therapy, preferably coupled with specific parasite enzyme inhibitors, may be the most effective approach (75).

In Mexico, CL occurs in 17 of 32 states and is considered a serious public health problem. Treatment with a localized current field radiofrequency device to generate precisely controlled heat as an alternative to expensive drug treatment appears to be effective and convenient for use in primary health care facilities. Lesions were first anesthetized with 1% lidocaine hydrochloride and moistened with normal saline solution. Treatment consisted of a single application of heat that produced 50°C for 30 s. After 4 weeks, 95% of 122 patients were totally cured (including those with infected ear cartilage), and at 8 weeks, 90% of 191 patients were cured (81).

ML is the most serious clinical form of CL and, once diagnosed, requires prolonged and close supervision of therapy; incomplete treatment can lead to severe sequelae and even death. For many years, mucosal involvement of leishmaniasis in America was attributed to *L. braziliensis* only. However, dissemination via blood or lymph or extension to mucosal tissue has been documented for *L. panamensis*, *L. guyanensis*, *L. mexicana*, and *L. amazonensis*. It is now accepted that most of the New World *Leishmania* species are capable of causing a wide spectrum of disease, depending on the immune status of the host, parasite strain, and anatomic exposure. The simultaneous presentation of both mucosal and active cutaneous lesions contrasts with the classical descriptions of ML caused by *L. braziliensis*, thus emphasizing the importance of early diagnosis of mucosal disease by examination of the mucosa in all patients with CL. In some cases, treatment with both conventional and experimental regimens may not be effective against ML (44).

Epidemiology and Prevention

L. mexicana Complex. *L. mexicana* (Table 8.5) causes chiclero ulcer and is common throughout Mexico, Belize, Guatemala, and the southern United States. It is transmitted among forest rodents by vectors that are not particularly attracted to humans. However, prolonged exposure of many forest workers leads to a high infection rate in these groups. The range of endemic infection has now been expanded within the United States to include areas in Arizona that are farther north than the southern Texas site previously identified. Apparently, wood rats serve as the primary wild reservoir hosts in these two states.

L. venezuelensis is found in the Lara and Yaracuy States, Venezuela, and has been recovered from humans, horses, and domestic cats; no wild reservoir hosts have been identified. Although it develops rapidly in hamsters (animal inoculation), it does not grow well in the blood-based media routinely used for culture.

Recovery of *L. garnhami* is limited to the Venezuelan Andes. Although the human is a known host, a single infection has also been recorded in the opossum, *Didelphis marsupialis*.

L. amazonensis has been found in Bolivia, Brazil, Colombia, French Guyana, and Paraguay and is likely to be found in other South American geographic locations where the appropriate vector is located. It is primarily an infection of forest rodents; however, marsupials and foxes can also be reservoir hosts. The vector tends to be nocturnal; this is probably the reason why human disease is not as common as with other species.

L. pifanoi is limited to the states of Yaracuy, Lara, and Miranda within Venezuela, and humans are the only known mammalian host. The wild mammalian host has not yet been identified.

L. (Viannia) braziliensis Complex. Unfortunately, the geographic distribution of *L. braziliensis* (Table 8.6) is not well defined, but infections have been reported from most Latin American countries including Argentina, Belize, Bolivia, Brazil, Colombia, Costa Rica, Ecuador, French Guyana, Guatemala, Honduras, Nicaragua, Panama, Paraguay, Peru, Suriname, and Venezuela. Many researchers think that it is unlikely that this broad a geographic range is accurate. The situation is even more confusing when ecologic and epidemiologic features of CL and ML differ in different regions. Humans are the main hosts, and wild hosts include sylvatic mammals such as rodents and marsupials. Infections have also been seen in dogs, mules, horses, and, rarely, cats. Extensive deforestation has been implicated in areas with suspected domestic animal transmission. Because there are questions regarding the reports of geographic range, it is difficult to accurately define vectors with proven transmission related to *L. braziliensis*. Human infections tend to be common in farming communities that develop along with deforestation, road construction, and mining.

L. peruviana is found in Peru on the western slopes of the Andes, including the inter-Andean valleys, generally at 900 to 3,000 m above sea level. It probably has a wider geographic range than reported. Transmission occurs in mountainous areas with little vegetation, and wild reservoir hosts probably include rodents and marsupials. Suspect vectors have been identified, but confirmation is often difficult. Human infection is usually contracted in and around the dwelling, and in some villages, the combined rate of present and past infection reaches 90%.

L. colombiensi has been found in Colombia, Panama, and Venezuela but probably has a wider geographic range, extending into Brazil and Peru, where appropriate wild reservoir hosts and vectors are found. Humans are the main host; however, a single isolate has been found from a sloth in Panama.

L. lainsoni occurs in the Amazon region of northern Brazil; however, the geographic range probably extends beyond these limits, as does the wild reservoir, *Agouti paca*, and the sand fly vectors. Evidence indicates that the vector, *Lutzomyia ubiquitalis*, does not like human blood, probably accounting for the low infection rate with *L. lainsoni*.

L. shawi is also found in the Amazon region of northern Brazil, south of the Amazon river. Humans are recognized hosts, and wild reservoir hosts include monkeys, sloths, and the coatimundi, as well as probably a few others.

L. naiffi infections have been recorded from the Brazilian states of Pará and Amazonas. Like many of the other species where the wild reservoir hosts and appropriate vectors are found beyond these recorded boundaries, it is strongly suspected that the infection also has a broader range into other areas of Brazil and surrounding countries. The only recorded wild reservoir host is the nine-banded armadillo, in which there is a high infection rate in what appears to be normal skin and viscera. Like *L. lainsoni*, the vector of *L. naiffi* does not prefer human blood, hence the low human infection rate. However, other vectors may be implicated and do prefer human blood.

L. (Viannia) guyanensis Complex. *L. guyanensis* (Table 8.7) is a very common cause of CL in Brazil, north of the Amazon river, and the Guyanas. Infections have also been recorded from Ecuador, Venezuela, and the lowland forests of Peru. Humans are known hosts, as are wild mammalian reservoir hosts such as the sloth and lesser anteater; other rodents and opossums have also been implicated. Like the wild reservoir hosts of *L. naiffi*, large numbers of parasites are located in what appears to be normal skin and viscera. The vector thrives in primary forest land, rather than in secondary forests or plantings of nonindigenous trees, and there may be a high human infection rate in such areas. Disease tends to be common in forest workers.

L. panamensis is found in Panama and the Canal Zone and has been reported as causing frequent infection in American military personnel stationed in these areas, as

well as in agricultural workers. It has also been found in western and central Colombia, Ecuador, Venezuela, Costa Rica, Honduras, and Nicaragua. Humans are known hosts, and the epidemiology is similar to that seen with *L. guyanensis*. The major wild reservoir host is the two-toed sloth; fewer infections have been found in two genera of the three-toed sloths that live in the forest canopy, as do the vectors.

Vaccines. A single-dose vaccine with killed antigen, using recombinant human interleukin-12 and alum as adjuvants, appears to be safe and fully effective in a primate model of New World CL. This information extends the murine data to primates, thus providing a basis for further human trials (36). Field trials of a vaccine against New World CL have also been tried in Ecuador, with very promising results after 12 months of follow-up (8). Other studies are under way and should provide results on the potency and stability of various candidate vaccines against New World CL (49).

New World Leishmaniasis: Visceral Leishmaniasis

New World VL (sometimes called American VL [AVL]) is caused by *L. chagasi* and has many similarities to Old World VL caused by *L. infantum*, including the fact that the infection is seen primarily in children and that both infections cause visceral and cutaneous disease.

Life Cycle and Morphology

The life cycle and morphology of *L. chagasi* are essentially the same as those of the species causing Old World VL (Figure 8.2). Amastigotes can be found throughout the body and are not confined to the macrophages of the skin. Organisms inoculated into the bite site by the sand fly are engulfed by tissue macrophages, which then enter the bloodstream and are carried to RE cell centers such as the bone marrow, spleen, and liver.

Clinical Disease

L. chagasi causes subclinical infections and AVL, which is potentially fatal if not treated, and it has recently been

associated with atypical cutaneous leishmaniasis (ACL) in Central America, particularly in Honduras (Table 8.9). Typically, AVL is associated primarily with malnourished children younger than 5 years, whereas the ACL presentations are seen mainly in children older than 5 years and young adults. Data indicate that this atypical disease presentation may be more common than was previously thought and may affect up to 10% of a local population (12). The fact that the same organism can cause AVL and ACL suggests that the host immune response may play a role in the outcome. The disease presentation includes nonulcerated cutaneous nodules.

Diagnosis

Confirmatory diagnosis depends on the demonstration of parasites, either amastigotes in stained smears of spleen, bone marrow, or lymph node aspirates or promastigotes in culture (Algorithm 8.1). Although tissue aspirates should contain many parasites, this is not always the case. If only a few are present, culture may not be successful. Intraperitoneal inoculation of aspirate material into hamsters is by far the most reliable means of isolating *L. chagasi*; however, there may be long delays before parasites are detected in the animals. PCR will probably become the test of choice, as with other types of leishmaniasis, but the practicality and cost issues mean that routine methods will continue to be the most likely approach, particularly since the majority of cases are seen in more remote rural areas.

Treatment

Although the treatment regimens are similar to those used for Old World VL, some patients are unresponsive to the recommended antimonial dosages; this has been seen in Bahia, Brazil. Alternatives would include increased dosages and/or the use of second-line drugs such as pentamidine. Unfortunately, serious side effects also increase when increased dosages are used. A review of available therapy for both Old World and New World VL is given in Table 8.10.

Table 8.9 New World (American) visceral leishmaniasis

Species and sand fly vector	Human disease and lesion	Geographic distribution	Important hosts	Comments
<i>L. chagasi</i> : <i>Lutzomyia longipalpis</i>	Visceral leishmaniasis, kala azar, post-kala azar dermal leishmaniasis, atypical cutaneous leishmaniasis	Most of Latin America (Argentina, Bolivia, Brazil, Colombia, Ecuador, Paraguay, Suriname, Venezuela, Guatemala, Guadeloupe, Honduras, Martinique, Mexico, El Salvador, Costa Rica)	Humans, dogs, foxes	Closely resemble <i>L. infantum</i> infections in Old World; fatal outcome unless treated; the term American visceral leishmaniasis (AVL) is preferred to kala azar (reserved for Indian VL) ^a

^a Although there is some controversy about whether *L. chagasi* is indigenous to the Americas or whether AVL is due to *L. infantum* which was introduced into the New World by immigrants in post-Columbian times via infected dogs, there appears to be strong evidence for the former hypothesis (38).

Table 8.10 Specific drugs for the treatment of visceral leishmaniasis (see also chapter 25)

Drug	Dosage	Side effects ^a	Comments ^a
Pentavalent antimonials (SbV) Sodium stibogluconate (SSG) (Pentostam) Sodium antimony gluconate Meglumine antimoniate (Glucantime)	Pentostam for VL (India, Kenya): 20 mg/kg/day (28 days Kenya, 40 days India); upper limit of safe, daily dose not as relevant, with the exception of AIDS patients	i.m. injections painful; recommend slow injection with 23- to 26-gauge needle; dilution of daily dose 1:10 with 5% DW; nausea, anorexia, abdominal pain, malaise, headache, arthralgias, myalgias, lethargy (beginning 7–10 days into therapy); VL patients tolerate SbV better than do CL or ML patients; symptoms resolve after therapy; serum amylase and lipase levels rise (peak at 7–14 days); may need to interrupt therapy for 5-fold increase in amylase and 15-fold increase in lipase levels; ECG abnormalities occur in 50% of patients receiving SSG	Variation in total antimony (Sb) content; cannot assume that one drug will work like another; lot variations may contribute to safety and efficacy differences; storage conditions important (4°C in the dark optimal) (79)
Amphotericin B deoxycholate Lipid-associated amphotericin B Liposomal amphotericin B (AmBisome) Cholesterol dispersion (Amphotec) Amphotericin B lipid complex (Abelcet)	Slow i.v. over 4–6 h, starting at 0.1 mg/kg daily, increasing to 1 mg/kg every 2 days until total dose of 20 mg/kg has been given; AmBisome regimen is 3 mg/kg daily on days 1–5, sixth dose on day 14, seventh dose on day 21 (total dose is 21 mg/kg); regimen for immunosuppressed patients is 4 mg/kg daily on days 1–5, 10, 17, 24, 31, and 38 (total dose of 40 mg/kg); in this group relapse is common	Fever, chills, thrombophlebitis, renal insufficiency, anemia, hypokalemia, anorexia, nausea; caution when used on patients previously receiving SbV, who may be predisposed to cardiac events; for treatment of patients with VL within the United States, AmBisome is recommended and should be used unless contraindicated	Used in cases of VL resistant to SbV compounds; cure rates in VL clinically resistant to SbV and pentamidine approach 100%; all drugs available in United States have been approved for other conditions; AmBisome now also approved for VL; AmBisome effective and safe for VL (Brazil, India, Kenya, Mediterranean); lipid-associated amphotericin B preparations probably not more effective than amphotericin B deoxycholate but can be given at higher doses with less toxicity; also more expensive
Pentamidine (as isethionate or methane sulfonate salt)	4 mg/kg daily 3 times/wk for 24 injections (8 wk); regimens of 4–6 mo have also been used	Pain, induration, sterile abscesses at injection site; hypotensive reactions if drug given too quickly; hypoglycemia diabetes may occur; high-dose, long-duration therapy more toxic than SbV and amphotericin B, giving it a limited role in treatment of VL	Provided as sterile powder, must be dissolved in DW; administered i.m. or slow i.v.; tends to be effective in Kenya with little toxicity; resistance in India now common; addition of SbV to pentamidine does not increase the cure rate
Aminosidine (paromomycin)	Parenteral (Kenya): 15 mg/kg/day for mean of 19 days (79% cure); parenteral (India): 20 mg/kg/day for 21 days (97% cure); accepted monotherapy for Indian VL at 16 mg/kg/day for 21 days	Possible auditory nerve damage and renal damage; vertigo and pancreatitis when given i.v.	Aminoglycoside with broad antiparasitic activity; if used in combination with standard doses of SbV, shorter duration (17–20 days) possible (Kenyan, Sudanese, Indian VL)
Immunotherapy	Has been used as monotherapy and adjunct therapy in SbV-resistant and primary VL in Kenya, Brazil, and India	Fever, chills, myalgias, fatigue, headache, depression	IFN- γ should be considered when faced with SbV-resistant VL and in selected cases of relapse; expensive (1, 7, 27, 29, 32)

^a DW, distilled water (sterile); IFN- γ , gamma interferon; i.m., intramuscular; i.v., intravenous; ECG, electrocardiogram.

Epidemiology and Prevention

The public health implications of widespread *L. chagasi* infections in Central and South America may be quite broad. Parasites that cause ACL appear to be genetically very similar to those that cause AVL. This suggests that with diminished immune capacity, cutaneous infection may cause visceral disease, particularly since it is well known that this occurs in AIDS patients. ACL cases may also serve as reservoirs for vector transmission, leading to additional cases of visceral disease. Certainly treatment of these ACL patients would be recommended as a preventive measure for reduction of the number of potential future cases. Subcutaneous nodules are often misdiagnosed and treated inappropriately. Also, ACL may serve as a marker for the possible occurrence of AVL in a particular area and could be used as an indicator to more closely monitor for the presence of AVL.

In areas where humans serve as the main reservoir host, treatment of active cases is likely to interrupt the cycle of transmission. Reservoir control has proven to be somewhat sporadic, and there is little indication that it has any impact on overall infection rates. Residual insecticide spraying, primarily for malaria vector control, was relatively successful; however, when spraying of DDT was discontinued, the incidence of AVL began to increase again. Vaccines hold a great deal of promise, but currently no commercial products are available. As the incidence of disease continues to increase, particularly in Brazil, the importance of reviewing procedures for acceptance of blood donors and subsequent transfusions is becoming more relevant and important. Currently, blood is not routinely monitored for antibodies; however, serologic studies would serve as a first approach to the study of transmission of leishmanial organisms through blood transfusion. A seroreactivity of 9% has been found, increasing to 25% in a periurban focus of AVL infection (42).

Control programs for AVL often include elimination or treatment of infected dogs. Although attempting to remove seropositive dogs is insufficient as an eradication measure, data suggest that elimination of the majority of seropositive dogs may affect the cumulative incidence of seroconversion in dogs temporarily and may also diminish the incidence of human cases of AVL (57). Since one of the current strategies is based on detection and destruction of infected dogs, the highly predictive, sensitive, and specific fucose-mannose ligand ELISA represents a useful tool for field control of New World VL (13).

Trypanosomiasis

African trypanosomiasis

Trypanosoma brucei gambiense

Trypanosoma brucei rhodesiense

American trypanosomiasis

Trypanosoma cruzi

Trypanosoma rangeli

Trypanosomes are hemoflagellates of the family Trypanosomatidae that live in the blood and tissues of their human hosts (Table 9.1). The African trypanosomes belong to the subgenus *Trypanozoon* and as a group are referred to as the *Trypanosoma brucei* complex. *T. brucei brucei* are parasites of domestic and wild animals and are not known to be infectious for humans. Human infections are caused by *T. brucei gambiense* (West African trypanosomiasis) and *T. brucei rhodesiense* (East African trypanosomiasis). Infections caused by *T. brucei rhodesiense* are much more fulminant than those caused by *T. brucei gambiense*, the parasitemia is much higher, and the disease has a much faster progression. It is not possible to differentiate the three trypomastigotes of *T. brucei gambiense*, *T. brucei rhodesiense*, and *T. brucei brucei* on the basis of morphology, and all three organisms can be recovered in animal reservoir hosts. In the past, differentiation was based on clinical signs and geographic area of isolation. Differentiation is now based on isoenzyme characteristics and DNA and RNA methods in addition to the aforementioned factors. It is estimated that 60 million people in 36 countries are at risk, and there are approximately 50,000 new cases per year of African trypanosomiasis (49). Based on available information from western and central Africa, there appears to be no increased risk of African trypanosomiasis among those infected with human immunodeficiency virus (HIV); however, this has not been totally confirmed. There are also unanswered questions concerning disease presentations and diagnostic test results in patients who are coinfecting with both organisms.

Trypanosomes infecting humans in the Americas belong to the subgenus *Tejaraia* (*T. rangeli*) and *Schizotrypanum* (*T. cruzi*). *T. rangeli* infections are asymptomatic, with no evidence of pathology; however, *T. cruzi* infections (American trypanosomiasis) can cause considerable morbidity and mortality.

African Trypanosomiasis

Trypanosoma brucei gambiense

Although the first descriptions of human sleeping sickness were made by European colonists in the late 19th and early 20th centuries, Atkins described a “sleepy distemper” in 1742 and David Livingstone described a “fly disease” in

Table 9.1 Classification of trypanosomes infecting humans

	Trypanosomatidae	Family
	Trypanosoma	Genus
Schizotrypanum	Trypanozoon	Subgenus
T. (S.) cruzi	T. (T.) brucei	Species
Tejaraia	T. (T.) brucei gambiense	Subspecies
T. (T.) rangeli	T. (T.) brucei rhodesiense	

1857 (49). In 1901, *T. brucei gambiense* was seen in the blood of a European steamboat captain working on the Gambia River. After Forde's discovery in 1901, Dutton in 1902 proposed the name *Trypanosoma gambiense*. Although a trypanosome was discovered in 1903 in the spinal fluid of a patient suffering from sleeping sickness and Castellani named it *Trypanosoma ugandense*, it was soon clear that the two organisms were identical. By 1909, the mode of transmission by the tsetse fly, *Glossina palpalis*, was confirmed. The primary area of endemic infection with *T. brucei gambiense* coincides with the tsetse fly belt through the heart of Africa, where 300,000 to 500,000 people may be infected in western and central Africa (Figure 9.1). The disease remains largely unchecked due to the sophisticated biological defense mechanisms adopted by the parasite, its tolerance to therapy, and the socioeconomic realities in a region

where priorities may not include adequate surveillance and control (49).

Life Cycle and Morphology

Trypanosomal forms are ingested by the tsetse fly (*Glossina* spp.) when a blood meal is taken (Figures 9.2 and 9.3). Once the short, stumpy trypomastigote reaches the midgut of the tsetse fly, it transforms into a long, slender procyclic stage. The organisms multiply in the lumen of the midgut and hindgut of the fly. After approximately 2 weeks, the organisms migrate back to salivary glands through the hypopharynx and salivary ducts, where the organisms attach to the epithelial cells of the salivary ducts and then transform to their epimastigote forms. In the epimastigote forms, the nucleus is posterior to the kinetoplast, in contrast to the trypomastigote, in which the nucleus is anterior to the kinetoplast (Figure 9.2). There is continued multiplication

Figure 9.1 Distribution of trypanosomes in Africa. (Armed Forces Institute of Pathology photograph.)

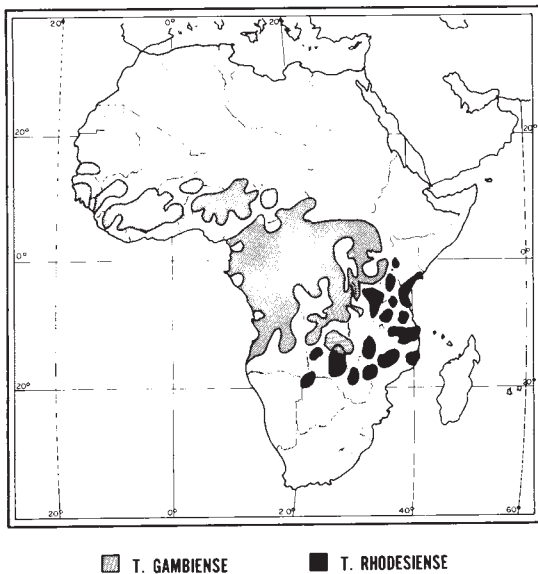

Figure 9.2 Life cycle stages of trypanosomes. Amastigotes have been confirmed in the life cycle of *Trypanosoma cruzi* as one of the stages in the human host, but this stage in humans in African trypanosomiasis is only suspected and not confirmed. (Illustration by Nobuko Kitamura.)

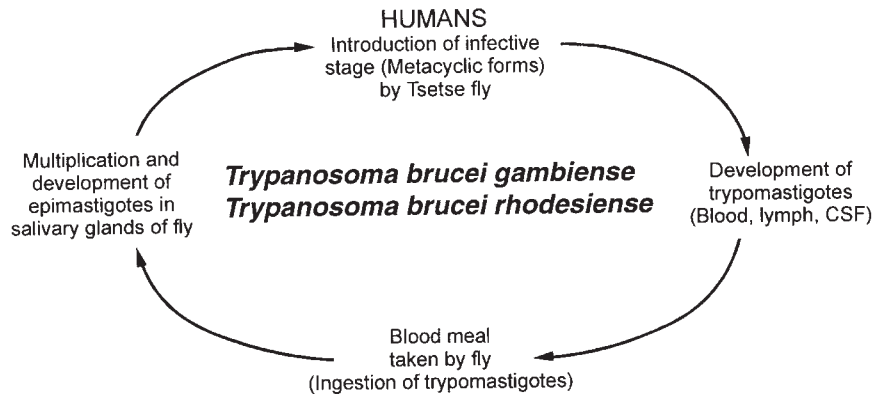

Figure 9.3 Life cycle of *Trypanosoma brucei gambiense* and *T. brucei rhodesiense*.

within the salivary gland, and metacyclic (infective) forms develop from the epimastigotes in 2 to 5 days. With development of the metacyclic forms, the tsetse fly becomes infective. During the act of feeding, the fly introduces the metacyclic trypanosomal forms into the next victim in saliva injected into the puncture wound. The entire developmental cycle in the fly takes about 3 weeks, and once infected, the tsetse fly remains infected for life.

The trypanosomal (trypomastigote) forms can be found in the blood, cerebrospinal fluid (CSF), lymph node aspirates, and fluid aspirated from the trypanosomal chancre (if one forms at the site of the tsetse fly bite). The trypomastigote forms multiply by longitudinal binary fission. The organism is highly pleomorphic, having a variety of trypanosomal forms in the same blood smear. The forms range from long, slender-bodied organisms with a long flagellum (trypomastigote) that attain a length of 30 μm or more to short, fat, stumpy forms without a free flagellum that are approximately 15 μm long. The short, stumpy forms do not divide in the bloodstream but are the infective stage for the tsetse fly.

In blood, the trypanosomes move rapidly among the red blood cells. An undulating membrane and flagellum may be seen with slower-moving organisms. The trypomastigote forms are 14 to 33 μm long and 1.5 to 3.5 μm wide (Figure 9.4). With Giemsa or Wright's stain, the granular cytoplasm stains pale blue and contains dark blue granules and possibly vacuoles. The centrally located nucleus stains reddish. At the posterior end of the organism is the kinetoplast, which also stains reddish, and the remaining intracytoplasmic flagellum (axoneme), which may not be noticeable. The flagellum arises from the kinetoplast, as does the undulating membrane. The flagellum runs along the edge of the undulating membrane until the undulating membrane merges with the trypanosome body at the anterior end of the organism. At this point, the flagellum becomes free to extend beyond the body (Figure 9.2). Although the trypomastigote is the

diagnostic stage seen in clinical specimens, amastigotes have been seen in the choroid plexus in mice.

A unique feature of African trypanosomes is their ability to change the surface coat of the outer membrane of the trypomastigote, helping to evade the host immune response. The trypomastigote surface is covered with a dense coat of approximately 10^7 molecules of the membrane-form variant surface glycoprotein (VSG). There are approximately 100 to 1,000 genes in the genome, responsible for encoding as many as 1,000 different VSGs. More than 100 serotypes have been detected in a single infection. It is postulated that the trypomastigote changes its coat about every 5 to 7 days (antigenic variation). This change is responsible for successive waves of parasitemia every 7 to 14 days and allows the parasite to evade the host humoral immune response (32). There is no evidence that the host immune system induces the VSG switches. During antigenic switching, VSG is both internalized by the trypomastigote and released or shed into the blood. This shed VSG is most probably responsible for the immune dysfunctions noticed during infections. There is a release of gamma interferon (which stimulates parasite growth), suppression of interleukin-2, and hypergammaglobulinemia. Based on studies using *T. brucei*, bloodstream forms when aggregated in the presence of antibodies can subsequently disaggregate, and this mechanism may function to aid survival of the trypomastigotes in the presence of antibody in the host prior to the occurrence of a VSG switching event (74). The disaggregation appears to be strictly energy dependent, and the organisms remain motile, metabolically active, and infective following this process.

Antigenic variation, however, is probably only one of several mechanisms enabling these parasites to thrive in spite of the host immune defenses. The ability to grow at high levels of gamma interferon, to avoid complement-mediated destruction, and to vary their susceptibility to a subclass of human high-density lipoproteins may also facilitate organism survival (29).

Figure 9.4 *Trypanosoma brucei gambiense* trypomastigotes in peripheral blood smears. Note the small kinetoplast.

The genome of *T. brucei* has been defined with a complete analysis of the 11 megabase-sized chromosomes. The 26-Mb genome contains 9,068 predicted genes, including approximately 900 pseudogenes and approximately 1,700 *T. brucei*-specific genes. There are 806 VSG genes. Based on this research, a number of potential drug targets have been identified (14).

Clinical Disease

In general, African trypanosomiasis caused by *T. brucei gambiense* (West African sleeping sickness) has a long, mild, chronic course that ends fatally with central nervous system (CNS) involvement after several years' duration. This is unlike the disease caused by *T. brucei rhodesiense* (East African sleeping sickness), which has a short course and ends fatally within a year.

After the host has been bitten by an infected tsetse fly, metacyclic trypomastigote stages are introduced into the

skin, where they multiply and set up a local inflammatory reaction. A nodule or chancre at the site (3 to 4 cm) may develop after a few days. However, this primary lesion will resolve spontaneously within 1 to 2 weeks. The chancre is seen frequently in white Europeans but rarely in patients indigenous to an area where the disease is endemic. Trypomastigotes may be detected in fluid aspirated from the ulcer. The trypomastigotes enter the bloodstream, causing a symptom-free low-grade parasitemia that may continue for months. This is considered stage I disease, where the patient can have systemic trypanosomiasis without CNS involvement. During this time, the parasites may be difficult to detect, even by thick blood film examinations. The infection may self-cure during this period without development of symptoms or lymph node invasion.

Symptoms may occur months to years after infection. The first distinct symptoms appear on invasion of the lymph nodes and are followed by the onset of remittent, irregular fevers with night sweats. Headaches, malaise, and anorexia frequently accompany the fevers. The febrile period of up to a week is followed by an afebrile period of variable duration and then another febrile period, and so on. Many trypomastigotes may be found in the circulating blood during fevers, but few are seen during afebrile periods. Lymphadenopathy is a consistent feature of Gambian trypanosomiasis. Enlarged lymph nodes are soft, painless, and nontender. Although any lymph node may be affected, posterior cervical regions are most frequently involved (Winterbottom's sign) (Figure 9.5). Trypomastigotes can be aspirated from the enlarged lymph nodes. In addition to lymph node involvement, the spleen and liver become enlarged. With Gambian trypanosomiasis, the blood-lymphatic stage may last for years before the sleeping sickness syndrome occurs.

Transient edema is frequently seen and occurs in the face, hands, feet, and other periarticular areas. Pruritus is common, and in light-skinned individuals, an irregular erythematous rash, suggestive of erythema multiforme, can be seen. The rash occurs 6 to 8 weeks after the onset of infection and is typically located on the trunk, shoulders, buttocks, and thighs. It usually lasts only a few hours, and it appears and disappears during the febrile period. Patients may experience delayed sensation to pain (Kerandel's sign). Laboratory findings include anemia, granulocytopenia, reduction in platelet counts, increased sedimentation rate, polyclonal B-cell activation with a marked increase in the levels of immunoglobulin M (IgM), heterophile and anti-DNA antibodies, rheumatoid factor, and circulating immune complex in serum. The sustained high IgM levels are a result of the parasite producing variable antigen types which allow the organism to evade the patient's defense system. *In an immunocompetent host,*

Figure 9.5 Winterbottom's sign (enlarged cervical lymph nodes in the posterior cervical triangle). (Armed Forces Institute of Pathology photograph.)

the absence of elevated IgM levels in serum rules out trypanosomiasis.

Once trypomastigotes invade the CNS, the sleeping sickness stage of the infection is initiated (stage II disease). The trypomastigotes are found primarily in the frontal lobes, pons, and medulla. Behavioral and personality changes are seen during CNS invasion. Gambian trypanosomiasis is characterized by steady progressive meningoencephalitis, apathy, confusion, fatigue, coordination loss, and somnolence. In the terminal phase of the disease, the patient becomes emaciated and progresses to profound coma and death, usually from secondary infection. Immunosuppression in patients with Gambian trypanosomiasis is manifested by decreases in both cellular and humoral immunity.

With invasion of the CNS (Figure 9.6), there is a progressive leptomeningitis, and CSF findings include increased protein levels, elevated IgM levels, lymphocytosis, and morular cells of Mott (Figure 9.7). Morular (mulberry) cells are altered plasma cells whose cytoplasm is filled with proteinaceous droplets (Figure 9.8). Morular cells are not seen in all patients; however, they are characteristic of African trypanosomiasis.

In humans with African trypanosomiasis, autoantibodies have been found, including autoantibodies directed to red blood cells, smooth muscle, liver and cardiolipid nucleic acids (DNA and RNA), and intermediate filaments of the cytoskeleton in smooth muscle cells. Autoantibodies to components of CNS myelin have also been found, as have those to neurofilament proteins in sera and CSF from untreated patients with stage II disease and CNS involvement (7). The CSF antibodies to

Figure 9.6 Coronal section of brain showing congested white matter and petechial hemorrhages. (Armed Forces Institute of Pathology photograph.)

neurofilament proteins were IgM in 22 of 25 patients and IgG in 8 of 25.

Diagnosis

Physical findings and clinical history are very important in establishing the diagnosis. Diagnostic symptoms include irregular fever, enlargement of the lymph nodes (particularly those of the posterior triangle of the neck [Winterbottom's sign]), delayed sensation to pain (Kerandel's sign), and erythematous skin rashes. Definitive diagnosis depends on demonstration of trypomastigotes in blood, lymph node aspirates, sternum bone marrow, and CSF. Due to the greater frequency of high parasitemia, there is a better chance of detecting organisms in body fluids in infections caused by *T. brucei rhodesiense* than in those caused by *T. brucei gambiense*. Because of periodicity, parasite numbers in the blood may vary; therefore, multiple specimens should be collected and a number of techniques should be used to detect the trypomastigotes (Figure 9.4; Tables 9.2 and 9.3). Health care personnel must adhere to standard precautions when handling specimens from patients with suspected cases of African trypanosomiasis because the trypomastigotes are highly infectious.

Chancre Aspirate. Organisms can be obtained from the chancre by using puncture techniques; the fluid is then examined as wet mounts and Giemsa-stained smears. This approach is seldom used; patients are generally not seen until after the chancre has already healed.

Figure 9.7 Morular cell in the hypothalamus. (Armed Forces Institute of Pathology photograph.)

Lymph Node Aspirate. When enlarged cervical lymph nodes are seen, they can be punctured and the aspirate can be examined as a wet preparation for the presence of motile trypomastigotes. The aspirated material can also be stained using Giemsa or other blood stains. Depending on a number of factors, the sensitivity ranges from about 40 to 80% (49).

Blood. Blood can be collected from either finger stick or venipuncture. Venous blood should be collected in a tube containing EDTA. Multiple slides should be made for examination, and multiple blood examinations should be done before trypanosomiasis is ruled out. Parasites are found in large numbers in the blood during the febrile period and in small numbers when the patient is afebrile. In addition to thin and thick blood films, a buffy coat concentration method is recommended to detect the parasites. Parasites can be detected on thin blood films with a detection limit at approximately 1 parasite/200 microscopic fields (high dry power magnification, $\times 400$); they can be detected on thick blood smears when the numbers are greater than 2,000/ml and when they are greater than 100/ml with hematocrit capillary tube concentration.

Figure 9.8 Close-up view of the meninges showing a morular cell. (Armed Forces Institute of Pathology photograph.)

Microhematocrit Centrifugation. The original microhematocrit centrifugation technique uses capillary tubes containing anticoagulant, filled with finger stick blood. The bottom of the tube is sealed with plasticine, and the tube is centrifuged in a hematocrit centrifuge for about 8 min. The trypomastigotes are concentrated at the buffy coat layer. The tubes are then placed in a special holder and examined through the glass at low magnification for motile organisms (21).

Microhematocrit centrifugation with use of the QBC malaria tube (glass capillary tube and closely fitting plastic insert; CBC malaria blood tubes [Becton Dickinson, Tropical Disease Diagnostics, Sparks, Md.]) has been used for the detection of blood parasites. At the end of centrifugation of 50 to 60 μ l of capillary or venous blood (5 min in a QBC centrifuge; $14,387 \times g$), parasites or erythrocytes containing parasites are concentrated into a small, 1- to 2-mm region near the top of the RBC column and are held close to the wall of the tube by the plastic

Table 9.2 Characteristics of East and West African trypanosomiasis

Characteristic	East African	West African
Organism	<i>Trypanosoma brucei rhodesiense</i>	<i>Trypanosoma brucei gambiense</i>
Vector	Tsetse fly, <i>Glossina morsitans</i> group	Tsetse fly, <i>Glossina palpalis</i> group
Primary reservoirs	Animals (wild and domestic)	Humans
Illness	Acute (early CNS invasion), <9 mo	Chronic (late CNS invasions), months to years
Lymphadenopathy	Minimal	Prominent
Parasitemia	High	Low
Epidemiology	Anthropozoonosis, game parks	Anthropozoonosis, rural populations
Diagnostic stage	Trypomastigote	Trypomastigote
Recommended specimens	Chancre aspirate, lymph node aspirate, blood, CSF	Chancre aspirate, lymph node aspirate, blood, CSF

Table 9.3 Methods available for the diagnosis of African trypanosomiasis (*T. brucei gambiense*)

Method	Description	Comments
Chancre aspirate	Puncture; fluid obtained is examined as wet preparation and Giemsa-stained smears (other blood stains are acceptable)	Not commonly used; patients are often seen after the chancre has already healed.
Lymph node aspirate	Puncture; fluid obtained is examined as wet preparation and Giemsa-stained smears (other blood stains are acceptable)	Sensitivity varies between 40 and 80%; yield is very low with seronegative patients. Not recommended unless clinical signs are present.
Blood	Both wet films and stained thick and thin blood films can be examined	Organism motility among red blood cells enhances detection; sensitivity about 1 organism per 200 microscopic fields (~10,000 trypomastigotes/ml) (using high dry objective). Stained thick blood film improves sensitivity with detection threshold of ~5,000 trypomastigotes/ml. Organism morphology better on thin blood film. Giemsa or other blood stains are acceptable.
Microhematocrit centrifugation	Centrifugation of capillary tubes containing anticoagulant filled with finger stick blood (end of tube sealed with plastic clay); tube examined under microscope, and organisms are concentrated at buffy coat layer	
Microhematocrit centrifugation (QBC)	High-speed centrifugation of blood in capillary tubes containing acridine orange; motile organisms identified by fluorescent nuclei and kinetoplasts in the buffy coat layer	Current production of QBC kit has been stopped; however, capillary tube production has been resumed (21). The technique is used sporadically within the United States (cost is a factor).
Mini-anion-exchange centrifugation	Separation of trypomastigotes from venous blood using anion-exchange chromatography; subsequent concentration at tip of glass tube	Sensitivity of <100 organisms/ml; procedure is very time-consuming. The columns are produced in Belgium. Method validation is under way.
Cerebrospinal fluid	White blood cell count used to determine disease stage; cell-counting chambers should have a capacity of 1 μ l (Fuchs-Rosenthal and Neubauer chambers); do not dilute CSF	Patients (trypomastigotes in lymph node or blood) with >20 cells/ μ l of CSF are treated as having second-stage disease; therapeutic approach depends on the geographic areas and drug selection. Trypomastigotes in CSF are confirmatory for second-stage disease; sensitivity is increased by centrifugation.
Antigen detection	A simple and rapid test, the card indirect agglutination trypanosomiasis test (TrypTect CIATT) is available, primarily in areas of endemic infection; an ELISA method has been used to detect antigen in serum and CSF	Good sensitivity but possible specificity issues with CIATT; ELISA antigen is rapidly cleared after therapy.
Antibody detection	CATT fast/simple agglutination assay for <i>T. brucei gambiense</i> -specific antibodies; latex agglutination is another option; immunofluorescence excellent (sensitivity and specificity), but lower with filter paper eluates; ELISA available for serum, filter paper eluates, and CSF	Sensitivity reported on whole blood (87–98%); negative predictive value is excellent for mass screening. Both false positives and false negatives have been reported. Can be performed with blood-impregnated filter paper. Latex agglutination shows higher specificity but lower sensitivity than fluorescence. Latex is also more specific than CATT on diluted specimens.
Molecular methods	A number of methods have been reported; however, cost and technical issues have prevented their use in the routine clinical laboratory	Some methods appear to be very sensitive; simplification of the method may lead to methods adaptable to routine clinical laboratory use.

float, thereby making them readily visible by microscopy. Tubes precoated with acridine orange provide a stain which induces fluorescence in the parasites. This method automatically prepares a concentrated smear, which represents the distance between the float and the walls of the tube. Once the tube is placed into the plastic holder (Paraviewer) and immersion oil is applied onto the top of the hematocrit tube (no coverslip is necessary), the tube is examined with a 40× to 60× oil immersion objective (there must be a working distance of 0.3 mm or greater) (refer to chapter 31).

The range of sensitivity for the QBC test has been as low as 55% up to >90% compared with microscopy. While most think the method is rapid, some think there are some disadvantages such as (i) the high cost of capillary tubes and equipment, (ii) problems in species identification and quantification, and (iii) technical problems, broken capillaries, and the fact that the capillaries cannot be stored for later reference. This may not be the most appropriate approach for a laboratory that receives a small number of specimens for blood parasite testing, but it could be helpful in other settings. Apparently the QBC kit is no longer in production, but capillary tube manufacture has been resumed (19).

Mini-Anion-Exchange Centrifugation. The mini-anion-exchange method allows the separation of trypomastigotes from venous blood by anion-exchange chromatography, with subsequent low-speed centrifugation into the tip of the glass tube. The tube is then examined under the microscope with a sensitivity of <100 organisms/ml. Validation of this approach is under way (21).

Cerebrospinal Fluid. If CSF is examined, a volume greater than 1 ml, preferably 5 ml or more, should be collected. CSF examination must be conducted with centrifuged sediments. The presence of Mott cells in the CSF is pathognomonic for trypanosomiasis. Mott cells are rarely observed when there are few white blood cells in the CSF. When trypomastigotes are present in undetectable numbers in the blood, they may be seen in aspirates of inflamed lymph nodes; however, attempts to demonstrate them histopathologically are not practical. Blood and CSF specimens should be examined during therapy to evaluate the response and again 1 to 2 months after therapy. Patients treated for CNS disease should be monitored clinically for 2 to 3 years after completion of therapy to detect a relapse.

Antigen Detection. An enzyme-linked immunosorbent assay (ELISA) method has been used to detect antigen in serum and CSF (73). It was noted that antigen was rapidly cleared from the circulation following successful therapy. This method could also be used for clinical staging of dis-

ease to determine whether there was CNS infection and for follow-up to therapy.

A simple and rapid test, the card indirect agglutination trypanosomiasis test (TrypTect CIATT), is available, primarily in areas of endemic infection, for the detection of circulating antigens in persons with African trypanosomiasis. The test is normally performed on a drop of freshly collected heparinized blood and is followed by a more specific confirmation test on diluted blood, plasma, or serum. The sensitivity of the test (95.8% for *T. brucei gambiense* and 97.7% for *T. brucei rhodesiense*) is significantly higher than that of lymph node puncture, microhematocrit centrifugation, and CSF examination after single and double centrifugation (72). Its specificity is excellent, and it has a high positive predictive value. A complement-mediated prozone phenomenon may occur, causing lower test sensitivity at lower sample dilutions. A simple solution is the addition of a Ca²⁺ chelating agent such as EDTA to the diluted blood, plasma, or serum (77).

Antibody Detection. The card agglutination test for trypanosomiasis (CATT/*T. b. gambiense*) is more sensitive than methods that require visualization of the trypomastigotes with clinical specimens and can be performed with blood, plasma, or serum. The test is produced by the Institute of Tropical Medicine in Antwerp, Belgium, and is widely used for mass population screening. This approach can also be used with blood-impregnated filter paper. It has been recommended that treatment with pentamidine should be considered for all serologically suspected individuals with a CATT-plasma end dilution titer of ≥1:16 in areas of moderate to high disease prevalence (20).

A semiquantitative ELISA, using VSG of *T. brucei gambiense* as the antigen, has been developed for the detection of antibodies of different immunoglobulin isotypes in serum and CSF of patients with sleeping sickness. In serum and CSF, a drastic increase in the level of IgG, basically IgG1, as well as in the IgM level, was seen; an increase in the IgG3 level was also seen, while the IgA level remained relatively normal. Measurement of immunoglobulin and trypanosome-specific antibody concentrations in serum and CSF allows calculation of intrathecal antibody synthesis and may be a possible tool for the determination of clinical stages of sleeping sickness (63). Both latex agglutination and immunofluorescence tests are also available; however, sensitivity results have not been as good with the latex approach as with fluorescence. Specificity with the latex test appears to be better than the CATT with diluted blood; use of the latex test also decreased the workload and costs (79, 93).

Serologic techniques which have been widely used for epidemiologic screening include indirect fluorescent-antibody assays, ELISA, the indirect hemagglutination

test, and the card agglutination trypanosomiasis test (see above). A major serodiagnostic problem in areas where the disease is endemic is that many in the population have elevated antibody levels due to exposure to animal trypanosomes that are noninfectious to humans. Serum and CSF IgM concentrations are of diagnostic value. CSF antibody titers should be interpreted with caution because of the lack of reference values and the possibility that the CSF contains serum as the result of a traumatic tap.

Molecular Methods. Accurate identification of trypanosome species, which is necessary to clarify the epidemiology of human and animal African trypanosomiasis, has been difficult. Great progress has been made over the last 10 years through the application of DNA probe technology, although this has also revealed greater complexity than was previously supposed (39). *T. brucei* organisms have been detected in human blood by using a nonradioactive branched-DNA-based method. Buffy coat specimens are used, and the results agree with those obtained using buffy coat microscopy. The assay can be performed with crude lysates without the need for extensive sample preparation. Also, because it amplifies the signal from a target molecule rather than the target itself, this technique is not prone to the artifact problems that can be seen with PCR-based tests (48). The development of a peptide nucleic acid fluorescence in situ hybridization probe appears to offer an excellent diagnostic tool. By combining this test with a cytospin step, the limit of detection from blood can be improved to 5 parasites/ml, a level of sensitivity that equals an optimal PCR detection limit with blood specimens (84). A newer PCR technique targets the gene encoding the small ribosomal subunit in order to identify and differentiate all clinically important African trypanosome species and some subspecies. This method appears to be more economical, simple, and sensitive than some other screening methods, and it yields more detailed information (24). Other real-time PCR options appear to be suitable for use within the routine clinical laboratory (12). The loop-mediated isothermal amplification (LAMP) reaction is a method that amplifies DNA with high specificity, efficiency, and rapidity under isothermal conditions with only simple incubators. An added advantage of LAMP over PCR-based methods is that DNA amplification can be monitored spectrophotometrically and/or with the naked eye without the use of dyes (58).

Animal Inoculation and Culture. *T. brucei gambiense* isolation in small laboratory animals is usually unsuccessful; in contrast, *T. brucei rhodesiense* readily infects animals. Cultivation is not practical for most di-

agnostic laboratories but is more successful than animal inoculation. See Algorithm 9.1.

KEY POINTS—LABORATORY DIAGNOSIS

Trypanosoma brucei gambiense

1. Trypomastigotes are highly infectious, and health care workers must use blood-borne-pathogen precautions.
2. Trypomastigotes may be detected in aspirates of the chancre and enlarged lymph nodes in addition to blood and CSF.
3. Concentration techniques, such as centrifugation of CSF and blood, should be used in addition to thin and thick smears (Giemsa or Wright's stain).
4. Trypomastigotes are present in largest numbers in the blood during febrile periods.
5. Examinations of multiple daily blood samples may be necessary to detect the parasite.
6. Blood and CSF specimens should be examined during therapy and again 1 to 2 months posttherapy.

Treatment

All drugs currently used in the therapy of African trypanosomiasis are toxic and require prolonged administration. Treatment should be started as soon as possible and is based on the patient's symptoms and laboratory findings. The choice of antiparasitic drug depends on whether the CNS is infected. Suramin or pentamidine isethionate can be used when the CNS is not infected. Although pentamidine is usually listed as an alternative drug, it appears that in early CNS involvement, the results (94% cure rate in a group of 52 patients observed for 2 years) are comparable to those obtained with melarsoprol or eflornithine in terms of tolerance and availability (31). Pentamidine isethionate does not cross the blood-brain barrier and is administered intramuscularly; side effects include an immediate hypotensive reaction, nausea, vomiting, and Herxheimer-type (inflammatory) reactions. Suramin (Bayer 205), a diamidine, is effective in treating the hemolymphatic stage and CNS disease of *T. brucei gambiense*. When suramin is used, a test dose should be given to the patient to ensure that the drug can be tolerated. It should not be given to patients with renal disease, and if protein, red blood cells, or casts are detected in the urine, treatment should be stopped. Suramin is given intravenously; its side effects include nausea, vomiting, loss of consciousness, seizures, pruritus, edema, and hepatitis. Although rare, fatalities have been reported during suramin therapy. Suramin can be obtained under an Investigational New Drug (IND) protocol from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, Ga., 30333;

Algorithm 9.1 African trypanosomiasis.

404-639-3670 (evenings, weekends, or holidays: 404-639-2888) (1).

Melarsoprol, a toxic trivalent arsenic derivative, is effective for both hemolymphatic and neural stages but is recommended for treatment of late-stage sleeping sickness. It is administered intravenously, and its side effects include nausea, vomiting, encephalopathy, and exfoliative dermatitis. Melarsoprol has been used for CNS involvement for years; however, relapse occurs in up to 6% of patients. Arsenic-related encephalopathy occurs in 10% of patients, and prednisolone treatment may help reduce the incidence. The mortality due to this side effect depends on whether supportive treatment is given, but it is often above 50% (67). Resistance of both *T. brucei gambiense* and *T. brucei rhodesiense* to melarsoprol has been noted.

Eflornithine (DL- α -difluoromethylornithine; DFMO) has been used for more than 10 years to treat melarsoprol-resistant *T. brucei gambiense* infection with or without CNS involvement; treatment is started intravenously and is followed by oral therapy. In one study, 47 patients with a relapse following a first treatment were treated with a 7-day course of intravenous eflornithine (100 mg/kg every 6 h) and monitored for 2 years; the failure rate was 6.5% (54). This approach appears to provide adequate treatment in cases of Gambian trypanosomiasis relapsing after treatment with another drug. Disadvantages of eflornithine therapy include the prolonged course of treatment and frequent side effects of diarrhea and anemia. With adequate treatment, non-CNS disease has a cure rate of >80%. All

treated patients should be followed up twice yearly for at least 2 to 3 years. Specific drug dosage information is provided in chapter 25; however, apparently eflornithine is no longer commercially available but can be obtained under an IND protocol from the CDC Drug Service (1, 49).

Nifurtimox (Lampit), a nitrofurantoin, has been used to treat patients infected with *T. brucei gambiense* who do not respond to melarsoprol. The relapse rate is quite high when nifurtimox is used alone, but the drug is quite effective when used in combination with melarsoprol (97). It is given orally. Side effects include confusion, tremor, vertigo, anorexia, and weight loss. This drug is not recommended for the treatment of *T. brucei rhodesiense* infections. Nifurtimox can be obtained under an IND protocol from the CDC Drug Service (1).

Epidemiology and Prevention

T. brucei gambiense is transmitted from person to person by the bite of the tsetse fly (*G. palpalis* and *G. tachinoides*) after infectivity develops within the insect. The development cycle in the fly, depending on temperature and moisture, varies from 12 to 30 days and averages 20 days. Fewer than 10% of tsetse flies become infective after obtaining blood from infected patients, and vertical transmission from infected fly to offspring is not known to occur. *G. palpalis* and *G. tachinoides* can be found in areas of thick shrubbery and trees near the banks of rivers, streams, or water holes; therefore, transmission readily occurs when people frequent these areas. Both female and male tsetse flies can transmit the infection. In addition to biological transmission, the tsetse fly may mechanically transmit the infection with its proboscis if it bites an uninfected person within a few hours of biting an infected person. Congenital transmission in humans has also been documented.

Although *T. brucei gambiense* can be transmitted to animals, no animal reservoirs for West African sleeping sickness have been documented. Trypanosomal strains isolated from hartebeest, kob, chickens, dogs, cows, and domestic pigs in West Africa are identical to those isolated from humans in the same area. These findings suggest that animals may serve as reservoirs; however, there is no indication that these animal trypanosomal forms are directly transmitted to humans and that a patent infection will develop. Epidemiologic evidence suggests that in areas of endemic infection, transmission may be entirely from human to human. Asymptomatic individuals are thought to be the residual reservoir of the disease.

In areas where West African sleeping sickness is endemic, *T. brucei gambiense* has been controlled by eliminating the parasite through regular population-screening programs. This approach effectively reduces the prevalence of the disease to low levels; however, with

interruptions in surveillance, resurgence of the disease will occur. An example of resurgence of West African trypanosomiasis was well documented in southern Sudan, where the disease prevalence found was among the highest ever documented.

Although game parks in Tanzania (Tarangire and Serengeti National Parks) were thought to be low-risk areas for African trypanosomiasis, during 2001 nine patients from these areas were diagnosed with *T. brucei gambiense* infection. All of the South African patients but one were European nationals. During their trip or shortly after their return, the patients, all febrile, were seen by general practitioners or emergency departments. Most patients were seen during the primary disease stage; however, several showed cerebral manifestations of the secondary stage. Most patients also showed a typical skin lesion, the trypanosome chancre. Diagnosis was established by examining thin and thick blood films. Although three patients had multiorgan failure, and specific medication was difficult to obtain, drug treatment proved successful in all but one patient, who died (53).

At present, there are no areas where *T. brucei gambiense* and *T. brucei rhodesiense* are endemic together. Although foci of both organisms exist in Uganda, they appear to be geographically separate. Based on evidence of the spread of cattle carrying *T. brucei rhodesiense* further north, a merger of the two foci could create tremendous problems since the diagnosis and treatment of the two diseases differ significantly (19, 26).

Vector control measures have met with limited success. Methods have included clearing streams of underbrush, eliminating breeding grounds, using insecticides, using fly traps, and releasing sterile male flies. Because tsetse flies have a low reproductive rate and have not developed insecticide resistance, they are very tempting control targets. The most effective control measures include an integrated approach to reduce the human reservoir of infection and to use insecticides and fly traps.

In regions where the disease is endemic, natives appear to be more resistant to infection than are new arrivals to the area, even though there is no evidence of acquired immunity. West African sleeping sickness affects primarily the rural populations, and tourists are rarely infected. Chemoprophylaxis is not recommended because of drug toxicity, and vaccines are unavailable. It may be possible to develop a vaccine, because immunity to reinfection occurs with *T. brucei gambiense*.

Tourists are usually not at great risk unless they are traveling and spending long periods in rural areas of western and central Africa. Persons visiting areas where the disease is endemic should avoid tsetse fly bites by wearing protective clothing (long-sleeved shirts and long pants); khaki or olive-colored clothing is optimal, since the tsetse fly is attracted to bright colors and very dark

colors. Because heavy clothing is not always practical owing to heat and humidity, other measures, including the use of insect repellents, bed netting, and screens, are recommended. It has also been recommended not to ride in the back of jeeps, pickup trucks, or other open vehicles; the tsetse fly is attracted to the dust created by moving vehicles and wild animals. Bushes should be avoided, since the tsetse fly is less active during the hot period of the day and rests in bushes but will bite if disturbed.

Trypanosoma brucei rhodesiense

T. brucei rhodesiense is closely related to *T. brucei gambiense*, and the two subspecies are morphologically indistinguishable. Stephans and Fantham in 1910 discovered *T. brucei rhodesiense* in the blood of a patient in Rhodesia with symptoms consistent with "sleeping sickness." In 1912, this organism was shown to be transmitted by a different species of tsetse fly (*Glossina morsitans*) from that associated with *T. brucei gambiense* (*G. palpalis*). *T. brucei rhodesiense* was also differentiated from *T. brucei gambiense* on the basis of virulence in rats and detection of a morphologic variant not previously found in *T. brucei gambiense*. Many investigators think that *T. brucei rhodesiense* is the human strain of *T. brucei*, a common trypanosome that is found in many game animals and causes a fatal disease known as nagana in cattle. In 1961, Ormerod indicated that the original strains of *T. brucei rhodesiense* probably arose in the Zambesi basins as mutants from *T. brucei* (11). In the early 1900s, human volunteer inoculation studies with *T. brucei* resulted in no human infections. Currently, it is accepted that there are two subspecies within the *T. brucei* species, and they have been designated *T. brucei gambiense* and *T. brucei rhodesiense*. *T. brucei rhodesiense* (which causes Rhodesian trypanosomiasis or East African sleeping sickness) is more limited in distribution than *T. brucei gambiense*, being found only in central East Africa, where the disease has been responsible for some of the most serious obstacles to economic and social development in Africa. Within this area, the vast majority of tsetse flies prefer animal blood, which therefore limits the raising of livestock. The infection has a greater morbidity and mortality than does *T. brucei gambiense* infection, and game animals, such as the bushbuck, and cattle are natural reservoir hosts. Biochemical evidence shows that the human-infective *T. brucei rhodesiense* differs from the human-infective *T. brucei brucei* because of its resistance to lysis by components in human serum. This resistance can be acquired by sensitive strains and is caused by the decreased internalization of a trypanolytic factor. Thus, *T. brucei rhodesiense* appears to be a host range variant of *T. brucei brucei* (49). While human- and non-human-infective strains are genetically closely related, very little gene flow appears

to be occurring between these two host range variants in natural populations. Restricted gene flow could be due to a lack of genetic exchange caused by lack of opportunity or some type of biological barrier. Evidence also suggests that genetic exchange can occur in the tsetse fly; however, large-scale studies of *T. brucei* genotypes in tsetse flies are difficult, especially since only 0.1% of the flies are usually infected (49).

Life Cycle and Morphology

The life cycle and reproduction of *T. brucei rhodesiense* are similar to those of *T. brucei gambiense* (Figure 9.3). The tsetse fly vectors for transmission of *T. brucei rhodesiense* are *G. pallidipes*, *G. morsitans*, and *G. tachinoides*. The morphology of *T. brucei rhodesiense* in tsetse flies and humans is similar to that of *T. brucei gambiense*, except that when the parasite is inoculated into laboratory animals, the posterior nucleate forms are more common.

Clinical Disease

T. brucei rhodesiense produces a more rapid, fulminating disease than does *T. brucei gambiense*. Fever, severe headaches, irritability, extreme fatigue, swollen lymph nodes, and aching muscles and joints are common symptoms. Progressive confusion, personality changes, slurred speech, seizures, and difficulty in walking and talking occur as the organisms invade the CNS. The early stages of the pathologic process parallel those of *T. brucei gambiense* infections; however, the disease progresses more rapidly, such that death may occur before there is extensive CNS involvement even though CNS invasion occurs early. The incubation period is short, often within 1 to 4 weeks, with trypomastigotes being more numerous and appearing earlier in the blood. Lymph node involvement is less pronounced, and Winterbottom's sign may be absent. Febrile paroxysms are more frequent, and the patients are more anemic and more likely to develop myocarditis or jaundice. Some patients may develop persistent tachycardia, and death may result from arrhythmia and congestive heart failure due to pancarditis. Myocarditis may develop in patients with Gambian trypanosomiasis but is more common and severe with the Rhodesian form. Review of a splenectomized patient with Rhodesian trypanosomiasis and CNS involvement revealed that the onset of symptoms, laboratory studies, and disease progression did not differ from those for reported cases in healthy individuals (65). However, the role of the spleen in trypanosomiasis is not well understood.

Diagnosis

The techniques used are similar to those for detecting Gambian trypanosomiasis; however, trypomastigotes are more numerous in the blood in the Rhodesian form (Table 9.2). A differential diagnosis may be possible

on geographic grounds, but there are areas where the two forms overlap. Because infection with *T. brucei rhodesiense* is so fulminant, the immune response with humoral antibody will be weaker than that for *T. brucei gambiense* infections; therefore, serodiagnosis may be difficult. Blood and CSF specimens should be examined during and 1 to 2 months after therapy.

T. brucei rhodesiense is more adaptable to cultivation than is *T. brucei gambiense*. A number of media have been described; however, cultivation is not a practical diagnostic approach. See Algorithm 9.1, Table 9.4, and the "Key Points—Laboratory Diagnosis" presented below.

KEY POINTS—LABORATORY DIAGNOSIS

Trypanosoma brucei rhodesiense

1. Trypomastigotes are highly infectious, and health care workers must use blood-borne-pathogen precautions.
2. Trypomastigotes may be detected in aspirates of the chancre and enlarged lymph nodes in addition to blood and CSF; trypomastigotes tend to be more numerous in the blood in Rhodesian trypanosomiasis, and diagnosis is normally confirmed from blood examination.
3. Concentration techniques, such as centrifugation of CSF and blood, should be used in addition to thin and thick smears (Giemsa or Wright's stain). However, concentration methods may not be required, since organisms tend to be numerous in the blood.
4. Trypomastigotes are present in the blood in largest numbers during febrile periods.
5. Examinations of multiple daily blood samples may be necessary to detect the parasite.
6. Blood and CSF specimens should be examined during therapy and 1 to 2 months posttherapy.
7. Culture is possible using well-described media but is probably not practical for most diagnostic laboratories; again, the use of blood-borne-pathogen precautions is mandatory.

Treatment

Because East African trypanosomiasis is such a serious illness, treatment should be started as soon as possible and is based on the patient's symptoms and laboratory findings. Within the United States, medication and therapeutic advice is available through the CDC. Without treatment, nearly all patients develop neural involvement and die; however, even in treated patients, in those with CNS infection, cure rates are above 80%. The choice of antiparasitic drug depends on whether the CNS is infected; usually patients are hospitalized during treatment. Suramin or pentamidine isethionate can be used early in the course of

Table 9.4 Methods available for the diagnosis of African trypanosomiasis (*T. brucei rhodesiense*)

Method	Description	Comments
Chancre aspirate	Puncture; fluid obtained is examined as wet preparation and Giemsa-stained smears (other blood stains are acceptable)	Not commonly used; patients are often seen after the chancre has already healed.
Lymph node aspirate	Puncture; fluid obtained is examined as wet preparation and Giemsa-stained smears (other blood stains are acceptable)	Normally not required, disease presents as acute febrile illness.
Blood	Both wet films and stained thick and thin blood films can be examined	Organism motility among red blood cells enhances detection; trypomastigotes are generally numerous. Organism morphology better on thin blood film. Giemsa or other blood stains acceptable.
Microhematocrit centrifugation	Centrifugation of capillary tubes containing anticoagulant filled with finger stick blood (end of tube sealed with plastic clay); tube examined under microscope; and organisms are concentrated at buffy coat layer	Simple method, widely used for epidemiology studies; based on large numbers of organisms in <i>T. brucei rhodesiense</i> infections. Buffy coat should be highly motile with organisms.
Microhematocrit centrifugation (QBC)	High-speed centrifugation of blood in capillary tubes containing acridine orange; motile organisms identified by fluorescent nuclei and kinetoplasts in the buffy coat layer	Current production of QBC kit has been stopped; however, capillary tube production has been resumed (21). The technique is used sporadically within the United States (cost is a factor).
Mini-anion-exchange centrifugation	Separation of trypomastigotes from venous blood using anion-exchange chromatography; subsequent concentration at tip of glass tube	Sensitivity of <100 organisms/ml; procedure is very time-consuming. The columns are produced in Belgium. Method validation is under way. Not required for diagnosis of <i>T. brucei rhodesiense</i> (many organisms present).
Cerebrospinal fluid	White blood cell count used to determine disease stage; cell-counting chambers should have a capacity of 1 μ l (Fuchs-Rosenthal and Neubauer chambers); do not dilute CSF	Patients (trypomastigotes in lymph node or blood) with >20 cells/ μ l of CSF are treated as having second-stage disease; therapeutic approach depends on the geographic areas and drug selection. Trypomastigotes in CSF are confirmatory for second-stage disease; sensitivity is increased by centrifugation.
Antigen detection	Not relevant for <i>T. brucei rhodesiense</i> due to large numbers of trypomastigotes in blood	Diagnostic method much more relevant for <i>T. brucei gambiense</i> infections.
Antibody detection	No equivalent to CATT available for screening for <i>T. brucei rhodesiense</i> ; development and testing under way for agglutination card tests and particle agglutination tests; immunofluorescence tests and ELISA for antibody available, but the sensitivity varies	Immunofluorescence tests and ELISA available in reference centers (highly skilled individuals are required for testing and interpretation).
Molecular methods	Molecular markers (serum resistance-associated gene, <i>T. brucei rhodesiense</i> ; receptor-like flagellar pocket glycoprotein, <i>T. brucei gambiense</i>) may be helpful in monitoring the distribution of both species	Could also be helpful for targeting therapy for cattle infected with <i>T. brucei rhodesiense</i> , as well as distinguishing species in humans exposed to both organisms.

the infection, when the CNS is not infected. Pentamidine isethionate does not cross the blood-brain barrier and is administered intramuscularly; side effects include an immediate hypotensive reaction, nausea, vomiting, and Herxheimer-type (inflammatory) reactions.

Suramin is the drug of choice for treating the hemolymphatic stage of *T. brucei rhodesiense* infections. When suramin is used, a test dose should be given to

the patient to ensure that the drug can be tolerated. It should not be given to patients with renal disease, and if protein, red blood cells, or casts are detected in the urine, treatment should be stopped. Suramin is given intravenously; its side effects include nausea, vomiting, loss of consciousness, seizures, pruritus, edema, and hepatitis. Although rare, fatalities have been reported during suramin therapy. Suramin can be obtained under

an IND protocol from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, Ga., 30333; 404-639-3670 (evenings, weekends, or holidays: 404-639-2888) (1).

Melarsoprol is capable of penetrating the blood-brain barrier and is the drug of choice when *T. brucei rhodesiense* CNS disease is suspected; it is effective for both hemolymphatic and neural stages. Melarsoprol has been used for CNS involvement for years; however, relapse occurs in up to 6% of patients. Arsenic-related encephalopathy occurs in 10% of patients, and prednisolone treatment may help reduce the incidence. The mortality due to this side effect depends on whether supportive treatment is given, but it is often above 50% (67). Resistance of both *T. brucei gambiense* and *T. brucei rhodesiense* to melarsoprol has been noted. Melarsoprol can be obtained under an IND protocol from the CDC Drug Service (1). All treated patients should be followed up twice yearly for at least 2 to 3 years. Specific drug dosage information is provided in chapter 25.

Epidemiology, Epidemics, and Prevention

The incidence of *T. brucei rhodesiense* infections is considerably lower than that of *T. brucei gambiense* infections, and the extent of distribution is smaller. East African trypanosomiasis is usually found in woodland and savannah areas away from human habitation. The tsetse fly vectors of Rhodesian trypanosomiasis are game feeders that may incidentally transmit the disease from human to human or animal to human. Because the infection results in acute rather than chronic disease, asymptomatic carriers are not a source of transmission as they are in Gambian trypanosomiasis. The disease is an occupational hazard for persons working in game reserves and a threat to visitors to game parks. *T. brucei rhodesiense* has been isolated from a variety of game animals (bushbuck, hartebeest, and lion) and domestic animals (cattle and sheep), a group that may prove to be the more important group of reservoir animals.

The incidence of East African trypanosomiasis is characterized by short epidemics interspersed with long periods of low (often undetectable) endemicity (50). The reasons for such outbreak situations have been widely discussed and debated. Studies of the composition of trypanosome strains present during epidemics have been directed at answering the following questions. (i) Are human-infective trypanosomes (*T. brucei rhodesiense*) distinct from those infecting animals (*T. brucei brucei*)? (ii) Are new strains responsible for the outbreaks? (iii) Are animals an important reservoir for strains that cause human disease? (iv) Can the occurrence of new outbreaks be traced to the movement of new "virulent" strains into the area?

Distinguishing the Two Organisms. Field data using restriction fragment length polymorphism analysis of

repetitive DNAs and isoenzymes confirm that the sub-specific distinction of *T. brucei rhodesiense* and *T. brucei brucei* appears to be correct (50). Although isoenzyme analysis had incorrectly detected taxonomy identity caused by convergent evolution, DNA patterns in restriction fragment length polymorphism indicate that strains of *T. brucei rhodesiense* from Zambia and from Kenya and Uganda are very different and have independent origins.

Animal Reservoirs of Sleeping Sickness. In the past, it was assumed that wild animals, particularly bushbuck, were the most important reservoir host of the parasites. More recently, cattle have been implicated in several outbreaks (50). Data show that between 21 and 33% of infected domestic animals (particularly cattle) can be infected with trypanosomes that are also infective for humans during an epidemic. Probabilities of transmission indicate that a fly infected with *T. brucei rhodesiense* is five times more likely to have picked up that infection from domestic cattle than from a human.

"New Strains" and Epidemics. In looking at changes in the ecology of a region, the appearance of a new strain, and the generation of new zymodemes by genetic exchange, it appears that there is little evidence to support the idea of new strains as a mechanism for the generation of epidemics but that the spread of a single existing strain group is more likely to be responsible.

Movement of People and Trypanosomes. It was originally thought that *T. brucei rhodesiense* originated in Zambia in the early 1900s and spread north to cause epidemics in Uganda and Kenya in the 1940s. However, analysis of trypanosomes from various locales does not support this idea. It is more likely that the origins of Rhodesian sleeping sickness in the Uganda foci were there all the time and actually coexisted with the outbreaks in Zambia (50).

Model for the Origin and Maintenance of Disease Foci in East Africa. A model can be proposed as follows: (i) each sleeping sickness focus has a single strain of human-infective trypanosome associated with it; (ii) this strain is maintained within the ecosystem of the focus, even in times of endemicity; and (iii) when favorable epidemiologic conditions are present, this strain generates an epidemic (49). A number of stages can be involved: (i) a new genotype arises that can be maintained in the population; (ii) once a transmission cycle is established, selection may maintain a single human-infective strain or a small number of such strains; and (iii) epidemic selection of this strain may occur when the tsetse fly biting rate increases. When the overall density of the infected human population increases, a full-blown epidemic

caused by a single trypanosome strain occurs. A period of endemicity then follows as control measures decrease the number of cases. The human-infective strains are left circulating until such time as ecologic changes trigger another epidemic.

Control Measures. Because Rhodesian trypanosomiasis is a zoonosis, control measures are more difficult to attain than with the Gambian form. In the past, reduction or elimination of game animals has been a major control method, although more recent information suggests that cattle are more relevant as reservoir hosts. Other measures used were the reduction of human contact in areas of endemic infection, reduction of vegetation around human settlements, insecticide spraying, use of fly traps, and prophylactic treatment of domestic animals. Tourists are usually not at great risk unless they are traveling and spending long periods in rural areas of eastern and central Africa. Persons visiting areas where the disease is endemic should avoid tsetse fly bites by wearing protective clothing (long-sleeved shirts and long pants); khaki or olive-colored clothing is optimal, since the tsetse fly is attracted to bright colors and very dark colors. Because heavy clothing is not always practical owing to heat and humidity, other measures, including the use of insect repellents, bed netting, and screens, are recommended. It has also been recommended not to ride in the back of jeeps, pickup trucks, or other open vehicles; the tsetse fly is attracted to the dust created by moving vehicles and wild animals. Bushes should be avoided, since the tsetse fly is less active during the hot period of the day and rests in bushes but will bite if disturbed.

With constant political change in Africa, vector control, mass treatment, prophylaxis, and population movement tracking will remain very difficult. Unfortunately, constant monitoring of areas of endemic infection is very difficult to accomplish and trained personnel continue to be scarce as other issues take priority.

American Trypanosomiasis

Trypanosoma cruzi

American trypanosomiasis (Chagas' disease) is a zoonosis caused by *T. cruzi*, which was discovered in the intestine of a triatomid bug in Brazil in 1909 by Carlos Chagas, who described the entire life cycle in reservoir hosts. After infected bugs were allowed to feed on a monkey, the trypomastigote form was found in the blood of the animal. Chagas then found the organisms in the blood of a child who had fever, anemia, and enlargement of the lymph nodes; he proved that the parasites were the cause of this common illness endemic in areas of Brazil. It is

interesting that this represents the first example where an animal parasite causing the disease and the insect vector were discovered prior to the disease itself. Based on his assumption that the organism multiplies by schizogony, Chagas named the parasite *Schizotrypanum cruzi*, a name that is still used by some. *T. cruzi* causes an acute or chronic parasitemia and invades the cells of many organs (e.g., the heart, esophagus, and colon). Chagas' disease has been found in a 15th- or 16th-century Peruvian mummy with megacolon and megaesophagus. It is one of the major health problems in Latin American countries.

It is estimated that 100 million persons are at risk of infection; between 16 million to 18 million are actually infected. There are approximately 50,000 deaths per year due to Chagas' disease. In certain areas of endemic infection, approximately 10% of all adult deaths are due to Chagas' disease. The southern United States, particularly Texas, is also now identified as having a number of cases. The geographic distribution of *T. cruzi* infection overlaps that of *T. rangeli* infection; therefore, the trypomastigotes may be misidentified (Table 9.5).

Two evolutionary lineages have been identified in *T. cruzi*, *T. cruzi* I and II. Prior to 2005, epidemiological and immunological data suggested that chronic infections occurring in Brazil and Argentina were caused primarily by *T. cruzi* II strains. Using PCR techniques, this hypothesis has been confirmed, and future studies can establish which strains are responsible for Chagas' disease in other geographic locations (36, 98).

Life Cycle and Morphology

The disease is transmitted to humans through the bite wound caused by reduviid bugs (triatomids, kissing bugs, or conenose bugs) (Figure 9.9). Humans are infected when metacyclic trypomastigotes are released with the feces while the insect is taking a blood meal and the feces are rubbed or scratched into the bite wound or onto mucosal surfaces such as eyes or mouth, an action stimulated by the allergic reaction to the insect's saliva. The organisms can also be transmitted as congenital infections, by blood transfusion, or by organ transplantation. On entry into the body, the metacyclic forms invade local tissues, transform to the amastigote stage, and begin to multiply within the cells. The local inflammatory process continues, forming the primary lesion, the chagoma, which blocks the lymphatic capillaries and causes edema.

A number of receptors have been identified that are involved in the invasion process of the trypomastigote into the host cell. In humans, *T. cruzi* can be found in two forms, amastigotes and trypomastigotes (Figures 9.2, 9.10, and 9.11). The trypomastigote does not divide in the blood but carries the infection to all parts of the body.

Table 9.5 Characteristics of American trypanosomiasis

Characteristic	<i>Trypanosoma cruzi</i>	<i>Trypanosoma rangeli</i>
Vector	Reduviid bug	Reduviid bug
Primary reservoirs	Opossums, dogs, cats, wild rodents	Wild rodents
Illness	Symptomatic (acute, chronic)	Asymptomatic
Diagnostic stage		
Blood	Trypomastigote	Trypomastigote
Tissue	Amastigote	None
Recommended specimens	Blood, lymph node aspirate, chagoma	Blood, but organisms rarely recovered

The amastigote form multiplies within virtually any cell, preferring cells of mesenchymal origin such as reticulo-endothelial, myocardial, adipose, and neuroglial cells. The parasites also occur in histiocytes of cutaneous tissue and in cells of the epidermis, as well as in the intestinal mucous membrane.

The trypomastigote (Figure 9.10) is spindle shaped and approximately 20 μm long, and it characteristically assumes a C or U shape in stained blood films. Trypomastigotes occur in the blood in two forms, a long slender form and a short stubby one. The nucleus is situated in the center of the body, with a large oval kinetoplast located at the posterior extremity. The kinetoplast consists of a small blepharoplast and a large oval parabasal body. A flagellum arises from the blepharoplast and extends along the outer edge of an undulating membrane until it reaches the anterior end of the body, where it projects as a free flagellum. When the trypomastigotes are stained with Giemsa stain, the cytoplasm stains blue and the nucleus, kinetoplast, and flagellum stain red or violet.

On invasion of a cell, the trypomastigote loses its flagellum and undulating membrane and divides by binary fission to form an amastigote (Figure 9.11). The

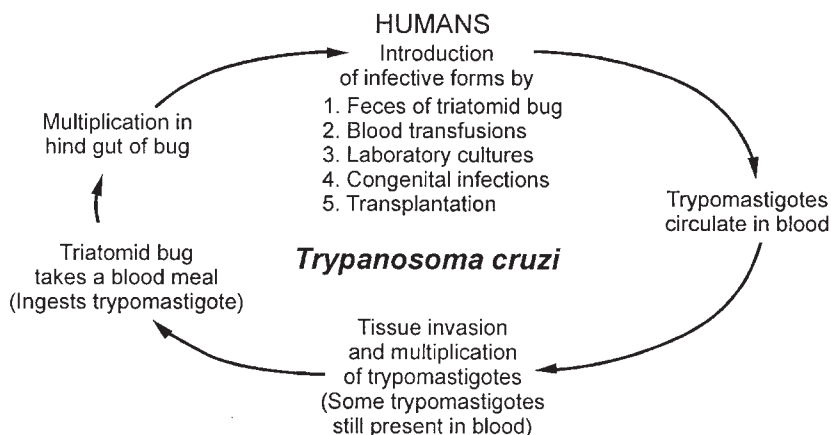

amastigote continues to divide and eventually fills and destroys the infected cell. Both amastigote and trypomastigote forms are released from the cell. The amastigote is indistinguishable from those found in leishmanial infections. It is 2 to 6 μm in diameter and contains a large nucleus and rod-shaped kinetoplast that stains red or violet with Giemsa stain. The cytoplasm stains blue. Only the trypomastigotes are found free in the peripheral blood.

Trypomastigotes are ingested by the reduviid bug as it obtains a blood meal. The trypomastigote transforms into an epimastigote that multiplies in the posterior portion of the midgut (Figure 9.12). After 8 to 10 days, metacyclic trypomastigotes develop from the epimastigotes and are passed in the feces to infect humans when rubbed into the insect's puncture wound or rubbed onto exposed mucous membranes.

Clinical Disease

In addition to contracting *T. cruzi* infections through the insect's bite wound or exposed mucous membranes, persons can be infected by blood transfusion, organ transplantation, placental transfer, and accidental ingestion of parasitized reduviid bugs. The clinical syndromes associated with Chagas' disease can be broken down into acute, indeterminate, and chronic stages. The acute stage is the result of the first encounter of the patient with the parasite, whereas the chronic phase is the result of late sequelae. In children younger than 5 years, the disease is seen in its severest form, whereas in older children and adults, the disease is milder and is commonly diagnosed in the subacute or chronic form rather than in the acute form. Overall, the incubation period in humans is about 7 to 14 days but is somewhat longer in some patients.

Early Disease. A localized inflammatory reaction of variable intensity may ensue at the infection site. In most cases, the reaction is mild and may not be apparent. An erythematous subcutaneous nodule (chagoma), seen

**Figure 9.9** Life cycle of *Trypanosoma cruzi*.

Figure 9.10 (Top and middle) *Trypanosoma cruzi* trypomastigotes in a peripheral blood smear. Note the large kinetoplast. (Bottom) Scanning electron micrograph of a trypomastigote of *T. cruzi*. (Bottom photograph courtesy of David T. John.)

most frequently on the face, may form. The chagoma is painful and may take 2 to 3 months to subside. In early stages of infection, amastigotes or trypomastigotes may be aspirated from the chagoma; if the route of inoculation is the ocular mucosa, edema of the eyelids and conjunctivitis may occur (Romaña's sign) (Figure 9.13). The edema does not pit on pressure, and the skin is dry. Although Romaña's sign is thought to be almost pathognomonic for early Chagas' disease, in an analysis of 300 patients with early disease, unilateral periorbital edema was found in only 48.7% of patients (11). The infective stages spread to the regional lymph nodes, which become enlarged,

Figure 9.11 *Trypanosoma cruzi* amastigotes in cardiac muscle.

hard, and tender. Similar chagoma lesions may develop in other body areas as the infection spreads hematogenously. Trypomastigotes appear in the blood about 10 days after infection and persist through the acute phase. These stages are rare or absent during the chronic phase.

Acute-Stage Disease. Acute-stage symptoms only occur in about 1% of patients, are usually seen in younger children, and are less obvious in older individuals because of the nonspecific nature of the symptoms and the lack of availability of health care. In general, symptoms last for 4 to 8 weeks and then may subside, even without therapy.

Figure 9.12 Epimastigotes of *Trypanosoma cruzi*.

Acute systemic signs occur around week 2 to 3 of infection and are characterized by high fevers, which may be intermittent, remitting, or continuous; hepatosplenomegaly; myalgia; erythematous rash; acute myocarditis; lymphadenopathy; keratitis; and subcutaneous edema of the face, legs, and feet. There may be signs of CNS involvement including meningoencephalitis, which has a very poor prognosis. Myocarditis is manifested by electrocardiographic changes, tachycardia, chest pain, and weakness. Amastigotes proliferate within and destroy the cardiac muscle cells, leading to conduction defects and a loss of heart contractility (Figures 9.14 to 9.17). Death may occur due to myocardial insufficiency or cardiac arrest. In infants and very young children with acute Chagas' disease, swelling of the brain can develop, causing death. Also, in some areas of endemic infection, a high frequency of early electrocardiographic abnormalities in children who are *T. cruzi* seropositive suggests a rapid evolution from infection to disease. Under such conditions, a public health chemotherapy program targeted to this population would be recommended (27).

Probably all patients with acute Chagas' disease show some degree of myocarditis, which is apparently directly related to the presence of parasitic antigens. Apparently, both CD4 and CD8 cells participate in the pathogenesis of myocarditis, possibly leading to chronic heart failure (37). The numbers of CD4 and CD8 cells may actually correlate better with myocarditis than does the presence of parasite antigens.

Indeterminate Stage. Patients in the acute stage of Chagas' disease may die within a few weeks or months, may recover, or may enter the chronic stage of infection. The patient may have a subpatent parasitemia and

Figure 9.13 (Upper) Female child with Romaña's sign. (Armed Forces Institute of Pathology photograph.) (Lower) Male child with Romaña's sign. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

will develop antibodies to a variety of *T. cruzi* antigens. Chronic Chagas' disease is diagnosed more commonly than the acute disease. The chronic stage may be initially asymptomatic (indeterminate stage), and even though trypomastigotes are seldom seen in peripheral blood, transmission by blood transfusion is a serious problem in areas where the disease is endemic. There are regional variations in disease severity, which may account for the geographic differences in morbidity. Approximately 8 to 10 weeks after infection, the indeterminate stage begins, during which the patients do not have any symptoms. Patients infected with low-virulence strains may remain infected for years with few to no problems.

Chronic Stage. Chronic Chagas' disease demonstrates close interaction between the parasite and the host, causing

Figure 9.14 An enlarged heart in a 46-year-old man 13 days after onset of acute Chagas' disease. (Armed Forces Institute of Pathology photograph.)

a number of different clinical syndromes. Approximately 30% of patients develop chronic Chagas' disease and experience cardiomyopathy, megacolon, and megaesophagus. Symptoms of the chronic stage are related to the damage sustained during the acute stage of the disease, the state of the host's immune system, and the inflammatory response. Other contributing factors include the host genetic background, environmental and social factors, the genetic composition of the parasite, mixed infections, and reinfections (16). The inflammatory response undergoes periods of exacerbation and is probably responsible for neuronal damage, microcirculatory changes, heart matrix deformations, and possible cardiac failure (51). Selenium deficiency has also been linked to some cardiomyopathies and appears to be a biological marker for Chagas' disease and related to progressive pathology (86).

Chronic Chagas' disease may develop years or decades after undetected infection or after the diagnosis of acute disease. The most frequent clinical sign of chronic Chagas' disease is cardiomyopathy manifested by cardiomegaly and conduction changes. Myocardial damage typical of catecholamine cardiotoxicity has been described as an explanation for sudden patient death. Death has been attributed to focal denervation with regional asynergy and consequent compensatory adrenergic stimulus with myotoxicity and

Figure 9.15 Acute chagasic myocarditis. (Original photograph by B. H. Kean; from *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

malignant arrhythmia (9). A review of the potential influence of associated risk factors such as smoking, alcoholism, obesity, and hypertension on the establishment of chronic chagasic cardiomyopathy showed that these factors apparently were not associated with increased risk (13).

Autoimmunity Hypothesis (Pros and Cons). The merits of the autoimmunity hypothesis for the pathogenesis of Chagas' disease have been debated for years. Although several auto- or cross-reactive antibodies have been identified in chagasic patients, no convincing evidence exists for their ability to induce the lesions seen in infected patients (55). Because so few organisms are isolated or seen in heart tissue, much of the cardiac tissue destruction is thought to be related to autoimmune antibodies, possibly due to cross-reactivity with related *T. cruzi* antigens (molecular mimicry) (40–43, 52, 62). There is massive lymphocyte polyclonal activation, which results in the generation of autoantibodies cross-reacting with parasites and host tissues. Degenerative abnormalities occur in cardiac, esophageal, and colon tissues, leading to megasyndrome. The mechanism that triggers the megasyndrome is unknown. An antibody that reacts with endocardium, vascular structures, and interstitium of striated muscle (EVI antibody) has been detected in patients with Chagas' disease. The EVI antibody has been detected in a significant number of patients with chagasic cardiomyopathy. Antibodies that react with the Schwann sheaths of somatic and autonomic peripheral nerves have also been detected. A correlation of prevalence and serologic

Figure 9.16 Open chagasic heart with thinning of wall. (Original photograph by B. H. Kean; from *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

titers was detected for the antinerve and EVI antibodies. These antibodies could be absorbed from the sera by using *T. cruzi* epimastigotes, which suggests the presence of cross-reacting antibodies between parasite and hosts. These antibodies may play a large role in the denervation that occurs with megaesophagus, megacolon, and cardiomegaly.

Abnormalities of the coronary microcirculation have been seen in patients with acute chagasic myocarditis and may cause transient ischemia consistent with the hypothesis of a microvascular factor as a cause of myocardial changes. These changes are linked to endothelium structure and integrity. If the protective capability of the endothelial cells is reduced, vasospasm and platelet aggregation within coronary microvessels may lead to focal pathology.

Various mechanisms have been proposed for the pathogenesis of chronic chagasic cardioneuromyopathy. Chronic interaction of chagasic IgG with myocardial muscarinic acetylcholine receptors, behaving as a muscarinic agonist, might lead to cell dysfunction or tissue damage. Also, these antibodies could produce desensitization, internalization, or degradation of cardiac muscarinic acetylcholine receptors, explaining the progressive blockade of these receptors in the myocardium with parasympathetic denervation. Data also suggest that cardiac autonomic impairment and early myocardial damage involving the right ventricle are independent phenomena in Chagas' disease (66). Cross-reactive antibodies to cardiac and parasite immunogenic glycolipids have been

detected and may be involved in Chagas' disease autoimmunity (95). Increases in the levels of asialoganglioside- and monosialoganglioside-reactive antibodies have also been detected in patients with chronic Chagas' disease (6). Molecular mimicry has also been proposed on the basis of data related to cross-reactive antibodies between cardiac myosin and the *T. cruzi* B13 protein.

Human chronic Chagas' cardiomyopathy appears to fulfill many of the criteria for autoimmune diseases, similar to insulin-dependent diabetes mellitus or rheumatoid arthritis. However, validation of the target antigens must involve the induction of cardiac lesions after immunization or passive transfer of antigen-specific T cells. Aberrant T-cell activation may also play a role in cardiac injury (30). Not all researchers agree that autoantibodies play a role in pathogenesis (8, 76). Also, some propose a multifactorial or "combined" theory to explain the sequence of events leading to chronic myocarditis. The actual clinical course may vary from heart failure to a slow but continuing loss of cardiac function, with possible ventricular rupture and thromboemboli.

Tissue Involvement Other than Cardiomyopathy.

Although it is less common than cardiac involvement, patients from certain areas are more likely to have dilation of the digestive tract with or without cardiomyopathy. These symptoms are most frequently seen in the esophagus and colon as a result of neuronal destruction (Figures 9.18 and 9.19). Megaesophagus characterized by dysphagia, chest

pain, regurgitation, and malnutrition is related to loss of contractility of the lower esophagus. Hypersalivation may occur, leading to aspiration with repeated bouts of aspiration pneumonia. Leiomyosarcoma of the esophagus in a patient with chagasic megaesophagus has been reported (2). Megacolon results in constipation, abdominal pain, and the inability to discharge feces. In some individuals, there may be acute obstruction leading to perforation, septicemia, and death. Cases of colon cancer have also been associated with chagasic megacolon.

Congenital Transmission. Congenital transmission can occur in both the acute and chronic stages of the disease. Common clinical findings of congenital infection are stillbirth, low birth weight, myocarditis, neurologic alterations, and death shortly after birth. Infants of seropositive mothers should be monitored for up to 1 year after birth. Monitoring should include examination of blood for parasites and serologic tests.

Immunocompromised Patients. Chagas' disease has been found in HIV-positive patients, and neurologic sequelae due to *T. cruzi* have been major findings in these patients (64). Individuals who were previously infected with *T. cruzi* and later become positive for HIV are at risk of reactivation of their Chagas' disease. These patients develop a severe multifocal or diffuse meningoencephalitis with numerous tissue parasites (89). Meningoencephalitis is a rare event in non-AIDS patients and is seen most frequently in immunocompetent children younger than 4 years. Because of the immunodeficiency associated with HIV infections, concomitant infection with *T. cruzi* may be difficult to recognize, particularly in individuals who have moved to areas where the disease is not endemic. *T. cruzi* infection may also have a protracted asymptomatic course in immunosuppressed HIV patients (25). Although a positive blood smear has been considered the key indicator of Chagas' disease reactivation in immunocompromised patients with chronic disease, this finding may occur late, rather than early, in the reactivation process (90). Apparently, there is no association between given

T. cruzi genotypes and specific clinical forms of Chagas' disease-HIV associations (81).

Recrudescence of *T. cruzi* infections in immunosuppressed patients, particularly transplantation patients, is a grave concern. Transplant recipients can also become infected through receipt of infected organs (19). For patients with end-stage Chagas' cardiomyopathy, heart transplantation is an option which has had variable success (28). Reactivation of the disease with the development of cutaneous lesions has been seen. Bone marrow transplant recipients are also at risk of Chagas' disease due to reactivation or transfusion. Prophylactic treatment of these patients has led to favorable outcomes.

In studies of the Indians in western Paraguay, there appears to be a link between *T. cruzi* seropositivity and human T-cell leukemia virus type 2 (HTLV-2) infection. In this particular group, an individual infected with HTLV-2 is 2.28 times more likely to be *T. cruzi* positive than an HTLV-2-negative person. The public health significance of these findings is emphasized by the fact that approximately 18 million people are infected with *T. cruzi* in the Americas and the frequency of HTLV-2 infection continues to increase (35).

The high levels of IgM present in patients with African trypanosomiasis are not found in patients with either acute or chronic Chagas' disease. Antigenic variation, which is characteristic of infections with African trypanosomes, is less common in *T. cruzi* disease. In spite of humoral and cellular immunity against *T. cruzi*, the infection is able to persist in the host. As occurs in African trypanosomiasis,

Figure 9.19 Megacolon in an adult male with Chagas' disease. (Armed Forces Institute of Pathology photograph.)

there is suppression of the immune response, with decreases in the levels of gamma interferon and interleukin-2, which help regulate cellular and humoral responses.

Diagnosis

Health care personnel working with specimens from patients suspected of having Chagas' disease must use standard precautions. Trypomastigotes are highly infectious, and certain strains of the parasite are more virulent than others. The diagnosis of Chagas' disease should be considered if there is a history of consistent exposure to reduviid bug bites, residence in or travel to areas where the disease is endemic, laboratory accident, or recent blood transfusion in an area where the disease is endemic. Chagomas appear similar to injury caused by trauma, insect bites, or bacterial and mycotic infections. The differential diagnosis of acute Chagas' disease should include brucellosis, endocarditis, salmonellosis, schistosomiasis, toxoplasmosis, tuberculosis, connective tissue diseases, and leukemia. Chronic Chagas' disease with cardiomyopathy may be confused with endocarditis, ischemic heart disease, and changes associated with rheumatic heart disease.

Routine Laboratory Methods. Acute Chagas' disease should be suspected in any individual from an area where the disease is endemic who develops an acute febrile illness with lymphadenopathy and myocarditis. The presence of a chagoma or Romaña's sign may be diagnostic; however, allergic reactions to insect bites may produce similar lesions. The definitive diagnosis depends on demonstration of trypomastigotes in the blood,

amastigote stages in tissues, or positive serologic reactions (Table 9.5). Methods used for examination of blood are similar to those used for the diagnosis of African trypanosomiasis discussed earlier in this chapter. Trypomastigote stages (Figure 9.10) may be easily detected in the blood in young children; however, in chronic disease, this stage is rare or absent except during febrile exacerbations. Trypomastigotes may be detected in blood by using thin and thick blood films or by buffy coat concentration techniques. The most sensitive methods for detection of trypomastigotes are concentration techniques such as the Strout method of buffy coat preparations (see chapter 31 for a discussion of concentration methods). With the Strout method, blood is collected without anticoagulant and allowed to clot. The serum is centrifuged at low speed to remove the remaining blood cells and then at a higher speed ($600 \times g$) to concentrate the parasites in the sediment. The stain of choice is Giemsa for both trypomastigote and amastigote stages.

Because of the overlap of geographic distribution, infections with *T. rangeli* trypomastigotes may have to be differentiated from those with *T. cruzi* trypomastigotes. *T. cruzi* trypomastigotes are usually C or U shaped on fixed blood films and have a large oval kinetoplast at the posterior end. *T. rangeli* trypomastigotes have a smaller kinetoplast a short distance from the posterior end, and there is no amastigote stage. In areas where kala azar occurs, amastigote stages (Figure 9.11) appear similar, and infections with *Leishmania donovani* and *T. cruzi* must be differentiated. This can be done by PCR, immunoblotting, culture (epimastigote in *T. cruzi* versus promastigote in *L. donovani*), serologic tests, animal inoculation, or xenodiagnosis.

Aspirates from chagomas and enlarged lymph nodes can be examined for amastigotes and trypomastigotes. Histologic examination of biopsy specimens may also be done. Aspirates, blood, and tissues can also be cultured, which is valuable in detecting low-grade parasitemias. The medium of choice is Novy-MacNeal-Nicolle medium. Cultures should be incubated at 25°C and observed for epimastigote stages for up to 30 days before they are considered negative. If available, laboratory animals (rats or mice) can be inoculated and the blood can be observed for trypomastigotes.

In the chronic stage of Chagas' disease, trypomastigotes are very rare or absent in the peripheral blood except during febrile exacerbations. Diagnosis depends primarily on culture, xenodiagnosis, or serologic tests. Some individuals with chronic Chagas' disease may have a depressed humoral immune response, being serologically negative. This response has been correlated with specific zymodemes. Chronic disease should be considered in individuals from areas of endemic infection who show

signs of cardiomegaly, cardiac conduction defects, severe constipation, or dysphagia.

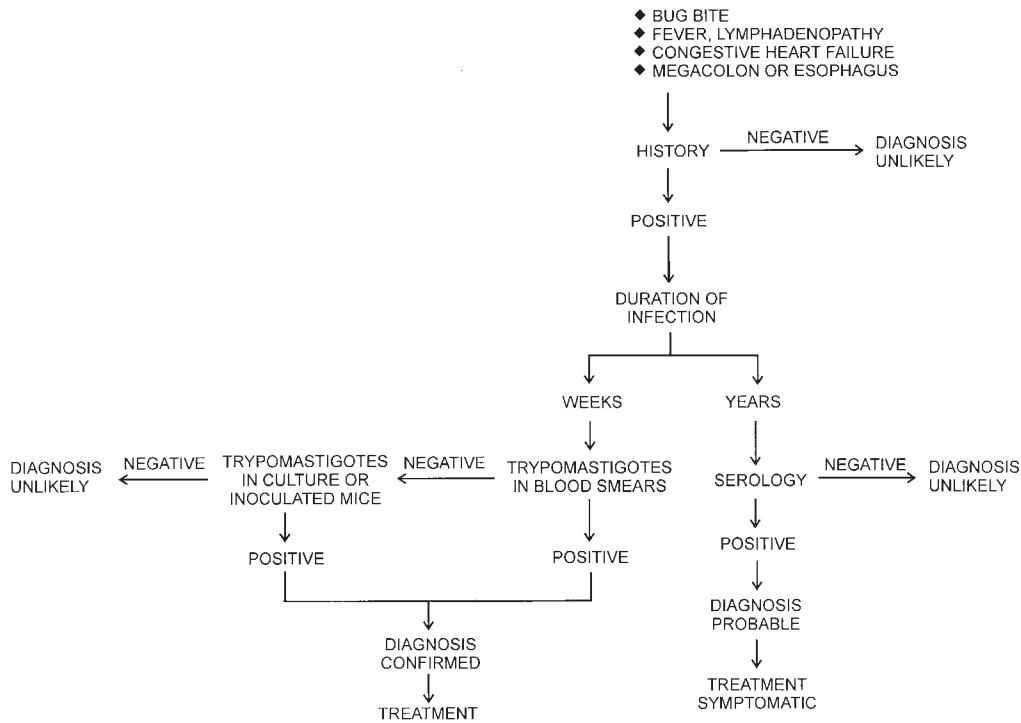

Follow-up blood specimens should be reexamined 1 to 2 months after therapy. If available, xenodiagnosis may be done. The patient may also be monitored through serologic tests and electrocardiograms (see Algorithm 9.2).

PCR. Although not routinely available except in specialized centers, PCR has been used to detect positive patients with as few as one trypomastigote in 20 ml of blood (4, 17, 18, 45). PCR may be very useful for the diagnosis of patients with chronic Chagas' disease because of the lack of sensitivity and specificity of serologic tests and the lack of sensitivity of xenodiagnosis. PCR testing may be very useful for monitoring patients who have received therapy in order to validate cures (38, 87). It has also been used to diagnose congenital infections by detecting *T. cruzi* in neonatal blood (96).

Immunoassays. Immunoassays have been used to detect antigens in the urine and sera of patients with congenital infections and those with chronic Chagas' disease (15, 22, 23, 75, 78). Determination of antigenuria can be valuable for early diagnosis of Chagas' disease and also for diagnosis of chronic cases in patients with conflicting serologic test results. A highly sensitive and specific chemiluminescent ELISA has been developed for blood bank screening and to monitor patients who are undergoing chemotherapy (3). Another ELISA using a recombinant antigen consisting of four different peptides has also been developed for screening blood donors and for epidemiologic studies and diagnosis (34).

Xenodiagnosis. In areas of endemic infection where reduviid bugs are readily available, xenodiagnosis can be used to detect light infections; this technique is most valuable for chronic infections when there are few trypomastigotes in the blood. Trypanosome-free bugs are allowed to feed on individuals suspected of having Chagas' disease. If organisms are present in the blood meal, the parasites multiply and can be detected in the bug's intestinal contents, which should be examined monthly for flagellated forms over a period of 3 months. To optimize this method, 20 third- or fourth-instar nymphs per day are allowed to feed on a patient for three consecutive days. A significant disadvantage of this technique is that not all triatomids are equally susceptible to infection and development of the epimastigote stage. Individuals who have been previously bitten by triatomids may be sensitized to their salivary secretions and may develop an anaphylactic reaction. Because the epimastigotes of *T. cruzi* and *T. rangeli* have heterogeneous morphologies, it may not be possible to make a definitive diagnosis microscopically.

AMERICAN TRYPANOSOMIASIS

Algorithm 9.2 American trypanosomiasis.

Alternative diagnostic techniques such as PCR and use of a monoclonal antibody may be needed, particularly in areas where there is geographic overlap (71).

Serologic Testing. Serologic tests used for the diagnosis of Chagas' disease include complement fixation (Guerreiro-Machado test), indirect fluorescent-antibody tests, indirect hemagglutination tests, and ELISA (57, 59, 61). The use of synthetic peptides and recombinant antigens has improved the sensitivity and specificity of these diagnostic techniques, particularly in the diagnosis of congenital disease by using IgM and IgA antibody detection and in the evaluation of cure (80, 94). Depending on the antigens used, cross-reactions have been noted to occur in patients with *T. rangeli* infection, leishmaniasis, syphilis, toxoplasmosis, hepatitis, leprosy, schistosomiasis, infectious mononucleosis, systemic lupus erythematosus, and rheumatoid arthritis. The Western blot method has been recommended for confirmatory serologic diagnosis of Chagas' disease (85). Another potential confirmatory assay using preserved protein antigens of *T. cruzi* discriminates chagasic from nonchagasic infections and may be useful for elucidating inconclusive results obtained by standard serologic tests; this is particularly relevant to blood bank testing (68). Long-lasting antibodies detected by a *trans*-sialidase inhibition assay and antibody re-

sponses to certain heat shock proteins can serve as sensitive markers for previous *T. cruzi* infection in patients who are parasite free and serologically cured (56). ELISA procedures have also been used to detect specific antibodies in naturally infected dogs (92).

Although Bolivian donor screening studies using indirect hemagglutination tests, indirect fluorescent-antibody tests, and four different ELISAs demonstrated 96.5 to 100% sensitivity and 87.0 to 98.9% specificity, use of a single test results in unacceptable numbers of false-negative samples in areas of highly endemic infection or in at-risk populations. Use of two tests would miss only 1 infected unit per 10,000 screened; however, the selection of tests depends on costs and feasibility (82).

KEY POINTS—LABORATORY DIAGNOSIS

Trypanosoma cruzi

1. Laboratory workers should use blood-borne-pathogen precautions when examining blood from Chagas' disease patients, because the trypomastigotes are infective.
2. Trypomastigotes are prevalent in the blood of patients with acute Chagas' disease; however, organism numbers are much smaller in the indeterminate and chronic stages of the infection.
3. *T. rangeli* cannot be differentiated from *T. cruzi* on

the basis of parasite morphology; patient information regarding geographic exposure is required for more appropriate interpretation of laboratory results.

4. In addition to thin and thick blood smears, concentration methods should be used to concentrate the trypomastigotes in the blood.
5. Immunoassays for antigen detection are now available and are highly sensitive and specific. Alternative methods such as culture and serologic testing can be used; however, these approaches may not be feasible without the use of a reference laboratory.

Treatment

Although numerous drugs have been tried, including those used to treat African trypanosomiasis and leishmaniasis, few have proven to be effective for therapy of Chagas' disease. In acute and congenital Chagas' disease and infections caused by laboratory accidents, treatment should be administered as soon as possible, even though in some cases symptoms are self-limited. Drug therapy has little effect on reducing the progression of chronic Chagas' disease.

Nifurtimox (Lampit), a nitrofururylidine derivative, is tolerated better in younger than older patients and should not be used during pregnancy. It reduces the duration and severity of illness and decreases mortality due to acute and congenital Chagas' disease. Reversible gastrointestinal, cutaneous, and neurologic adverse effects are common. Treatment success varies from one country to another, possibly indicating differences in the susceptibility of strains of *T. cruzi*. There is no indication that treatment of patients with chronic Chagas' disease is beneficial. Nifurtimox must be taken orally for prolonged periods, and there can be severe side effects including abdominal pain, nausea, vomiting, anorexia, and neurologic symptoms.

Benznidazole (RO-7-1051, Rochagan, Radanil), an imidazole derivative, is effective in reducing or suppressing parasites in the acute stages of disease but has limited capacity to produce a parasitic cure. It appears to be slightly more active and better tolerated than nifurtimox (33). Benznidazole is taken orally for prolonged periods and, similarly to nifurtimox, has little effect on changing clinical manifestations or reducing the progression of chronic Chagas' disease. Side effects include peripheral polyneuropathy, abdominal pain, nausea, vomiting, and severe skin reactions.

Allopurinol, a purine analog, was found in limited clinical trials to be as effective as nifurtimox and benznidazole in treating Chagas' disease. The drug is taken orally, and its side effects include skin rashes in patients with renal impairment, epigastric pain, transient diar-

rea, and pruritus. In a study using itraconazole or allopurinol in patients with chronic Chagas' disease, parasitologic cure was evident in 44% of those treated with allopurinol and 53% of those treated with itraconazole. Electrocardiographic evaluation showed normalization in 36.5 and 48.2%, respectively, of patients with chronic or recent cardiopathy (5).

Symptoms associated with megaesophagus and megacolon may be treated with dietary measures or may require surgery. Patients with chronic chagasic heart disease may receive supportive therapy or be managed in some cases with pacemakers. With the use of a low cyclosporin dosage, 80% survival at 24 months has been reported for heart transplantation (67).

Epidemiology and Prevention

Chagas' disease is a zoonosis occurring throughout American continents and involves reduviid bugs living in close association with human reservoirs (dogs, cats, armadillos, opossums, raccoons, and rodents) (Table 9.5) (47, 83, 98). The most ubiquitous sylvatic reservoir host is the opossum, *Didelphus*, which is found throughout much of the range of *T. cruzi* in the Americas. Multiple nesting or resting sites of the opossum encompass many types of triatomine habitat. High *T. cruzi* prevalence rates are partly due to the fact that opossums eat triatomines and may also transmit infection via anal gland secretions. Sylvatic cycles of *T. cruzi* transmission extend from southern Argentina and Chile to northern California. Housing conditions are extremely important in transmission; the prevalence and incidence of infection are very high in human dwellings where the vector has adapted to living in the mud and in thatch walls and palm leaf roofs. The reduviid bug has easy access to humans to obtain blood meals and transmit the infection in this type of dwelling. A significant reduction in transmission was noted to occur in houses with walls made of plaster where cracks and crevices were covered, in contrast to houses with mud or thatch walls. Human infections occur mainly in rural areas where poor sanitary and socioeconomic conditions and poor housing provide excellent breeding places for reduviid bugs. These conditions allow maximum contact between the vector and humans. Although 12 species of reduviids occur within the United States, they have not adapted themselves to household habitation (10). Humans should avoid sleeping in thatch, mud, or adobe houses; bed nets should be used by persons sleeping in these types of houses. Travelers planning to stay in hotels, resorts, or other well-constructed housing facilities are not at high risk for contracting Chagas' disease. Insecticides can be used to kill the vectors and reduce the risk of transmission. Also, one must remember that in some countries, the blood supply may not always

be screened for Chagas' disease and so blood transfusions may carry a risk of infection. The severity of Chagas' disease varies with the geographic area and may be related to strain differences in *T. cruzi*. Efforts have been made to characterize isolates based on enzyme profiles and have resulted in subpopulation classifications or schizodemes (zymodemes) (69, 70).

Transmission to humans is highly dependent on the defecation habits of the insect vector. In areas where the local species of reduviid bug does not ordinarily defecate while feeding, there are no human infections. This may explain why there are few human infections in the United States, even though sylvatic infections are known to occur in southern states. A number of autochthonous cases have been reported in the United States, in both Texas and California. The reduviid species involved in transmitting the infection to humans vary with the geographic area. Various species involved include *Panstrongylus megistus*, *Rhodnius prolixus*, *Triatoma brasiliensis*, *T. infestans*, *T. protracta*, *T. guasayana*, and *T. sordida* (Table 9.6).

Until recently, control of Chagas' disease has been mainly through the use of insecticides to eliminate the reduviid vector. In certain areas, insecticide resistance in triatomids has been noted. In addition to residual insecticide-spraying programs, construction of reduviid-proof dwellings and education are essential for effective control programs. Improvements in unsanitary living conditions, plastering of walls to obtain a smooth, crack-free surface, and replacement of palm-thatched roofs with metal roofing have been shown to considerably reduce the number of reduviids in houses. Although control of Chagas' disease is feasible, few countries have initiated control programs because of both political and economic constraints.

Transmission can occur through organ transplants and blood transfusion (91). Some of the countries in areas where the disease is endemic have laws mandating serologic testing of blood donors. Financial constraints may hinder the implementation of these laws, and there is a lack of standardization of currently available serologic tests. An alternative approach to serologic screening in the United States, because of a lack of Food and Drug Administration-approved tests, is the use of a questionnaire to identify prospective donors who may have resided in high-risk areas (60). This approach may not be practical, since even in vector-free areas in countries with endemic infection a significant portion of the donor blood units were positive for antibodies to Chagas' disease. In areas where seroprevalence is high, rather than discarding all positive blood units, laboratorians add gentian violet to the units and store them at 4°C for 24 h before use to kill the organism.

Table 9.6 *Trypanosoma cruzi*: principal vectors

Species	Geographic area
<i>Panstrongylus megistus</i>	Eastern seaboard of Brazil
<i>Rhodnius prolixus</i>	Venezuela, Colombia, French Guiana, Guyana, Suriname; most important vector in northern South America and Central America
<i>Triatoma brasiliensis</i>	Central and eastern Brazil
<i>T. dimidiata</i>	Ecuador, Colombia, western Central America
<i>T. infestans</i>	Brazil, Bolivia, Peru, Chile, Argentina, Paraguay, Uruguay
<i>T. sordida</i>	Brazil, Argentina, Bolivia, Paraguay, Uruguay; often associated with chickens
<i>T. guasayana</i>	Argentina

Evaluation of electrocardiographic (ECG) changes among urban workers in Sao Paulo, Brazil, showed that there were 2.2% positive sera for *T. cruzi* among 27,081 workers. A much higher percentage of workers with ECG abnormalities (42.7%) were seropositive for *T. cruzi* compared with the percentage of workers with ECG abnormalities (19.8%) who were seronegative. Based on these data, it appears that the high frequency of ECG abnormalities emphasizes the importance of providing medical assistance to this group (44).

Laboratory personnel working with *T. cruzi* must be aware of the hazard involved in handling the highly infectious trypomastigote form. Precautions would include the use of gloves and eye protection. All clinical specimens must be handled by using standard precautions.

Trypanosoma rangeli

T. rangeli was first described by Tejera during an examination of intestinal contents from the reduviid *R. prolixus*. The infection in human blood was first found by DeLeon in Guatemalan children. *T. rangeli* infections are encountered in many areas where *T. cruzi* also occurs; consequently, the two parasites may be confused and must be differentiated morphologically (Table 9.5). No pathology is associated with *T. rangeli* infections. In a study conducted in Venezuela, the relatively high frequency of *T. rangeli* infections detected in patients with acute-stage Chagas' disease (18.6%) complicated the diagnosis of *T. cruzi* infection. More than 2,600 cases of human infection have been documented in Venezuela,

Guatemala, Panama, Colombia, El Salvador, Costa Rica, Peru, and Brazil, the majority of which have been in Venezuela and Guatemala (46).

Life Cycle and Morphology

After the reduviid bug is infected during a blood meal, *T. rangeli* migrates from the intestine to the hemolymph and then to the salivary glands, where infective metacyclic forms can be found (Figure 9.20). Transmission to humans is through the bite of the reduviid (triatomid) bug *R. prolixus* and related species by inoculation of metacyclic trypomastigotes into the wound from the infected saliva. Infections with *T. rangeli* and *T. cruzi* can coexist in the reduviid vector. The trypomastigote is approximately 30 μm long and has a free flagellum (Figure 9.21). The nucleus is anterior to the middle of the body, and the small kinetoplast is subterminal.

Clinical Disease

Human infections are apparently asymptomatic, and trypomastigotes have been noted in the blood for longer than a year. No evidence of pathogenicity has been detected in human volunteers (26).

Diagnosis

Trypomastigotes can be detected in the blood of infected patients by using thin and thick blood smears and buffy coat concentration techniques (Table 9.5). The parasites can be stained with Giemsa or Wright's stain (see the discussion of *T. cruzi* for a description of the trypomastigote). Infections can also be detected by xenodiagnosis, in which the reduviid vector is allowed to obtain a blood meal from an infected patient and then the hemolymph and salivary glands are examined for epimastigotes and metacyclic trypomastigotes. In addition, blood can be cultured (Tobie's medium and Novy-MacNeal-Nicolle medium) or injected into laboratory animals (mice) and examined for epimastigotes and trypomastigotes, respectively. Although there are no serologic tests for *T. rangeli*, serologic cross-reactions have been noted to occur with tests for *T. cruzi*. A 48-kDa protein has been

Figure 9.21 *Trypanosoma rangeli* trypomastigote in a peripheral blood smear. Note the small kinetoplast. (Armed Forces Institute of Pathology photograph.)

identified that is a specific and abundant intracellular antigen for *T. rangeli* epimastigotes. Results suggest that this antigen may be a useful marker for the identification and characterization of *T. rangeli* isolates (88).

KEY POINTS—LABORATORY DIAGNOSIS

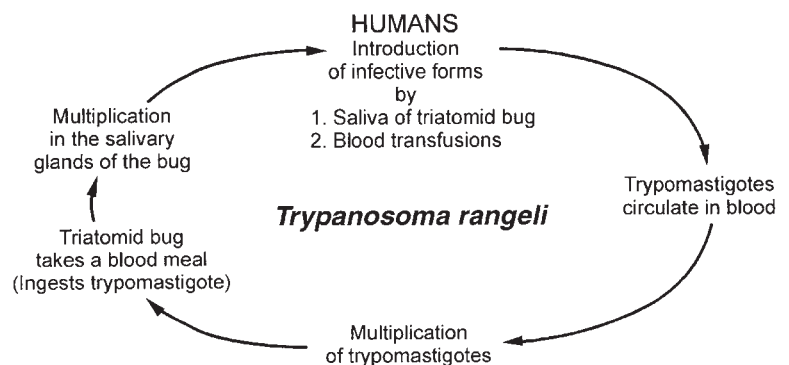

Trypanosoma rangeli

1. *T. rangeli* trypomastigotes can be detected in the peripheral blood by using thin and thick blood smears and concentration techniques; however, in practice *T. rangeli* is rarely seen in human blood (69).
2. *T. rangeli* trypomastigotes are morphologically similar to African trypanosome trypomastigotes.
3. *T. rangeli* infections can occur together with *T. cruzi* infections; therefore, *T. rangeli* trypomastigotes must be differentiated from trypomastigotes of *T. cruzi* in the peripheral blood.

Epidemiology and Prevention

T. rangeli infections have been found in both Central and South America and often overlap with *T. cruzi* infections. In some areas, *T. rangeli* infections are five to six times more frequent than *T. cruzi* infections in the population.

Figure 9.20 Life cycle of *Trypanosoma rangeli*.

Animals naturally infected with *T. rangeli* include opossums, rodents, anteaters, raccoons, dogs, and non-human primates. The organisms appear to be harmless to animals; however, they do reduce the life span of the reduviid vector (26).

Intestinal Nematodes

Ascaris lumbricoides

Enterobius vermicularis

Trichuris trichiura

Capillaria philippinensis

Hookworms (*Ancylostoma duodenale*
and *Necator americanus*)

Trichostrongylus spp.

Strongyloides spp.

The largest number of helminth organisms that parasitize humans is found in the roundworm group. Several roundworms are important in causing disease; some of these have other mammalian hosts, and some are considered to be pathogenic only under certain circumstances. Consequently, there is great variation in life cycle stages and pathologic sequelae found in humans.

Nematodes are unsegmented helminths with bilateral symmetry, have a fully functional digestive tract, are usually long and cylindrical, and vary from a few millimeters to over a meter long. Their numbers per patient vary considerably; however, worm size and numbers do not necessarily correlate with symptoms or pathologic changes.

All nematodes that are parasitic in humans have separate sexes, with the male usually being smaller than the female. Egg production varies considerably from species to species but tends to be consistent within a specific group. The number of eggs produced per day can range from a few (*Strongyloides stercoralis*) to more than 200,000 (*Ascaris lumbricoides*).

The life cycle of nematodes has five successive stages: four larval stages and the adult. In most cases, the third-stage larva is the infective stage. The eggs and larvae of nematodes living in the intestinal tract are passed outside the body in the feces or may be deposited on the perianal skin by the female worm. Eggs of certain species are almost fully embryonated, while other species may require an extended period of egg embryonation in the soil. In some cases, the eggs are infective when swallowed and other eggs will hatch in the soil, thus initiating infection by larval penetration of the human skin rather than egg ingestion.

As Table 10.1 shows, nematodes are long-lived worms. Usually, the host response to the presence of these worms is directly related to the worm burden. Diagnosis of these infections depends on the recovery and identification of adult worms, eggs, or larvae; specific information is provided in Table 10.2.

World Health Organization estimates suggest that over 3.5 billion people carry nematode infections; filarial infections are not included in this figure. With these numbers in mind, it is not uncommon for almost any laboratory within the United States to occasionally recover helminth eggs, larvae, or adults from human specimens. Unfortunately, lowering the intensity of infection in a host population through the use of chemotherapy may produce minimal declines in transmission relative to its initial endemic level (17).

Table 10.1 Normal life spans of the most common intestinal nematodes

Nematode	Life span	Comments
<i>Ascaris lumbricoides</i>	1–2 yr	Infection may be aborted by spontaneous passage of adult worms
<i>Enterobius vermicularis</i>	Several months to years	Reinfection due to both self-infection and outside sources is extremely common
<i>Trichuris trichiura</i>	Several years	Often accompanies <i>Ascaris</i> infection (both are acquired by egg ingestion from contaminated soil)
Hookworms		
<i>Necator americanus</i>	4–20 yr	Symptoms are directly related to worm burden; many infections are asymptomatic
<i>Ancylostoma duodenale</i>	5–7 yr	
<i>Strongyloides stercoralis</i>	30+ yr	Autoinfection capability can lead to dissemination and the hyperinfection syndrome in the compromised host

It is well known that large numbers of people in sub-Saharan Africa are infected with both human immunodeficiency virus type 1 (HIV-1) and intestinal helminths. There may be detrimental immunologic effects from coinfection with these two pathogens (11, 43). Based on recent studies, the high helminth prevalence and possible adverse interactions between helminths and HIV suggest that helminth diagnosis and treatment should be a part of the routine care of HIV-infected patients (50).

Ascaris lumbricoides

The number of people infected with *Ascaris lumbricoides* worldwide is probably second only to the number infected with the pinworm, *Enterobius vermicularis*. *A. lumbricoides* was well known in Roman times as *Lumbricus teres* (confused with the common earthworm) and has probably been infecting humans for thousands of years. It is prevalent in moist, warm climates but can also survive in the temperate zones. In most countries of Central and South America, the average infection rates range up to approximately 45%. Also, foci of high prevalence among young children still persist in the southeastern United States (Table 10.3).

Life Cycle and Morphology

The adult worms are cylindrical, with a tapering anterior end. They are the largest of the common nematode parasites of humans; females measure 20 to 35 cm long, and males are 15 to 31 cm long, with a curved posterior

end (Figure 10.1). Also, the three well-developed lips are characteristic of this group.

The life cycle of *A. lumbricoides* is usually referred to as an “indirect cycle” since there is extensive migration throughout the body prior to adult worm maturation and egg production. Infection in humans is acquired through ingestion of the embryonated eggs from contaminated soil (Figure 10.2). On ingestion, the eggs hatch in the stomach and duodenum, where the larvae actively penetrate the intestinal wall; they are then carried to the right heart via the hepatic portal circulation. Larvae within the eggs undergo one or possibly two molts prior to penetration of the intestinal wall. From the right heart they are carried into the pulmonary circulation, where they are filtered out by the capillaries. After approximately 10 days in the lung, the larvae break into the alveoli, migrate via the bronchi until they reach the trachea and pharynx, and then are swallowed. The worms then mature and mate in the intestine, with the eventual production of eggs, which are passed in the stool. The entire developmental process from egg ingestion to egg passage from the adult female takes from 8 to 12 weeks. During her life span, she may deposit a total of 60,000,000 or more eggs.

Both unfertilized and fertilized eggs are passed (Figures 10.3 and 10.4). Often only female worms are recovered from the intestine. Fertilized eggs become infective within 2 weeks if they are in moist, warm soil, where they may remain viable for months or even years. The fertilized egg is broadly oval, with a thick, mammillated coat, usually bile stained a golden brown. These eggs

Table 10.2 The most common intestinal nematodes

Characteristic	<i>Ascaris lumbricoides</i>	<i>Enterobius vermicularis</i>	<i>Trichuris trichiura</i>	Hookworms (<i>Necator americanus</i> , <i>Ancylostoma duodenale</i>)	<i>Trichostrongylus</i> spp.	<i>Strongyloides stercoralis</i>
Usual time to infective stage	2–3 wk in soil; second-stage larva in egg	4–6 h; first-stage larva in egg	2–3 wk in soil; first-stage larva in egg	5–7 days in soil; free, third-stage larva	3–5 days in soil; free, third-stage larva	5–7 days in soil; free, third-stage larva
Mode of infection	Ingestion of infective egg	Ingestion of infective egg	Ingestion of infective egg	Skin penetration by <i>N. americanus</i> ; ingestion and skin penetration by <i>A. duodenale</i>	Ingestion of third-stage larva	Skin penetration
Development and location in human host	Obligatory larval migration through liver and lungs; adults in small intestine	Direct development to adult in intestinal tract; adults in cecum, appendix, colon, and rectum	Direct development to adult in intestinal tract; adults in cecum, appendix, and colon	Larval migration through lungs; adults attached to mucosa of small intestine	Direct development to adult in intestinal tract; adults in small intestine	Larval migration through lungs; adult females in mucosal epithelium of small intestine; autoinfection may occur
Prepatent period	2 mo	3–4 wk	3 mo	6–8 wk	2–3 wk	2–4 wk
Normal life span	Up to 1 yr or slightly longer	1–2 mo	Up to 15 yr or more; usually 5–10 yr	Up to 15 yr or more; usually 5–10 yr	Up to 1 yr or slightly longer	Up to many years (30+)
Diagnosis by usual means	Bile-stained, mammillated, thick-shelled eggs (45–75 by 35–50 μm) in 1-cell stage in feces; infertile eggs (85–95 by 43–47 μm) have thinner shells and distorted mammillations; mature or immature adults may be found in feces or may spontaneously migrate out of the anus, mouth, or nares	Smooth, thick-shelled eggs (50–60 by 20–32 μm) in cellulose tape preparations; rarely seen in feces; adult or immature worms may be found in feces	Unembryonated, bile-stained, thick-shelled eggs (50–54 by 20–23 μm) with mucoid plugs at each end, in feces	Thin-shelled eggs (56–75 by 36–40 μm) in 4- to 16-cell stage in feces	Large, thin-shelled eggs (73–95 by 40–50 μm), tapered at one end, in feces; inner membrane of egg frequently wrinkled; ovum already in advanced cleavage when passed	First-stage larvae (108–380 by 14–20 μm) in feces; larvae have a short buccal cavity and a prominent, conspicuous genital primordium

(continued)

Table 10.2 The most common intestinal nematodes (continued)

Characteristic	<i>Ascaris lumbricoides</i>	<i>Enterobius vermicularis</i>	<i>Trichuris trichiura</i>	Hookworms (<i>Necator americanus</i> , <i>Ancylostoma duodenale</i>)	<i>Trichostrongylus</i> spp.	<i>Strongyloides stercoralis</i>
Diagnostic problems	Fertile eggs may lose outer mammillated layer (decolorate eggs); infertile eggs may be difficult to recognize; also, will not float in usual solution of ZnSO ₄ (sp gr, 1.18) used for concentration	Eggs not usually seen in feces; cellulose tape method should be used to demonstrate eggs from perianal region	Rarely presents a problem; routine stool examination	Eggs of the 2 species are indistinguishable; if eggs hatch in feces owing to delay in examination, these first-stage larvae must be differentiated from <i>Strongyloides</i> larvae	May be confused with hookworm eggs	Larvae may be passed sporadically and may be found only by culture, concentration procedures, or use of Entero-Test or duodenal intubation
Clinical notes	Owing to potential migration of adult worms (as a result of fever, drugs, anesthetics), all infections should be treated; pulmonary symptoms may be present during larval migration (prior to egg recovery in the stool); eosinophils present but not impressive	Generally, only symptomatic patients treated because of high reinfection rate; there may or may not be eosinophilia	Light infections usually not treated; patients may be asymptomatic, with eggs an incidental finding; <i>Ascaris</i> and <i>Trichuris</i> infections often found together; moderate eosinophilia in heavy infections (usually will not exceed 15%)	Skin penetration by larvae produces allergic reaction (ground itch, cutaneous larva migrans); pulmonary symptoms usually present only in heavy infection; iron deficiency anemia and eosinophilia up to 70% may be present	Rarely seen in the United States; common in the Orient, Europe, Middle East, and Africa; light infections usually not treated	Hyperinfections may lead to death in the compromised or immunosuppressed host; patient may become symptomatic many years after original infection (without additional exposure); eosinophilia 10–40% or higher

Table 10.3 Factors related to continuing *Ascaris lumbricoides* infections in urban communities in developing countries and DALYs lost to a range of causes, including ascariasis^a

Factor	Value
Estimates for 1990 ^b	
Population	2,500 million
Daily fecal output of population	500,000 tons
No. infected with <i>A. lumbricoides</i>	1,000 million
Daily fecal output contaminated with eggs of <i>A. lumbricoides</i>	200,000 tons
Daily discharge of eggs of <i>A. lumbricoides</i>	2 × 10 ¹⁴ eggs
Population of urban communities	750 million
Daily fecal output of urban population	150,000 tons
Number of urban people infected with <i>A. lumbricoides</i>	300 million
Daily fecal output contaminated with eggs of <i>A. lumbricoides</i> in urban communities	60,000 tons
Daily discharge of eggs of <i>A. lumbricoides</i>	6 × 10 ¹³ eggs
Estimates for urban communities in the year 2000 ^{b, c}	
Population	2,200 million
Daily fecal output	440,000 tons
No. infected with <i>A. lumbricoides</i>	880 million ^d
Daily fecal output contaminated with eggs of <i>A. lumbricoides</i>	1,760,000 tons
Daily discharge of eggs of <i>A. lumbricoides</i>	1.76 × 10 ¹⁴ eggs
Comparison of DALYs ^e lost to a range of causes globally	
Total intestinal helminths	39 million
<i>Ascaris lumbricoides</i>	10.5 million
<i>Trichuris trichiura</i>	6.4 million
Hookworms	22.1 million
Malaria	35.7 million
Schistosomiasis	4.5 million
Tuberculosis	46.5 million
Measles	34.1 million
Vitamin A deficiency	11.8 million
Diabetes mellitus	8 million
Total maternal causes (hemorrhage, sepsis, eclampsia, hypertension, obstructed labor, and abortion)	29.7 million
Motor vehicle accidents	31.7 million

^a Adapted from I. Coombs and D. W. T. Crompton. How much human helminthiasis is there in the world? *J. Parasitol.* 85:397–403, 1999; D. A. P. Bundy, This wormy world—then and now, *Parasitol. Today* 13:407–408, 1997; and M. S. Chan, The global burden of intestinal nematode infections—fifty years on, *Parasitol. Today* 13:438–443, 1997.

^b The world's population in 1990 was about 5,000 million, with about half living in developing countries (about 70% rural and 30% urban). About 1,000 million people in developing countries are infected with *A. lumbricoides*. About 200 g of stool is produced per person daily. About 1,000 eggs of *A. lumbricoides* are present daily in each gram of stool from an infected person.

^c It is assumed that the prevalence of *A. lumbricoides* will not have changed and that, overall, the proportion of infected people in rural and urban communities will be the same.

^d Probably underestimated and could be as high as 1,565 million.

^e DALY, disability-adjusted life year; based on disabilities experienced translated into years of health lost.

Figure 10.1 Adult *Ascaris lumbricoides* (male).

measure up to 75 μm long and 50 μm wide. Unfertilized eggs are usually more oval, measure up to 90 μm long, and may have a pronounced mammillated coat or an extremely minimal mammillated layer. Often, both types of eggs are found in the same stool specimen. The total absence of fertilized eggs means that only female worms are present in the intestine.

The occurrence of *A. lumbricoides* usually peaks in childhood or early adolescence. Although the percentage of humans harboring *A. lumbricoides* is high, little is known about these infections in pregnant women and the possible impact on the fetus. In a clinical and epidemiologic study of an infant with diarrhea and failure to thrive, the child became ill at 7 days of age, symptoms became worse at 21 days of age, and *Ascaris* eggs were found in the stool at 40 days of age. The minimum

prepatent period after ingestion of the infective eggs is 60 days. After consideration of other possibilities, this case is very suggestive of congenital transmission. Further studies are necessary, but if confirmed, these findings will certainly reinforce the recommendations for antiparasitic treatment of pregnant women to prevent neonatal infection.

Clinical Disease

Infection with *A. lumbricoides* continues to be a significant health problem throughout the world. Prevalence data in one of the first studies of its kind demonstrate that roundworm infection occurs at a high level in the population examined. There is a high within-individual correlation over time, indicating that there is individual predisposition to infection with *A. lumbricoides*. There is unequivocal evidence for a genetic component, accounting for 30 to 50% of the variation in worm burden. Shared environmental effects account for 3 to 13% of the total phenotypic variance. The remarkable consistency of the results through time and across different measures of the burden phenotype strongly indicate their validity and suggest the utility of future evaluations focused on identifying the specific genes responsible for these sizable genetic effects. Many of the parasitic helminth infections lend themselves to genetic analysis, and future studies may lead to significant improvements in pharmacologic agents (77).

Pathogenesis caused by *Ascaris* infections is attributed to (i) the host immune response, (ii) effects of larval migration, (iii) mechanical effects of the adult worms, and (iv) nutritional deficiencies due to the presence of the adult worms. Although the initial passage of larvae through the liver and lungs usually elicits no symptoms, there can be signs of pneumonitis if the number of larvae is quite large. When the larvae break out of the lung tissue and into the alveoli, there may be some damage to the bronchial epithelium.

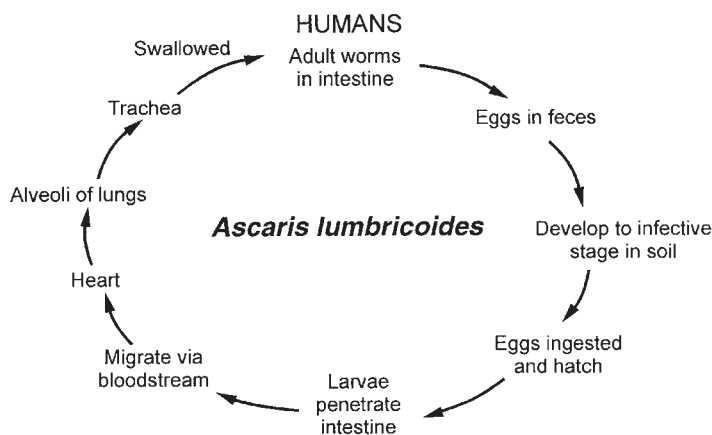

Figure 10.2 *Ascaris lumbricoides* life cycle.

Figure 10.3 *Ascaris lumbricoides* unfertilized eggs; these eggs can also be decorticate (loss of the bumpy coat), as can the fertilized egg seen in Figure 10.4.

With reinfection and subsequent larval migrations, there may be intense tissue reactions, even with small numbers of larvae (Figure 10.5). There may be pronounced tissue reaction around the larvae in the liver and lungs, with infiltration of eosinophils, macrophages, and epithelioid cells. This condition has been called *Ascaris* pneumonitis and is accompanied by an allergic reaction consisting of dyspnea, a dry or productive cough, wheezing or coarse rales, fever (39.9 to 40.0°C), transient eosinophilia, and a chest X ray suggestive of viral pneumonia. This picture of transient pulmonary infiltrates that clear within a couple of weeks and are associated with peripheral eosinophilia is frequently called Loeffler's syndrome. In addition to eosinophils and Charcot-Leyden crystals, the sputum may contain larvae, although this finding is not common and examination of gastric washings may be more helpful. Asthma and urticaria may continue during the intestinal phase of ascariasis.

Figure 10.4 (A) *Ascaris lumbricoides*, fertilized egg; (B) *A. lumbricoides*, fertilized decorticate egg.

Eosinophilic gastroenteritis is an inflammatory disease characterized by eosinophilic infiltration of the gastrointestinal tract accompanied by varying abdominal symptoms and usually by peripheral eosinophilia. Although the precise etiology of this condition has not been determined, allergies to certain allergens such as foods, drugs, and parasites have been repeatedly proposed as causing the disease. In one rare case, a woman who had extensive eosinophilic infiltration in the descending and rectal colon, with a high titer to immunoglobulin G (IgG) antibody against *Ascaris suum*, was treated successfully with prednisolone (71).

A case of hepatic ascariasis occurring in a 3-year-old child with acute lymphoblastic leukemia suggests that *Ascaris* worms not only can enter the biliary tree and cause hepatic ascariasis but also potentially can carry pathogens on their surface and provide an alternate

Figure 10.5 *Ascaris lumbricoides* larvae in lung tissue. (From a Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

portal of entry for severe infections in neutropenic patients. At autopsy, two hepatic parenchymal abscesses were seen in the right lobe, each containing *Ascaris* worms, which were also found in the duodenum, common bile duct, and right intrahepatic duct. Cultures also grew *Klebsiella* spp., *Enterobacter cloacae*, and *Candida albicans* (J. A. Lecciones, M. S. Cortet, S. Tungol, C. D. V. Macalunga, and M. A. Cruz, *Abstr. 91st Gen. Meet. Am. Soc. Microbiol.* 1991, abstr. L-43, 1991). Another case involved a 25-year-old woman with sickle cell trait and a normal delivery 3 months earlier who presented with acute obstructive cholangitis with septicemia and multiple hepatic abscesses. After removal of 60 adult *Ascaris* worms, surgical drainage of the hepatic abscesses, and wide-spectrum antibiotic therapy, the patient recovered. This case also points up the potential complications that can be seen with *Ascaris* infections, particularly when they occur in areas where this infection is not endemic. Endoscopy was successful in 19 of 25 patients resistant to medical therapy. Surgery remains important in the management of ascariasis complicated by biliary or pancreatic strictures and stones or by the presence of worms in the gallbladder (10).

The presence of adult worms in the intestine usually causes no difficulties unless the worm burden is very heavy; however, because of the tendency of the adult worms to migrate, even a single worm can cause serious sequelae. Worm migration may occur as a result of stimuli such as fever (usually over 38.9°C), the use of general anesthesia, or other abnormal conditions. This migration may result in intestinal blockage; entry into the bile duct, pancreatic duct, or other small spaces; or

entry into the liver or peritoneal cavity. The worms can also migrate out of the anus or come out the mouth or nose. Other body sites, such as the kidneys, appendix, or pleural cavity, have been involved. A Swiss patient with acute pancreatitis and no evidence of gallstones or history of alcohol abuse died after a short fulminant illness. Autopsy findings revealed an *Ascaris* worm impacted within the ampulla of Vater, a reminder that nonindigenous causes of biliary tract obstruction need to be considered (49).

Through analysis of published reports, epidemiologic aspects of *Ascaris*-induced intestinal obstruction were identified. In 9 studies of at least 100 patients admitted to the hospital with ascariasis, intestinal obstruction was the single most common complication and accounted for 38 to 88% of all complications. Both the proportion and number of cases per 1,000 population were significantly related to the local prevalence of ascariasis. In 12 studies of at least 30 patients with *Ascaris*-induced intestinal obstruction, the case fatality rates ranged from 0 to 8.6%. The mean age of patients with obstruction was ≥ 5 years in six of seven studies in which age was specified (25).

In children, particularly those younger than 5 years, there may be severe nutritional impairment related to the worm burden. Directly measurable effects include increased fecal nitrogen and fecal fat and impaired carbohydrate absorption, all of which would return to normal with elimination of the adult worms. Worms can also be spontaneously passed without any therapy.

An association between helminthic infection and educational achievement has long been recognized. In one study, children treated with mebendazole for ascariasis showed significant improvement in several test scores, learning ability, concentration, and eye-hand coordination after 5 months of treatment (33). In another study, low test results in language, social, gross motor, and fine motor skills were associated with low weight for age, and lower language test scores were associated with infections with intestinal parasites and *Ascaris* in particular. Developmental disabilities are a significant and frequently undetected health problem in developing countries; malnutrition associated with intestinal helminth infections may be an important contributory factor to these disabilities (53).

Immunology and Host Resistance

Gastrointestinal nematode infections cause vigorous immune responses, although the mechanisms involved are not fully understood. A number of circulating immunoglobulins have been identified in *A. lumbricoides* infections, including IgG1 to IgG4, IgA, and IgE. The levels of IgG4 and IgE are elevated in helminth infections,

and antiparasite IgE responses are associated with infection resistance. However, apparently IgG4 antibody can block IgE-mediated immunity and thus can block allergic responses in humans (11, 76).

The T-cell component of the immune system plays an important role in resistance to gastrointestinal nematodes. Different nematode species may stimulate the same Th2 cascade, and functional resistance to certain species depends on different subsets of mediators and effectors within the cascade. Functional effectors at the base of the Th2 cascade probably include eosinophilia, IgA, IgE, proliferation of mast cells, and increased mucus secretion. Physiological changes in the intestine, such as increased mucosal permeability and smooth muscle contractivity, may produce an environment in which worms become trapped in mucus and are swept from the gut; these changes are driven by interleukin-4 (IL-4) and IL-13.

It is well recognized that some helminth infections, including ascariasis, can suppress host immune responses. Worms may also subvert host immunity through the stimulation of inappropriate effectors. Various excretory-secretory products from parasitic nematodes can also modulate host immune responses. These products may interfere with immune effectors or influence mediators involved in induction and control. Overall, there remain many questions related to the deworming of human populations and the effect this could have on host susceptibility to certain pathogens (e.g., HIV) and on pathogen-induced immunopathology (11).

Diagnosis

In the larval migration phase of infection, diagnosis can be made by finding the larvae in sputum or in gastric washings. The typical Loeffler's syndrome is more likely to be seen in areas where transmission is highly seasonal.

During the intestinal phase, the diagnosis can be made by finding the eggs (unfertilized or fertilized) or adult worms in the stool (Figures 10.3 and 10.4). The eggs are most easily seen on a direct wet smear or a wet preparation of the concentration sediment.

Caution. Remember that unfertilized *Ascaris* eggs do not float with use of the zinc sulfate flotation concentration method (the eggs are too heavy). Also, if too much iodine is added to the wet preparations, the eggs may look like very dark debris. Eggs may be very difficult to identify on a permanent stained smear because of stain retention and asymmetric shape.

Intestinal disease can often be diagnosed from radiographic studies of the gastrointestinal tract, in which the worm intestinal tract may be visualized (Figures 10.6 and 10.7). This may be particularly obvious when two worms are lying parallel, like "trolley car lines" (Figure 10.8) (9).

Figure 10.6 *Ascaris lumbricoides*. Two spot films from an upper gastrointestinal barium study show that white barium in the small bowel outlines an adult worm that has displaced the barium and appears dark. (From a Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Other involved body sites may present specific symptoms indicative of bowel obstruction, biliary or pancreatic duct blockage, appendicitis, or peritonitis (Figure 10.9). Since acute abdomen caused by ascariasis is more commonly seen in developing countries, clinicians in developed countries may not consider this potential problem when seeing a patient with similar symptoms. Increased awareness of ascariasis presenting as an acute abdomen is required for optimal patient care; this may be possible only for an experienced radiologist (64). Therapeutic measures are related to specific symptoms and involved areas. Refer to Algorithm 10.1 for detailed information.

KEY POINTS—LABORATORY DIAGNOSIS

Ascaris lumbricoides

1. Both fertilized and unfertilized eggs can easily be recovered by the sedimentation concentration method. (Unfertilized eggs do not float with use of the zinc sulfate flotation concentration method.)
2. Because of the potential problems caused by migration of the adult worms, patients who are undergoing elective surgery and receiving general anesthetic should be checked for the presence of *A. lumbricoides* if there is any possible exposure history (some anesthetics stimulate the worms to migrate). Usually, a single stool examination will suffice to rule out the infection.
3. Larvae can be recovered from sputum (larval migration through the lungs); however, this is not a common finding.
4. Eggs may be very difficult to recognize on a permanent stained smear. They are usually very darkly stained and may be mistaken for debris.

Figure 10.7 *Ascaris lumbricoides*. Small bowel barium study shows adult worms that present as longitudinal dark lines against the white barium in the small bowel. The worms have ingested the barium, and their guts appear as white lines between the dark body outlines. (From a Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Treatment

There are a number of modern anthelmintic agents that represent a vast improvement over some of the older remedies, and none of the recommended drugs require pre- or posttreatment purging or fasting. Mebendazole is considered the drug of choice for both children and adults; ivermectin and albendazole are alternatives but are con-

Figure 10.8 *Ascaris lumbricoides*, paired worms in the gut (X ray). (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 10.9 *Ascaris lumbricoides*, adult worms in the gut. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

sidered investigational for this condition by the U.S. Food and Drug Administration. Specific drugs and dosages are listed in chapter 25. Although these drugs are effective in eliminating the adult worms, there is no conclusive evidence that they are effective against the larval migration phase of the infection. If other body sites are involved, surgical intervention may be necessary.

The prognosis for treated intestinal disease is excellent; however, in cases of perforation or surgical procedures, there may be complications. Also, the prognosis may be extremely poor in cases of massive larval migration through the lungs.

Some individuals seem to be susceptible to heavy infections while others are not; deworming has a greater impact on the intensity of infection than on its prevalence; and mass chemotherapy is likely to be a more effective means of controlling morbidity than is selective treatment of heavily infected individuals only. Enhancing coverage and child-targeted treatment represent a more cost-effective approach than increasing the frequency of treatment. A study to compare the effects of mass, targeted, and selective chemotherapy with levamisole as an intervention for the control of ascariasis in areas of endemic infection revealed that in terms of cost per 1,000-egg reduction in intensity and cost per person treated, the mass and targeted approaches were considerably more cost-effective than the selective approach (36).

Epidemiology and Prevention

Since the ultimate transmission of ascariasis depends on fecal contamination of the soil, the use of appropriate sanitary facilities is the primary means of prevention. There are apparently no practical means of killing the eggs while they are in the soil, especially when they are

Algorithm 10.1 Ascariasis.

in clay soil under favorable environmental conditions (warmth and moisture). In some areas of the world where infections are common, some mass population treatment plans have been used with great success, even in areas with high reinfection rates. The use of human feces, or “night soil,” for fertilization of crops should be recognized as a potential hazard. Any vegetables or fruits from such fields cannot be eaten raw or unprocessed. Even with proper pretreatment of night soil, *Ascaris* eggs remain viable and infective more often than eggs of any other helminth species.

In looking at the health of schoolchildren, four significant environmental influences on helminth infections have been identified: (i) an inadequate water supply, (ii) availability of school canteens, (iii) regular water/sanitation maintenance regimes, and (iv) overcrowded classrooms. Helminth infections are strongly associated with anemia, stunting and low weight, and the environmental conditions mentioned above. Although mass anthelmintic drug campaigns have taken place, reinfection is common and drug therapy alone is insufficient for elimination of the problem, particularly in a school environment (38).

Using *A. suum* as a model for *A. lumbricoides*, the ability of sludge treatment processes to kill the eggs of parasitic roundworms was examined. Both unembryonated and embryonated eggs were used, with interesting results. After 1 week in an anaerobic sludge digester, 95% of *A. suum* eggs produced two-cell larvae *in vitro*, with 86% progressing to motile larvae; after 5 weeks in the digester, 51% progressed to motile larvae. Between 42 and 49% of eggs stored in a sludge lagoon for 29 weeks

were viable and able to develop motile larvae. Of embryonated eggs prior to treatment, >98% survived up to 5 weeks in an anaerobic sludge digester. More than 90% of embryonated eggs survived for 29 weeks in the sludge lagoon and were able to develop motile larvae (40).

Enterobius vermicularis

Enterobius vermicularis has been known since ancient times and has been studied extensively through the years; its original name was *Oxyuris vermicularis*. *E. vermicularis* is thought to cause the world’s most common human parasitic infection. It has been said, “You had this infection as a child; you have it now; or you will get it again when you have children!” The infection is more prevalent in the cool and temperate zones, where people tend to bathe less often and change their underclothes less frequently. Prevalence in children can be high, a fact that has been recorded despite the difficulties in confirming the infection.

Although there has been some discussion of *Enterobius gregorii* being a distinct species of pinworm, it appears that this organism may actually be a young stage of *E. vermicularis*. A series of 849 male pinworms from a single individual were examined. Based on spicule morphology, the worms were classified into different groups. However, various transitional forms were observed in the spicule morphology in the worms with intermediate body size between *E. vermicularis* and *E. gregorii*, showing that the basal portion of the spicule of *E. vermicularis* develops after completion of the *E. gregorii*-type basal portion (34).

Life Cycle and Morphology

The female worm measures 8 to 13 mm long by 0.3 to 0.5 mm wide and has a pointed tail (hence the name “pinworm”) (Figure 10.10). The male is much smaller, measuring 2 to 5 mm long by 0.1 to 0.2 mm wide, and has a curved caudal end. Infection in humans is initiated by the ingestion of infective eggs, which hatch in

Figure 10.10 *Enterobius vermicularis*, adult female pinworm. (Photomicrograph by Zane Price.)

Figure 10.11 *Enterobius vermicularis* life cycle.

the intestine (cecal region), where they develop into the adult worms (Figure 10.11). It probably takes about 1 month for the female to mature and begin egg production. After fertilization of the female worms, the males usually die and may be passed out in the stool. In gravid females, almost the entire body is filled with eggs. At this point, the female migrates down the colon and out of the anus, where the eggs are deposited on the perianal and perineal skin. Occasionally, the female worm migrates into the vagina. It is speculated that after egg deposition, the female worm returns to the intestine; however, this has not been proven (9). Occasionally, when the bolus of stool passes out of the anus, adult worms become attached to the stool and can be found on the surface. Adult worms can also sometimes be picked up on the Scotch tape preparations used to diagnose this infection. Although egg deposition usually does not occur in the intestine, some eggs may be recovered in the stool. The eggs are fully embryonated and infective within a few hours. Although transmission is often attributed to the

Figure 10.12 *Enterobius vermicularis* eggs on a Scotch tape preparation.

ingestion of infective eggs by nail biting and inadequate hand washing, airborne eggs can also be inhaled and ingested.

The eggs have been described as being shaped like footballs with one side flattened. They are oval, compressed laterally, and flattened on one side and measure 50 to 60 μm long by 20 to 30 μm wide (Figure 10.12).

Clinical Disease

Pinworm infection is the most common helminth infection within the United States and Western Europe; prevalence rates in some areas may be as high as 30 to 50%. The most striking symptom of this infection is pruritus, which is caused by the migration of the female worms from the anus onto the perianal skin before egg deposition. The sometimes intense itching results in scratching and occasional scarification. In most infected people, this may be the only symptom, and many individuals remain asymptomatic.

The degree of infection varies tremendously from patient to patient. As many as 5,000 worms have been removed from a single patient; however, most cases average less than 1 migrating worm per evening. Women are symptomatic three times as often as men, and young people are symptomatic more frequently than older people.

Eosinophilia may or may not be present. Although tissue invasion has been attributed to the pinworm, these cases are not numerous. Infections tend to be more common in children and occur more often in females than in males. In heavily infected females, there may be a mucoid vaginal discharge, with subsequent migration of the worms into the vagina, uterus, or fallopian tubes, where they become encapsulated. Other symptoms have also been attributed to pinworm infection, particularly in children; they include nervousness, insomnia, nightmares, and even convulsions (9).

In one report, a homosexual man presented with severe abdominal pain and hemorrhagic colitis, eosinophilic inflammation of the ileum and colon, and numerous unidentifiable larval nematodes in the stool. By using morphologic characteristics and molecular cloning of nematode rRNA genes, the parasites were identified as larvae of *E. vermicularis*; these larvae are rarely seen and are not thought to cause disease. The authors state that occult enterobiasis is widely prevalent and may be a cause of unexplained eosinophilic enterocolitis (48). Although enterobiasis is an uncommon cause of acute appendicitis in children within the United States, this infection may be associated with acute appendicitis, chronic appendicitis, or ruptured appendicitis or with no significant symptoms (3).

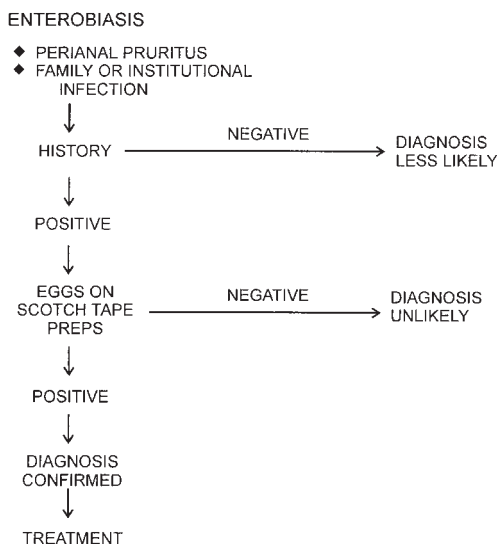

Other uncommon ectopic sites have included the peritoneal cavity, lungs, liver, urinary tract, and natal cleft. Pathologic examination usually reveals chronic

granulomatous inflammation with or without central necrosis, which is surrounded by polymorphonuclear neutrophilic leukocytes, eosinophils, and fibroblasts. Macrophages, giant cells, epithelioid cells, and Charcot-Leyden crystals may also be present. During a case of suspected transverse colon carcinoma, histologic examination of the mass revealed eggs of *E. vermicularis* embedded in granulomatous tissue in the submucosa of the colon; no malignancy was found (46). Apparently, this is the first report of enterobiasis presenting as colon carcinoma.

Diagnosis

Although the patient history of anal itching, irritability, and insomnia may suggest a pinworm infection, diagnosis depends on demonstrating the eggs or adult worms. This is normally accomplished by sampling the perianal and perineal skin with cellulose tape (Scotch tape), which is applied sticky side down to the skin. The tape is transferred to a glass slide and examined under the microscope for the presence of eggs or adult worms (see chapter 29). Commercial paddles are also available for the collection of eggs and/or adult pinworms. Eggs are rarely found in the stool (approximately 5% of the time), and sampling of the perianal folds yields more accurate results. Since the female worms migrate on a sporadic basis, a series of four to six consecutive tapes may be necessary to demonstrate the infection. The tapes are used late in the evening, when the patient has been sleeping for several hours, or first thing in the morning before the patient takes a shower or goes to the bathroom. These samples can be taken from children at home and transported to the laboratory for examination. Refer to Algorithm 10.2.

Algorithm 10.2 Enterobiasis.

In cases of ectopic infection, diagnosis usually requires biopsy and histologic examination. Although rare, histologic examination of tissue is particularly important in differentiating malignancy from parasitic infection.

KEY POINTS—LABORATORY DIAGNOSIS

Enterobius vermicularis

1. The cellulose tape (Scotch tape) preparation is recommended as the diagnostic test of choice (a minimum of four to six consecutive negative tapes is required to rule out the infection). Commercial paddles or other collection devices are also acceptable. Although the paraffin swab is also an option, this method is seldom used.
2. Adult worms may be found on or under the surface of the stool specimen, particularly in children. The adult worms can also be found on the tapes.
3. Eggs are occasionally recovered in stool, but this is an incidental finding and not the specimen of choice.

Treatment

Although several drugs such as pyrantel pamoate or mebendazole are extremely effective in eliminating the worms, the decision to treat should be based on evidence of infection and consideration of whether the patient is symptomatic. Repeat reinfection is always possible; thus, repeated treatment may be necessary to ensure that the patient is free of infection. Repeat treatment after about 2 weeks is routinely recommended to eliminate any infection acquired from ingestion of eggs that remain in the environment following the first treatment. Asymptomatic individuals are rarely treated, particularly in a group situation in which more susceptible individuals are not present. Treatment often includes counseling for the parents, who may be very upset at learning that their children have “worms.” They may not realize how prevalent the infection is, particularly in children, and that many children never have any symptoms or sequelae of the infection. In a group situation, often only one or several individuals will be symptomatic and continue to be infected. Treatment of the entire group, followed by retreatment of the more susceptible individuals, may provide an infection-free group for a longer period.

Epidemiology and Prevention

Since this infection is so common and transmission is so easy (anus-to-mouth contamination, soiled nightclothes, airborne eggs, and contaminated furniture, toys, and other objects), prevention is marginal. Improved personal and group hygiene combined with group therapy can be helpful. It is also recommended that children sleep in closed garments and maintain short, clean fingernails. Sunlight and UV lamp radiation will destroy the eggs in the

environment, and dry heat can be used to sterilize metal toys. The eggs are not killed by the level of chlorination used in swimming pools. Recent studies also reveal that *Enterobius* infestation can occur in cockroaches, which may serve as potential reservoirs for these helminths and have considerable public health significance (14). *Under most circumstances, total prevention is neither realistic nor possible.*

Trichuris trichiura

Trichuris trichiura was first described by Linnaeus in 1771 and was studied extensively in the late 1880s, and early 1900s. Two early names include *Trichocephalus trichiurus* and *Trichocephalus dispar*. Well-preserved *Trichuris* eggs were found in feces in the rectum of a 9-year-old Inca girl whose frozen body was recovered in a stone building at the 17,568-ft altitude near Santiago, Chile; it was calculated that the child had died approximately 450 years earlier (9). In 1991, a well-preserved mummy of a 25- to 30-year-old man was found in a glacier in the Alps at an altitude of 3,200 m; it was estimated that the man had died about 5,200 to 5,300 years earlier. In studies of material from the colon, preservation and processing of material in sodium acetate-acetic acid-formalin fixative revealed the presence of *T. trichiura* eggs, the oldest finding of *Trichuris* in a human (3200 to 3300 BC) (6).

Infection with *T. trichiura* is more common in warm, moist areas of the world and is often seen in conjunction with *Ascaris* infections. Worm burdens vary considerably, and individuals with few worms are unaffected by the presence of these parasites. Prevalence rates of 20 to 25% have been reported from the southern United States (9).

Life Cycle and Morphology

Whipworms are much larger than pinworms, measuring 35 to 50 mm long (female) or 30 to 45 mm long

Figure 10.13 *Trichuris trichiura* adult worms. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

(male); the male has a 360° coil at the caudal extremity (Figure 10.13). The adult worms are rarely recovered from the stool, since they are attached to the wall of the intestine. The head portion of the worm is very thin and is embedded in the mucosa, while the posterior end is much thicker and lies free in the lumen of the large intestine. The large, posterior end has been described as the whip handle while the thin, anterior end is the whip itself, hence the name whipworm.

Human infection is acquired through ingestion of the fully embryonated eggs from the soil (Figures 10.14 and 10.15). The eggs hatch in the small intestine and eventually attach to the mucosa in the large intestine. The adults mature in about 3 months and begin egg production. The eggs are barrel shaped with clear, mucoid-appearing polar plugs (Figures 10.15 and 10.16). They measure 50 to 54 μm long and 22 to 23 μm wide. They are passed in the unsegmented stage and require 10 to 14 days in moist soil for embryonation to occur. Distorted eggs that are much larger than normal have been seen following therapy with mebendazole and with other drugs. This is not a common

Figure 10.14 *Trichuris trichiura* life cycle.

Figure 10.15 *Trichuris trichiura* eggs. (Illustration by Sharon Belkin.)

finding but is something to consider if distorted eggs are seen. There are also some reports in the literature that *T. vulpis* (dog whipworm) eggs have been recovered in human stools (67). These eggs tend to be larger (70 to 80 μm long by 30 to 42 μm wide) and have prominent but small polar plugs compared with those of *T. trichiura*. Several studies have also confirmed that larger eggs among others of normal size have been recovered in human stool in cases where the larger egg size was not associated with treatment. Studies also confirm that these larger eggs can develop to the infective stage (9).

Clinical Disease

The differential diagnosis of chronic diarrhea requires consideration of several diseases, including celiac disease, inflammatory bowel disease, and irritable bowel syndrome. Patients infected with *T. trichiura* may present with a chronic dysentery-like syndrome if they have a massive infestation leading to anemia and growth retardation. In some cases, diarrhea may last for years without blood and mucus. However, once blood is evident, medical intervention may occur; in some cases the diagnosis requires colonoscopy. Also, in these cases, prolonged therapy may be necessary to eliminate the parasites (28).

Mechanical damage to the mucosa and the allergic response by the host appear to be the main reasons for any abnormalities associated with *T. trichiura* infection and are definitely related to the worm burden, the length of the infection, and the age and overall health status of the host. Although the worm is actually threaded into the epithelium of the cecum, damage produced by this process is minimal unless there is dysentery, during which the mucosa may be edematous and friable, and there may be abdominal cramps, severe rectal tenesmus, and rectal prolapse (Figures 10.17 and 10.18). The dysentery seen in severe infections may mimic that seen in amebiasis. Most infections are light to moderate, with minimal or no symptoms.

Hypochromic anemia may be seen in patients with prolonged, massive infection; however, the anemia is due

Figure 10.16 *Trichuris trichiura* eggs; note the two polar plugs, one at each end of the egg.

to malnutrition and blood loss from the friable colon and is not related to blood ingestion by the parasite. In a study of 409 Jamaican schoolchildren, iron deficiency anemia was associated with *Trichuris* infections involving over 10,000 eggs/g but not with less severe infections (56). Although eosinophils and Charcot-Leyden crystals are present in the stool in patients with dysentery, a peripheral eosinophilia on the differential smear is not always seen and the degree of eosinophilia may not correlate with the severity of infection (it rarely exceeds 15%). Heavy infections tend to be rare in developed countries, and complications requiring surgical intervention are also rarely described. A case of colonic obstruction and perforation has been described in an 84-year-old woman. She was originally admitted for a chest infection; 2 days after admission, she suffered from nausea and vomiting, followed by bowel stoppage 2 days later. A partial right-sided ileocelectomy was performed; pathology

Figure 10.17 *Trichuris trichiura*, rectal prolapse.

revealed a heavy infestation with *T. trichiura*, causing a pseudotumor following a proliferative inflammatory response (7).

There are few data on mucosal immune responses to intestinal helminths in humans, particularly involving the IgE system, which is thought to be important in parasite expulsion. Cooper et al. (22) did find evidence of an IgE-mediated immune mucosal response to *Trichuris* infections, but it was not sufficient to cause parasite expulsion. On examination of rectal biopsy specimens, children with *Trichuris* dysentery syndrome had significantly greater numbers of mast cells and cells with surface IgE than did the control group. Unanswered questions involve possible antibody-mediated immunity and protection against invading larvae and whether *Trichuris* dysentery syndrome develops in some children because they have a defect in antiparasite cell-mediated immunity. Probably both cellular and humoral responses are required to eliminate the worms from the colon.

A study in England was designed to determine whether *T. trichiura* dysentery is associated with evidence of a systemic inflammatory response and whether the plasma protein disturbance has special characteristics compared with the situation in uninfected children in the area of endemic infection (21). C-reactive protein, α -antitrypsin, total globulin, and fibronectin levels and plasma viscosity were significantly higher in children with *T. trichiura* dysentery. There appeared to be an acute-phase response in intense trichuriasis and a specific elevation of the fibronectin level in plasma. Also, plasma viscosity remained abnormally high 6 months after treatment, although it was lower than at diagnosis.

It appears that an increase in the rate of epithelial cell turnover in the large intestine may lead to the expulsion of

Figure 10.18 Numerous adult *Trichuris trichiura* worms attached to the colonic mucosa of a patient who died of trichuriasis. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Trichuris. This increased rate of epithelial cell movement is under immune control by the cytokine IL-13 and the chemokine CXCL 10 (19). Such a host protective mechanism may help explain the roles played by the intestinal epithelium in mucosal defense.

***Trichuris suis* Therapy for Active Ulcerative Colitis**

Inflammatory bowel disease, including Crohn's disease, probably occurs from a failure to downregulate a chronic Th1 intestinal inflammatory process. Induction of a Th2 immune response by intestinal helminths reduces the Th1 inflammatory process. Ulcerative colitis is more common in Western industrialized countries than in underdeveloped countries, particularly those where helminth infections are common. People with helminth infections exhibit altered immunologic antigen responses. It has also been shown in animal models that helminths prevent or improve colitis through the induction of regulatory T cells and modulatory cytokines. The use of *Trichuris suis* in the therapy of ulcerative colitis has been a controversial and debated issue for several years. A recent randomized, double-blind, placebo-controlled trial conducted at the University of Iowa and selected private practices has shown improvement in 43.3% of patients treated with ova compared with 16.7% who received placebo.

Although the benefit was temporary in some patients who received a single dose of 2,500 *T. suis* eggs,

improvement could be sustained with maintenance therapy every 3 weeks. Consequently, this approach appears to be safe and effective in patients with active colitis (70).

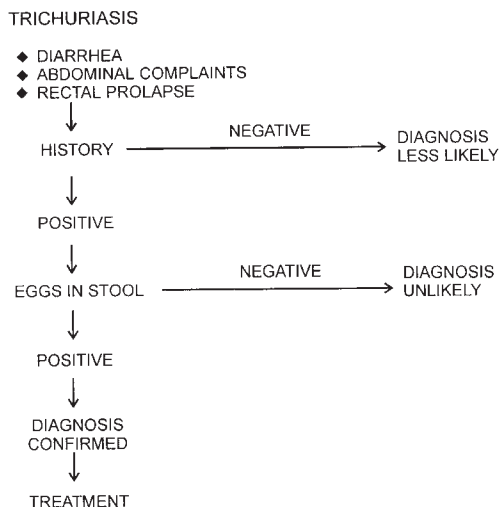

Diagnosis

Most whipworm infections can be easily diagnosed by finding the characteristic eggs in the stool. These eggs should be quantitated (rare, few, moderate, many), since light infections usually cause no problems and do not require therapy.

Note. *T. trichiura* eggs submitted in stool preserved with polyvinyl alcohol do not concentrate as well as those preserved in formalin. *However, the very small numbers of eggs that might be missed in a concentrate obtained from polyvinyl alcohol-preserved stool material are not clinically significant.* If the specimen was collected early in the infection, when egg production was minimal, eggs would be seen in later specimens (if they were submitted because of patient symptoms).

Although dysentery with *T. trichiura* and dysentery with *Entamoeba histolytica* are very similar, whipworm dysentery is usually more chronic, associated with malnutrition, and likely to cause rectal prolapse. Recovery and identification of the eggs or protozoan trophozoites would differentiate the two infections. Whipworm infections in heavily infected children may be accompanied by infection with *E. histolytica* and enteropathogenic bacteria. In severe infections, the adult worms are usually visible on the rectal mucosa. Refer to Algorithm 10.3.

Algorithm 10.3 Trichuriasis.

KEY POINTS—LABORATORY DIAGNOSIS

Trichuris trichiura

1. Eggs are normally recovered by using the routine ova and parasite examination from the direct wet mount or the concentration procedure. Egg recovery is generally not as good when concentrations are performed using polyvinyl alcohol-preserved fecal specimens; formalin or other non-polyvinyl alcohol preservatives are recommended.
2. These eggs should be quantitated on the laboratory report (rare, few, moderate, many), since light infections may not require treatment.
3. Adult worms are very rarely seen.
4. Most infections are mild; however, in very heavy infections, dysentery may have to be differentiated from that caused by *E. histolytica*.
5. The eggs can usually be identified from the permanent stained smear, but morphology is more easily seen in the wet mount preparations (either direct wet mounts or from concentrated sediment).

Treatment

Several available drugs are very effective, including mebendazole and albendazole. Exact information and dosages are provided in chapter 25. Therapy may not be necessary, depending on the number of eggs recovered in the stool. In investigating the relationship between whipworm infection and cognition in a large group of Jamaican children, a recent study concluded that albendazole treatment of children with mild to moderate *T. trichiura* infections produced little benefit in cognition if they were adequately nourished; however, children who were undernourished were more likely to benefit (66).

Epidemiology and Prevention

The geographic range of *T. trichiura* is similar to that of *A. lumbricoides*, and the two infections are often found together in the same host. Infection rates are highest in children; the eggs contaminate the soil where the children play, and the children reinfect themselves with eggs transferred from the soil to their mouths. The eggs do not survive dry conditions or intense cold.

Adequate disposal of feces reduces both the number of infections and the worm burdens. This approach is particularly important when one is dealing with children who may be used to defecating on the ground.

Capillaria philippinensis

The first proven case of human infection with *Capillaria philippinensis* occurred in 1963 in a patient from the Philippines who died 3 days after admission to the hos-

Figure 10.19 *Capillaria philippinensis* eggs.

pital with a diagnosis of malabsorption syndrome (9). Although the significance was not recognized until 4 years later, *C. philippinensis* eggs were found in the stools and autopsy showed parasitism of the large and small intestines. In 1967, health authorities recognized infections causing severe symptoms and death in adult males, an infection that is now known to be widely distributed in the Northern Luzon area of the Philippines. Since that time, the disease has become widespread in Thailand and cases have been reported in Japan, Taiwan, Iran, and Egypt.

The adult female worms are 2.5 to 4.3 mm long, while males are 2.3 to 3.17 mm long. These worms live in the mucosa of the small bowel, most commonly the jejunum. Human infection is initiated by the ingestion of raw fish; the infective larvae are located in the mucosa of the fish intestine. Specific details of the life cycle are not clearly known; however, there does seem to be an internal autoinfection capability (23). The female worms produce eggs that resemble those of *T. trichiura*. They are thick shelled, with less prominent polar plugs, and the shell is striated (Figure 10.19). The eggs are somewhat smaller than those of *T. trichiura*, measure 36 to 45 by 20 μm , and require 10 to 14 days in the soil to embryonate and 3 weeks to develop into the infective form in fish.

Life Cycle and Morphology

Although the exact mode of transmission is unknown, experimental infection is transmitted through small fish that serve as the intermediate host; often, whole, small fish may be ingested. Development to the infective stage in the fish takes at least 3 weeks. In areas of the Philippines where this infection occurs, people also eat raw shrimp, crabs, and snails. They also tend to defecate in the fields or water where the fish, shrimp, crabs, and snails are obtained, thus completing the life cycle. The worms live burrowed into the mucosa of the small bowel, mainly the jejunum. The adult worms are small. The male has ventrolateral caudal expansions and a very long, smooth

spicular sheath. The female has two almost equal parts, with the anterior containing the esophagus and stichosome (esophageal glands) and the posterior containing the intestine and reproductive system. Females produce eggs with thin shells and free larvae, as well as the typical thick-shelled eggs that pass in the stool. All stages of development are seen in the human host, and internal autoinfection is a normal part of the life cycle. Eggs that are passed in stool have been described as “peanut shaped,” with flattened bipolar plugs and striated shells, measuring 36 to 45 μm long by 20 μm wide and somewhat resembling *T. trichiura* eggs.

Clinical Disease

Symptoms are related to the worm burden; with large numbers of worms, there may be intestinal malabsorption and fluid loss along with electrolyte and plasma protein imbalance. Most of the abnormality is found in the small intestine, where the wall is thickened and indurated and contains many larval and adult worms. Watery stools are passed (up to eight per day), with fluid loss of several liters. Patients lose weight rapidly and develop muscle wasting, abdominal distention, and edema. Death from pneumonia, heart failure, hypokalemia, or cerebral edema may occur within several weeks to a few months (29). In some cases, patients reported chronic abdominal pain and diarrhea over a period of many months prior to diagnosis. On gastroduodenoscopy and subsequent histology, the jejunal mucosa revealed flattened villi, crypt proliferation, acute inflammation, and eosinophilic granulomata.

Diagnosis

Diagnosis is based on recovery and identification of the eggs in the stool, which might also contain larvae or adult worms. Knowledge of the geographic range would also provide specific clues to a possible infection. Unfortunately, without some index of suspicion, patients may go for many months with the cause of their symptoms remaining unexplained.

Treatment

Some of the more common therapeutic agents, including mebendazole and albendazole, are effective in treating this infection and result in dramatic improvement in the patient’s condition within the first day. Specific drug and dosage information is provided in chapter 25.

Epidemiology and Prevention

Although the life cycle is not completely known, the geographic range is known and expanding. Raw infected fish, shrimp, crabs, and snails may serve to transmit the larvae. In areas where this infection is endemic, adequate cooking of all suspect foods should reduce the number of cases.

Infections have now been described in the Philippines, Thailand, Japan, Iran, Egypt, Taiwan, and Indonesia.

Hookworms (*Ancylostoma duodenale* and *Necator americanus*)

Although the “Old World” hookworm, *Ancylostoma duodenale*, was mentioned in ancient Egypt in 1600 BC and in the Persian literature in approximately AD 1000, the first good description was written by Dubini in 1843. Diagnosis was confirmed in the late 1800s by finding eggs in stool, particularly in patients suffering from “miner’s anemia.” Final delineation of the complete life cycle was completed in 1897 by Arthur Looss from both his accidental self-infection and additional studies on dogs. Although the geographic ranges of *A. duodenale* and the “New World” hookworm *Necator americanus* used to be much more distinct, nowadays there are many areas of the world where both are found. *N. americanus* was described by Stiles in 1902 as a new species and was soon found to be widely distributed throughout the Western Hemisphere (see below); it is known as the “American hookworm” or the “American murderer.”

Hookworm infections are found in moist, warm areas and are responsible for much human disease, although they cause more morbidity than actual mortality. Although there are distinct morphologic differences between the two most common human hookworms (adult worms), the diagnostic stage (egg) is essentially identical for both. Globally, about 900 million people harbor hookworms. In looking at various hookworm isolates, molecular biology-based studies have been very helpful in determining correct classification relationships. Studies of the nucleotide sequences of the second internal transcribed spacer of rDNA of adult worms of *N. americanus* from Togo, Africa, and Sarawak, Malaysia, suggest that there is population variation in the sequence of *N. americanus* or that *N. americanus* from the two countries may represent genetically distinct but morphologically similar species. However, comparison of the sequence differences among other hookworm species supports genetically distinct species (58). As these types of studies continue to examine former classification schemes, we may see generic and species name changes in future publications.

Life Cycle and Morphology

Adult males measure 7 to 11 mm long by 0.4 to 0.5 mm wide. The adult *Ancylostoma* worm tends to be larger than the *Necator* worm. Adult worms are rarely seen, since they remain firmly attached to the intestinal mucosa by means of well-developed mouth parts (teeth in *A. duodenale* and cutting plates in *N. americanus*) (Figure 10.20).

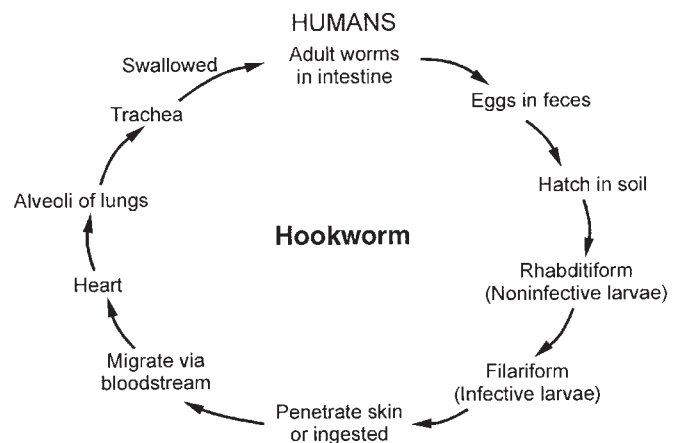

Figure 10.20 (A) *Ancylostoma duodenale* mouth parts (teeth); (B) *Necator americanus* mouth parts (cutting plates). (Illustration by Sharon Belkin; adapted as a composite from a number of photographs, including those in E. K. Markell, M. Voge, and D. T. John, *Medical Parasitology*, 7th ed., The W. B. Saunders Co., Philadelphia, Pa., 1992.)

Infection in humans is acquired through active skin penetration of filariform larvae from the soil (Figure 10.21). The larvae are normally in a motionless, resting position; stimuli for movement include touch, vibration, water currents, heat, light, human breath, and skin extracts such as fatty acids (32). During skin penetration, infective hookworm larvae encounter hyaluronic acid; hookworm hyaluronidase activity has been confirmed and can facilitate passage of the infective larvae through the epidermis and dermis during larval migration (37). The infective larvae of *N. americanus* secrete various classes of proteolytic enzymes with two overall pH optima of 6.5 and 8.5. Since skin penetration is mandatory for the infective larvae, the effect of each of these enzyme classes against macromolecules derived from human skin has been examined. Larval secretions were shown to degrade collagen types I, III, IV, and V, fibronectin, laminin, and

Figure 10.21 Hookworm life cycle.

Figure 10.22 (A) Hookworm egg; (B) *Trichostrongylus* egg. (Illustration by Sharon Belkin.)

elastin. All the skin macromolecules tested were hydrolyzed by aspartyl proteinase activity. Studies of the effect of proteinase inhibitors revealed that larval penetration was significantly inhibited only by pepstatin A, confirming the importance of the aspartyl proteinase activity during skin penetration (12). After skin penetration, the larvae are carried by the venules to the right heart and then to the lungs. Larvae break into the alveoli, migrate via the bronchi until they reach the trachea and pharynx, and are then swallowed, bringing them to the small intestine, where they reside. They attach to the mucosa by using a temporary mouth structure, mature sexually, and finally develop the permanent characteristic mouth structure that they use to attach to the mucosa. The females begin to deposit eggs about 5 months after the initial infection, although the prepatent period may be 6 to 10 months. If mature filariform larvae of *A. duodenale* are swallowed, they can develop into mature worms in the intestine without migrating through the lungs. A *Necator* infection produced by percutaneous exposure of a volunteer to three larvae was monitored by periodic egg counts for 18 years and 4 months (8). Until this report, the longest infection recorded was 15 years.

The eggs are usually in the early cleavage stage when passed in the stool (Figures 10.22 and 10.23). They are oval with broadly rounded ends and measure approximately 60 μm long by 40 μm wide. They characteristically have a clear space between the developing embryo and the thin eggshell. Although hookworm eggs and eggs of *Trichostrongylus* spp. are similar, specific size differences can be seen in Figure 10.24. Egg survival and larval development are maximum in moist, shady, warm soil (sandy loam), where larvae hatch from the eggs within 1 to 2 days. The infective filariform larvae develop within 5 to 8 days and may remain viable in the soil for several weeks.

A review by Schad (61) of hookworm developmental biology provides some excellent information on the relationship between arrested development of hookworms

Figure 10.23 (A) Immature hookworm egg; (B) embryonated hookworm egg.

and vertical transmission. Epidemiologic evidence supports the theory that *A. duodenale* may enter a period of arrested parasitic development for approximately 8 months, as a mechanism allowing the species with the shorter adult life span to survive the dry climatic season in the host. Experimental evidence is based on two self-induced *A. duodenale* infections with very long prepatent periods of 40 weeks (hypobiotic state), about five times the normally expected prepatent period. Clinical evidence involved a group that was exposed to infection and after 11 days left the area where the infection was endemic; hypobiotic larvae were shown to have remained in 8 of 15 patients, with adult and immature worms being expelled after repeated therapy 253 days after the only known exposure. Arrested development is a prerequisite for vertical transmission, and there is mounting evidence that congenital infection can occur (61). Apparently, arrested

Figure 10.24 (Left) *Trichostrongylus orientalis*, immature egg; (right) hookworm, immature egg.

larvae tend to be highly resistant to most therapeutic agents; control programs that do not take into account this aspect of the life cycle will not achieve optimal results.

Clinical Disease

Initial symptoms after larval penetration of the skin often depend on the number of larvae involved. There may be minimal to severe pruritus and possible secondary infection if the lesions become vesicular and are opened by scratching. The development of vesicles from the erythematous papular rash is called ground itch.

Any pneumonitis due to migrating larvae depends on the number of larvae present. These larvae do not cause the same level of sensitization seen with *Ascaris* or *Strongyloides* infection.

Symptoms from the intestinal phase of the infection are caused by (i) necrosis of the intestinal tissue within the adult worm mouth and (ii) blood loss by direct ingestion of blood by the worms and continued blood loss from the original attachment site, possibly as a result of anticoagulant secreted by the worm (Figure 10.25).

Patients with acute infections involving many worms may experience fatigue, nausea, vomiting, abdominal pain, diarrhea with black to red stools (depending on the level of blood loss), weakness, and pallor. As in many other parasitic infections, heavy worm burdens in young children may have serious sequelae, including death. During this acute intestinal phase, there is an increased peripheral eosinophilia.

In chronic infections, the main symptom is iron deficiency anemia (microcytic, hypochromic) with pallor, edema of the face and feet, listlessness, and hemoglobin levels of 5 g/dl or less. There may be cardiomegaly and both mental and physical retardation.

Figure 10.25 Hookworm, section of a worm attached to the mucosa. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

The hookworms cause gastrointestinal blood loss, and in clinical studies significant blood losses have been reported with *A. duodenale*. However, there has been no evidence that endemic *A. duodenale* infection has a greater impact than *N. americanus* infection on the iron status of populations. In a sample of 525 schoolchildren in Tanzania, the degree of anemia and iron deficiency associated with the two hookworm species was compared at the individual and community school levels. Hemoglobin and ferritin concentrations decreased with increasing proportions of *A. duodenale*. In children infected with only *N. americanus* larvae, the prevalence of anemia was 60.5% and the prevalence of low ferritin levels was 33.1%, while in children with at least 50% *A. duodenale* larvae, the respective prevalences were 80.6 and 58.9%. When children were grouped by prevalence of *A. duodenale* at the school level, children from high-prevalence ($\geq 20\%$) schools had significantly worse iron deficiency and anemia than did children from low-prevalence schools. Since the species of hookworm being transmitted within a community influences the burden of iron deficiency anemia in the community, this factor should be considered in prioritizing and planning programs for hookworm and anemia control (1). It is also well documented that there is a relationship between the hookworm worm burden and anemia during pregnancy; women with moderate or heavy hookworm infections were more likely to suffer from anemia than were women having light infections. These findings support routine therapy within prenatal care programs in areas where infection is highly endemic (45).

Egg counts of 5/mg of stool are rarely clinically significant, counts of more than 20/mg are usually associated

with symptoms, and counts of 50/mg or more represent very heavy worm burdens.

Immunology and Host Resistance

There is a mixed Th1-Th2 response in hookworm infection with subsequent immunosuppression of gamma interferon responses. There is also evidence for protective immunity in hookworm infection, including antilarval IL-5- and IgE-dependent mechanisms (55). Antihookworm antibodies show cross-reactivity with *A. lumbricoides* and *Schistosoma mansoni*, while IgG4 or IgE responses tend to be more specific. The levels of polyclonal IgG in serum and intestinal IgG, IgM, and IgE in the intestines are also elevated, while intestinal IgA levels are reduced.

Eosinophilia is common, usually develops 25 to 35 days after exposure, and peaks about a month (*N. americanus*) to 2 months (*A. duodenale*) later. Proliferative lymphocyte responses tend to be variable, while cytokine results indicate that hookworm infection produces a mixed Th1-Th2 response. There is significant production of Th1 (gamma interferon and IL-12) and Th2 (IL-4, IL-5, and IL-13) cytokines. There are also high levels of IL-10 and tumor necrosis factor alpha.

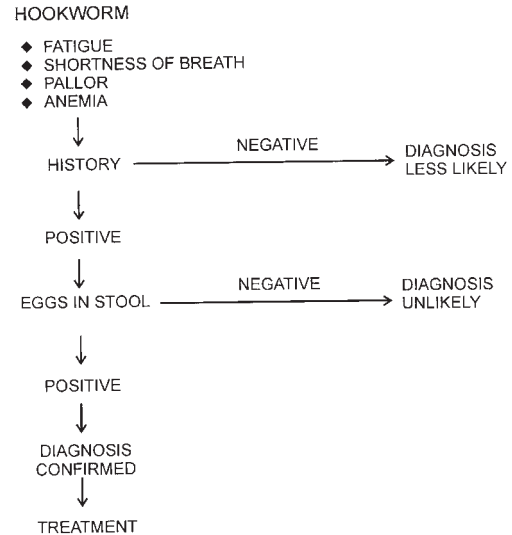

Hookworm-mediated immunosuppression has relevant implications for vaccine development. Unless preexisting infections are cleared by therapy, vaccine-induced immunity may be susceptible to immunosuppression. Also, if the vaccine is only partially effective, vaccine recipients may be susceptible to reinfection, which might further suppress vaccine efficacy. Careful selection of vaccine candidates may prevent this problem. Currently, the ASP-2 protein secreted by infective larvae of *N. americanus* is under development as a recombinant vaccine (30).

There is evidence for a protective role of helminth infection against asthma and malaria; however, helminth infection may increase susceptibility to HIV/AIDS or tuberculosis. People with hookworm infection are also more likely to be infected with *A. lumbricoides* and *T. trichiura*, findings that can only partially be explained by overlapping areas of endemic infection and potential exposure.

Diagnosis

Definitive diagnosis of hookworm infection depends on demonstration of the eggs in stool, especially since the symptoms cannot be differentiated from malnutrition (Figures 10.22 and 10.23). The eggs are best seen in the direct smear or the concentration sediment; they are distorted on the permanent stained smear.

Note. If the stool specimen is stored at room temperature (no preservative) for more than 24 h, the larvae continue

Algorithm 10.4 Hookworm.

to mature and hatch. These larvae must be differentiated from *Strongyloides* larvae, since therapy is often quite different for the two infections.

Many infections seen in the United States are not severe, and eggs in the stool may represent an incidental finding. Radiographic findings include intestinal hypermotility, proximal jejunal dilatation, and coarsening of the mucosal folds (9). Refer to Algorithm 10.4.

In one study examining stools for helminth eggs by the Kato-Katz method and by a modified Harada-Mori nematode larval culture method, there was an 81.8% agreement between the two methods for the detection of hookworm infection, an infection that was endemic in the study population and highly prevalent in pregnant women in the area (51).

KEY POINTS—LABORATORY DIAGNOSIS

Hookworms (*Ancylostoma duodenale* and *Necator americanus*)

1. Eggs are normally passed in the stool in the unembryonated state (usually about an 8- to 32-cell stage of development). There are typically a thin shell and clear space between the developing embryo and the shell.
2. If the stool remains unpreserved for over 24 h, the eggs may continue to develop and the larvae may hatch. These larvae must be differentiated from those of *S. stercoralis*, since therapies for the two infections are different.
3. The eggs are normally distorted on the permanent stained smear, and morphology is more easily seen in wet preparations.

Treatment

Several effective therapeutic agents, including mebendazole, pyrantel pamoate, and albendazole, are available in the United States. Additional studies support the data showing that despite its relatively low cost and wide availability, pyrantel pamoate at a single-dose rate of 10 mg/kg of body weight is not effective against *A. duodenale* and should not be considered a drug of choice at this dose rate. In contrast, albendazole (at a single 400-mg dose) cleared hookworm infections completely (57). Confirmatory studies also indicate that in the southern region of Mali, single-dose treatment with mebendazole is not an effective treatment for hookworm infections and that despite its relatively low cost and wide availability, mebendazole should not be considered a drug of choice in the mass treatment of hookworm infections (18). See chapter 25 for specific drug and dosage recommendations.

Adequate nutrition can prevent and overcome disease symptoms but not the infection itself. Apparently, adequate absorption of iron and nutrients is not possible in heavy infections, even with extensive dietary supplements.

Epidemiology and Prevention

Sanitary disposal of feces is the primary means of infection control. This is sometimes difficult in poor rural communities where sanitary facilities are minimal or absent. An overall prevention approach also requires educational programs. The wearing of shoes and the use of soil sterilization have not proven to be practical.

Several factors influence hookworm prevalence: infection in the human population, defecation onto the soil, acceptable environmental conditions, and human contact with the infective larvae in soil. Environmental conditions include temperature, rainfall pattern, and the presence of open, sandy soil.

A significant increase in the prevalence of hookworm infection has been seen in an area of Haiti where intestinal parasites are common but hookworm has not been common. Changing environmental conditions, specifically deforestation and subsequent silting of a local river, have caused periodic flooding with deposition of a layer of sandy loam topsoil and increased soil moisture. These conditions, all of which are conducive to hookworm transmission, have allowed hookworm to reemerge as an important human pathogen in this area. This example emphasizes the value of longitudinal surveillance data for monitoring disease prevalence. Shifts in the prevalence of infectious diseases can be caused by environmental changes, including planned human activity, or can be an indirect consequence of political strife, and these factors should always be considered when changes in infectious disease patterns are detected.

A. duodenale (Old World hookworm) is found primarily in southern Europe, the north coast of Africa,

northern India, northern China, and Japan. *N. americanus* (New World hookworm) is found throughout the southern United States, the Caribbean, Central America, northern South America, central and southern Africa, southern Asia, Melanesia, and Polynesia. In some areas such as northern Ghana, both hookworms are present; mixed infections have been confirmed using PCR (24).

Trichostrongylus spp.

Trichostrongylus nematodes are commonly found in herbivores throughout the world. Various species have been found in humans, and some are more clinically important than others. Throughout the world, there are certain areas of endemic infection where the percentage of positive patients is substantial, and at least 10 species have been found to be human parasites. Human infections tend to be prevalent in Iran.

Life Cycle and Morphology

Trichostrongylus spp. are small worms, similar to hookworms, and live embedded in the mucosa of the small intestine. Unlike the adult hookworms, the adult worms have no distinct buccal capsule with special mouth parts (teeth or cutting plates).

Infection in humans is acquired through ingestion of the infective larvae contaminating plant material. After reaching the small intestine, the larvae mature in 3 to 4 weeks without any migratory pathway through the lungs. The eggs are very similar to those of hookworms, being oval and somewhat longer, with the ends being more pointed than in hookworm eggs (Figures 10.22 and 10.24). The eggs may hatch within 24 h under favorable conditions (warm, moist soil) and develop into infective larvae after about 60 h.

Clinical Disease

Symptoms are related to the worm burden and damage to the intestinal mucosa. Hemorrhage and desquamation may occur (similar to findings in hookworm infection); however, symptoms are usually not clinically significant unless several hundred worms are present. Patients present with epigastric pain, diarrhea, anorexia, nausea, dizziness, and generalized fatigue or malaise. Heavy worm loads may lead to the development of anemia and cholecystitis, as the worms enter the biliary tract. A *Trichostrongylus* infestation has been seen masquerading as conditioning toxicity of the gut in a bone marrow transplant recipient, another reason to consider all possibilities in immunocompromised patients (15).

Diagnosis

The definitive diagnosis can be made by identification of eggs in the stool. Hatched larvae can also be differentiated from those of hookworms and *S. stercoralis* (Figure 10.26).

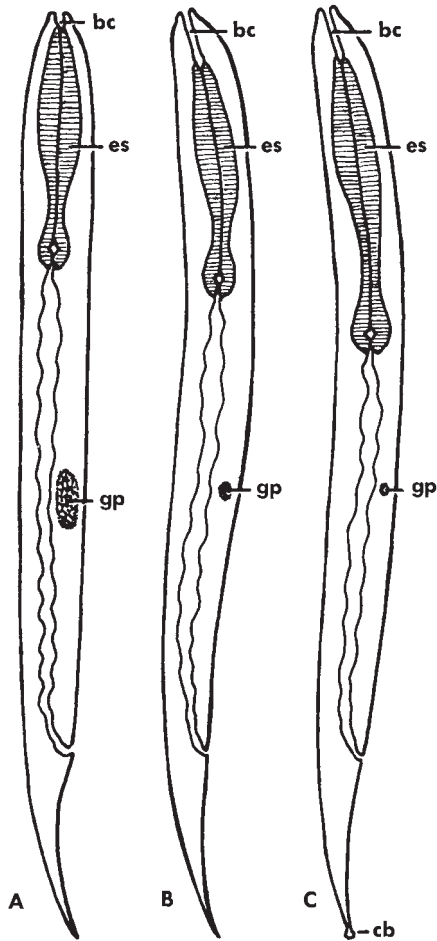

Figure 10.26 Rhabditiform larvae. (A) *Strongyloides stercoralis*; (B) hookworm; (C) *Trichostrongylus* sp. Abbreviations: bc, buccal cavity; es, esophagus; gp, genital primordium; cb, bead-like swelling of caudal tip. (Illustration by Nobuko Kitamura; from L. S. Garcia, in S. M. Finegold and E. J. Baron, *Diagnostic Microbiology*, 7th ed., The C. V. Mosby Co., St. Louis, Mo., 1986.)

Treatment

Several anthelmintic agents are available, including pyrantel pamoate, mebendazole, and albendazole, some of which are also used for the other nematode infections. Specific drug and dosage information is presented in chapter 25.

Epidemiology and Prevention

Since the infection is found in herbivores throughout the world, any grazing areas are constantly being reinfected. In some areas of the world where animal dung is formed into solid masses, dried, and burned for fuel, this practice may be important in the transmission of animal *Trichostrongylus* to humans. The main preventive measures are adequate cleaning and cooking of all vegetables prior to eating.

Strongyloides spp.

Strongyloides stercoralis was first found in 1876 in the feces of French soldiers with diarrhea who were returning from Indochina. A series of workers dealt with the classification, life cycle differentiation, and possible pathogenesis of this worm during the early 1900s. Early work led to demonstration of the internal autoinfective portion of the life cycle, which has become extremely important, particularly when one is working with immunocompromised patients. *S. stercoralis* is most commonly found in warm areas but can survive in colder climates. The infection is most often found to overlap the geographic range of hookworm infections and has been reported as the most commonly diagnosed helminth infection at the University of Kentucky Medical School. It is very important to consider this infection in military personnel and travelers who, many years earlier, were in an area where the infection is endemic. More than 30 to 40 years after acquisition of the original infection, persistent, undiagnosed disease can be found in these individuals. If for any reason they become immunocompromised, the result can be disseminated disease leading to the hyperinfection syndrome and death.

Life Cycle and Morphology

The life cycle of *S. stercoralis* is one of the more complex cycles and can be seen in Figure 10.27. Human infection is acquired by skin penetration of the filariform larvae (infective larvae) from the soil. These larvae are long and slender (up to 630 μm long by 16 μm wide) and may remain viable in soil or water for several days. After penetration of the skin, the larvae are carried via the cutaneous blood vessels to the lungs, where they break out of the pulmonary capillaries into the alveoli. They then migrate via the respiratory tree to the trachea and pharynx, are swallowed, and enter the mucosa in the duodenum and upper jejunum. Development of the female worms to adults usually takes about 2 weeks, after which the females begin egg production by parthenogenesis. The eggs are oval and thin shelled, and they measure 50 to 58 μm long by 30 to 34 μm wide (generally a bit smaller than hookworm eggs). They hatch, and the rhabditiform larvae (noninfective larvae) pass out of the intestinal tract in the feces. These larvae are passed out onto the soil in the feces and develop into free-living male and female worms, eventually producing infective filariform larvae (egg, noninfective larvae, and infective larvae). In temperate climates, the free-living male and female worms do not develop; however, the rhabditiform larvae that pass out in the stool develop into the filariform (infective) larvae, which are then ready to infect the next host through skin penetration.

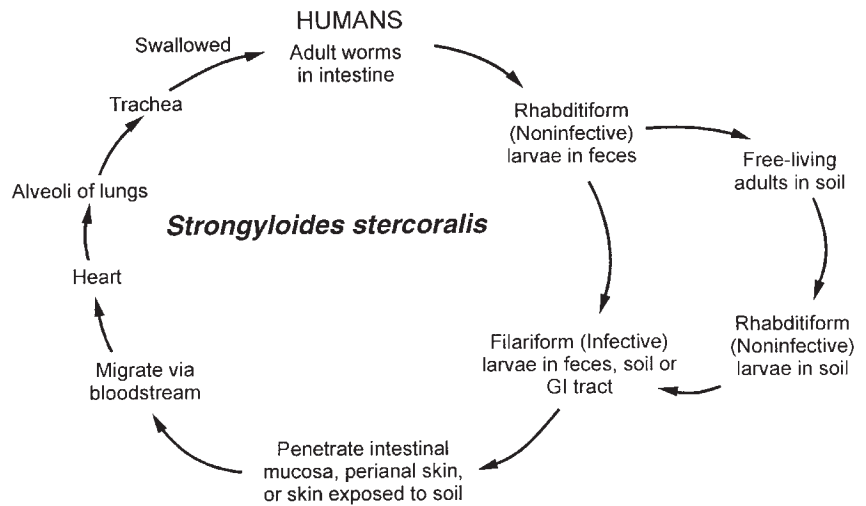

Figure 10.27 *Strongyloides stercoralis* life cycle.

S. fuelleborni is also transmitted primarily by skin contact. However, investigations into the high prevalence of *S. fuelleborni* in African children have led to the post-partum identification of larvae in breast milk. In Papua New Guinea, high rates of infection (up to 65%) in children younger than 3 months suggest that transmammmary infection might also occur in this area, although the parasite has not been identified in breast milk. Also, *S. fuelleborni* has been identified as the causative agent of “swollen belly syndrome,” a fulminant and fatal enteritis that has been well documented in infants younger than 6 months in areas of highly endemic infection in Papua New Guinea. It has been suggested that transmammmary infection followed by early external autoinfection from dirty diapers may result in rapid multiplication of worms in these young children (4).

In situations in which autoinfection occurs, some of the rhabditiform larvae that are within the intestine develop into the filariform larvae while passing through the bowel. These larvae can then reinfect the host by (i) invading the intestinal mucosa, traveling via the portal system to the lungs, and returning to the intestine or (ii) being passed out in the feces and penetrating the host on reaching the perianal or perineal skin.

The rhabditiform larvae that normally pass out in the stool measure up to 380 μm long by 20 μm wide, with a muscular esophagus (club-shaped anterior, then a restriction, and a posterior bulb) (Figure 10.28). There is a genital primordium packet of cells, which is fairly obvious and can be seen about two-thirds of the way back from the anterior end (Figure 10.29). One of the key morphologic differences between these larvae and those of hookworm is the length of the mouth opening (buccal capsule). The opening in the rhabditiform larvae of *S. stercoralis* is extremely short (only a few micrometers),

while the mouth opening in hookworm rhabditiform larvae is approximately three times as long (Figures 10.26 and 10.28). These differences can be seen by examining the larvae under the microscope with the low (10 \times) or high dry (40 \times) objectives.

Strongyloides spp. have the ability to switch between alternative free-living developmental pathways in response to changing environmental conditions. Anterior chemosensory neurons (amphidial neurons) are thought to respond to environmental cues and, via signal transduction pathways, control the direction of larval development. Larvae that pass to the exterior may develop directly to infectivity by the homogonic route or may develop by the heterogonic route to establish a population of soil-dwelling dioecious adult worms.

Figure 10.28 Buccal cavity (rhabditiform larvae). (A) *Strongyloides stercoralis*; (B) hookworm.

Figure 10.29 (Upper) *Strongyloides stercoralis* rhabditiform larva; note the packet of genital primordial cells toward the right side of the image. (Lower) *S. stercoralis* rhabditiform larva; note the packet of genital primordial cells in the middle of the field (enlarged).

The infective larvae produced by either route are environmentally resistant, developmentally arrested worms that can develop further only after entering the host. Studies confirm that neurons homologous to the two classes (ASF and ASI) do occur in *S. stercoralis* and that they control the direction of free-living development in this species (5). Apparently, the free-living cycle develops most frequently in tropical climates with moist soil while the parasitic life cycle may predominate in more temperate climates.

Review of the Life Cycle. The life cycle of *S. stercoralis* contains the following phases, some or all of which may be present, depending on environmental conditions:

1. Free-living forms in the soil that can produce infective larvae (capable of human skin penetration, common in the moist, warm tropics).
2. Noninfective rhabditiform larvae that pass in the stool and transform into infective filariform larvae while in the soil (capable of human skin penetration, common in temperate zones and responsible for most human infections).

3. Autoinfection, which involves development of filariform larvae in or on the body (may account for continued infection 30 to 40 years after the host has left the original area where the infection is endemic) (26).

Comments on the Life Cycle. Although it is generally accepted that the life cycle presented above is correct, the skin-penetrating larvae travel from the skin to the intestine via an obligatory route that includes the blood, lungs, trachea, and upper gastrointestinal tract (the standard pulmonary route). It is also assumed that following autoinfection, the larvae follow the same route to return to the duodenum, where they mature. However, review information and data from Schad et al. (62) provide evidence to indicate that the pulmonary route is just one of several possible pathways to the duodenum, regardless of whether the larvae penetrated the skin or the intestine. Direct sampling of the larvae within the trachea gave an estimate of the number of larvae within the duodenum, presumably transmitted by the pulmonary route, that was insufficient to account for the number actually found there. In spite of some caveats, these studies definitely challenge the current accepted understanding of the life cycle. The pulmonary migration route for all skin-penetrating nematodes may not be as universally applicable as was once thought (62).

Clinical Disease

The pathologic changes associated with strongyloidiasis can vary both in severity and in the areas of the body involved. Some individuals may remain totally asymptomatic, with the only abnormal clinical finding being a peripheral eosinophilia (75).

Considering the life cycle, the three areas of primary involvement would be the skin (cutaneous), the lungs (pulmonary), and the intestinal mucosa (intestinal).

Cutaneous. Initial skin penetration usually causes very little reaction, although there may be some pruritus and erythema if the number of penetrating larvae is large. In some patients, the reaction at the site of larval penetration may last several weeks. With repeated infections, the patient may mount an allergic response that prevents the parasite from completing the life cycle. The larvae may be limited to skin migration (larva migrans). The term “larva currens” (racing larva) was proposed in 1958 and is now generally accepted for cases of strongyloidiasis in which there is one or more rapidly progressing linear urticarial tracks starting near the anus. There is speculation that some of these cases may involve larvae of other species of *Strongyloides*. These tracks may progress as fast as 10 cm/h, with an intermittent movement, usually on the thighs. Onset is sudden, and the lesions may disappear within 12 to 18 h (9).

Pulmonary. Larval migration through the lungs may stimulate symptoms, depending on how many larvae are present and the intensity of the host immune response. Some patients may be asymptomatic, while others may present with pneumonia. With a heavy infective dose or in the hyperinfection syndrome, individuals often develop cough, shortness of breath, wheezing, fever, and transient pulmonary infiltrates (Loeffler's syndrome). There have been cases reported in which the larvae were even found in the sputum during this larval migration.

Intestinal. Although the timing may vary from person to person, gastrointestinal symptoms such as diarrhea, constipation, anorexia, and abdominal pain usually begin about 2 weeks after infection, with larvae being detectable in the stool after 3 to 4 weeks. In heavy infections, the intestinal mucosa may be severely damaged, with sloughing of tissue, although this type of damage is unusual (Figure 10.30). Parasitized individuals may show villous atrophy and crypt hyperplasia. There is infiltration of the lamina propria by IgA-positive plasma cells and of the epithelium by intraepithelial lymphocytes. Infection is also associated with increased expression of secretory component and decreased expression of HLA-DR in epithelial cells. These changes tend to correlate with the degree of clinical severity. In a group of immunocompetent patients with chronic *S. stercoralis* infection, no abnormality of mucosal structure and no increase in the levels of nonspecific inflammatory cells were found. Likewise, there was no increase in the numbers of mucosal T cells or macrophages (74). The symptoms may mimic peptic ulcer, with abdominal pain, which may be localized in the

Figure 10.30 Mucosal damage caused by larval penetration in strongyloidiasis. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

right upper quadrant. Radiographic findings may mimic those of Crohn's disease of the proximal small intestine. In immunocompetent patients, there is leukocytosis with peripheral eosinophilia of 50 to 75%, while in patients with chronic cases, the eosinophilia may be much lower. Some of these chronic infections have lasted for over 30 years as a result of the autoinfective capability of the larvae. One case of chronic strongyloidiasis persisted for approximately 65 years.

Chronic Infection. Chronic infections are usually asymptomatic; however, there may be symptoms that are unrelated to autoinfection. These symptoms include intermittent vomiting, diarrhea, constipation, and loud gurgling noises produced by movement of gas, fluid, or both in the gastrointestinal tract. Anal pruritus, urticaria and larval currens rashes, recurrent asthma, and nephrotic syndrome have also been associated with chronic disease. With development of the hyperinfection syndrome, intestinal obstruction, ileus, and gastrointestinal bleeding can also occur.

Hyperinfection Syndrome. Autoinfection is probably the mechanism responsible for long-term infections that persist years after the person has left the area where the infection is endemic. The parasite and host reach a status quo so that neither suffers any serious damage. If for any reason this equilibrium is disturbed and the individual becomes immunosuppressed, the infection proliferates, with large numbers of larvae being produced and found in every tissue of the body, including the gastric mucosa. Several conditions, including increased use of immunosuppressive therapy, predispose an individual to the hyperinfection syndrome (42). However, the distinction between autoinfection and hyperinfection tends to be quantitative rather than being specifically defined (Table 10.4).

In contrast to the usual *Strongyloides* hyperinfection syndrome seen in patients with some forms of immunodeficiency, in which small intestinal and pulmonary symptoms are seen, in one group of patients only a characteristic transmural eosinophilic granulomatous inflammation, affecting mostly the colonic wall and clinically mimicking ulcerative colitis or Crohn's disease, has been found. This eosinophilic granulomatous enterocolitis apparently results from a florid inflammatory response by eosinophils, histiocytes, and giant cells, with formation of granulomas that destroy the larvae entering the colon (31).

Strongyloides hyperinfection and dissemination are recognized complications in kidney transplant recipients; however, strongyloidiasis in renal transplant recipients receiving cyclosporin A has not been described, nor have any cases of strongyloidiasis complicating heart, liver, lung, or pancreas transplantation been published

Table 10.4 Strongyloidiasis hyperinfection syndrome^a

Body site	Symptoms	Diagnosis	Comments
Gastrointestinal tract	Crampy or bloating abdominal pain; watery diarrhea, constipation, anorexia, weight loss, difficulty swallowing, sore throat, nausea, vomiting, gastrointestinal bleeding; ileus and small bowel obstruction; diffuse abdominal tenderness, hypoactive bowel sounds; hypoalbuminemia; hypokalemia	Direct stool exam shows numerous rhabditiform and filariform larvae; occasionally adult worms and eggs; mucosal ulceration common in small intestine	Symptoms are very common, but nonspecific; some patients are asymptomatic
Cardiopulmonary system	Cough, wheezing, choking sensation, hoarseness, chest pain (pleuritic); hemoptysis; palpitations, atrial fibrillation, dyspnea, respiratory collapse (rare)	Direct sputum exam shows rhabditiform and filariform larvae; occasionally eggs; chest X rays show bilateral or focal interstitial infiltrates	If condition goes undiagnosed and steroids are given, symptoms may improve temporarily
Skin and connective tissue	Pruritic linear streaks on lower trunk, thighs, and buttocks; petechial and purpuric rashes; evidence of vasculitis	Larvae can be seen in skin biopsy	Associated gram-negative bacterial sepsis and/or disseminated intravascular coagulation may be present
Central nervous system	Meningeal symptoms; hyponatremia and meningitis; signs of aseptic meningitis in spinal fluid (pleocytosis, elevated protein, normal glucose, negative cultures); gram-negative bacterial infection	Larvae recovered in spinal fluid	Typical gram-negative bacteria isolated include <i>Escherichia coli</i> , <i>Proteus mirabilis</i> , <i>Klebsiella pneumoniae</i> , <i>Enterococcus faecalis</i> , and <i>Streptococcus bovis</i> ; immunosuppressed patients may develop <i>Candida</i> infections
Other infected organs	Liver: elevated liver enzymes	Larvae may be seen in various tissues	Other body sites include mesenteric lymph nodes, gallbladder, diaphragm, heart, pancreas, muscle, kidneys, and ovaries

^aAdapted from reference 42.

prior to this case. One possible explanation for this observation is the antiparasitic activity of cyclosporin A found in animal studies. In one renal transplant patient, *Strongyloides* hyperinfection occurred immediately after cyclosporin A treatment was discontinued. Approximately 44 days after transplantation, ongoing cellular rejection was confirmed via renal biopsy and cyclosporin A treatment was discontinued according to protocol. His earlier history was unremarkable, and several stool specimens examined for parasites were negative; he had never had any eosinophilia. Based on respiratory symptoms, he underwent bronchoscopy, and *S. stercoralis* filariform larvae were recovered from sputum, bronchoalveolar lavage fluid, and three stool specimens. After treatment with thiabendazole, the patient remained on a prophylactic regimen of thiabendazole at 25 mg/kg twice a day for 2 days every month. In situations where information on the donor is not readily available (possible strongyloidiasis), the recipient should be monitored for evidence of clinical strongyloidiasis and prophylaxis may be justified, since most episodes of

hyperinfection occur during the first 3 months following transplantation. Also, discontinuation of cyclosporin A treatment in a setting in which no prior screening for *Strongyloides* had taken place might place a patient at risk for dissemination (54). Specific conditions associated with immunosuppression and strongyloidiasis can be seen in Table 10.5 (20, 42, 59).

The possibility of hyperinfection also puts patients with asthma and intestinal strongyloidiasis at significant risk if their lung disease is treated with systemically administered corticosteroids. Apparently, fewer than 10 days of therapy with corticosteroids has led to disseminated strongyloidiasis (16, 42). This potential situation demonstrates the need to screen all asthmatics who come from areas where *S. stercoralis* is endemic, including the southeastern United States, for the presence of this parasite. Various immunosuppressive drugs that have been associated with hyperinfection include the glucocorticoids (both high and low doses), vinca alkaloids (vincristine and vinblastine), and others, although in many cases glucocorticoids were given at the same time (20, 42, 59).

Table 10.5 Strongyloidiasis: associated conditions related to immunosuppression^a

Condition	Description	Comments
Immunosuppressive drugs		
Glucocorticoids	Both high- and low-dose steroids; can begin as early as 20 days after therapy started; suppression of eosinophilia and lymphocyte activation	Most directly linked with hyperinfection syndrome; used for lupus, lymphoma, rheumatoid arthritis, leprosy, polymyositis, corneal ulcer, and Bell's palsy
Vinca alkaloids	Vincristine; decrease intestinal motility, longer time for larvae to change from noninfectious to infectious	Several reports, but information anecdotal
Cyclosporin A	No proven association; some evidence that drug may be anthelmintic	Widespread use, but does not appear to play a role in hyperinfection
Other drugs	Azathioprine, cyclophosphamide, antithymocyte globulin, anti-CD _w , chlorambucil, 6-mercaptopurine, methotrexate, bleomycin, adriamycin, doxorubicin, daunorubicin, ifosfamide, melphalan, carmustine, VP16, mitoxantrone, and total-body irradiation	Because glucocorticoids were administered at the same time, hyperinfection link to these drugs may or may not be correct
Hematologic malignancies	Case reports of hyperinfection syndrome prior to therapy with immunosuppressives	Chronic parasite-induced inflammation may contribute to lymphoma
Transplant recipients		
Kidney	Majority of transplant hyperinfection cases seen with kidneys	Probably caused by glucocorticoids in response to organ rejection
Heart	Case of graft rejection	Patient treated with increased doses of corticosteroids
Bone marrow	Few cases reported	Supposition that drugs (bisulfan, cyclophosphamide) may prevent egg hatching; therefore, hyperinfection would be rare in these cases
HTLV-1	Associated with increased strongyloidiasis, failure of conventional therapy, and hyperinfection syndrome	Suggested that serum IgE confers some protection against heavy infections and response may be inhibited by HTLV-1 infection
Hypogammaglobulinemia	Seen in case of multiple myeloma and nephrotic syndrome	Immunity to infective-stage larvae not protective against autoinfective larvae

^aAdapted from references 20, 42, 59, 63, and 65.

In addition to the actual tissue damage caused by the migrating larvae, the patient may die of sepsis and/or meningitis, primarily as a result of the intestinal flora. Cerebrospinal fluid cultures have grown *Escherichia coli*, *Proteus mirabilis*, *Klebsiella pneumoniae*, *Enterococcus faecalis*, and *Streptococcus bovis*, as well as other isolates. Migrating larvae have been found in CSF, meningeal vessels, the dura, and the epidural, subdural, and subarachnoid spaces (42). Other causes of death may include peritonitis, brain damage, or respiratory failure.

Few cases of reactive arthritis have been reported, and the number of cases may be underestimated. A case of reactive arthritis combined with uveitis associated with a long-standing, heavy *Strongyloides* infection was found in a 32-year-old patient positive for human T-cell leukemia virus type 1 (HTLV-1). Treatment with thiazibenzazole and ivermectin resulted in rapid improvement. A case of myelitis associated with eosinophilia in blood

and cerebrospinal fluid was identified as being caused by *S. stercoralis*; apparently, this is the first report of myelitis in the course of strongyloidiasis (35).

HTLV-1 Infection. The prevalence of *S. stercoralis* is significantly higher in HTLV-1 carriers than HTLV-1 noncarriers in Japan and elsewhere. Since cellular immunity plays a major role in the host defense against strongyloidiasis, infection with HTLV-1 appears to change the immune system capability, leading to severe clinical manifestations and disseminated disease (13). Hypereosinophilia, which is common in patients with mild strongyloidiasis, is often not seen in these patients and may be inhibited by the HTLV-1 infection. The relationship between *S. stercoralis*, infection with HTLV-1, and serum IgE levels reveals some very interesting information. The prevalence of *Strongyloides* infection is significantly higher in HTLV-1 carriers than in those

without HTLV-1 infection. The level of IgE is low in HTLV-1 carriers and is significantly lower in HTLV-1 carriers than in noncarriers among people with *Strongyloides* infection. This information suggests that serum IgE may confer some degree of protection against heavy infections with *Strongyloides* and that this response may be inhibited by HTLV-1 infection.

HIV Infection. Although it is well known that many people are coinfecting with HIV and *S. stercoralis*, few cases of hyperinfection have been found in this patient group, many of whom previously received steroids for *Pneumocystis* pneumonia or non-Hodgkin's lymphoma. Due to documented cases of posttreatment hyperinfection after therapy for intestinal infection, questions remain regarding screening of HIV-positive individuals for strongyloidiasis and treating infected patients with anthelmintics.

***S. fülleborni* Infection.** Children suffering from the swollen belly syndrome caused by *S. fülleborni* usually present with protein-losing enteropathy, abdominal distention, and respiratory distress at about 8 to 10 weeks of age. The diarrhea is generally not severe, and there is no significant fever. Severe hypoproteinemia without proteinuria is very characteristic and leads to peripheral edema and ascites. Egg counts are often greater than 100,000/g of stool. Untreated, the condition is associated with a high mortality (4).

Diagnosis

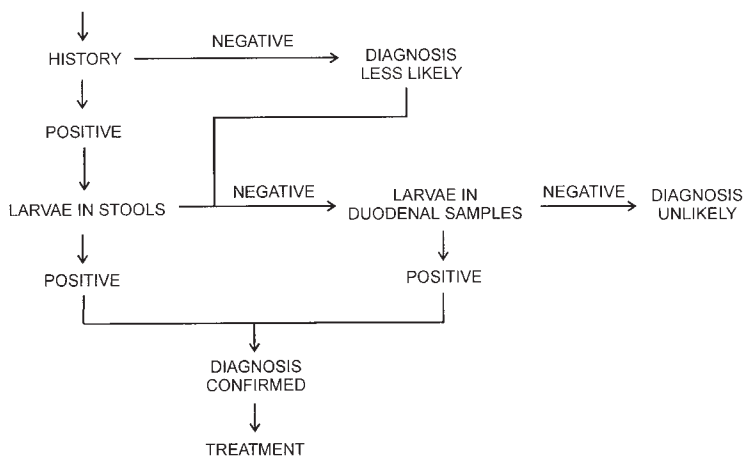

Confirmation of the infection depends on recovery and identification of the adult worms, larvae, or eggs from the stool, duodenal material, or sputum. Fecal specimens

may not be positive, even after the routine ova and parasite examination, including the concentration procedure, is performed. Numbers of larvae found in the stool also vary from day to day. It is well known that the detection of *S. stercoralis* larvae in the stools may be very difficult, particularly in patients with chronic, low-level infection (Table 10.6). This problem can be attributed to irregular and low output of the larvae, as well as the sensitivity of current diagnostic methods. Patterns of *S. stercoralis* detection vary widely among infected patients, and intermittent larval shedding can lead to inflated estimates of drug efficacy. It is important to remember that prior to entering a patient in a clinical trial of drug efficacy, it has been recommended that four consecutive stool specimens should be examined for *S. stercoralis* to determine the patient's infection status.

Some suggest that sampling of duodenal contents may recover larvae if stools are negative, while others think that duodenal sampling may not be effective. Special techniques that have been recommended for the recovery of duodenal contents include the Entero-Test capsule (see chapter 29). There are also special concentration techniques (Baermann) and methods for larva culture (Harada-Mori, petri dish), which are discussed in detail in chapter 28. These techniques provide a means of recovery of larvae from large amounts of stool material, and often the filariform larvae are recovered. To differentiate the *Strongyloides* filariform larvae from those of the hookworm, one should examine the tail under the microscope. *Strongyloides* filariform larvae have a slit in the tail, while hookworm filariform larvae have a pointed tail (Figure 10.31). Refer to Algorithm 10.5.

STRONGYLOIDIASIS

- ◆ ABDOMINAL PAIN

- ◆ EOSINOPHILIA
- ◆ IMMUNOCOMPROMISED PATIENT

Algorithm 10.5 Strongyloidiasis.

Table 10.6 Diagnostic methods for strongyloidiasis^a

Method	Pros	Cons	Comments
Direct wet mount	Simple to perform	Sensitivity very low	Other methods much more sensitive
Concentration wet mount (formalin ethyl acetate concentration)	Simple to perform; centrifugation at 500 × g for 10 min	Sensitivity low for a single stool sample	Four stools recommended to determine patient's infection status
Permanent stained smear (trichrome, iron-hematoxylin)	Performed as a routine part of the ova and parasite examination	Larval morphology may be distorted	If anything seen, reexamine concentration sediments
Baermann concentrate	Examination of much larger amount of stool	Messy to set up, possible exposure to infectious larvae	Handle with gloves; decontaminate glassware, etc., when test completed
Harada-Mori, agar plate concentration	Considered "mini" Baermann procedures; relatively simple to set up	Will require checking for several days; not as sensitive as Baermann concentrate	Not routinely performed, but can be helpful
Agar plate culture	Often considered the most sensitive method for larval recovery and identification	Must be examined for 5 days before calling culture negative	More sensitive than formalin ethyl acetate concentration if larvae are present at <50/g of stool
Duodenal contents	Some studies indicate good sensitivity for larval recovery; use of the Entero-Test capsule helpful	Sensitivity debated; duodenal intubation invasive	Multiple stool exams may be more helpful, particularly if agar plate cultures set up
Serologic tests	More widely available; sensitive but not always specific	May not distinguish present from past infection; sensitivity decreased in patients with HTLV-1 infections and hematologic malignancies	Sensitivity may be lower in travelers, but helpful in immigrants with chronic infection; gelatin particle agglutination reported more sensitive than ELISA
Skin test	Immediate hypersensitivity	Coinfection with HTLV-1 decreases sensitivity	Further developmental work required

^aAdapted from references 39, 42, 52, 68, and 69.

Agar plate cultures are also recommended and tend to be more sensitive than some of the other available diagnostic methods (60); stool is placed onto agar plates, and the plates are sealed to prevent accidental infections and held for 2 days at room temperature. As the larvae crawl over the agar, they carry bacteria with them, thus creating visible tracks over the agar. The plates are examined under the microscope for confirmation of larvae, the surface of the agar is then washed with 10% formalin, and final confirmation of larval identification is made via wet examination of the sediment from the formalin washings (see chapter 28). The agar consists of 1.5% agar, 0.5% meat extract, 1.0% peptone, and 0.5% NaCl. This approach is thought to be more sensitive and has become more widely used (2, 39, 41, 44, 60).

Becoming more widely available, the application of enzyme-linked immunosorbent assay (ELISA), immunoblotting, and gelatin particle agglutination methods has been investigated for both the diagnosis and postchemotherapy evaluation of human strongyloidiasis (47, 68).

These methods appear to be both sensitive and specific and have demonstrated significant decreases in antibody levels after therapy. However, when treatment was not effective, the individuals did not show a significant fall in antibody titers. More detailed studies to determine appropriate intervals for serologic evaluation and criteria for successful cure are required before these tests become more widely used.

Note. Debilitated or immunocompromised patients should always be suspected of having strongyloidiasis, particularly if they experience unexplained bouts of diarrhea and abdominal pain, repeated episodes of sepsis or meningitis with intestinal bacteria, or unexplained eosinophilia. However, a recent comparative study of the occurrence of *Strongyloides* spp. in 554 AIDS and 142 non-AIDS patients demonstrated similar prevalences of infection in the two groups, thus indicating no significant statistical differences (27). Nevertheless, diagnosing intestinal parasites in HIV/AIDS patients is necessary, especially in those

Figure 10.31 Tail (filariform larvae). (A) *Strongyloides stercoralis*; (B) hookworm.

reported to be chronic alcoholics and those who are not receiving antiretroviral treatment. It is also important to check pre-hematopoietic stem cell transplantation patients in areas of endemic infection in the United States (59).

In contrast to *S. stercoralis*, the diagnosis of *S. fuelleborni* infection is made by finding eggs, rather than larvae, in the stool. Children with swollen belly syndrome tend to have very heavy infections and excrete large numbers of eggs daily. The eggs are oval and approximately 50 to 70 μm long.

KEY POINTS—LABORATORY DIAGNOSIS

Strongyloides stercoralis

1. Recovery of the rhabditiform (noninfective) larvae is normally from the stool concentrate. *Caution: Filariform (infective) larvae can also be recovered in the stool.* A minimum of four stools are recommended before indicating that the patient is not infected (routine formalin, ethyl acetate sedimentation concentration); use centrifugation at $500 \times g$ for 10 min.
2. If the stool specimens are negative, examination of duodenal contents is recommended (duodenal aspirates, Entero-Test capsule); however, the overall sensitivity of the method varies.
3. Various concentrates (Baermann) and cultures (Harada-Mori, petri dish) can also be used for larval recovery.
4. Eggs are rarely seen in the stool but may be recovered from duodenal contents.

5. In very heavy infections, eggs (less common), larvae (both types), and adult worms may be recovered in the stool.
6. If agar plates are used (culture, method of choice), they must be dried sufficiently to eliminate free water on the agar prior to use. If fresh agar plates have just been prepared, the drying time may be longer than if prepackaged commercial plates, which are shipped with little to no free moisture on the surface of the agar, are used. They need to be examined at 24 h and 3 and 5 days.

Treatment

At present, the recommended drug of choice is ivermectin; however, thiabendazole has been used very successfully for many years; specific dosages are provided in chapter 25. In some cases, repeated therapy is necessary, and the cure rates vary (42). Patients with the hyperinfection syndrome should be hospitalized during therapy for proper monitoring. Thiabendazole has been used to treat children with swollen belly syndrome due to *S. fuelleborni* infection. This approach seems to be effective, but reinfection is very likely to occur in areas of endemic infection.

Side effects with thiabendazole occur in most patients and include nausea, foul-smelling urine, neuropsychiatric effects, malaise, and dizziness. Rectal administration of ivermectin has also been reported and may be helpful in patients who cannot absorb or tolerate oral therapy (72).

Mebendazole has also been used to treat strongyloidiasis; however, it is poorly absorbed. Albendazole has also been used to treat patients with strongyloidiasis, as well as those with the hyperinfection syndrome. Few side effects have been seen, and this drug is an excellent alternative to ivermectin. It is important to remember that HTLV-1 infection may be a possibility in patients with uncomplicated intestinal strongyloidiasis who do not respond to standard therapy (73).

Epidemiology and Prevention

Contact with contaminated infective soil, feces, or surface water should be avoided. Communities where close living conditions and poor sanitation facilities exist, including both rural and urban areas in the developing world, often have high prevalence rates of strongyloidiasis. Also, closed communities such as institutions for the mentally handicapped may have high rates of infection and transmission. The geographic distribution is quite broad and includes both tropical and temperate climates. It is important to remember that internal autoinfection allows for maintenance of the parasite within the host for years following the initial exposure. Since all infected individuals

are at risk for hyperinfection and disseminated disease, the identification of people who may have contracted their infection many years earlier is of great clinical significance. Individuals found to have the infection should be treated. *All patients who are going to receive immunosuppressive drugs should be screened for strongyloidiasis before therapy.*

Baylisascaris procyonis

Lagochilascaris minor

Toxocara canis and *T. cati*
(visceral larva migrans and
ocular larva migrans)

Ancylostoma braziliense and
A. caninum (cutaneous larva migrans)

Human eosinophilic enteritis

Dracunculus medinensis

Angiostrongylus (Parastrongylus)
cantonensis (cerebral
angiostrongyliasis)

Angiostrongylus (Parastrongylus)
costaricensis (abdominal
angiostrongyliasis)

Gnathostoma spinigerum

Gnathostoma doloresi,
G. nipponicum, *G. hispidum*, and
G. binucleatum

Anisakis simplex, *A. physeteris*,
Pseudoterranova decipiens,
Contracaecum osculatium,
Hysterothylacium aduncum, and
Porrocaecum reticulatum
(larval nematodes acquired from
saltwater fish)

Capillaria hepatica

Thelazia spp.

Trichinella spp.

Although *Trichinella spiralis* was first seen in human tissue at autopsy in the early 1800s, it was not until 1860 that Friedrich von Zenker concluded that the infection resulted from eating raw sausage (10). The consumption of rare or raw pork as the cause of trichinosis was experimentally proved a few years later. By the 1900s, trichinosis was definitely recognized as a public health problem. This particular infection has a cosmopolitan distribution but is more important in the United States and Europe than in the tropics or the Orient. The prevalence in autopsies within the United States has declined from 15.9% of human diaphragms studied at autopsy from 1931 to 1944 to 4.5% from 1948 to 1963; in recent years, the prevalence has decreased to 2.2% and the mortality associated with this infection has decreased to less than 1%. In 1990, only 105 cases of human trichinosis were reported in the United States, and by 1994 the number had dropped to 35 (53). During 1997 to 2001 the incidence decreased to a median of 12 cases annually and no reported deaths (77). However, in many areas of the world, trichinosis remains a problem (55).

During the 5-year period from 1997 to 2001, 72 cases were reported to the Centers for Disease Control and Prevention. Of these, 31 cases were associated with eating wild game: 29 with bear meat, 1 with cougar meat, and 1 with wild-boar meat (77). In comparison, only 12 cases were associated with eating commercial pork products; 4 of these cases were traced to a foreign source. Nine cases were associated with eating noncommercial pork from home-raised or direct-from-farm swine where U.S. commercial pork production industry standards and regulations are not applicable.

Studies of isolates of *Trichinella* spp. from Arctic, temperate, and tropical areas have confirmed that there are major differences related to their genetic structure and overall biology. Various species are involved, depending on the geographic area. *Trichinella* forms a complex of species, all of which appear to be the same morphologically but, based on DNA studies and comparative features, are actually quite different (Tables 11.1 and 11.2) (5). There are now 11 recognized *Trichinella* species or genotypes, *T. spiralis*, *T. nativa*, *T. nelsoni*, *T. britovi*, *T. pseudospiralis*, *T. murrelli*, T6, T8, T9, *T. papuae*, and *T. zimbabwensis* (37, 45, 69, 71, 92). *Trichinella* is quite different from many other helminths because all stages of development (adult and larva) occur within a single host. More than

Type	Animals infected	Geographic location	Comments
Encapsulated	Mammals		Encapsulated species/genotypes infect only mammals; cluster into 4 main geographic groups
<i>T. spiralis</i>		Cosmopolitan	
<i>T. britovi</i>		Temperate regions	
<i>T. murrelli</i>		Temperate regions	
<i>Trichinella</i> T8		Temperate regions	
<i>Trichinella</i> T9		Temperate regions	
<i>T. nativa</i>		Arctic region	
<i>Trichinella</i> T6		Arctic region	
<i>T. nelsoni</i>		Equatorial region	
Nonencapsulated			
<i>T. pseudospiralis</i>	Mammals, birds	Cosmopolitan	Palaearctic, Nearctic, and Australian regions
<i>T. papuae</i>	Wild pigs, saltwater crocodiles	Equatorial region	Can complete life cycle in both poikilothermic and homoiothermic animals
<i>T. zimbabwensis</i>	Farmed Nile crocodiles	Equatorial region	Can complete life cycle in both poikilothermic and homoiothermic animals

^a Data from references 45, 69, and 71.

100 different mammals are susceptible to infection, and the cysts can remain viable and infectious for many years, even in decaying muscle tissue. These factors ensure successful transmission and the survival of the parasite.

Life Cycle and Morphology

Human infection is initiated by the ingestion of raw or poorly cooked pork, bear, walrus, or horse meat or meat from other mammals (carnivores and omnivores) containing viable, infective larvae (Figure 11.1; Table 11.3). The tissue is digested in the stomach, and the first-stage larvae (L1) are resistant to gastric juice. The excysted larvae then invade the intestinal mucosa, develop through four larval stages within about 36 h, mature, and mate by the second day. By the sixth day of infection, the female worms begin to deposit motile larvae, which are carried by the intestinal lymphatic system or mesenteric venules to the body tissues, primarily striated muscle (Figures 11.2 and 11.3). Deposition of larvae continues for approximately 4 to 16 weeks, with each female producing up to 1,500 larvae in

the nonimmune host. Newborn larvae can penetrate almost any tissue but can continue their development only in striated muscle cells. With the exception of *T. pseudospiralis*, *T. papuae*, and *T. zimbabwensis*, invasion of striated muscle cells stimulates the development of nurse cells (Table 11.1) (55). As the larvae begin to coil, the nurse cell completes the formation of the cyst within about 2 to 3 weeks. Within the human host, the cyst measures about 400 by 260 μm , and within the cyst, the coiled larva measures 800 to 1,000 μm in length. At this point, the larvae are fully infective.

The very active muscles including the diaphragm, muscles of the larynx, tongue, jaws, neck, and ribs, the biceps, and the gastrocnemius, which have the greatest blood supply, are invaded. The encysted larvae may remain viable for many years, although calcification can occur within less than a year. As few as 5 larvae/g of body muscle can cause death, although 1,000 larvae/g have been recovered from individuals who died from causes other than trichinosis.

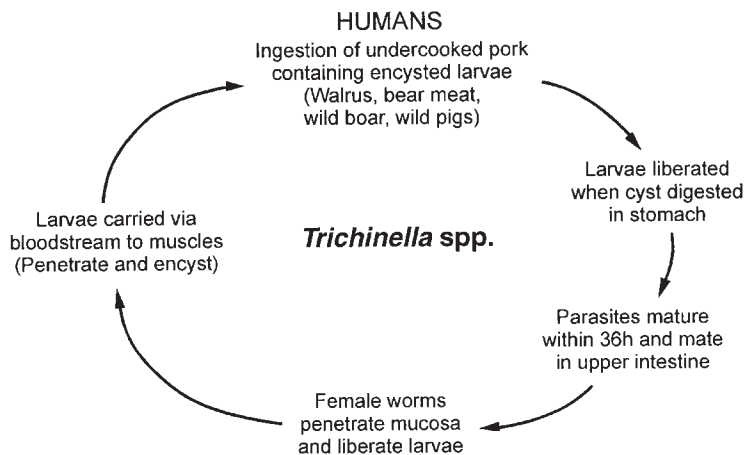

Figure 11.1 Life cycle of *Trichinella* spp. A number of infected meat sources other than pork are relevant for the various species of *Trichinella*.

Table 11.3 Tissue nematodes

Name	How acquired	Location in body	Symptoms	Diagnosis
<i>Trichinella spiralis</i> (<i>T. nativa</i>) (<i>T. nelsoni</i>) (<i>T. britovi</i>) (<i>T. pseudospiralis</i>) (<i>T. murrelli</i>) (<i>Trichinella</i> T6) (<i>Trichinella</i> T8) (<i>Trichinella</i> T9) (<i>T. papuae</i>) (<i>T. zimbabwensis</i>)	Ingestion of raw or rare meats (pork, bear, walrus, other carnivores and/or omnivores)	Active muscles contain encysted larvae (diaphragm, tongue, larynx, neck, ribs, biceps, gastrocnemius)	Diarrhea (larval migration through intestinal mucosa), nausea, abdominal cramps, general malaise; muscle invasion: periorbital edema, pain, swelling, weakness, difficulties in swallowing, breathing, etc.; most severe symptom is myocarditis; high eosinophilia (20–90%)	Biopsy or autopsy specimen (muscle) compression smear or routine histology; artificial digestion of muscle to release larvae (larvae are very infective and precaution should be taken); serologic testing can be very helpful
<i>Baylisascaris procyonis</i>	Ingestion of viable eggs in the soil (most probably from raccoon feces)	CNS and eye contain larvae	Eosinophilic meningitis, unilateral neuroretinitis	Biopsy or autopsy specimen, routine histology; eggs from raccoon feces measure 80 μm long by 65 μm wide, have a thick shell with a finely granulated surface, and resemble <i>Ascaris lumbricoides</i> eggs
<i>Lagochilascaris minor</i>	Life cycle and route of human infection unknown; suspect ingestion of viable eggs in the soil	Adult worms, larvae, and eggs occur in life cycle within human lesions (neck, throat, nasal sinuses, tonsillar tissue, mastoids, brain, lungs)	Pustule swelling, pus in lesions; chronic granulomatous inflammation	Identification of adult worms, larvae, or eggs from lesions, sinus tracts, or biopsy or autopsy specimens
<i>Toxocara canis</i> and <i>T. cati</i> (visceral and ocular larva migrans)	Ingestion of infective eggs (dog/cat ascarids) from fecal material in the soil	Usually the liver; migratory pathway may include the lungs and even back to the intestine	Migration of larvae may cause inflammation and granuloma formation; there may be fever, hepatomegaly, pulmonary infiltrates, cough, and neurologic symptoms; high eosinophilia (up to 90%; 20–50% common)	Confirmation at autopsy; serologic test (ocular fluids as well as serum if eye involved)
<i>Ancylostoma braziliense</i> and <i>A. caninum</i> (cutaneous larva migrans)	Skin penetration of filariform/infective larvae of dog/cat hookworms; infection can also occur via ingestion of infective larvae	Larval migration in the skin produces linear/raised/vesicular tracts; can be on any area of the body	Intense itching, pneumonitis (if larvae migrate to deeper tissues)	Picture of linear tracts; possible removal of larva from tunnel

<i>Dracunculus medinensis</i> (fiery serpent)	Ingestion of infected copepod/water flea (<i>Cyclops</i>)	Adult worms develop in deep connective tissue; gravid female migrates to feet and ankles (can occur anywhere), where blister forms for larval deposition into the water through the ruptured blister on the skin	Before blister formation: erythema, tenderness, urticarial rash, intense itching, nausea, vomiting, diarrhea, or asthmatic attacks; if secondary infection occurs, there may be cellulitis, arthritis, myositis, etc.	Formation of cutaneous lesion with appearance of adult female worm depositing larvae into the water; calcified worms can also be found on X ray
<i>Angiostrongylus cantonensis</i> (eosinophilic meningitis) (cerebral)	Accidental ingestion of infective larvae in slugs, snails, or land planarians	Brain tissue, eye (rare), lung tissue (rare)	Severe headache, convulsions, limb weakness, paresthesia, vomiting, fever, eosinophilia up to 90%	Presumptive: severe headache, meningitis or meningoencephalitis, fever, ocular involvement; definitive: examination of tissues (surgical specimens)
<i>Angiostrongylus costaricensis</i> (abdominal)	Accidental ingestion of slugs, often on contaminated salad vegetables	Bowel wall	Pain, tenderness, palpable tumor-like mass in right lower quadrant, fever, diarrhea, vomiting, eosinophilia (60%), and leukocytosis	Worm recovery and clinical history
<i>Gnathostoma spinigerum</i>	Ingestion of raw, poorly cooked, pickled freshwater fish or chicken (and other birds), frogs, or snakes	Migration of larvae in deep cutaneous or subcutaneous tissues (may appear anywhere), eyes, or CSF (less common)	Migratory swellings (hard, nonpitting) with inflammation, redness, pain	Worm recovery and clinical history
<i>Anisakis</i> , <i>Contracaecum</i> , <i>Pseudoterranova</i> , <i>Hysterothylacium</i> , and <i>Porrocaecum</i> spp.	Ingestion of raw, pickled, salted, or smoked saltwater fish	Wall of gastrointestinal tract	Nausea, vomiting; may mimic gastric/duodenal ulcer, carcinoma, appendicitis; stool positive for occult blood	Worm recovery and clinical history
<i>Capillaria hepatica</i>	Accidental ingestion of eggs from soil	Liver	May mimic hepatitis, amebic abscess, or other infections involving the liver	Histologic identification
<i>Thelazia</i> spp.	Larval deposition by flies	Conjunctival sacs/migrating over cornea	Excessive lacrimation, itching, pain (feeling of foreign object in eye)	Worm recovery (from eye) and identification

Figure 11.2 *Trichinella* spp., encysted larva in muscle. (Illustration by Sharon Belkin.)

There are species differences in low-temperature (freezing) survival, infectivity, and capsule formation (55). Also, studies on a pig farm indicate that even in the absence of a known source of infected meat (garbage containing meat scraps or dead animals), the rat population maintained the infection, probably through cannibalism. Consequently, to reduce transmission of *T. spiralis* between rats and swine, rat populations in an agricultural ecosystem must be controlled. It is also important to limit access to the farmyard by wild and feral animals.

Although recommendations have been made to use several species designations, some publications still use the single species designation *Trichinella spiralis* (Tables 11.2 and 11.3). Genetic relationships among many *Trichinella* isolates are currently being assessed by dot blot hybridization, restriction endonuclease, and gel electrophoresis techniques. On the basis of the presence of repetitive DNA sequences in the *Trichinella* genome, distinctive banding patterns have been seen among the isolates, and taxonomic changes will continue to occur.

Clinical Disease

Pathologic changes due to trichinosis can be classified as (i) intestinal effects and (ii) muscle penetration and larva encapsulation (Table 11.4). Any damage caused in either phase of the infection is usually based on the original number of ingested cysts; however, other factors such as the patient's general health, age, and size also play a

Figure 11.3 (A) *Trichinella spiralis*, encysted larva in muscle ($\times 85$). Adjacent muscle has been replaced by fibrous tissue and is infiltrated with chronic inflammatory cells. (Armed Forces Institute of Pathology photograph.) (B) Coiled larva of *T. spiralis* in a teased muscle preparation (wet mount, $\times 193$). (Armed Forces Institute of Pathology photograph.)

role in the disease outcome. Symptoms of trichinosis are generally separated into three phases, with phase 1 being related to the presence of the parasite in the host prior to muscle invasion and phase 2 being related to the inflammatory and allergic reactions due to muscle invasion. There may also be an incubation period of up to 50 days. Phase 3 is the convalescent phase or chronic period (Table 11.5).

Symptoms that may develop within the first 24 h include diarrhea, nausea, abdominal cramps, and general malaise, all of which may suggest food poisoning, particularly if several people are involved. Studies also indicate

Table 11.4 *Trichinella spiralis*: life cycle stages and clinical conditions^a

Stage in life cycle	Time after infection when symptoms begin	Clinical condition
Excysted larvae enter intestinal mucosa	2–4 h 24 h	Gastrointestinal symptoms
Worms mature and mate	30 h	
Females deposit larvae/muscle invasion begins	Day 6 Day 7	Facial edema/fever
Heaviest muscle invasion	Day 10 Day 11	Maximum fever (40–41°C) Muscle inflammation/pain
Decrease in larval deposition	Day 14	Eosinophilia/antibody
Larvae differentiated	Day 17 Day 20	Maximum eosinophilia
Encapsulation of larvae	Day 21	Myocarditis/neurologic symptoms
Intestine free of adult worms	Day 23 Day 26	Respiratory symptoms
Encapsulation almost complete	Mo 1 Mo 2	Fever subsides
Adult worms die	Mo 3	Death from myocarditis or encephalitis
Cyst calcification begins	Mo 6 Mo 8	Slow convalescence Myocarditis/neurologic symptoms subside
Cyst calcification usually complete	Yr 1	
Most larvae still viable within calcified cyst	Yr 6	

^aAdapted from reference 10.

that the diarrhea can be prolonged, lasting up to 14 weeks (average, 5.8 weeks) with few or no muscle symptoms. It is still unknown whether this clinical presentation is related to variant biological behavior of Arctic *Trichinella* organisms, to previous exposure to the parasite, or to other factors.

During muscle invasion, there may be fever, facial (particularly periorbital) edema, and muscle pain, swelling, and weakness. The extraocular muscles are usually the first to be involved, followed by the muscles of the jaw and neck, limb flexors, and back. Muscle damage may cause problems in chewing, swallowing, breathing, etc., depending on which muscles are involved. The most severe symptom is myocarditis, which usually develops after the third week; death may occur between the fourth and eighth weeks. Other severe symptoms, which can occur at the same time, may involve the central nervous system (CNS). Although *Trichinella* encephalitis is rare, it is life-threatening. Technological advances such as the computed tomogram, angiogram,

and electroencephalogram are of no diagnostic assistance and probably add nothing to traditional diagnostic information, which includes eosinophilia, sedimentation rate, and muscle biopsy.

It is estimated that 10 to 20% of the patients with trichinosis have CNS involvement and that the mortality rate may reach 50% in these patients if they are not treated. Symptoms may mimic those of polyneuritis, acute anterior poliomyelitis, myasthenia gravis, meningitis, encephalitis, dermatomyositis, and polyarteritis nodosa. There may be focal paresis or paralysis (quadriplegia to single muscle group).

Peripheral eosinophilia of at least 20%, often over 50%, and possibly up to 90% is present during the muscle invasion phase of the infection. Fever can also be present at this time and can persist for several days to weeks, depending on the intensity of the infection. However, once the larvae begin to encapsulate, patient symptoms subside; eventually the cyst wall and larvae calcify.

Table 11.5 Trichinosis: incubation period, larval numbers, and degree of illness

Characteristic	Mild disease	Moderate disease	Severe disease	Abortive disease
No. of larvae/g of muscle	10, probably subclinical	50–500	1,000 or more	Less than 10
Incubation period (days)	21	16	7	30
Intestinal phase (phase 1) (days 2–7) ^a	Nausea, abdominal aches, cramps, loss of appetite, vomiting, mild fever, mild diarrhea or constipation; frontal headaches, dizziness, weakness	As with mild disease, symptoms may mimic the flu	Same symptoms as indicated in mild to moderate disease; diarrhea may be severe	Patient may be asymptomatic
Muscle invasion phase (phase 2) (days 9–28) ^b	Penetration of larvae initiates inflammatory response (extraocular muscles) in masseters; muscles of the larynx, tongue, diaphragm, and neck; intercostals; and muscular attachments to tendons and joints; headache, fainting, urticaria, splinter hemorrhages beneath the fingernails and toenails, conjunctivitis, loss of appetite, hoarseness, dysphagia, dyspnea, and edema of the legs may also occur; range of symptoms is based on number of larvae and general health, age, size of patient		Muscular pain, facial edema (swelling of eyelids), fever, chills, eosinophilia, tachycardia, coma, respiratory difficulties; neurologic symptoms may be severe (may stimulate meningitis); myocarditis is a serious complication, may lead to congestive heart failure	Symptoms may or may not be seen
Convalescent phase (phase 3)	Decrease in muscular symptoms, beginning in the second month; fever and itching subside		Evidence of congestive heart failure may appear (if patient becomes active too soon)	Change in symptoms may or may not be obvious

^a Symptoms reflect mucosal irritation.

^b Encystment occurs after day 14.

In an outbreak in Spain, 44 members of eight families were examined. Various people had suggestive symptoms (10 of 44), hypereosinophilia (20 of 44), and positive serologic test results (15 of 44). Three groups could be identified according to the home-prepared product each had ingested (pork sausage, blood pudding, and loin). In these cases, the common source of all infections was the poorly cooked pork sausage, since the blood pudding is boiled for a long time at high temperature and the loin is always served thoroughly fried or roasted. Twelve months later, all had a normal eosinophil count and negative serologic test results (86). Another outbreak in Spain involved 38 people, 15 of whom were hospitalized after the ingestion of sausage made from uninspected wild boar meat and infected pork. Almost all patients had myalgias, about half reported diarrhea and/or vomiting, 75% reported periorbital edema, and 76% had fever. Sixteen patients were positive for *T. britovi* by indirect fluorescent-antibody test (IFAT) and 20 were positive by Western blotting (33). The ingestion of wild boar containing *T. pseudospiralis* in France and bear meat containing *T. nativa* from New York and Tennessee has also been implicated in recent outbreaks (16, 75).

There have also been a number of outbreaks due to consumption of horse meat; these outbreaks

were caused by different species of *Trichinella* and were associated with differences in clinical symptoms. Although most human infections have been attributed to *T. spiralis*, these outbreaks clearly demonstrate that different species produce different clinical syndromes (Table 11.6).

Diagnosis

Depending on the severity of the infection, trichinosis can mimic many other conditions. Most mild cases with a small loading dose of infective larvae may present with flu-like symptoms. Unless the clinician recognizes an appropriate history, fever, myalgia, periorbital edema, and/or rising eosinophilia (50% or higher), the cause may go undetected. Often, the first clue is the patient's history of possible ingestion of raw or rare pork or other infected meat. There may also be other individuals from the same group with similar symptoms. Trichinosis should always be included in the differential diagnosis of any patient with periorbital edema, fever, myositis, and eosinophilia, regardless of whether a complete history of consumption of raw or poorly cooked pork is available. If present, subconjunctival and subungual splinter hemorrhages also add support for such a presumptive diagnosis. If the meat consumption history is incomplete, food poisoning, intestinal flu, or typhoid may be suspected. It is very rare to

recover adult worms or larvae from stool or other body fluids (blood, cerebrospinal fluid [CSF], etc.), even if the patient has diarrhea.

Muscle biopsy (gastrocnemius, deltoid, and biceps) specimens may be examined by compressing the tissue between two slides and checking the preparation under a microscope at low power (10× objective). However, this method does not provide positive results until 2 to 3 weeks after the onset of the illness. It is also important to remember that not all species form the capsule (Figure 11.4). Muscle specimens or samples of the suspect meat can also be examined by using an artificial digestion technique to release the larvae. These techniques are described in detail in chapter 30.

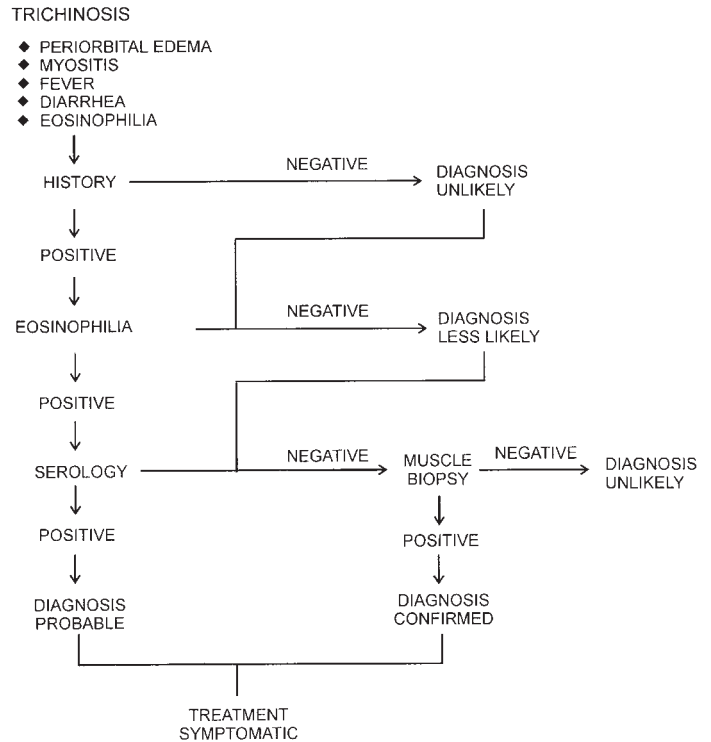

Serologic tests are also very helpful, the standard two being the enzyme immunoassay (EIA) and the bentonite flocculation test, which are recommended for trichinosis. The EIA is used for routine screening, and all EIA-positive specimens are tested by bentonite flocculation for confirmation. A positive reaction in both tests indicates infection with *T. spiralis* within the last few years. Often, antibody levels are not detectable within the first month postinfection. The titers tend to peak in the second or third months postinfection and then decline over a period of a few years. The IFAT has also been used to track the course of disease after infection. Antibody detection using IFAT was reported at 70.2% of patients 1 week after onset of disease and increased to 91, 94.3,

and 100% 2, 3, and 4 weeks, respectively, after the onset. The antibody detection decreased to 25% 4 months after therapy (90). More information on serologic testing is presented in chapter 22. Refer to Algorithm 11.1 for a detailed review.

A dot enzyme-linked immunosorbent assay (ELISA) with purified antigens has been developed for detecting *T. spiralis* in swine. This test is as sensitive as an ELISA with excretory-secretory products as the antigen and Western immunoblot analysis and is nearly as specific as

Figure 11.4 Unencapsulated *Trichinella pseudospiralis*. (Image courtesy of the Centers for Disease Control and Prevention, Atlanta, Ga.)

Algorithm 11.1 Diagnosis of trichinosis.

the Western blot. Also, the dot ELISA is much easier to perform than is a Western blot analysis (83).

A modified double-sandwich ELISA has been developed using polyclonal antibodies against larval somatic antigens. In experimental studies, the first detection of coproantigen occurred as early as day 1 postinfection, peaking on day 7 and then disappearing by week 3. These results were confirmed using the coagglutination test (Co-A). Based on these studies, this approach could be used to confirm early infection in humans (11).

KEY POINTS—LABORATORY DIAGNOSIS

Trichinella spiralis

1. The history and clinical findings may suggest possible trichinosis (consumption of rare or raw infected meat). Remember to check hematology results for a possible eosinophilia (can reach 50% or higher).
2. Using compression slides, examination of suspect meat may reveal larvae (artificial digestion procedure) (see chapter 30). Note that not all species of larvae form the capsule; however, the unencapsulated larvae can still be seen in a “squash” preparation of biopsy material.
3. Larvae or adult worms are rarely recovered in fecal specimens during the intestinal phase (diarrhea).

4. Examination of muscle tissue obtained at biopsy may confirm the diagnosis (tissue compression between two slides or the artificial digestion technique).
5. Serologic tests for antibody detection may be very helpful; coproantigen detection tests are being developed.

Treatment

Therapy depends on the phase of the disease, the immune status of the patient, and the intensity and length of the disease. For the early phase of infection, the objective is to reduce the number of larvae that will invade the muscles. Once larval invasion of the muscles has occurred, the objective becomes to reduce muscle damage. The current recommendation for the gastrointestinal phase is the use of mebendazole (200 to 400 mg/day for 3 to 5 days) or albendazole (400 mg/day); after the first 3 to 5 days of mebendazole therapy, the dose is changed (400 to 500 mg/day) and given for 10 days. For acute, severe infection, steroids are recommended (prednisolone, 40 to 60 mg/day) along with mebendazole (5 mg/kg/day) or albendazole (400 to 800 mg twice a day for 8 to 14 days). For moderate or mild infection, steroids can be given as required; once fever and allergic signs diminish, steroid administration can be discontinued. Unfortunately, the disease is often

not diagnosed until well after muscle invasion has begun. At this point, supportive therapy may be the only option. Summary information can be found in chapter 25.

Epidemiology and Prevention

The *Trichinella* cycle that is maintained in nature occurs among cannibalistic and carrion-feeding carnivores. While domestic pigs and rats tend to be secondary hosts, the majority of human infections have been from infected pork. In reviewing data on trichinellosis in the United States from 1997 to 2001, pork was implicated in 30% of the cases and wild game was implicated in 43% (77). Sausage was the most frequently implicated pork product and was often from noncommercial sources (77). While cases acquired from pork consumption continue to decline, the proportion of cases acquired from wild game meat has increased. However, the absolute numbers remain at about 9 to 12 per year. Continued multiple-case outbreaks and the identification of nonpork sources of infection require ongoing education and control measures.

In other parts of the world, the infected-meat source statistics vary; in the former Soviet Union, >90% of the cases have been attributed to the ingestion of poorly cooked bear and wild boar meat. Factors contributing to the slow decline of trichinellosis incidence in Russia and to the increase in the number of cases originating from wild-animal meat include the distribution and consumption of veterinary-uncontrolled pork, poaching and distribution of wild-animal meat, and poor compliance with regulations (65). Twenty-seven outbreaks of human disease occurred in China between 1964 and 2004 and were associated with mutton, dog, and game meat. However, the quarantine of infected meat is not mandatory in China (89). Although outbreaks are rare in Israel, outbreaks have been detected in immigrant agricultural workers; infected wild-boar meat was implicated (49). In tropical Africa, the infected meat source tends to be bush pigs and warthogs. Most infections in Central and South America have been associated with domestic pigs. It is difficult to say with certainty exactly which animals may be infected throughout the world; very few comprehensive studies of wild animals have been attempted. In one study of *Trichinella* infection in wildlife in the southwestern United States, the range of *T. murrelli* was extended from previous reports limiting this species to the eastern United States. Thus, *Trichinella* infection is now documented in three states bordering Mexico, New Mexico, Arizona, and Texas (73). Information is also now available confirming the presence of anti-*Trichinella* antibodies in a human population living in Papua New Guinea (58, 64).

Although *T. spiralis* and *T. pseudospiralis* are found worldwide, the other species tend to have a more narrow

Table 11.7 Trichinellosis: prevention and control measures

Potential infection source (reference)	Prevention and control measures
Meat preparation (55)	<ol style="list-style-type: none"> 1. Cook meat products until the juices run clear or to an internal temperature of 160°F (71°C). 2. Freeze pork less than 6 in. thick for 20 days at 5°F (-17°C) to kill any encysted larvae. Other options would be -10°F (-23°C) for 10 days or -20°F (-29°C) for 6 days. However, remember that <i>T. nativa</i> in bear meat probably survives freezing for a year or longer. 3. Cook wild game meat thoroughly. Freezing wild game meats, unlike freezing pork, even for long periods, may not effectively kill all encysted larvae. 4. Clean meat grinders after preparing ground meats. 5. Curing (salting), drying, smoking, or microwaving meat does not consistently kill infective larvae.
Pig farms (68)	<ol style="list-style-type: none"> 1. Barriers must be in place to prevent entrance of rodents and other potential hosts into the pigsty and food store. 2. New animals should not be admitted to the farm prior to serologic testing for antibodies to <i>Trichinella</i> spp.^a 3. Procedures for sanitary disposal of dead animals must be used at all times. 4. No raw or improperly heated swill or waste food containing meat may be present at the farm. 5. No rubbish dumps should be located in the immediate vicinity of the farm.

^a The use of serologic tests has been an important technological advance, not only for the diagnosis of human infection but also for the identification of infected animals (76, 82).

geographic range (Table 11.2). *T. nativa* and *Trichinella* T6 are found primarily in the Arctic regions; *T. britovi*, *T. murrelli*, *Trichinella* T8, and *Trichinella* T9 are found in the temperate zones; and *T. nelsoni*, *T. papuae*, and *T. zimbabwensis* are found in equatorial areas.

Countries in the European Union, Eastern European countries, and the former members of the Soviet Union require direct inspection of pork, using microscopic examination of small tissue samples of pig diaphragm or examination of pooled digested tissue samples; within the United States, the U.S. Department of Agriculture requires strict standards for the freezing, cooking, and curing of pork and pork products (40, 68). A number of excellent preventive measures have been identified for implementation during the preparation of potentially infected meat sources, as well as control measures for commercial pig farms (Table 11.7). Recent information also confirms the need to review the intentional feeding of animal products and kitchen waste to horses, a high-risk practice which requires implementation of regulations to ensure that such feeds are rendered safe for horses, as is currently required for products fed to swine (56).

In 1981, the U.S. Department of Agriculture issued a news release that suggested that microwave cooking might not kill the larvae. On the basis of a number of subsequent studies, the current recommendation states that “*all parts* of pork muscle tissue must be heated to a temperature not lower than 137°F (58.3°C)” (55). It has been recommended that an internal meat thermometer be used when cooking pork; the meat can be tested after being removed from the microwave oven if the oven is not equipped with an internal thermometer. Reduction in the number of cases is due primarily to regulations requiring heat treatment of garbage and low-temperature storage of the meat. Occasional outbreaks are frequently due to problems with feeding, processing, and cooking of pigs raised for home use.

Baylisascaris procyonis

Although *Baylisascaris procyonis* was first isolated from raccoons in 1931 in New York, it was also recognized in raccoons in Europe. The genus was defined in 1968 and was named after H. A. Baylis, who had been with the British Museum of Natural History in London.

It was first recognized as causing neural larva migrans (NLM) in rodents and then recognized as being able to produce serious NLM in >100 different species of birds and mammals. The potential for causing human disease was considered by earlier parasitologists but has been recognized only during the last twenty years. Approximately 15 confirmed human cases have been documented (32).

Life Cycle and Morphology

B. procyonis is an ascarid normally found in raccoons (*Procyon lotor*), has a normal ascarid-like life cycle, causes a very serious zoonotic disease in humans, and is

most often reported from North America (Figure 11.5) (32). Raccoons are infected by ingesting infective eggs and by eating larvae encysted in the tissue of intermediate hosts, such as rodents, rabbits, and birds. The larvae then penetrate the mucosa of the small intestine and develop there before reentering the intestinal lumen to mature. Raccoons may be infected by up to 60 worms, and young animals have a higher prevalence of infection. These adult worms produce >150,000 eggs/worm/day; infected raccoons can shed as many as 250,000 eggs/g of feces. This level of egg production can lead to significant environmental contamination.

B. procyonis eggs are somewhat oval, are dark brown, and measure from 63 to 88 µm by 50 to 70 µm. The eggs contain a single-celled embryo and a thick shell with a finely granular surface; they are not infective immediately after being passed but can survive in moist soil for years (Figure 11.6). *Toxocara* eggs tend to be somewhat larger and have a coarsely pitted thick shell.

Human infections result from ingestion of eggs that are passed in very large numbers (millions of eggs/day) in the feces of infected raccoons; the human then becomes the accidental intermediate host. Once ingested, the eggs hatch in the intestinal tract, releasing the immature larvae. Rather than developing to adult worms as occurs in the raccoon, the larvae begin to migrate extensively throughout the body tissues, causing visceral larva migrans (VLM) and/or NLM. Although this infec-

Figure 11.5 Life cycle of *Baylisascaris procyonis*. Accidental infection in the human leads to visceral larva migrans (VLM), ocular larva migrans (OLM), and/or neural larva migrans (NLM), which are very serious diseases that can cause death. Infections are seen primarily in very young children.

Figure 11.6 *Baylisascaris procyonis* eggs; note the larvae within the egg shells. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 11.7 *Baylisascaris procyonis*, CNS atrophy, sclerosis, and larval granuloma in the brain in a 2-year-old boy who died following 14 months of CNS problems. tion presents as acute fulminant eosinophilic meningoencephalitis, two features of the life cycle are somewhat different from those of other helminths causing larva migrans: there is targeted migration to the CNS and continued growth of the larvae to a much larger size within the CNS. Despite different courses of therapy, there are no documented neurologically intact survivors of this infection.

Clinical Disease

The first confirmed cases of human *B. procyonis* infection were described in the 1980s. Risk factors have been identified as contact with infected raccoons, their feces, or a contaminated environment. Geophagia or pica has also been identified as a potential risk, which is often seen in children younger than 2 years. Tissue damage is caused by the actual larval migration, as well as an intense inflammatory reaction (Figures 11.7 and 11.8). Unlike other helminth larvae that cause VLM, the larvae of *B. procyonis* continue to grow during the migratory phase of the life cycle and can reach lengths of 2 mm. In addition to continued growth, the larvae tend to exhibit very vigorous migratory behavior and remain viable for long periods. They tend to invade the eyes, causing ocular larva migrans (OLM), which has also been found in immunocompetent adults, and the spinal cord and brain, causing NLM, found primarily in infants and young children. Larval migration can cause permanent neurologic damage, blindness, or death. It is also important to realize that with the absence of a definitive diagnostic test, the prevalence of subclinical cases is totally unknown. However, it is probably higher than is currently recognized. Unfortunately, even with clinical cases, most patients are diagnosed only after there has already been severe CNS damage.

Patients can present with eosinophilic meningoencephalitis or unilateral neuroretinitis; the presentation probably depends on the number of eggs that were ingested. Larvae tend to enter the CNS approximately 1 to 4 weeks after infection, and the disease may progress very rapidly. OLM may present with a broad range of symptoms, including chronic endophthalmitis with retinal detachment, posterior pole granuloma, vitreous abscess, pars planitis, optic neuritis, keratitis, uveitis, iritis, hypopyon, and meandering retinal tracks containing larvae. A new clinical entity, diffuse unilateral subacute neuroretinitis (DUSN), is also caused by *B. procyonis* (51). DUSN is a form of OLM characterized by progressive unilateral visual loss, retinal pigmentation, and optic nerve anatomy changes, all of which lead to severe ocular damage.

The neural form may present with symptoms ranging from mild neuropsychologic problems to seizure, convulsions, ataxia, coma, and death. Patients may exhibit sudden lethargy, irritability, loss of muscle coordination, decreased head control, spasmodic contractions of the neck muscles, stupor, nystagmus, obtundation, coma, hypotonia, and hyperreflexia. Infants who have survived meningoencephalitis demonstrate sequelae including hemiparesis, inability to sit or stand, ocular muscle paralysis, cortical blindness, and severely delayed development. Survivors are left in a persistent vegetative state or with severe neurologic deficits, including blindness, all of which can require extensive supportive care.

Diagnosis

Human infections with *B. procyonis* are rare and are often diagnosed by a process of elimination; when all other recognized causes of larva migrans have been explored, *B. procyonis* may be considered. There are approximately 15 documented cases, almost all of which have been seen in young children. Results obtained from routine hematologic and cerebrospinal fluid examinations are usually consistent with a parasitic infection but are nonspecific. Definitive diagnosis requires identification of the larvae in tissues; however, this can be difficult depending on the body site. Cross sections of larvae tend to measure 60 to 70 μm , and the larvae have prominent, single lateral alae and paired, conical excretory columns (smaller than central intestine) (Figure 11.8A). Ocular examinations may reveal retinal lesions, larval tracks, or migrating larvae; these findings may provide the tentative diagnosis

of a helminth infection. Using IFAT, ELISA, and Western blotting, anti-*Baylisascaris* antibodies can be detected in cerebrospinal fluid. Currently, the only source of serologic testing is the Department of Veterinary Pathobiology at Purdue University, West Lafayette, Ind. [K. Kazacos, phone (765) 494-7558] (32). Acute- and convalescent-phase titers demonstrate severalfold increases in both serum and CSF antibody levels; there is no cross-reactivity with *Toxocara*. With the availability of a reliable serologic test, there is less need to perform a brain biopsy. *In most cases, the clinical history provides the main clues.*

The liver and lungs do not tend to be involved in *Baylisascaris* infections, but cerebral lesions are often detected. Well-formed granulomas can be seen in any part of the nervous system. The damage tends to be prominent, even showing tracks with tissue disruption. Differential diagnosis findings are summarized in Table 11.8.

Treatment

There is no effective cure for *B. procyonis* infection; treatment is symptomatic and involves systemic corticosteroids and anthelmintic agents. Unfortunately, NLM is usually not responsive to anthelmintic therapy; by the time the diagnosis is made, extensive damage has already taken place. Drugs that can be tried include albendazole, mebendazole, thiabendazole, levamisole, diethylcarbamazine, and ivermectin. Experimental data from animal studies indicate that albendazole and diethylcarbamazine may have the best CSF penetration and larvicidal activity. Unfortunately, since the diagnosis does not occur until the onset of symptoms, larval invasion of the CNS has already taken place. Therefore, treatment is started late in the course of the infection.

Considering the potential outcomes associated with delaying treatment until symptoms begin, prophylactic treatment for asymptomatic children exposed to raccoons or contaminated environments is now being considered. Since the anthelmintics do not appear to be problematic, prophylaxis seems appropriate for specific individuals. Albendazole has been used in these cases; treatment has been discontinued when environmental testing has proven to be negative.

Ocular infections have been treated successfully by using laser photocoagulation therapy to destroy the intraretinal larvae (1). Systemic corticosteroids have been used to decrease or prevent resulting intraocular inflammatory responses from the killed larvae.

Epidemiology and Prevention

The relationship between *B. procyonis* infection, raccoons, and humans has now been well defined. Recent reports of patent *B. procyonis* infections in dogs have caused concern because of the potential for expanded

Table 11.8 Differential diagnosis of *Baylisascaris procyonis* infection

Infection	Geographic areas	Clinical findings	Comments
<i>Baylisascaris procyonis</i>	Americas from Canada to Panama, Europe, Japan, Soviet Union, Asia	Peripheral and CSF eosinophilia, meningoencephalitis	Eosinophilic meningoencephalitis; history of pica or geophagia, age of patient extremely important in suspecting infection
<i>Toxocara</i> spp.	Cosmopolitan	VLM	Uncommon cause of NLM; antibodies in blood and CSF
<i>Angiostrongylus cantonensis</i>	Southeast Asia, China, Japan, Jamaica, Western Pacific Islands, Hawaii, Madagascar, Cuba, Egypt, Puerto Rico, New Orleans, Nigeria, eastern Australia, Africa	Eosinophilic meningitis	Relatively benign course, good prognosis
<i>Gnathostoma spinigerum</i>	Southeast Asia, China, Japan	Severe neurologic sequelae, myeloencephalitis, focal cerebral hemorrhage (with xanthochromia), radiculopathy, migrating cutaneous swellings	Poor prognosis
Less common causes of eosinophilic meningoencephalitis in humans Neurocysticercosis Paragonimiasis Toxocarasis Neurotrichinosis Schistosomiasis	Cosmopolitan in many areas; more narrow geographic areas would apply to schistosomiasis	Could mimic infection with <i>B. procyonis</i>	History critical in suspecting any of these infections
<i>Coccidioides immitis</i>	Southwestern United States, Central and South America	Intense basilar enhancement, hydrocephalus, acute infarction on neuroimaging, positive CSF serology	Disseminated disease, most common cause of eosinophilic meningitis in United States
Acute disseminated encephalomyelitis	Cosmopolitan	Acute encephalopathy, cerebral white matter changes on neuroimaging	Monophasic nonprogressive illness, more discrete multifocal grey and white matter abnormalities on neuroimaging; generally good prognosis

human exposure. Groups of raccoons tend to defecate in common areas called latrines, which tend to be present off the ground in fallen logs (firewood may be contaminated), rocky outcroppings, and trees. In areas that have been carefully investigated such as Pacific Grove, Calif., many latrines are present and are located directly on the ground, on roofs, in attics, and on steps and fences. These findings suggest that a very large number of raccoons are present in this location. The eggs remain viable in the soil for extended periods, often years. The eggs also have a sticky surface coating that causes them to adhere to objects, including human hands and toys. Apparently, incineration or soaking the feces with volatile solvents such as mixtures of xylene and ethanol appears to be the only means of killing the eggs (32). In some cases, removal

and disposal of several inches of topsoil may also be indicated. Recognition of this new human infection and prevention of the establishment of raccoon latrine sites around areas of human habitation and recreational use are critical to successful control.

This infection is of great public health concern and has the potential to cause extensive damage in the human host, particularly young children (32). Risk is highest for young children or infants with pica or geophagia; these individuals need to be kept away from potentially contaminated areas. Raccoons should be discouraged from visiting yards by refraining from putting out food and by not leaving dog food uncovered and available. Keeping pet raccoons, particularly in homes with young children, should be discouraged.

Although *B. procyonis* was thought to be absent from many regions, it is now becoming clear that where raccoons are found, *B. procyonis* is also likely to be present. The infection has also been found in a 3-day-old domestic lamb, suggesting that mammalian fetuses, in general, should be added to the list of those at risk for NLM due to ascarid parasites (4). The increasing number and recognition of cases highlight the critical importance of controlling and preventing this potentially devastating zoonotic infection (29). Certainly education for the public will be paramount in helping to determine at-risk populations and preventing additional infections.

Lagochilascaris minor

Although human infections with *Lagochilascaris minor*, which is normally found in the small intestine of the cloudy leopard, have been documented, neither the natural life cycle nor the route of human infection is known (48). Human cases have been recorded from the West Indies, Suriname, Costa Rica, Mexico, Venezuela, Colombia, and Brazil. The cases of human infection are characterized by lesions in the oropharynx and other soft tissues in the head and neck. The first sign of infection may be a pustule, usually on the neck, which increases in size to a large swelling. After the skin breaks, living adults, larvae, and eggs are expelled at intervals in the pus. Eggs are continually developing into larvae and then into adults in the tissues at the base of the abscess; thus, the life cycle is a continuing process. Adult male worms measure up to 9 mm long, and the females are about 1.5 cm; the eggs resemble those of *Toxocara cati* and measure 45 to 65 μm by 59 to 73 μm . Irregularly shaped pits are present on the egg surface; 20 to 32 pits surround the equator of an egg (Figure 11.9). The area of induration increases, with the development of sinus tracts. Chronic granulomatous inflammation may last for months. Other tissues that have been involved include the throat, nasal sinuses, tonsillar tissue and mastoids, brain, and lungs. Although thiabendazole has been tried, efficacy was not really documented. Albendazole has also been tried, but it was possible to confirm only transitory elimination of adult worms.

A study in which wild rodents were used as experimental intermediate hosts of *L. minor* has provided some additional information about the life cycle and epidemiology of this parasite (66). After inoculation of infective eggs, larvae were found in viscera, skeletal muscle, and adipose and subcutaneous tissues from all rodents. Adult worms were recovered in the cervical region, rhinopharynx, and oropharynx of domestic cats fed the rodent tissues. Based on this study, it appears that (i) wild rodents act as intermediate hosts; (ii) under natural

Figure 11.9 *Lagochilascaris minor* egg; note the pits in the egg shell (somewhat similar to *Toxocara* eggs). (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

conditions rodents could act as either intermediate hosts or paratenic hosts of *L. minor*; (iii) despite the occurrence of an autoinfection cycle in felines (definitive hosts), the cycle is completed only when intermediate hosts are provided; and (iv) in the wild, rodents could serve as a source of infection for humans since they are frequently used as food (guinea pigs and agoutis as examples) in regions with the highest incidence of human lagochilascariasis. Thus, humans are accidental hosts, possibly becoming infected by eating raw meat from wild rodents containing L3 larvae. It is quite possible that autoinfection also occurs; this possibility is suggested by the chronicity of the disease in patients over a number of years.

Toxocara canis and *T. cati* (Visceral Larva Migrants and Ocular Larva Migrants)

The VLM syndrome was described by Beaver and colleagues in New Orleans in 1952. This syndrome is caused by the migration of larvae of *Toxocara canis*, *T. cati*, and some other animal helminths. Within 10 years of the initial report, more than 2,000 cases had been reported from 48 countries and from every region of the United States. The disease, frequently seen in young children, usually does not cause severe problems, although it persists for months to more than a year. One serious possible complication is invasion of the eye (OLM), often resulting in a granulomatous reaction in the retina. Larva migrans caused by *Toxocara* spp. are widely recognized as zoonotic infections throughout the world and may be much more common than previously thought. Infection rates in dogs have been reported to be 2 to 90%, and the highest rates are seen in puppies as a

result of transmission from their dams. The overall incidence of infected dogs older than 6 months is probably less than 10% (79).

Life Cycle and Morphology

Humans acquire the infection by ingesting infective eggs of the dog (primarily) or cat ascarid *T. canis* or *T. cati* (Figures 11.10 and 11.11). Puppies are often infected by vertical transfer of larvae from their dams transplacentally or lactogenically, and egg shedding by puppies can begin as early as 2 weeks of age. In cats, lactogenic but not transplacental transmission occurs. Young kittens and puppies tend to recover from the infections between 3 and 6 months of age. Infections in older animals are acquired by the ingestion of infective eggs from the soil or ingestion of larvae in infected rodents, birds, or other paratenic hosts. Eggs are shed in the feces and take about 2 to 3 weeks to mature and become infective. After the eggs are accidentally ingested by a human, the larvae hatch in the small intestine, penetrating the intestinal mucosa and migrating to the liver. Migratory routes include the lungs and/or other parts of the body, or the larvae may remain in the liver. During this migration, the larvae do not mature, even if they make their way back into the intestine. The larvae are usually <0.5 mm long and 20 μ m wide. Information also implicates the ingestion of uncooked meats as a potential cause of human toxocariasis, with possibly the first North American case following ingestion of raw lamb liver being reported by Salem and Schantz (78). Although transplacental and lactogenic transmission

has not been reported to occur in humans, in a study of *Toxocara* titers in maternal and cord blood, 6 (35%) of 17 mothers in the *Toxocara* antibody-positive group had previously miscarried compared with 3 (8.6%) of 35 *Toxocara*-negative mothers (84).

Most infections are probably asymptomatic and/or go unrecognized. VLM tends to be seen in younger children, around the age of 3 years, while OLM is more likely to occur in older children, around 8 years. However, this does not tend to be the case with *B. procyonis*, where most cases of VLM, NLM, and OLM have been identified in very young children.

Although VLM is generally associated with *T. canis* or *T. cati*, other helminths have also been implicated in disease. *B. procyonis* has been implicated in VLM, NLM, and OLM in humans. An excellent review of the diagnostic morphology of four larval ascaridoid nematodes that may cause VLM includes identification keys for *Toxascaris leonina*, *B. procyonis*, *Lagochilascaris sprenti*, and *Hexametra leidy* (12). If discovered in tissue sections, the four species of ascaridoid larvae described in the study by Bowman (12) can be differentiated from other known ascaridoids that may cause VLM.

Clinical Disease

Clinical symptoms depend on the number of migrating larvae and the tissue or tissues involved. Infections may range from asymptomatic to severe disease. Larvae often remain in the liver and/or lungs, where they become encapsulated in dense fibrous tissue. Other larvae may continue

Figure 11.10 Life cycle of *Toxocara* spp., the cause of visceral larva migrans (VLM) and ocular larva migrans (OLM).

Figure 11.11 *Toxocara canis*: (A) immature egg; (B) mature egg containing larva; (C) adult worms. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

to migrate throughout the body, causing inflammation and granuloma formation. The most outstanding feature of the disease is a high peripheral eosinophilia, which may reach 90%. The overall severity of the clinical picture depends on the initial dose of infective eggs. As few as 200 *T. canis* larvae in small children may produce a peripheral eosinophilia of 20 to 40% for more than a year, with no other detectable symptoms. Patients with 50% eosinophilia usually have symptoms, which might include fever, hepatomegaly, hyperglobulinemia, pulmonary infiltrates, cough, neurologic

disturbances, and endophthalmitis. Although a rare complication of toxocariasis, CNS involvement can cause seizures, neuropsychiatric symptoms, or encephalopathy (8, 88).

The VLM syndrome is most commonly seen in children 1 to 4 years of age; however, rare cases have been seen in adults, in whom the illness includes mild pulmonary involvement suggestive of VLM. Severe bronchospasm resulting in respiratory failure was not reported until 1992; the case was confirmed by ELISA (30).

A report from Mexico City reviewed six adult patients with toxocariasis presenting with rheumatic symptoms, including lower-extremity nodules, edema suggestive of thrombophlebitis, and synovitis of a knee without effusion. Some of the patients reported having a prolonged, nonproductive cough, generalized pruritus, and migratory cutaneous lesions. One patient with monoarthritis subsequently developed orchitis. All patients had an eosinophilia of 14 to 20%. One patient was biopsy positive, two had positive serologic test results, and the diagnosis was never confirmed in the other three (43). In another case, a 17-year-old boy with palpable purpura, oligoarthritis, acute abdominal pain, microhematuria, and cutaneous vasculitis was found to have toxocariasis with a clinical history including hypereosinophilia and domestic contact with a puppy (34). The infection was confirmed using serologic tests, and complete spontaneous resolution occurred within a few days.

The relationship between asthma and covert toxocariasis remains unclear; however, in a 1999 study, the seroprevalence of anti-*T. canis* antigen (E/S antigen) was 26.3% in asthmatic patients and 4.5% in the controls. All asthmatic patients with anti-*Toxocara* immunoglobulin E (IgE) had cutaneous reactivity to E/S antigen. Therefore, the authors concluded that asthmatic patients with anti-*Toxocara* IgE and IgG were experiencing a covert toxocariasis (52). Significantly elevated levels of IgE/anti-IgE immune complexes have been detected in sera of patients with symptomatic disease, including VLM and OLM (61). While specific IgG may act via antibody-dependent cell-mediated cytotoxicity mechanisms, IgE/anti-IgE immune complexes may participate in VLM and OLM by inducing type III hypersensitivity.

Evidence suggests that ocular disease can occur in the absence of systemic involvement and vice versa for VLM. Although these facts may be explained by possible strain differences of *Toxocara* spp., VLM may reflect the consequences of the host inflammatory response to waves of migrating larvae while OLM may occur in individuals who have not become sensitized (27).

Patients with symptoms that do not fall into the more strict categories of VLM or OLM are often described as having covert toxocariasis. These cases are characterized

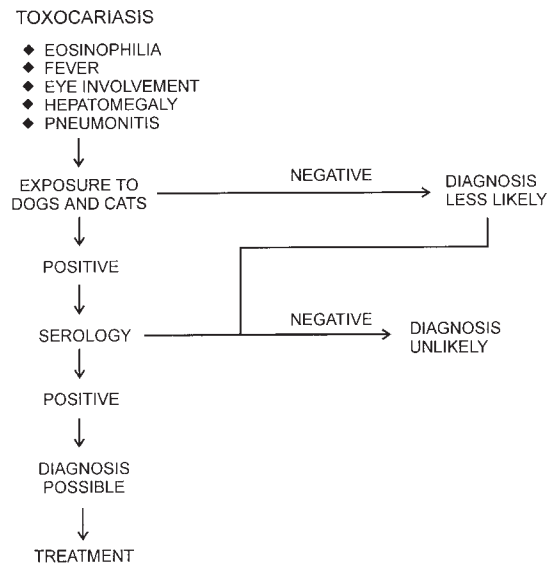

by symptoms including abdominal pain, anorexia, behavior disturbances, cervical adenitis, wheezing, limb pains, and fever (79).

Diagnosis

VLM symptoms caused by *Toxocara* spp. must be differentiated from those caused by other tissue-migrating helminths (ascarids, hookworm, filariae, *Strongyloides* spp., and *Trichinella* spp.), as well as other hypereosinophilic syndromes. OLM may be confused with retinoblastoma, ocular tumors, developmental anomalies, exudative retinitis, trauma, and other childhood eye problems. It is important to remember that in OLM, peripheral eosinophilia may be absent. OLM should be considered in any child with unilateral vision loss and strabismus who has raised, unilateral, whitish or gray lesions in the fundus. VLM should be suspected in any pediatric patient with an unexplained febrile illness and eosinophilia. If the patient has a history of pica and there is hepatosplenomegaly and multisystem disease, then VLM becomes even more likely.

The suspected diagnosis can be confirmed only by identification of larvae in autopsy or biopsy specimens. However, if children are found to have *Ascaris* or *Trichuris* infections, one might suspect toxocariasis, since all three infections are transmitted via ingestion of contaminated soil. Since biopsy specimens are usually not recommended, serologic testing has become widely accepted as the most appropriate approach. In patients with presumptive ocular toxocariasis, higher antibody titers have been detected in the aqueous humor than in the serum, suggesting localized antibody production. The EIA is recommended and uses third-stage larva secretory antigen. The test is highly specific, and there are no cross-reactions with sera obtained from patients infected with other commonly occurring human parasites. The diagnostic titers vary between VLM throughout the body and OLM. A titer of 1:32 is considered diagnostic for VLM, while a titer of 1:8 is considered diagnostic for OLM. This lower titer for OLM raises the possibility of a false-positive diagnosis in a patient who has an asymptomatic *Toxocara* infection and an ocular disease due to other etiology. Measurement of antibody levels in ocular fluid should increase the specificity of the ELISA, yielding a better definitive diagnosis for the patient. The serologic tests become very important when one is trying to differentiate OLM from retinoblastoma, which may have serious consequences. Serologic testing for toxocariasis is recommended in patients with Fuchs heterochromic cyclitis and retinal scars in the absence of toxoplasmosis (85). Refer to Algorithm 11.2 for a detailed review.

A commercial ELISA kit has been evaluated and found to have an overall diagnostic sensitivity of 91%

Algorithm 11.2 Diagnosis of toxocariasis.

and specificity of 86%, with cross-reactivity being seen with sera from patients with strongyloidiasis, trichinellosis, filariasis, and fascioliasis. However, because these infections tend to be infrequent, potential cross-reactivity may not be relevant unless the geographic area includes a high prevalence of any of the above-mentioned infections (36).

Although many cases of VLM are diagnosed by serologic testing, toxocariasis has generally been defined as an infection with *Toxocara* spp., with no attempt to identify the species involved. Studies involving preabsorption of patient sera with cross-reacting antigens and review of follow-up reactivity changes in the sera have confirmed the ability to specifically identify the infecting parasite as *T. canis* or *T. cati*. This ability to distinguish between the two species should be helpful in further biological, epidemiologic, and clinical studies of toxocariasis (57). In cases of encephalitis and myelitis with CSF eosinophilia, parasitic infection should be suspected and appropriate serologic tests should be performed (54). Other more unusual presentations have included thrombocytosis and eosinophilic pleural effusion (6, 39). The probability of hepatic toxocariasis can be further evaluated using imaging techniques and ultrasonography. Findings would include focal ill-defined hepatic lesions, hepatosplenomegaly, biliary dilatation, sludge, and periportal lymph node enlargement (38).

Although the currently recommended serologic test for toxocariasis is EIA, when interpreting serologic results a measurable titer does not always represent current infection. A small percentage of the U.S. population

(2.8%) exhibits a positive titer that reflects the prevalence of asymptomatic toxocariasis.

In one study, pseudocystic transformation of the peripheral vitreous appeared to be a rather specific and sensitive ultrasonographic biomicroscopic sign in patients with presumed peripheral toxocariasis, and this finding will aid diagnosis in difficult cases (87). In a group of 48 patients with diverse inflammatory conditions of the retroiridal space who were examined by ultrasonographic biomicroscopy, no characteristic *Toxocara*-associated pseudocystic images were seen.

KEY POINTS—LABORATORY DIAGNOSIS

Toxocara canis and *T. cati* (Visceral and Ocular Larva Migrans)

1. Biopsy specimens are usually not recommended.
2. Serologic tests are recommended. Serum samples can be sent to the appropriate state Department of Public Health (check the applicable state submission requirements). These specimens are often sent to the Centers for Disease Control and Prevention. History information is required, and each sample must be specified as “serum” or “eye fluid,” so that a correct interpretation of the results can be made.
3. Tissue specimens containing larvae can be referred to a reference center (university or Armed Forces Institute of Pathology, Washington, D.C.).

Treatment

Diethylcarbamazine, thiabendazole, ivermectin, and albendazole are effective in some cases but not in others. Corticosteroids may also be given to patients with VLM or OLM. Destruction of the larva by photocoagulation is recommended when the larva is visible in the eye. (Specific drug and dosage information is provided in chapter 25.) Even when the eye is involved, the prognosis is usually favorable, particularly when a prompt diagnosis is made and treatment is effective. Albendazole is the treatment of choice. Although mebendazole is poorly absorbed outside the gastrointestinal tract, it has been used with some success (27).

Epidemiology and Prevention

Given that (i) *Toxocara* worms are commonly found in dogs and cats, (ii) puppies and kittens are infected early in life, and (iii) pets and children are often found in the same household, it is not surprising that the combination of small children playing in contaminated soil and pets passing large numbers of infective eggs leads to VLM and/or OLM. However, it is important to remember that this disease can also occur in adults (43). The eggs become

infective after about 3 weeks and remain viable in the soil for months. Examination of soil from parks and playgrounds in various areas of the world has demonstrated infective *Toxocara* eggs that contribute to the high infection rate seen in dogs (20).

One preventive measure includes worming dogs and cats periodically with mebendazole to keep them free of worms. Another recommendation is preventing children from eating dirt, particularly soil that could be contaminated by neighborhood or family pets. Proper curbing of dogs in the street during defecation has also been recommended. Another approach involves protection of sandboxes in public parks from *Toxocara* egg contamination. The recommendation is to cover the sandboxes with clear vinyl sheets at night and on rainy days.

In summary, the following preventive measures should be emphasized: regular deworming of dogs and cats, beginning at 2 weeks of age; removal of cat and dog feces in places adjacent to homes and children’s playgrounds; ensuring that children’s sandboxes are covered when not being used; regular hand washing after handling soil and before eating; and teaching children not to put dirty objects into their mouths.

Ancylostoma braziliense and *A. caninum* (Cutaneous Larva Migrans)

Cutaneous larva migrans (CLM), also called creeping eruption, was recognized as a clinical syndrome before the 1800s. Various reports were published during the late 1800s; however, it was not until 1926 that the most common etiologic agent of CLM in the southern United States was found to be *Ancylostoma braziliense*, a very common hookworm of dogs and cats. *A. caninum*, the common hookworm of dogs, has been implicated in cases of CLM. Other species are also capable of producing CLM, although they are less common than *A. braziliense*.

Life Cycle and Morphology

Infection in humans is acquired through skin penetration by infective larvae from the soil (Figure 11.12). These larvae can also cause infection when ingested. When the larvae penetrate the skin, they produce pruritic papules, which after several days become linear tracks that are elevated and vesicular (Figure 11.13). Movement by the larvae in the tunnel may extend the track several millimeters each day.

Clinical Disease

Within a few hours after larval penetration of the skin, an itching red papule develops. As the worm begins to migrate from the area of the papule, a serpiginous track

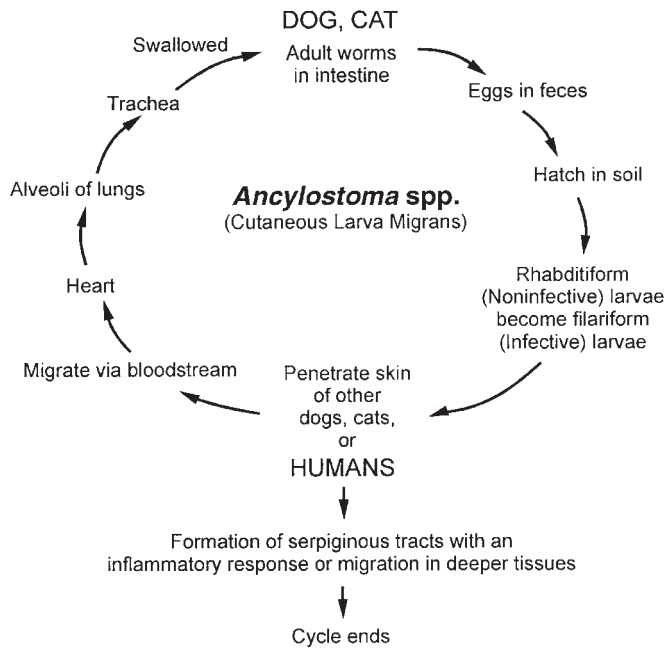

Figure 11.12 Life cycle of *Ancylostoma* spp., the cause of cutaneous larva migrans (CLM).

appears. The surrounding tissues are edematous and very inflamed. The larva continues to migrate several centimeters each day, and the older portion of the track dries and becomes scarred. This process is associated with severe pruritus, and scratching can lead to secondary infection. Larvae that first enter the skin and cause creeping eruption may later migrate to the deeper tissues (lungs). Deeper-tissue migration may lead to pneumonitis with larval recovery in the sputum (13). A peripheral eosinophilia, as well as many eosinophils and Charcot-Leyden crystals in the sputum, may also be present.

Figure 11.13 Linear tracks caused by migration of *Ancylostoma* spp. (cutaneous larva migrans [CLM]). (From a Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Diagnosis

Diagnosis can usually be made on the basis of the characteristic linear tunnels or tracks and a history of possible exposure; however, other organisms (less common) can also cause CLM.

KEY POINTS—LABORATORY DIAGNOSIS

Ancylostoma braziliense and *A. caninum* (Cutaneous Larva Migrants)

1. Diagnosis is usually based on possible exposure history and/or the presence of the linear tracks. Biopsy is not recommended. However, newer PCR methods for the detection and identification of larvae in human tissues may provide improved test results.
2. There may be an elevated eosinophilia (peripheral or sputum).

Treatment

Treatment is generally carried out with thiabendazole, which can be administered either by mouth or topically. Specific drug dosages are provided in chapter 25. Symptoms can also be treated with antihistamines, antipruritic agents, sedatives, and/or topical anesthetics.

Epidemiology and Prevention

Most infections are acquired from contact with larvae in moist or sandy soil. Such areas include beaches and sandboxes. Dogs and cats tend to defecate in such areas, providing a perfect situation for accidental infection with the filariform larvae. Specific preventive measures include covering all sandboxes when they are not being used, keeping dogs and cats away from beaches, and periodic deworming of domestic dogs and cats.

Human Eosinophilic Enteritis

As a general definition, primary eosinophilic gastrointestinal disorders selectively affect the gastrointestinal tract, with eosinophil-rich inflammation, in the absence of known causes of eosinophilia, including parasitic infections, drug reactions, and malignancy. Becoming more common, these disorders include eosinophilic esophagitis, eosinophilic gastritis, eosinophilic gastroenteritis, eosinophilic enteritis, and eosinophilic colitis. It is well known that eosinophils are important members of the gastrointestinal mucosal immune system and that eosinophilic gastrointestinal problems involve mechanisms that include IgE-mediated and delayed Th2-type responses.

Segmental eosinophilic inflammation of the gastrointestinal tract may occur as an isolated condition or part of a multisystem problem. During the past 20 years, an increasing number of cases have been reported in northern Queensland, Australia (21, 74). All of the patients were Caucasians, and they ranged in age from 16 to 72 years, with no previous illness. They presented with severe abdominal pain, occasional diarrhea, weight loss, and dark stools; all cases were associated with eosinophilia and elevated levels of IgE in serum.

The conclusion that the etiologic agent was *A. caninum* was determined for the following reasons. A single adult *A. caninum* worm was found within a segment of inflamed ileum of one patient. Human hookworms do not occur in urban Australia, and no hookworm eggs were being passed in the stool. In contrast, all of the patients were closely associated with dogs, almost all of which were infected with hookworms. Also, all patients treated with anthelmintic agents responded with a return to normal peripheral blood eosinophil counts. The similarities between this case and the 33 previously reported cases (21) implicate *A. caninum* as the cause of eosinophilic enteritis (EE) in that group of patients. It has been speculated that *A. caninum* causes human EE by inducing allergic responses to its secretions, including cysteine proteinases, which are involved in pathogenesis in other parasites. Recent immunologic studies involving ELISA and Western blotting for IgG and IgE antibodies to excretory-secretory antigens from adult *A. caninum* also suggest that this parasite is a major cause of EE and peripheral blood eosinophilia (PE) (47).

The combination of an affluent, rapidly growing Caucasian population with large numbers of infected dogs as pets, human exposure to infective larvae in a tropical climate with appropriate temperature and humidity, and advanced medical facilities led to the recognition of this association between the parasite infection and subsequent human disease. It also appears that climate directly influences the rate of human enteric infection by canine hookworms (22). Although there are other causes of EE, this disease entity may become more commonly recognized in other areas of the world, thus confirming the causative agent as the common dog hookworm (74).

Mebendazole, pyrantel pamoate, and albendazole have been used for the treatment of EE. However, unless there is an awareness of this relatively new syndrome, the causative agent may not be considered in the differential diagnosis.

Dracunculus medinensis

Some people speculate that the fiery serpent of biblical times was, in fact, *Dracunculus medinensis* (48). The clinical syndrome was well known in ancient Egypt

and during the Greek and Roman periods (10). The contemporary term, guinea worm disease, derives its name from a European explorer who named the disease for the geographic area in which it was found, along the western African coast. The staff of Aesculapius, Roman god of medicine, may have originated from the ancient, still used procedure of removing the adult worm by slowly winding it around a stick (Figure 11.14). Although the worms are very long and thin, they are not true filarial worms but, rather, are grouped in their own order.

Life Cycle and Morphology

Human infection is acquired from ingestion of infected copepods (*Cyclops* water fleas) (Figure 11.15). The released larvae penetrate the duodenal mucosa and develop in the loose connective tissue. The possibility also exists that paratenic hosts, such as tadpoles and frogs, are important means of transporting infective larvae of *Dracunculus* species up the food chain, thus facilitating transmission to the definitive hosts.

The worms are very long, with the females measuring up to 1 m in length by 2 mm in width. The male is much smaller and inconspicuous (2 cm long). The worms mature in the deep connective tissue, and the females migrate to the subcutaneous tissues when they are gravid and contain coiled uteri filled with rhabditiform larvae. Maturation takes approximately 1 year. At this stage

Figure 11.14 *Dracunculus medinensis*, blister on leg (contains female worm); note removal of the adult worm. (Illustration by Sharon Belkin.)

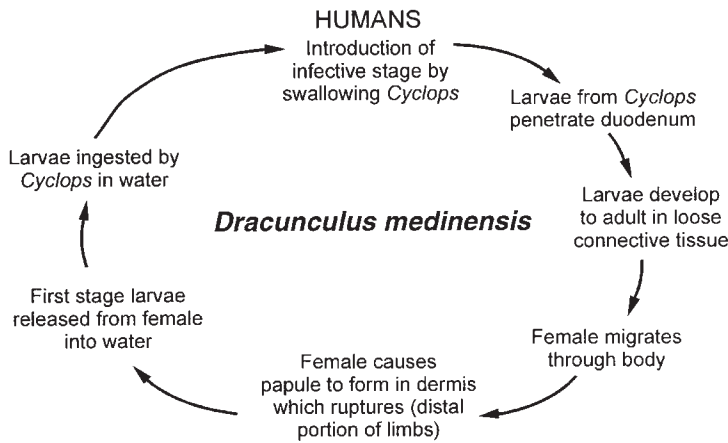

Figure 11.15 Life cycle of *Dracunculus medinensis*, the cause of guinea worm disease.

in the life cycle, the female migrates to the skin and a papule is formed in the dermis, usually by the ankles or feet (although papules can be anywhere on the body). The papule changes into a blister within 24 h to several days. Eventually, the blister ulcerates, and on contact with freshwater, a portion of the uterus prolapses through the worm's body wall, bursts open, and discharges thousands of larvae into the water (Figures 11.16 to 11.20). This may happen several times until all of the larvae are discharged. The larvae are then ingested by an appropriate species of *Cyclops*. Development takes about 8 days before the larvae are infective for humans.

Although the adult worms are often described as creamy white, there are reports of red worms that appear to be female *D. medinensis*. These infections occurred in an area of Pakistan where the incidence of guinea worm in 1988 was 15%. Unfortunately, examination of histologic sections was unable to determine the cause of

the red color; however, blood was excluded as a possible cause.

Clinical Disease

After ingestion of an infected copepod, no specific pathologic changes are associated with larval penetration into the deep connective tissues and maturation of the worms. Once the gravid female begins to migrate to the skin, there may be some erythema and tenderness in the area where the blister will form. Several hours before blister formation, the patient may exhibit some systemic reactions, including an urticarial rash, intense pruritus, nausea, vomiting, diarrhea, or asthmatic attacks. The lesion

develops as a reddish papule, measuring 2 to 7 cm in diameter. Symptoms usually subside when the lesion ruptures, discharging both the larvae and worm metabolites.

In a 1995 study in Nigeria, 1,200 people were surveyed for dracunculiasis. Many (982 [82%] of 1,200) were infected, and most infections involved the lower limbs (98%). Worms were also seen emerging from the umbilicus, groin, palm, wrist, and upper arm. Of the 982 infected individuals, 206 (21%) were totally incapacitated, 193 (20%) were seriously disabled, 431

(Armed Forces Institute of Pathology photograph; contributed by Everett L. Schiller, Johns Hopkins University School of Public Health, Baltimore, Md.)

(44%) were mildly incapacitated, and 152 (16%) were unaffected (62).

If the worms are removed at this time, healing usually occurs with no problems. If the worm is damaged or broken during removal, there may be an intense inflammatory reaction with possible cellulitis along the worm's migratory track. If secondary infection occurs, there may be serious sequelae, including arthritis, synovitis, and other symptoms, depending on the site of the lesion.

Diagnosis

Diagnosis can be confirmed at the time the cutaneous lesion forms, with subsequent appearance of the adult worm. Infected lesions must be distinguished from carbuncles, deep cellulitis, focal myositis or periostitis, and even rheumatism. Calcified worms may also be found in subcutaneous tissues by radiography. They may appear as linear densities (up to 25 cm), tightly coiled structures, or sometimes nodules.

Treatment

For centuries, the worms have been removed by slowly being wound around a stick (Figures 11.14 and 11.19). This approach works well unless the worm is accidentally broken and secondary infection occurs. Allergic manifestations can be decreased by using epinephrine (10).

Four drugs have been used with various degrees of success: niridazole, thiabendazole, metronidazole, and mebendazole. The action seems to involve suppression of inflammation rather than any specific effect on the adult worms, although 400 to 500 mg/day for 6 days has been reported to kill the worms directly (1).

The prognosis is usually quite good unless there are complications. Specific drug dosage information is provided in chapter 25.

Epidemiology and Prevention

Disease transmission depends on several factors: (i) water sources where *Cyclops* spp. breed, (ii) direct contact between infected humans and the water source, and (iii) use of this water source for drinking. In various parts of the world, certain types of water sources (e.g., step wells in India, covered cisterns in Iran, and ponds in Ghana) provide all of these transmission requirements. The disease can be eliminated within 1 to 2 years by provision of safe drinking water.

In 1986, approximately 3.5 million cases of dracunculiasis occurred in 20 countries, and 120 million people were at risk for the disease. The target date for eradication of guinea worm infection of 1995 had been set by the African Regional Office of the World Health Organization and accepted by the United Nations Children's Fund and the United Nations Development Program. Although much progress has been achieved, some of the remaining obstacles to eradication include civil wars in Africa and apathy of some officials (15). By the end of 2004, Asia was free from dracunculiasis, while all remaining countries in Africa with endemic infection reported a 50% reduction in cases from 2003 and 2004. During 2005, Ghana and Sudan have reported 95% of the world's cases; however, the continued lack of security in some areas has delayed case reporting and disease interventions. With the settlement of Sudan's civil war and a new challenge grant from the Bill & Melinda Gates Foundation, completion of eradication efforts by 2009 in Sudan and earlier elsewhere may become reality. It is hoped that this infection will eventually join smallpox as one that can actually be eradicated from the world (17, 35).

Angiostrongylus (Parastrongylus) cantonensis (Cerebral Angiostrongyliasis)

Human infection with the rat lungworm *Angiostrongylus cantonensis* was first detected in 1945 in a 15-year-old Taiwanese boy with suspected meningitis. It has been recognized in the Pacific areas for many years, with Thailand, Tahiti, and Taiwan being areas of high endemicity. Sporadic cases have also been reported in other parts of the world, including Australia, Fiji, Sri Lanka, Egypt, Madagascar, Central America, and Cuba. The first case in the United States was reported in 1995 (60). Apparently, many gastropods in New Orleans are competent hosts for *A. cantonensis*. Also, the presence of infected rats and primates (at the Audubon Zoo) indicates that there is a reservoir of infection in New

Orleans. The infection is associated with eosinophilic meningitis and sometimes eye involvement (3). Currently there are four species within the genus: *A. cantonensis*, *A. costaricensis*, *A. malaysiensis*, and *A. mackerrase* (these four are now placed in the new genus *Parastrongylus*). Since most parasitologists may continue to use the genus name *Angiostrongylus*, this generic designation is used throughout this chapter.

Life Cycle and Morphology

Mature adult worms of *A. cantonensis* inhabit the pulmonary arteries of a wide variety of rodents, primarily those within the genera *Rattus* and *Bandicota*. Eggs laid by the female lodge in the pulmonary arteries. On hatching, the first-stage larvae enter the alveolar space, migrate up the trachea and down the alimentary tract, and are excreted in the feces. Terrestrial snails, slugs, and aquatic snails serve as intermediate hosts, either by first-stage larval penetration of tissues or by the ingestion of contaminated rodent feces. Larval development continues in the mollusk, where third-stage, infective larvae develop within about 2 weeks. When ingested by rodents, the infective third-stage larvae migrate to the brain via the circulation and develop into fourth-stage larvae and then young adults within 4 weeks. They then go to the subarachnoid space, enter the venous system, and arrive in the pulmonary arteries, where sexual maturity occurs within another 2 weeks.

Human infection begins with the accidental ingestion of infective larvae in several species of slugs, snails, or land planarians (Figure 11.21). Ingestion of infected raw paratenic hosts, including fish, amphibians, reptiles, crustaceans, and vegetables contaminated with larvae, also leads to infection of the human host. Survival of the fifth-stage larvae is not certain; some probably die in the brain and spinal cord while some reach the eye chamber; very few probably reach the lungs. In the natural life cycle, infective larvae have also been found in land crabs, coconut crabs, and freshwater prawns, which are often consumed raw in the Pacific Islands. In summary, human infection can originate through the following: by ingestion of L3 larvae in raw or undercooked intermediate or paratenic hosts, by drinking infected water, by oral contact with hands contaminated with mollusk larvae, or possibly through the skin.

The worms are very thin and delicate, measuring 17 to 25 mm long by 0.26 to 0.36 mm wide. The young adults within the brain tissue are approximately 2 mm long.

Clinical Disease

The incubation period is normally around 20 days but may be twice that. The main symptom in all reported

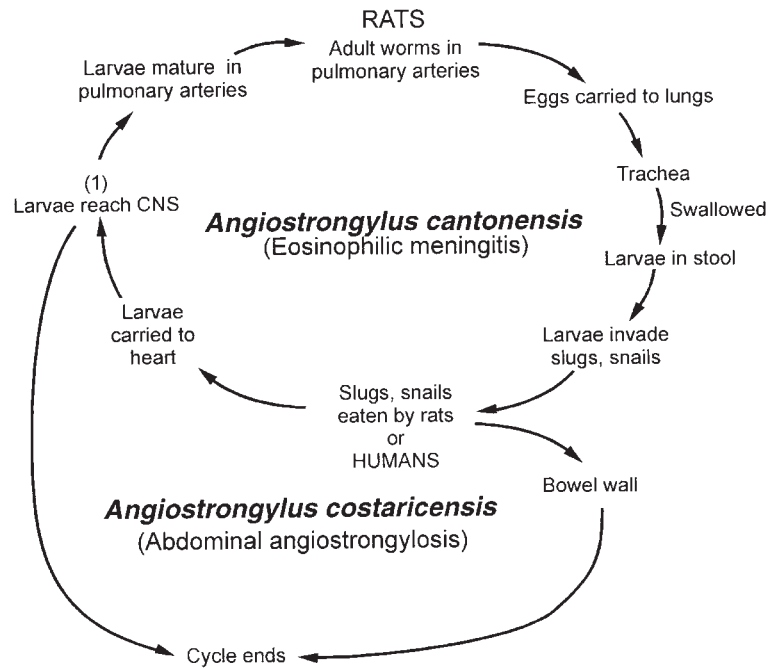

Figure 11.21 Life cycle of *Angiostrongylus* spp. [see (1) in figure]. Humans present with encephalitis when worms die in the brain tissue.

cases was severe headache. Other symptoms include convulsions, weakness of the limbs, paresthesia, vomiting, constipation, nausea, anorexia, facial paralysis, neck stiffness, and fever. Pulmonary symptoms are usually absent, although immature adult worms have been seen in lung tissue sections. Recovery of larvae in sputum or stool has not been reported. The spinal fluid usually contains white blood cells (100 to 2,000/mm³ with many eosinophils). There is often a peripheral eosinophilia with moderate leukocytosis (Figure 11.22). In most cases, the disease is self-limiting and the patient recovers within a month.

Figure 11.22 *Angiostrongylus cantonensis* in the central canal of the spinal cord. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Eye involvement is characterized by visual impairment, pain, possible retinal hemorrhage, and retinal detachment. Living worms have been removed in some cases (Figure 11.23). Ocular angiostrongyliasis has been reported from Thailand, Taiwan, Vietnam, Indonesia, Japan, Papua New Guinea, and Sri Lanka. Worms have been found in the anterior chamber, retina, and other sites, causing multiple symptoms and rare cases of blindness.

The patient from New Orleans was an 11-year-old boy who presented with myalgia, headache, low-grade fever, and vomiting. He had no travel history but admitted

Figure 11.23 *Angiostrongylus cantonensis* adult male worm in the eye. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

that, on a dare, he had eaten a raw snail from the street a few weeks earlier. While serologic tests for VLM and *Toxoplasma gondii* were negative, the results for *A. cantonensis* were positive (60).

Most patients, including the one from New Orleans, recover uneventfully and do not require hospitalization. Symptoms gradually disappear, with the meningeal problems resolving first, followed by the visual abnormalities and finally by the paresthesia.

Diagnosis

A presumptive diagnosis can be made in areas where infections are endemic on the basis of symptoms of severe headache, meningitis, or meningoencephalitis, with fever and ocular involvement. A peripheral eosinophilia and eosinophils in the CSF would also be highly suggestive. Lesions can also be seen in the brain by computed tomography. Larvae or young adult worms can often be recovered in the CSF, and the serologic ELISA can also provide confirmation. Both adult and young *A. cantonensis* worm antigens purified by immunoaffinity chromatography have been used to detect antibody in serum and CSF by ELISA. Infected patients had increased levels of IgG, IgA, IgM, and IgE, with higher IgM and IgE levels in serum than in CSF. Both worm antigens were highly sensitive in ELISA for serum antibodies but less so in tests for antibodies in CSF (91).

Treatment

If the worm is found in the eye, surgical removal of the worm is normally recommended. Anthelmintic agents are usually not used, although both mebendazole and thiabendazole have been tried. Mebendazole is currently the drug of choice (1). These drug trials have been inconclusive, and symptomatic therapy is normally recommended. However, since pathogenesis is frequently ascribed to dead or dying worms, anthelmintics should be used with caution. Corticosteroids may also eliminate some symptoms.

Epidemiology and Prevention

The lack of host specificity, the natural mobility of rats, and the expansion of the geographic range of the large African land snail have all contributed to the spread of this infection throughout the tropical and subtropical areas of the world. It is often difficult to identify the specific source of human infections; however, awareness of the various possible hosts may decrease the number of infections. Angiostrongyliasis is an emerging public health problem in mainland China (19). No overall control measures have been recommended. However, control of the spread of infected rats and mollusks to areas where *A. cantonensis* is not endemic will help restrict the geographic range.

Angiostrongylus (Parastrongylus) costaricensis (Abdominal Angiostrongyliasis)

At the time *Angiostrongylus costaricensis* was described in 1971, the natural host was unknown. The cotton rat, the black rat, and a number of other rodents harbor the adult worms, while various slugs harbor the larvae. Human infections are most common in Costa Rica (where there are about 600 per year) but have been reported in other areas of Mexico and Central and South America.

Life Cycle and Morphology

The life cycle is similar to that of *A. cantonensis*, with human infection being initiated by accidental ingestion of the appropriate slug, frequently on contaminated salad vegetables (Figure 11.21). This infection is called abdominal angiostrongyliasis, and the worms cause inflammatory lesions of the bowel wall.

The eggs are oval and about 90 μm long, have a thin shell, and are unembryonated (they may be embryonated in humans, with some larvae being released from the egg). The adult worms measure 42 by 350 μm (females) and 22 by 140 μm (males).

Clinical Disease

Abdominal angiostrongyliasis is found mainly in children under 13 years, and some groups have reported that two-thirds of these are male. The appendix is often involved; however, the worms can also be found in the terminal ileum, cecum, ascending colon, regional lymph nodes, and mesenteric arteries. There may be inflammation, thrombosis, and regional necrosis, with granulomas and areas of eosinophilic infiltrates around eggs and larvae in various stages of development. The most common symptoms are pain and tenderness, with a palpable mass in the lower right quadrant, along with fever and possibly vomiting and diarrhea. Occasionally, the worms are present in the liver; the symptoms may mimic those of VLM. Leukocytosis is present, with eosinophilia of up to 80%. Clinical symptoms occur about 2 weeks after infection and include abdominal pain in the right iliac fossa and right flank, fever, anorexia, vomiting, diarrhea, and constipation.

Diagnosis

Eggs or larvae may be seen in tissue sections, with most specimens being diagnosed on microscopic findings. Without histologic sections, the diagnosis is made on clinical grounds. Radiology may reveal abnormalities in the terminal ileum, cecum, and ascending colon. Contrast medium studies show spasticity, filling defects, and irritability at the cecum and ascending colon. When

the liver is involved, there may be leukocytosis and eosinophilia, as well as elevated liver enzyme levels.

Treatment

Several drugs have been tried; the drug of choice is thiabendazole, with another option being mebendazole (1).

Epidemiology and Prevention

The ingestion of raw slugs in the areas of endemicity is considered strictly accidental. Most of the infections reported from Costa Rica have been in children, with a higher incidence in boys than in girls. Prevention involves rodent control to break the normal parasite cycle, as well as thorough washing of vegetables and other foods prior to consumption.

Recently, *A. costaricensis* has been reported in several primates at the Miami MetroZoo (siamang) and the Monkey Jungle in Miami (Ma's night monkeys). Also *A. costaricensis* was found in an opossum trapped in the MetroZoo, as well as in four raccoons near the MetroZoo. These are the first records from all four species of hosts. The primates were zoo born and the raccoons and opossum were native, thus indicating that this parasite is now endemic at these two sites (51a).

Gnathostoma spinigerum

Although many *Gnathostoma* species have been mentioned in the literature, *G. spinigerum* is considered to be the most medically important. This parasite is normally found in dogs and cats; the largest number

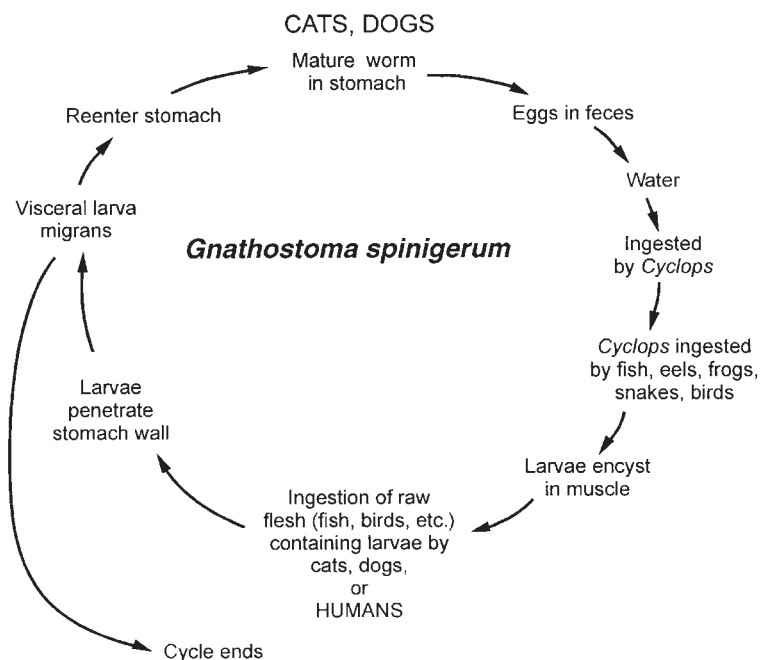

of infections, both in humans and in reservoir hosts, is found in Thailand (10). Areas of endemicity include China, the Philippines, and other areas in the Far East. However, the first record of a confirmed case of *G. doloresi* infection has been reported from Japan; the parasite was dissected from the skin and was identified as a third-stage larva. Although the entire life cycle is not fully understood, the patient reported eating raw brook trout about 2 months before the onset of the creeping eruption (59). Another case report from Japan describes colonic ileus due to nodular lesions caused by *G. doloresi* (80).

Life Cycle and Morphology

Within the definitive host (cats, dogs, and some wild carnivores), the adult worm lies coiled in a tumor-like mass in the stomach wall. Eggs are extruded from the stomach lesions and are passed out with the feces. These eggs hatch 10 to 12 days after reaching water, releasing first-stage larvae. The larvae are then ingested by copepods, where they develop into second-stage larvae within about 2 weeks. When an infected copepod is then ingested by any of the many intermediate hosts (fish, amphibians, reptiles, birds, and mammals), the third-stage larvae encyst. Once the intermediate host is ingested by the definitive host, the parasites become localized in the stomach wall, where they mature in 2 to 12 months (14).

Human infections are acquired by the ingestion of raw or poorly cooked or pickled freshwater fish, chicken and other birds, frogs, or snakes (Figure 11.24). There is also speculation that human infection can occur from the ingestion of copepods containing the advanced third-stage

Figure 11.24 Life cycle of *Gnathostoma spinigerum*.

larvae or by actual skin penetration of larvae from handling infected meat. Three cases of parasitologically proven gnathostomiasis in neonates have been reported; these infections were presumably transmitted prenatally or perinatally from mother to infant (14).

The adult worms, which are found in the stomach lesions, are 25 to 54 mm (females) and 11 to 25 mm (males) long. The anterior half of the worm is covered with leaflike spines (Figures 11.25 and 11.26).

Clinical Disease

In most cases, the incubation period is difficult to determine. The disease is usually seen in two very different clinical forms, larval gnathostomiasis and eosinophilic myeloencephalitis.

Larval Gnathostomiasis. Cutaneous and visceral forms are seen, with the visceral larval migration including pulmonary, gastrointestinal, urogenital, ocular, otorhinolaryngeal, and cerebral tissues. In the human host, the larvae do not mature into adults in the wall of the stomach but, rather, migrate throughout the body. Several days after ingestion of the larvae, penetration of the intestinal wall may lead to

Figure 11.25 *Gnathostoma spinigerum*, adult worm. [Illustration by Sharon Belkin; adapted from reference 10; originally adapted from I. Miyazaki, Studies on *Gnathostoma* occurring in Japan (Nematoda: Gnathostomidae). II. Life history of *Gnathostoma* and morphological comparison of its larval forms, *Kyushu Mem. Med. Sci.* 5:123-140, 1954.]

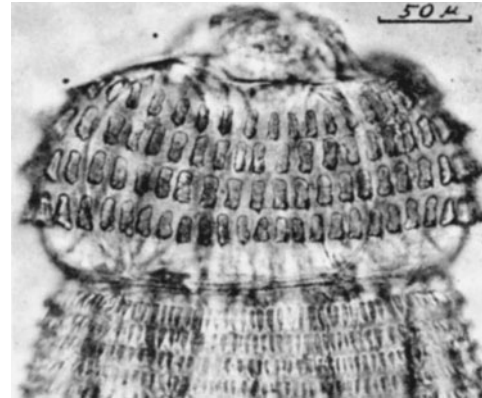

Figure 11.26 Head of adult gnathostoma. (Armed Forces Institute of Pathology photograph.)

epigastric pain, vomiting, and anorexia. These symptoms subside as the larvae begin to migrate through the tissues in deep cutaneous or subcutaneous tunnels. Evidence of this migration appears either as lesions similar to those found in patients with CLM or, more commonly, as migratory swellings with inflammation, redness, and pain. This swelling is hard and nonpitting and may last for several weeks. After it disappears, it may reappear in a location not far from the first swelling, which can be on the upper extremity, shoulder, neck, thorax, face, scalp, abdominal wall, thigh, or foot. Sometimes the lesions are painless, and sometimes there is pain and pruritus. These swellings probably result from the allergic response of the host to the presence of the worms, and an eosinophilia of 35 to 80% is reported in patients with cutaneous involvement.

If worm migration occurs relatively close to the surface of the body, creeping eruption, cutaneous abscesses, or nodules may be seen. Visceral migration can lead to serious sequelae, depending on the organ(s) affected (Table 11.3).

Eosinophilic Gnathostomiasis. Neurologic manifestations are seen as a complex group of symptoms called eosinophilic myeloencephalitis. More serious symptoms can occur if the eyes or CNS is involved. The larval migration occurs along a peripheral nerve, into the spinal cord, and then into the brain. Symptoms include pain, paralysis, seizures, coma, and death. Sudden severe headache and sensory impairment followed by coma can occur and mimics a cerebrovascular accident. In rare instances, cutaneous migratory swellings and neurologic symptoms occur in the same patient. In areas of endemic infection, cerebral hemorrhage in a younger individual should indicate possible infection with *Gnathostoma* spp. The spinal fluid may be xanthochromic or bloody. Ocular invasion probably occurs via the optic nerve, although penetration through the sclera may be possible.

Diagnosis

Patient symptoms may also suggest sparganosis, cutaneous paragonimiasis, CLM, and myiasis. Spinal fluid that is bloody or xanthochromic and contains many eosinophils may be suggestive of infection with *A. cantonensis*. A definitive diagnosis depends on recovery and identification of the worms. Newer serologic methods may also be helpful.

Treatment

The only effective therapy is surgical incision of the lesion and removal of the worm. Albendazole has also been recommended as an adjunct to surgical removal (1). Worm removal from the eye may also prevent CNS invasion. The prognosis is usually good unless the CNS is involved. Additional therapeutic information is presented in chapter 25.

Epidemiology and Prevention

Most infections are probably caused by the ingestion of raw or poorly cooked fish, domestic ducks, and chickens. The larvae do not survive cooking, and they can be killed by immersion in strong vinegar for at least 5 h. Unfortunately, soaking in lime juice or storage at 4°C for 1 month does not kill the larvae. Untreated groundwater is also a potential problem and source of transmission because it can contain infected copepods. Once the life cycle is established in an area, potential infection can become a serious public health issue for residents. Increases in world travel and the importation of food require heightened awareness of this infection, particularly in areas like Europe and North America, where the infection is not endemic.

Gnathostoma doloresi, *G. nipponicum*, *G. hispidum*, and *G. binucleatum*

Other *Gnathostoma* species causing human infection include *G. doloresi*, *G. nipponicum*, *G. hispidum*, and *G. binucleatum*. The general life cycle is identical to that of *G. spinigerum*, with slight variations related to the second, paratenic, and definitive hosts. Patient symptoms are also similar to those seen with *G. spinigerum* infections. In Japan, freshwater fish are the most likely source of *G. doloresi*, *G. hispidum*, and *G. nipponicum* (2). In Myanmar, an outbreak among Korean emigrants was reported; 38 of 60 individuals became symptomatic after ingesting raw freshwater catfish, freshwater bream, and snake-headed fish in a local Korean restaurant (18). Although positive serologic test results were based on the use of *G. doloresi* antigen, *G. spinigerum* was suspected as the causative agent and is known to be present in the Yangon area of Myanmar.

An increasing number of human cases have also been reported in Sinaloa, Mexico, most of which occurred in persons who had eaten raw fish dishes such as “cebiche.” A report confirming five cases from Mexico described

the first known outbreak of acute gnathostomiasis on the American continent (28). These patients were seropositive to *G. doloresi* antigen. Five species of fish and four species of ichthyophagous birds collected from three lakes and a nearby estuary were infected with third-stage larvae of *G. binucleatum*, a species found in Ecuador and Mexico.

Anisakis simplex, *A. physeteris*, *Pseudoterranova decipiens*, *Contracaecum* *osculatum*, *Hysterothylacium aduncum*, and *Porrocaecum reticulatum* (Larval Nematodes Acquired from Saltwater Fish)

Anisakiasis was first recognized and reported in the Netherlands. Since this infection was reported in Japan in 1965, hundreds of Japanese cases have been documented, as have several in the United States (10). Up to 1990, more than 12,000 cases were reported from Japan and only 519 cases were reported in 19 countries outside of Japan. Less than 100 cases have been reported from the United States; however, this infection is probably misdiagnosed and underreported. With the tremendous increase in the popularity of sushi and sashimi, it is likely that the number of case reports will increase over the next few years. It is well recognized that human infection can occur from the ingestion of raw or poorly cooked marine fish or squid. Anisakid larvae known to cause human infections include *Anisakis simplex*, *A. physeteris*, *Pseudoterranova decipiens*, *Contracaecum osculatum*, *Hysterothylacium aduncum*, and *Porrocaecum reticulatum*. Within this group, *A. simplex* and *P. decipiens* are considered the most important human parasites.

Life Cycle and Morphology

The primary hosts of *Anisakis* are dolphin, porpoise, and whale; those of *Pseudoterranova* are seal, fur seal, walrus, and sea lion. These sea mammals ingest third-stage larvae, which penetrate the gastric mucosa and develop into adult male and female worms. The worms live in clusters, with their anterior ends embedded in the gastric wall. Eggs are then passed out into the sea, where the second-stage larvae are ingested by small marine crustacea (krill) and develop into third-stage larvae. These are then transmitted from krill to fish or from fish to fish, etc., via the normal food chain. Generally, these larvae reside in the viscera of the fish; however, some fish contain larvae within the muscle. More than 150 species of fish can serve as intermediate hosts. Herring, salmon, mackerel, cod, and squid tend to transmit *Anisakis* infection, while cod, halibut, flatfish, greenling, and red snapper can transmit *Pseudoterranova*.

Human infection is acquired by the ingestion of raw, pickled, salted, or smoked saltwater fish or squid (Figure 11.27). The larvae often penetrate into the walls of the digestive tract (frequently the stomach), where they become

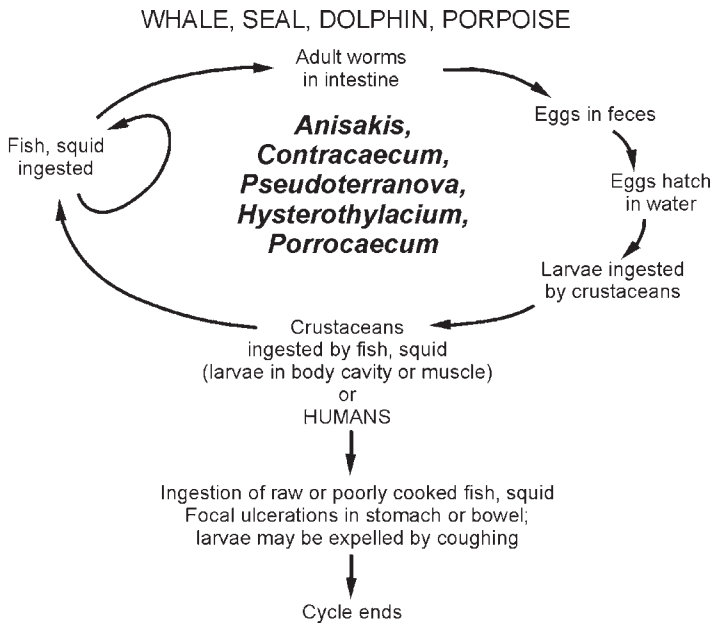

Figure 11.27 Life cycle of *Anisakis*, *Contracaecum*, *Pseudoterranova*, *Hysterothylacium*, and *Porrocaecum* spp. (larval nematodes acquired from saltwater fish).

embedded in eosinophilic granulomas (Figure 11.28). Occasionally, the throat is involved. These large larvae (third stage) measure 1 to 3 cm long or more by 1 mm wide. Histologic sections are characterized by the large body size, moderately thick cuticle, and large lateral cords that extend into the body cavity.

Clinical Disease

The clinical manifestations of anisakiasis are varied, depending on the site of penetration of the larvae. There may be acute gastric presentation, which is the most

Figure 11.28 Scanning electron micrograph of an *Anisakis simplex* larva penetrating human stomach tissue in vitro. Note the tunnel created in the mucosa and the burrow in the submucosa. (Reprinted with permission from J. A. Sakanari and J. H. McKerrrow, Identification of the secreted neutral proteases from *Anisakis simplex*, *J. Parasitol.* 76:625–630, 1990.)

commonly recognized clinical syndrome. Intestinal anisakiasis is also seen, sometimes with acute symptoms and sometimes with a mild, chronic presentation; intestinal disease develops within 2 days after infection and occurs most often in the ilial region. Occasionally ectopic disease occurs, where the larvae are found outside of their usual location, usually elsewhere in the gastrointestinal tract. Within North America, one of the most common presentations has been described as the “tingling-throat syndrome” and is often associated with infection by *Pseudoterranova* larvae. In these cases, the patient may even feel the worm in the oropharynx or proximal esophagus. The patient often coughs up the worm, which is then submitted to the laboratory for identification. Larvae in other true ectopic sites are rare, with the abdominal cavity being the most common; mild symptoms are usually the case, and the larvae may be found at surgery for totally unrelated causes. Apparently *P. decipiens* tends to be less invasive than *A. simplex* and is usually expelled by vomiting. *A. simplex* larvae tend to penetrate the gastrointestinal wall, invading the abdominal cavity.

It is well known that *A. simplex* can cause allergic reactions in sensitized patients. At present, a nonseafood diet is recommended for any patients with any kind of *A. simplex* allergy. However, it appears that patients can tolerate the ingestion of seafood when the parasites are dead and noninfective. It has also been suggested that immunologic methods to detect specific antibodies against *Anisakis* should be used routinely before eosinophilic gastroenteritis is diagnosed as the primary disorder. Data indicate that a Th2 mechanism plays an important role in the inflammatory infiltrate produced by the attachment of parasites to the gastrointestinal wall (26).

There may be nausea or vomiting, often within 24 h after ingestion of raw marine fish (Figures 11.28 and 11.29). Depending on the location of the larvae, infections can mimic gastric or duodenal ulcer, carcinoma, appendicitis, or other conditions requiring surgery. There is usually a low-grade eosinophilia (10% or less) and a positive result for occult blood in the stool.

There are also two reported cases of pulmonary anisakiasis. One of the cases involved a 22-year-old man in Japan, who developed high fever, respiratory distress, and pleural effusion after consumption of raw fish. A parasitic infection was suspected, and various immunoserologic tests were performed. Since extragastrointestinal anisakiasis was strongly suspected, this diagnosis was confirmed by a microplate ELISA and Western blot analysis with a monoclonal antibody (50).

Worms have been recovered or seen after surgery for intestinal obstruction, in eosinophilic granulomas, from a portion of resected small intestine, during gastroscopic examination, in vomitus, and in histologic sections.

Diagnosis

A presumptive diagnosis can be made on the basis of the patient's food history. Definitive identification is based on larval recovery or histologic examination of infected tissue. Although serologic reagents have been developed, they are not commercially available (46). Molecular biology-based methods may also provide some additional diagnostic tools. A rise in the levels of total and specific IgE in the first month after an allergic reaction, consistent with the patient's history of gastroallergic anisakiasis, can provide valuable information, particularly if the parasite cannot be seen by fiber-optic gastroscopy (23).

Treatment

There is no recommended therapy other than removal of the larvae, often through surgery. Gastric endoscopy is usually effective in larval location and removal. If the diagnosis is confirmed and there is no ileus, then surgical intervention can be avoided; the larvae will die and become absorbed within several weeks.

Epidemiology and Prevention

Although the distribution of anisakid larvae in infected marine fish is worldwide, within the United States salmon and Pacific rockfish (red snapper) are implicated most often in transmission. Although *Anisakis* normally has a marine life cycle, *A. simplex* and other anisakid parasites have been found in populations of river otter in the Pacific Northwest. This has been linked to the ingestion of shad during their spawning runs and outmigration. Thus, consumption of shad that are infected with anisakid worms may be confirmed as an emerging parasitic disease of veterinary and human medical concern (81).

Raw, pickled, salted, or smoked marine fish should be avoided. All fish intended for raw, partly cooked, or marinated consumption should be blast-frozen to -35°C (-31°F) or below for 15 h or be normally frozen to -23°C (-10°F) or below for 7 days. This disease could be totally prevented by thorough cooking of all marine fish. Also, sushi served at professional sushi bars and restaurants is rarely responsible for infections. Generally in these settings, fish other than salmon, cod, mackerel, herring, whiting, and haddock are used for sushi preparation.

It is also interesting that even under severe conditions, *P. decipiens* is a well-established parasite of the Antarctic fauna. This cosmopolitan species can complete its life cycle even at subzero temperatures (67).

During the last few years, the finding of allergic hypersensitivity symptoms in anisakiasis has emphasized that this widespread etiologic agent can induce acute symptoms as well as chronic urticaria. Additional reports will certainly confirm the importance of this infection as a potentially growing public health problem (9, 24, 25).

Capillaria hepatica

Capillaria hepatica infection is commonly found in rats, other rodents, and other mammals. Human cases have been reported from various parts of the world, including the United States. Infection occurs via accidental ingestion of eggs from the soil. These eggs hatch and are carried via the portal system to the liver, where the larvae mature in approximately 4 weeks and begin to deposit eggs in the liver parenchyma (Figure 11.30). Symptoms of this infection mimic those of hepatitis, amebic liver abscess, trichinosis, VLM, Loeffler's syndrome, Hodgkin's disease, and histoplasmosis. In the first case reported from Maine, the patient presented with a subacute history of severe abdominal pain, fevers, and weight loss. After open laparotomy for resection of the hepatic mass and treatment with thiabendazole, he recovered; the source of the infection was unknown but was probably accidental ingestion of soil contaminated with mature *Capillaria* eggs. (42)

In a true human infection, no eggs are found in the stool. Diagnosis requires histologic examination. Eggs in liver biopsy specimens can be identified on the basis of their characteristic morphology. The recent development of an IFAT may lend itself to testing of human sera for the detection of early *C. hepatica* infection (7).

Note. In cases of spurious infection, in which infected animal liver has been ingested, *C. hepatica* eggs may be passed in the stool. These eggs measure 51 to 68 μm long by 30 to 35 μm wide and resemble those of *C. philippinensis* (45 by 21 μm), which can be seen in the stool in true human infection (see chapter 10).

Figure 11.30 *Capillaria hepatica* eggs in liver. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) For information on intestinal capillariasis with *Capillaria philippinensis*, see chapter 10.

Thelazia spp.

Thelazia spp. have been recovered from the human conjunctiva and may damage the eye tissues. The worms are 1 to 1.5 cm long and are threadlike. They may be found in the conjunctival sac or lachrymal glands or migrating over the cornea. Symptoms are mild and include excessive lacrimation, itching, or pain (as with a foreign object in the eye). After use of a topical anesthetic, the worms can be safely removed with forceps (63).

Thelazia californiensis has been reported from California, and the larvae are transmitted by a fly belonging to the genus *Fannia*.

Dirofilaria *Dirofilaria* and *Dirofilaria*
Nochtiella spp.

The filarial nematodes are a group of arthropod-borne worms that reside in the subcutaneous tissues, deep connective tissues, lymphatic system, or body cavities of humans. Some adult filarial worms can survive in the human host for many years, causing a number of chronic and debilitating symptoms, including inflammatory reactions. The female worms produce large numbers of larvae called microfilariae, which are highly motile, threadlike prelarvae that in some species maintain the egg membrane as a sheath; these are called sheathed forms, while those that rupture the egg membrane are called unsheathed forms. Once released by the female worm, microfilariae can be detected in the peripheral blood or cutaneous tissues, depending on the species. The microfilariae, which may survive for 1 to 2 years, are not infective for other vertebrate hosts, nor do they undergo any further development in the vertebrate host. The infections are transmitted to humans by the bites of obligate blood-sucking arthropods that had become infected through ingesting larvae (microfilariae) contained in a blood meal obtained from a mammalian host (Table 12.1). Each parasite has a complex life cycle, and human infections are not easily established unless there is intense and prolonged exposure to infective larvae. After exposure, it may take years before significant pathologic changes in the human host are evident. The asymptomatic incubation period can be from 6 months to 3 years; therefore, the chances of eliciting a relevant patient history are rare, at best. For this reason, some physicians recommend routine posttravel serologic testing for patients who have been exposed, even years before.

Depending on the species, microfilariae may exhibit periodicity in the circulation. A circadian fluctuation in which the largest number of microfilariae occurs in the blood at night is called nocturnal periodicity; these microfilariae circulate in the peripheral circulation between 9 p.m. and 2 a.m. Some species are nonperiodic or diurnal. In the latter form, the microfilariae circulate at somewhat constant levels during the day and night. Subperiodic or nocturnally subperiodic microfilariae are those that can be detected in the blood throughout the day but are detected at higher levels during the late afternoon or at night. Only a small number of the total microfilarial population is found in the circulating blood, even at peak levels for microfilariae normally found in the blood. When not in the peripheral blood, the microfilariae are found primarily in the capillaries and blood vessels of the lungs. The basis for filarial periodicity is unknown; however, it may be an adaptation to the biting habits of the relevant vector.

Table 12.1 Characteristics of species causing human filariasis

Species	Distribution	Vector	Location of adult	Features of microfilariae				
				Location	Periodicity	Sheath and appearance	Length (μm) (range)	Tail nuclei
<i>Wuchereria bancrofti</i>	Tropics and subtropics worldwide; mainly India, China, Indonesia (nocturnal); Eastern Pacific (subperiodic)	Mosquito (<i>Culex</i> , <i>Aedes</i> , <i>Anopheles</i>)	Lymphatic	Blood, hydrocele fluid	Nocturnal, subperiodic	Present; graceful, sweeping curves; blue/pale with Giemsa	260 (244–296)	Do not extend to tip of tail; tail tapers to delicate point; terminal nucleus elongate
<i>Brugia malayi</i>	Southeast Asia, Indonesia, India (nocturnal); Indonesia, Southeast Asia (subperiodic)	Mosquito (<i>Mansonia</i> , <i>Anopheles</i> , <i>Coquilletidia</i>)	Lymphatic	Blood	Nocturnal, subperiodic	Present; stiff, with secondary kinks; pink with Giemsa	220 (177–230)	Subterminal and terminal; tail often constricted between 2 terminal nuclei; terminal nucleus round
<i>Brugia timori</i>	Islands of Timor and Lesser Sunda in Indonesia	Mosquito (<i>Anopheles</i>)	Lymphatic	Blood	Nocturnal	Present; tapering gradually; nearly invisible	310 (290–325)	Subterminal and terminal; no tail constriction between 2 terminal nuclei; terminal nucleus elongate to oval
<i>Loa loa</i>	Africa	Deerfly (<i>Chrysops</i>)	Subcutaneous	Blood	Diurnal	Present	275 (250–300)	Continuous to tip of tail; pointed tail; terminal nucleus elongate
<i>Mansonella perstans</i>	South and Central America, Africa	Biting midge (<i>Culicoides</i>)	Body cavities, mesentery, perirenal	Blood	None	Absent	195 (190–200)	Continuous to tip of tail; bluntly rounded tail
<i>Mansonella ozzardi</i>	South and Central America, Caribbean	Biting midge (<i>Culicoides</i>), blackfly (<i>Simulium</i>)	Subcutaneous, possible body cavities	Blood	None	Absent	200 (173–240)	Do not extend to tip of tail; pointed tail
<i>Mansonella streptocerca</i>	West and Central Africa	Biting midge (<i>Culicoides</i>)	Subcutaneous	Skin	None	Absent	210 (180–240)	Single row to tip of tail, tail curved “shepherd’s crook”
<i>Onchocerca volvulus</i>	South and Central America, Africa	Blackfly (<i>Simulium</i>)	Subcutaneous	Skin	None	Absent	254 (221–287)	Do not extend to tip of tail; finely pointed tail
<i>Dirofilaria immitis</i>	Japan, Australia, United States	Mosquito	Pulmonary nodules (coin lesion)	Immature worms have been found in the lungs of humans				
Other <i>Dirofilaria</i> spp.	See comment	Mosquito	Subcutaneous tissues	<i>D. tenuis</i> is found in raccoons, <i>D. repens</i> is found in dogs and cats; subcutaneous dirofilariasis has been found in the United States, Africa, Asia, Europe, and South America; rare gravid <i>D. tenuis</i> worms have been found in humans.				

Microfilarial periodicity may be altered by reversing the working and sleeping habits of the host. This reversal may take up to a week to complete. For species exhibiting nocturnal periodicity, it has been noted that the insect vector bites primarily at night, whereas in areas of nonperiodic disease, the vector bites mainly during the day.

Basic Life Cycle

All of the human filarial infections have the same basic life cycle, including five larval molts, three in the insect vector and two in the human host. Infection begins with the bite of an infected arthropod vector.

1. Infective L3 larvae are deposited into the skin or blood of the human via the bite of the vector. Larvae pass through the puncture wound and then reach the lymphatic system.
2. A 6- or 12-month period is required for sexual maturity to occur; during this time, the parasite undergoes two molts and the adult worm develops (L5). The adult worms reside in the lymphatics or the lymph nodes.
3. The adult female worm gives birth to L1 larvae called microfilariae. Up to 50,000 microfilariae per day can be produced by the female worm.
4. Microfilariae are ingested by the arthropod vector; two molts occur, and the infective L3 larvae develop and are capable of infecting the human host.

The Endosymbiont

Infection with *Wuchereria bancrofti*, *Brugia malayi*, or *Brugia timori* causes lymphatic filariasis, while *Onchocerca volvulus* causes “river blindness,” which can lead to severe ocular involvement and blindness. These parasites contain an endosymbiotic alpha-proteobacterium of the genus *Wolbachia*; these bacteria are *Rickettsia*-like, matrilineally inherited, obligate intracellular bacteria. They are required for larval worm development and adult worm viability and fertility. *Wolbachia* spp. have also been implicated in the pathogenesis of filariasis, including inflammatory responses related to filarial chemotherapy and death of the parasites. These bacteria have also been linked to the onset of lymphedema and blindness (40, 55, 116). Female adult worms carry the largest load of bacteria, most of which are concentrated around the reproductive structures.

Filarial and *Wolbachia* antigens activate the release of proinflammatory and chemotactic cytokines, which induce cellular infiltration and amplification of the inflammatory process. Toll-like receptors (TLRs), especially TLR4, appear to play a role in this process. Repeated and extensive exposure to filarial and *Wolbachia* antigens can

lead to scarring and fibrosis in lymphatic filariasis and skin thickening and corneal scarring in onchocerciasis.

Like other bacteria in the family Rickettsiaceae, *Wolbachia* is sensitive to the tetracyclines (tetracycline and doxycycline) and to azithromycin and rifampin. The use of anti-*Wolbachia* antibiotics is promising as a means to improve the success of other mass treatment programs (55). In one study using doxycycline treatment on the major cause of lymphatic filariasis, *Wuchereria bancrofti*, an 8-week course was found to be a safe and well-tolerated treatment for lymphatic filariasis, with significant activity against adult worms and microfilaraemia (117).

Human Pathogens

There are eight filarial species in which the human is the definitive host, six of which are thought to be pathogenic. *W. bancrofti*, *B. malayi*, and *B. timori* all cause lymphatic filariasis. *Loa loa* causes Calabar swellings and allergic manifestations. *Mansonella streptocerca* causes skin disease. *O. volvulus* causes dermatitis and eye lesions. *Mansonella ozzardi* and *Mansonella perstans* are thought to be nonpathogenic.

An estimated 300 million people, primarily in India, Southeast Asia, and sub-Saharan Africa, live in areas where lymphatic filariasis is endemic, and at least 130 million people are probably currently infected (25). Globally, approximately 2 billion people are at risk for lymphatic filariasis (31). It is estimated that genital disease is present in 25 million infected men and that lymphedema, or elephantiasis, of the leg is present in 15 million people, most of whom are women. Approximately 30 million people are exposed to onchocerciasis, with probably at least 18 million being infected, 270,000 of whom are blind. Conditions associated with human filariasis have a tremendous impact on the physical health, economic well-being, and quality of life of infected persons and the communities in which they live.

It is interesting that in some areas of endemic infection, people do not accept the mosquito theory of transmission but believe in other physical, spiritual, and hereditary causes of lymphatic filariasis. Manifestations are often treated with herbal preparations that are used orally, smeared on the affected parts after scarification, or given as an enema. Although the etiology is thought to be different, the perception of the developmental process of elephantiasis closely parallels medical understanding (4).

Wuchereria bancrofti

Ancient Egyptian, Hindu, and Persian physicians (600 BC) were the first to note elephantiasis, which was probably due to *W. bancrofti*. Demarquay discovered microfilariae

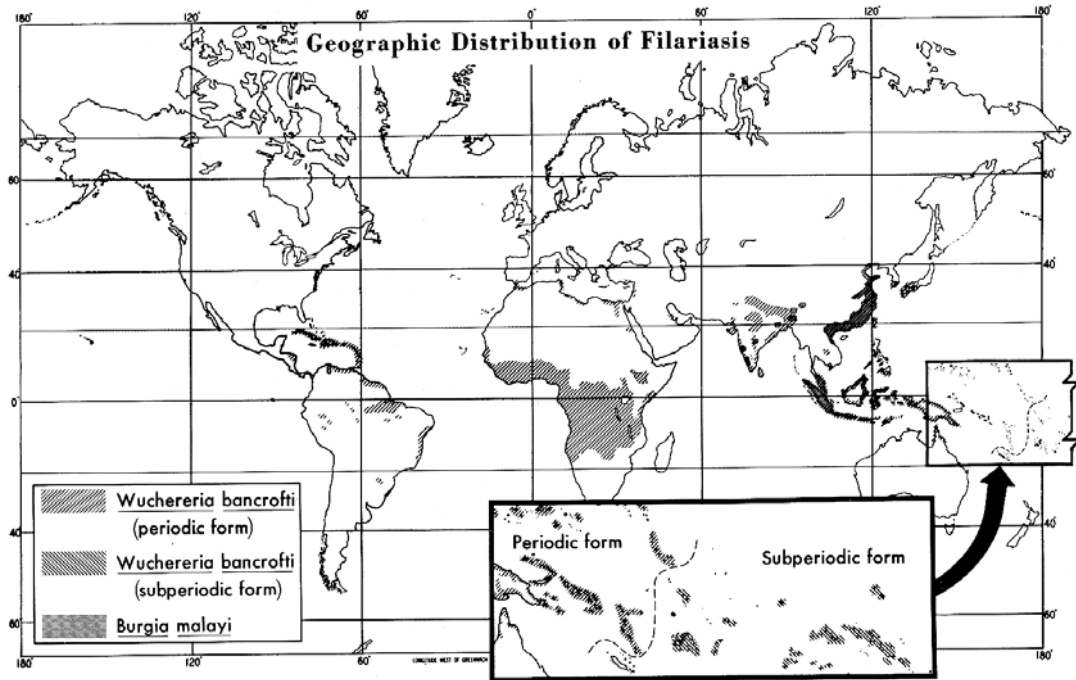

Figure 12.1 Distribution of *Wuchereria bancrofti* and *Brugia malayi* infections in humans. (Armed Forces Institute of Pathology photograph.)

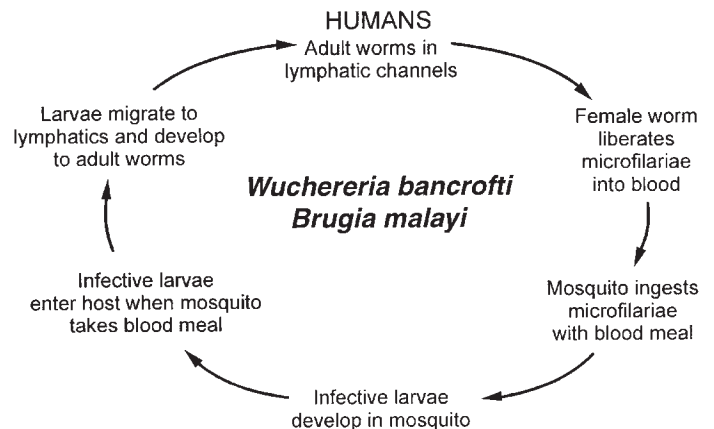

in hydrocele fluid in 1863, Wucherer found organisms in chylous urine in 1868, Lewis found the microfilariae in blood in 1872, and the adult worm was found in a lymphatic abscess by Bancroft in 1872. By 1900, the entire life cycle of *W. bancrofti* had been elucidated; however, it was Patrick Manson’s discoveries that showed for the first time that an arthropod was a vector for a parasitic disease. He had clarified the uptake of microfilariae by *Culex* mosquitoes and their subsequent maturation to infective forms. *W. bancrofti* infections are widely distributed throughout the tropics and subtropics (Figure 12.1). Humans are the only known reservoir hosts. At one time

there was an endemic focus in the region of Charleston, S.C., which was probably related to the slave trade.

Life Cycle and Morphology

Humans and mosquitoes are necessary to complete the life cycle of *W. bancrofti* (Figure 12.2). The intermediate host, a mosquito, acquires the infection by ingestion of microfilariae in the blood meal. The major vectors in urban and semiurban areas are culicine mosquitoes, while anophelines are involved in the rural areas of Africa and *Aedes* is found in the Pacific Islands. An individual within an area of endemic infection is exposed to approximately

Figure 12.2 Life cycles of *Wuchereria bancrofti* and *Brugia malayi*.

50 to 300 infectious larvae each year. Within hours after their arrival in the mosquito stomach, the microfilariae lose their sheaths. The larvae then penetrate the wall of the gut, migrate to the thoracic muscles, and develop into infective (filariform) larvae over a period of 7 to 21 days. The larvae migrate to the labella (distal end of the proboscis) of the mosquito and enter the skin of the definitive host through the puncture wound when a blood meal is taken. The infective larvae enter the peripheral lymphatic system and migrate to lymph vessels distal to the lymph nodes, where they grow to mature female and male adults and mate. Thousands of developing embryos can be found within the uteri of the female. Microfilariae are released from the gravid female and can be detected in the peripheral circulation in 8 to 12 months postinfection; however, filariasis without microfilaremia is not uncommon.

Adult worms are minute and threadlike, have a smooth cuticle, and are found in the lymph nodes and lymphatic channels. Adult males are about 40 mm long by 0.1 mm in diameter. Adult females are 80 to 100 mm long by 0.24 to 0.30 mm in diameter. To perpetuate their life cycle, sheathed microfilariae invade the blood; sometimes they can also be found in hydrocele fluid and chylous urine. The microfilariae range from 244 to 296 μm long and actively move about in the lymph or blood. The microfilaria has a sheath, and the body nuclei do not extend to the tip of the tail (Figures 12.3 to 12.6). Stains such as Giemsa, Wright's, or Delafield's hematoxylin have been used to help differentiate morphological features and thus identify the microfilariae to the species level. Stained microfilariae are about 245 to 300 μm long.

In most regions of the world where filariasis is endemic, *W. bancrofti* microfilariae exhibit periodicity, either nocturnal or subperiodic. In areas of nocturnal

Figure 12.3 *Wuchereria bancrofti* microfilaria in a peripheral thick blood film. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*. Photograph courtesy of L. Garcia.)

Figure 12.4 *Wuchereria bancrofti* microfilaria. (Upper) Head of microfilaria; note the sheath and very clearly delineated nuclei. (Lower) Tail of microfilaria; note that the sheath and the tail nuclei do not go all the way to the end of the tail. periodicity, the microfilariae are in their highest concentrations in the circulating blood at night, generally between 9 to 10 p.m. and 2 to 4 a.m., and are scant or absent during the daylight hours. A subperiodic form of filariasis occurs in the Pacific region, where humans exhibit a microfilaremia all the time but the largest numbers are detected between noon and 8 p.m.

Clinical Disease

Lymphatic Disease. Estimates of 82 to 142 days for the prepatent period have been obtained from experimental human infections, and manifestations of filariasis can range from none to severe, depending on host factors and parasite strains (Algorithm 12.1). Early symptoms of filariasis include high fevers (filarial or elephantoid fever), lymphangitis, and lymphadenitis. Filarial fever usually begins with a high fever and chills that last 1 to 5 days before spontaneously subsiding, and in many cases, patients with filarial fevers do not have a microfilaremia. The lymphangitis extends in a distal direction from the affected nodes where the filarial worms reside

Figure 12.5 Characteristics of human microfilariae. (A) *Wuchereria bancrofti*; (B) *Brugia malayi*; (C) *Onchocerca volvulus*; (D) *Loa loa*; (E) *Mansonella perstans*; (F) *Mansonella streptocerca*; (G) *Mansonella ozzardi*. (Illustration by Nobuko Kitamura.)

(Figure 12.7). Lymphadenitis and lymphangitis develop in the lower extremities more commonly than in the upper. However, in some areas of endemic infection such as northeastern Brazil, factors other than filarial worms can be the cause of subclinical pathology of the leg lymphatics and are not specific for bancroftian filariasis (71). In addition to limbs, there can be genital (almost exclusively a feature of *W. bancrofti* infection) and breast involvement. The lymph nodes most often affected are the epitrochlears and femorals. The nodes are firm, discrete, and tender and tend to remain enlarged, while the lymph

Figure 12.6 Key to microfilariae commonly found in the blood.

vessel is indurated and inflamed. The overlying skin is tense, erythematous, and hot, and the surrounding area is edematous. Occasionally, abscesses form at the lymph node or along the lymphatic system and may take 2 to 3 months to heal.

In lymphatic vessels that harbor the worms, an inflammatory reaction includes the infiltration of plasma cells, eosinophils, and macrophages in and around the affected vessel. Repeated inflammatory attacks lead to hyperplasia of the endothelium in addition to cellular infiltration. There is an increase in hydrostatic pressure resulting from the damage to the lymph vessel, which causes an increase in vessel wall permeability. The chronic leakage of fluid containing high levels of protein into the surrounding tissues (lymphedema) results in the hard or brawny edema, with thickening and verrucous changes in the skin, also known as elephantiasis (Figure 12.8). Histologic examination of the skin shows hyperkeratosis and acanthosis, with scarring and a loss of dermal elasticity. Regional lymph nodes proximal to the worms eventually become fibrotic, and the proximal lymph vessels become stenotic and obstructed, leading to the development of collateral lymph channels. Elephantoid tissue is a mixture of lymph and fat in a matrix of fibrotic tissue. There is the danger of secondary bacterial, particularly streptococcal, or fungal infection in patients with lymph stasis. A specific syndrome, acute dermatolymphangioadenitis, is not caused by filarial worms per se but probably results from secondary bacterial infections (27).

Obstructed Lymphatics. Obstructed genital lymphatics may lead to hydrocele or scrotal lymphedema (112). In one area of endemicity, approximately 11% of those

Figure 12.7 (Upper) *Wuchereria bancrofti* female in lymph node (cross section). (Armed Forces Institute of Pathology photograph.) (Lower left) Inguinal nodes enlarged due to filariasis. (Adapted from the Public Health Image Library, Centers for Disease Control and Prevention.) (Lower right) Scrotal lymphangitis due to filariasis. (Adapted from the Public Health Image Library, Centers for Disease Control and Prevention.)

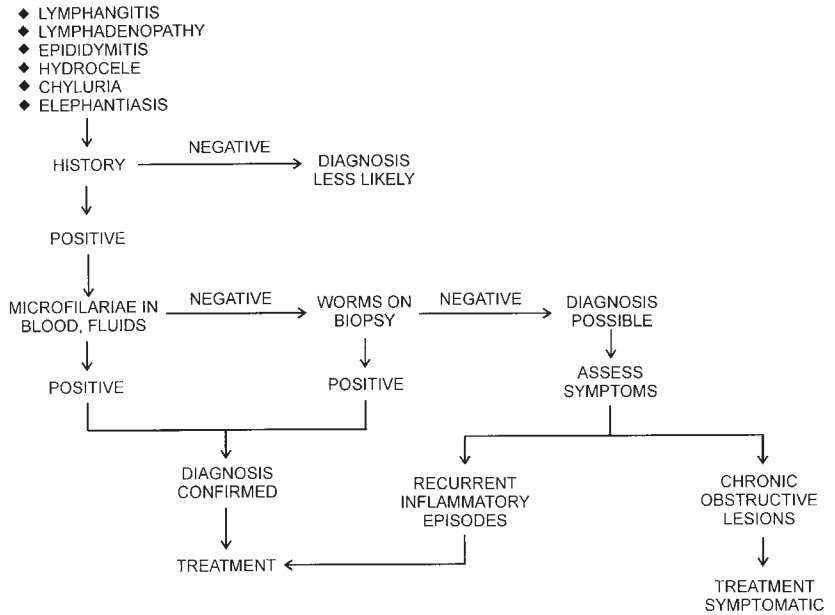

at risk developed lymphedema (112). Many of these individuals progressed through sequential phases: uninfected, microfilaremic, and amicrofilaremic to irreversible obstructive lymphatic pathology. Early lymphatic damage was noted in 90% of the men at risk presenting with hydrocele, whereas 90% of the women at risk had no detectable clinical signs of filariasis on physical examination.

Lymph Varices. Lymph varices near the scrotal surface are readily seen and may rupture. Obstruction of the retroperitoneal lymphatics may cause the renal lymphatics to rupture into the urinary tract, leading to chyluria. Chyluria

is often prominent in the morning and is intermittent. Almost half of the microfilaremic patients have renal abnormalities characterized by proteinuria and hematuria.

Acute Filarial Lymphangitis. Acute filarial lymphangitis occurs when the adult worms die, leading to severe localized inflammation. This syndrome appears to be uncommon in untreated individuals (28). The dead worms may be absorbed, or they may calcify or produce abscesses. The inflammatory reaction evoked by the filarial infection is a result of host reactions to the products of the developing worm or its death. Microfilariae do not appear to be responsible for the major sequelae

BANCROFTIAN AND MALAYAN FILARIASIS

Algorithm 12.1 Bancroftian and Malayan filariasis.

of lymphatic filariasis. The immune response to infection varies considerably, with the antibody response being lowest in asymptomatic microfilaremic patients and highest in amicrofilaremic patients. Chronic disease is also strongly associated with acute-disease incidence, and microfilaremia has a statistically significant association with acute disease in the leg, arm, and breast but not the scrotum (7).

Amicrofilaremic Patients. Some patients may harbor adult worms without a peripheral microfilaremia, or the microfilaremia may be so low that it cannot be detected by the usual laboratory procedures. Other patients may have a heavy microfilaremia but be clinically asymptomatic. Many individuals who are thought to be microfilaremic but clinically asymptomatic may have symptoms of elephantiasis. Microfilariae are more easily detected in individuals with hydrocele than in individuals with symptoms of elephantiasis. Even though microfilaremia appears to be rare in children younger than 5 years, children born to mothers harboring microfilaria are more likely to be microfilaremic than are children born to a-filaremic mothers, suggesting in utero acquisition of tolerance.

Tropical Eosinophilia. Many patients infected with lymphatic filaria do not have microfilaremia. Some may be experiencing tropical eosinophilia (Weingarten's) syndrome. This syndrome is characterized by pulmonary

infiltrates, peripheral eosinophilia, cough, asthmatic attacks (especially at night), and a history of prolonged residence in the tropics. These patients have high peripheral eosinophilia counts, high immunoglobulin E (IgE) levels, and high antifilarial antibody titers. Microfilariae are not detected in the peripheral blood but may be found in lung biopsy specimens. On treatment with diethylcarbamazine (DEC), there is usually a prompt response and the symptoms disappear.

Infection in Women of Reproductive Age. In a study reviewing pretreatment microfilarial densities, there was a reduction among women of approximately reproductive age; this reduction was statistically significant. However, a comparison of pregnant women and controls showed no evidence that the reduction was specifically related to pregnancy. It has been suggested that the observed reduction in microfilarial intensity may result from hormonal changes associated with female reproduction, possibly in combination with other factors (6).

Immunologic Responses. Asymptomatic microfilaremic individuals generally have a marked Th1 hyporesponsiveness but a strong Th2 response. In contrast, amicrofilaremic individuals with lymphatic pathology have strong Th1 and Th2 responses. There is a decrease in the gamma interferon (IFN- γ) level and a significant rise

Figure 12.8 *Wuchereria bancrofti* elephantiasis of lower extremities. (Panel A from A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman; panel B adapted from the Public Health Image Library, Centers for Disease Control and Prevention.)

in interleukin-4 (IL-4) production in infected patients, suggesting a profound form of anergy. In infected individuals, the levels of IgG and IgE are elevated. The highest levels of IgE were found in microfilaremic individuals with acute manifestations of filariasis or hydrocele, while the highest concentrations of parasite-specific IgE were found in amicrofilaremic individuals. This may suggest a protective effect for IgE, because the highest ratios of specific to total IgE are found in patients with tropical pulmonary eosinophilia. The predominant serum antibody response is IgG4. Filarial antigenemia, IgG4 antibody, and household infection are significant risk factors for microfilaremia (123). The ratio of IgG4 to IgE is highest in asymptomatic microfilaremic individuals, whereas chronic disease (elephantiasis) is associated with elevated levels of IgG1 (3, 68). Chronic disease is associated with a specific IgG1 to IgG3 response rather than a Th1 or IgE response. IgG4 levels decline with successful therapy. For signs and symptoms to develop, prolonged exposure to infected mosquitoes is required, and even then the host response is variable.

In French Polynesia, individuals harboring adult worms had a higher filaria-specific IgG4 level but lower IgG3 and IgE levels than did individuals without adult worms, independent of the presence of microfilariae. Low filaria-specific IgG1 and IgG2 levels were associated with the presence of microfilariae but independent of the presence of adult worms. The filarial antibody responses were associated with the parasitological status of individuals

but not with clinical symptoms such as hydrocele or limb lymphangitis or elephantiasis. The reduction of filaria-specific immunoglobulin levels was higher after treatment with DEC than with ivermectin, a finding that reflects drug efficacy for the adult worms (76). There appears to be a clear association between IgG2 indirect fluorescent-antibody positivity and a negative microfilarial status and negative specific circulating-antigen status. These findings suggest that specific antisheath antibodies are associated with an immunologic resistance mechanism that is expressed with highest prevalence in young individuals prior to the development of patent microfilaremia (109).

Children and Adolescents. There is evidence that children acquire infection early in life and that antifilarial antibody responses may peak in early childhood. Apparently, helminth-specific immune responses acquired during gestation persist into childhood, and this prenatal sensitization biases T-cell immunity induced by BCG vaccination away from IFN- γ responses associated with protection against mycobacterial infection (69).

Often, little attention is paid to the signs and symptoms of bancroftian filariasis in childhood. There appears to be a predominance of lymph node involvement, where the adult worms are located in the vessels of draining lymph nodes, often the inguinal nodes. There are no signs of inflammation in the overlying skin. In the adult population, adult worms are usually found in extranodal lymphatic vessels.

Certainly, in areas of endemic infection, filarial infection should be considered in children and adolescents with adenopathy. Ultrasound and other noninvasive methods should be considered; biopsy is probably not necessary (33).

Diagnosis

Routine Blood Tests. Filarial infections should always be considered in the differential diagnosis of individuals who have resided in or migrated from areas where filariasis is endemic and have had a significant insect bite history. In areas of endemic infection around the world, the presumptive diagnosis of filarial infections is frequently based on clinical evidence; however, definitive diagnosis is based on the detection of microfilariae, primarily in the blood. Microfilariae may also be found in hydrocele fluid and urine, particularly in patients who have high microfilaremias or who have been treated recently with DEC.

When a patient is suspected of having filariasis, the clinical history helps determine the most appropriate specimen and collection time. The optimal time for drawing blood to detect nocturnal periodic *W. bancrofti* infections is between 10 p.m. and 4 a.m. Blood used to detect subperiodic *W. bancrofti* may be drawn any time, although peak microfilaremias occur in the late afternoon. Finger prick, earlobe, or venous blood (using EDTA anticoagulant [purple-top tube]) may be taken for direct wet, thin, and thick blood smears. Blood films may be stained with Giemsa or Delafield's hematoxylin stain; however, Giemsa stain does not stain the microfilarial sheath adequately, although hematoxylin stains do so (see chapter 31). Examination of a thin blood film for microfilariae should include low-power review of the entire film, not just the feathered edge. Sheathed microfilariae often lose their sheath when drying on thick films.

Because of the insensitivity of the wet, thin, and thick blood films, larger blood volumes are recommended for examination to detect low microfilaremias. Also, it may be somewhat impractical to obtain blood from a patient late at night or in the early-morning hours. Microfilariae concentrate in the peripheral capillaries; therefore, the numbers of microfilariae in finger prick blood may be similar to those in venous blood. In certain areas, a primary problem with obtaining venous blood is the unwillingness of people to submit to phlebotomy.

Concentration Methods. The Knott technique allows up to 1 ml of blood to be concentrated per 10 ml of 2% formalin so that the sediment can be examined as a wet preparation or stained for microfilariae. Another concentration technique involves the use of polycarbonate filters

(Nucleopore) to trap microfilariae on the filter after the red blood cells have been lysed (30). The 3- to 5- μ m-pore-size filters may be examined directly on a microscope slide because the filters are transparent when wet. Infection has been rapidly diagnosed by the detection of microfilaria using a microhematocrit tube coated with acridine orange (QBC method) (see chapter 31). The major disadvantage of the QBC method is the necessity for a fluorescence microscope.

In addition to concentration techniques to detect low levels of microfilariae, a provocative test has been used to induce microfilariae to appear in the blood through treatment with a single dose of DEC. Blood should be drawn within 15 min to 1 h after administration of DEC. A fall rather than a rise in microfilaremia may be detected with the subperiodic strain of *W. bancrofti* after administration of DEC.

Only the microfilariae of *W. bancrofti*, *B. malayi*, and *L. loa* have sheaths; all others are nonsheathed. In addition to the presence or absence of a sheath, the body nuclei should be closely examined for their morphology and location in the tail of the microfilaria. Histopathologic examination of a tissue biopsy specimen may be used for diagnosis to reveal adult worms and microfilariae. Patients who have been treated for lymphatic filariasis should have blood specimens reexamined for microfilariae 2 to 6 weeks posttherapy.

Serologic Methods. A wide variety of serologic tests have been used for diagnostic and epidemiologic purposes. Except for patients not native to the area of endemicity, immunodiagnostic tests are of limited value. Current tests lack both sensitivity and specificity, and most people from the region of endemicity have a positive serologic response. This response may be due to exposure to non-human filarial antigens from infected mosquitoes; also, filarial antigens may cross-react with antibodies to other parasitic diseases. The immune response of the filaria-specific immunoglobulin IgG4 is considerably increased in active filarial infections. The detection of IgG4 antibodies also reduces the cross-reactivity of nonfilarial antibodies (120). The IgG2 level appears to be increased in patients with elephantiasis (94). Studies also suggest that specific antisheath antibodies are associated with an immunologic resistance mechanism that in the endemic community is expressed with highest prevalence in young individuals before development of patent microfilaremia (111). Patients with tropical pulmonary eosinophilia have a marked IgE response in addition to elevated eosinophilia.

The recombinant antigen BmR1 has been extensively employed in both enzyme-linked immunosorbent assay and immunochromatographic rapid dipstick (*Brugia* Rapid) formats for the specific and sensitive detection of

IgG4 antibodies against the lymphatic filarial parasites *B. malayi* and *B. timori*; however, in sera of individuals infected with *W. bancrofti* the IgG4 reactivity to BmR1 is variable and thus is not recommended for detection (34, 78). A rapid-format, qualitative flowthrough immunofiltration test has been developed for the identification of total IgG antibodies to recombinant filarial antigen WbSXP-1. This test system employs colloidal gold-protein A reagent as the antibody capture reagent. In a study of 1,230 sera, the sensitivity of the test was 90.8% for patients with proven brugian filariasis ($n = 70$) and 91.4% for patients with proven bancroftian filariasis ($n = 140$). This rapid test is performed with reagents that can be stored at room temperature, is user friendly, and is applicable for field use as an initial screening method. It is also recommended for epidemiologic monitoring of bancroftian and brugian filarial infections (11).

Antigen Detection. Because of the lack of sensitivity of direct-detection methods and problems with obtaining blood specimens within correct time frames, detection of circulating antigens has been used diagnostically (97). Antigen detection has also been used to monitor therapy. Assays for the detection of circulating antigen of *W. bancrofti* rely on two diagnostic tests, an Og4C3 enzyme-linked immunosorbent assay (Trop Bio Og4C3 antigen test; Trop Bio) and an immunochromatographic card test (NOW ICT; Binax). The sensitivity of the Trop Bio test is close to 100%, while the specificity is about 99 to 100%. The ICT test has a sensitivity of 96 to 100% and a specificity of 95 to 100% (109, 122). In looking at the possibility of false-positive test results with the NOW card test, it is clear that the test performs well if the card results are read at the 10-min time limit; false positives may occur if the cards are held and read after 10 min (110). Studies using both of these methods emphasize the benefits of testing to determine the estimation of circulating filarial antigen in a population (23, 82, 90).

PCR Amplification. PCR assays are becoming useful diagnostic tools because they can discriminate between past and present infection and can be used to monitor therapy and to detect and differentiate multiple filarial infections (35, 53, 66, 73). An evaluation of the diagnostic capability of PCR using diurnally collected sputum from patients with bancroftian filariasis has been carried out; the data were excellent, and this approach appears to have great potential (1). A seminested PCR has been used to detect *W. bancrofti* in carriers and in long-term storage blood samples, with no cross-reactivity related to *B. malayi*, *Plasmodium falciparum*, or *P. vivax* (58). A PCR-restriction fragment length polymorphism (PCR-RFLP)-

based method to detect and differentiate a broad range of filarial species in a single PCR has recently been developed. This approach provides differentiation to the species level for *W. bancrofti*, *B. malayi*, *B. pahangi*, *Dirofilaria immitis*, and *D. repens*. The PCR-RFLP of ITS1 rRNA genes cloned from *W. bancrofti*, *B. malayi*, and *B. pahangi* as universal priming sites will be useful in diagnosing and differentiating filarial parasites in humans, animal reservoir hosts, and mosquito vectors (79).

Ultrasonography. Infection with *W. bancrofti* not only affects the structure and function of lymphatic vessels but also is associated with extralymphatic pathology and disease. Since it is now possible to detect living adult worms by ultrasonography, a great deal of emphasis is placed on lymphatic pathology (32). However, the finding of renal damage in asymptomatic microfilaremic carriers has led to increased recognition of the importance of extralymphatic complications in bancroftian filariasis (28, 29). Filarial pathology of the male genitalia is apparently underreported if physical examination alone is used. Compared with ultrasonography, the sensitivity of physical examination in one study was only 44.3% (119). Ultrasonography is also very helpful in assessing lymphatic filariasis in children after treatment and in women (41, 70). In one study, the surprisingly large number of worm nests detectable in microfilaremic women suggests that ultrasonography would be appropriate for diagnosis and posttherapy monitoring of female patients infected with *W. bancrofti* (70). Often the “filaria dance sign” can be seen; this is a characteristic pattern of movement exhibited by adult worms that has been described as rapid and random.

KEY POINTS — LABORATORY DIAGNOSIS

Filariasis

1. A travel and geographic history should be obtained to maximize the best type of specimen and optimal collection time for the filarial infection suspected.
2. In addition to multiple thin and thick blood films, Knott or membrane concentration techniques should be used to detect microfilariae normally found in the peripheral blood.
3. It is important to examine every portion of the thin and thick blood films; microfilariae are often found at the outside edges or in the original drop from which the thin film was “pulled.”
4. Giemsa stain does not stain the *W. bancrofti* sheath as well as a hematoxylin-based stain (Delafield’s hematoxylin).
5. Serologic tests are more meaningful in patients

who have not resided in the areas of endemicity for extended periods.

6. Antigen detection tests are commercially available and may be very helpful in the detection of circulating filarial antigens.
7. PCR may prove to be valuable in the diagnosis of lymphatic filariasis; however, these procedures are often limited to research facilities.
8. Ultrasonography has proven to be very valuable in assessing lymphatic filariasis in both adults and children; this approach can be much more sensitive than a physical examination alone.

Treatment

It is recognized that some patients with lymphatic filariasis may be asymptomatic; however, if they have microfilaria in the blood, they probably have subclinical disease. Early treatment of these patients is recommended to prevent additional disease manifestations such as lymphatic damage. For patients who appear to have no circulating microfilariae but have a confirmed presence of adult worms, treatment with DEC and albendazole is recommended (56).

Diethylcarbamazine. The two important drugs in the treatment of filariasis are DEC and ivermectin, which may be used in combination with albendazole (see chapter 25) (Table 12.2) (42, 43). Treatment differs depending on the objective, interruption of transmission by microfilaria suppression or treatment of an individual patient. DEC, a piperazine derivative, rapidly kills microfilariae and can kill some but not all adult worms. The effect on adult worms is apparently related to the total dose given, with spaced doses over a period of months to years probably being superior to a more concentrated dose. DEC can be administered orally. Side effects from rapid destruction of microfilariae and possibly adult worms include fever, urticaria, and lymphangitis. These reactions may be controlled by administering antihistamines or by giving low initial doses of DEC and gradually increasing the dose. Nonspecific adverse reactions to DEC treatment include headache, nausea, vomiting, generalized malaise, and vertigo. These symptoms develop within a day or two and may last for several days. A wide variety of treatment regimens have been used to optimize the antifilarial activity of DEC (72, 96). In areas of endemicity, prolonged low-dose administration has successfully reduced transmission and pathologic sequelae (123). Drug combinations containing DEC are the most effective against microfilarial prevalence and intensity relative to single drugs or other combinations (118).

Ivermectin. Ivermectin (Mectizan; 22,23-dihydroavermectin B₁) is a semisynthetic macrocyclic lactone derivative of avermectin. The drug is taken orally and has been successfully used either alone or in combination with DEC to treat *W. bancrofti* infections (65, 99, 121). The mechanism of action involves chloride ion permeability. Few severe side effects, good microfilaricidal activity, and single-dose oral administration have encouraged its use. In individuals with higher microfilaremia levels, more severe side effects include fever, headache, myalgia, sore throat, and cough. Although there is a rapid and complete clearance of microfilariae in patients treated with one dose of ivermectin in contrast to those treated with DEC, the microfilaria counts begin to rise again after a few months (20). The rate of increase is variable and may be related to the variability of the parasite or host response. At higher therapeutic doses, ivermectin may have cidal activity against the adult worms. It appears that albendazole given in combination with ivermectin as a single dose is more effective in clearing microfilariae than is ivermectin alone and also has the benefit of reducing intestinal helminth infections (12, 59). A significant decrease in the prevalence of *W. bancrofti* infection in mosquitoes has been seen following the addition of albendazole to annual ivermectin-based mass treatments in Nigeria (101).

Tissue Removal and Hydrocele Drainage. Surgical removal of elephantoid tissue has been satisfactory for scrotal elephantiasis but not for effects on the extremities. The use of elastic pressure bandages may help to reduce the induration, but the underlying fibrosis is unaffected. Hydrocele drainage can be repeated or managed surgically; drug treatment should be emphasized for patients with active infection.

Posttherapy Allergic Responses. Microfilaricidal chemotherapy with either DEC or ivermectin induces an acute inflammatory reaction due to an IL-5-dependent increase of eosinophil numbers, eosinophil degranulation, and elevated levels of proinflammatory cytokines such as IL-6, tumor necrosis factor alpha, and IFN- γ . Long-term effects of drug-induced clearance of microfilariae include a reversal of the parasite-specific hyporesponsiveness with restoration of Th1 cell-mediated responses and resistance to reinfection (124). Also, high levels of nitrite and nitrate in serum are released during microfilarial clearance, and sustained elevated levels have been observed 6 months after chemotherapy, suggesting a role of nitric oxide (NO) in the elimination of microfilariae. There is also evidence to indicate that although microfilaremic individuals may regain the ability to produce IFN- γ to parasite antigens posttreatment, they subsequently become hyporesponsive to microfilaria-containing antigens; this appears to be

Table 12.2 Treatment options for bancroftian filariasis

Drugs	Findings	Comments	Reference
DEC plus iodine added to salt	Reduced microfilaremia and transmission to low levels	Well accepted by community, no reported side effects	43
DEC, mass administration: 3 options	Long-term effect on microfilarial intensities	At the end of 10 yr, community microfilaremia levels approached pretreatment levels; suppressive effect most pronounced in (iii)	72
(i) 12-day treatment	Only 11% of pretreatment		
(ii) Semiannual single-dose treatment	Only 13% of pretreatment		
(iii) Monthly low dose	Only 2% of pretreatment		
DEC, single dose, 6 mg/kg	Reduced blood microfilarial counts, clearance of 69% of subjects; reduced filarial antigen levels	Low-endemicity setting; mass treatment with DEC alone may be sufficient to interrupt transmission	96
DEC plus albendazole	Combination is highly effective against adult <i>W. bancrofti</i> ; reduced filarial antigen levels	Healthy Egyptian adults with microfilaria counts of >80/ml	56
DEC plus albendazole	Albendazole and DEC effective in treating intestinal helminths; more effective than DEC alone in treating <i>W. bancrofti</i>	Combining chemotherapy of intestinal helminths and lymphatic filariasis; no increase in severity of adverse reactions	42
DEC plus albendazole	Average microfilarial intensity decrease of 4.6% of pretreatment values	Most effective against microfilarial intensity relative to single drugs	118
DEC plus ivermectin	Average microfilarial intensity decrease of 0.7% of pretreatment values	Most effective against microfilarial intensity relative to single drugs	118
Ivermectin	Ivermectin annual therapy for onchocerciasis did not interrupt transmission of <i>W. bancrofti</i>	Question of whether mass ivermectin administration for onchocerciasis would also impact lymphatic filariasis in areas where both organisms are endemic	100
Ivermectin	In villages where onchocerciasis is hyperendemic, after 14 yr of ivermectin no <i>W. bancrofti</i> in population; in adjacent villages, prevalence of 3% found	Despite long period of ivermectin, <i>Mansonella perstans</i> did not appear to respond in this setting	65
Ivermectin plus albendazole	After the third round of mass drug administrations, significant decreases in mosquito infections and infectivity seen	The combination of albendazole and ivermectin appears to be superior to ivermectin alone for reducing the frequency of <i>W. bancrofti</i> infection in mosquitoes	101
Ivermectin plus albendazole	Average microfilarial intensity decrease of 12.7% of pretreatment values	Relative efficacies of drug combinations not well documented, but provide valuable estimates of drug effect using existing data	118
Ivermectin plus albendazole	No significant differences in severity of posttreatment reactions in those coinfecting with <i>M. perstans</i>	Coinfection with <i>M. perstans</i> does not alter posttreatment reaction profiles to single-dose ivermectin-albendazole in <i>W. bancrofti</i> infection in this region	59
Doxycycline	<i>Wolbachia</i> endosymbionts are vital for larval development and adult-worm fertility and viability; this dependency on the bacterium for survival of the parasites provides a new approach to treat filariasis with antibiotics; doxycycline almost completely eliminated microfilaremia at 8–14 mo follow-up; ultrasonography detected adult worms in only 6 (22%) of 27 individuals treated with doxycycline compared with 24 (88%) of 27 treated with placebo at 14 mo after the start of treatment; filarial antigenemia in the doxycycline group fell to about half of that before treatment; adverse events were few and mild	An 8-wk course of doxycycline is safe and well tolerated for lymphatic filariasis, with significant activity against adult worms and microfilaremia	117

independent of the recurrence of microfilaremia and the response to nonparasite antigens (49).

Epidemiology and Prevention

W. bancrofti infections are widely distributed throughout the tropical and subtropical regions of Africa, Asia, Central and South America, the Caribbean islands, and the Pacific Islands. This species infects an estimated 115 million individuals; however, based on diagnostic test limitations, the actual number may be twice as great. *Anopheles* and *Culex* mosquitoes are night-biting vectors for the nocturnally periodic *W. bancrofti*, while the subperiodic strain is transmitted by day-biting *Aedes* mosquitoes. In areas of endemicity, exposure begins early in childhood, with microfilaria rates increasing with age, although the infection may not be clinically apparent.

Since these helminths do not multiply within the human host, infection levels are related directly to the number of infective larvae to which humans are exposed. Thus, prevalence and infection levels in an area of endemicity depend on the intensity of transmission. Factors that influence transmission include vector breeding sites, parasite longevity, levels of microfilariae in the blood when the vector bites, microfilarial load in the population, prevalence of lymphatic pathology, and immunologic tolerance. Transmission is quite inefficient, and nonresidents who move into areas of endemicity rarely develop patent infections; however, they may develop signs of acute disease (60).

Individual protection involves the use of insect repellents and bed netting; however, long-term protection has been sought through vector control and the use of chemotherapy. To carry out vector control properly, one must identify the species responsible for transmission, including its feeding, flight, and breeding habits. Because identification of filarial species in infected vectors by microscopy is difficult, DNA hybridization has been used to help identify mosquito populations involved in transmission. Wet pit latrines are favorite breeding sites for mosquitoes, and sanitation improvement to reduce breeding places in urbanized communities where the infections are endemic is a very effective means of control. Although vector control and mass treatment have been successful in small isolated areas, these approaches have been difficult in large areas.

In areas of endemic infection, DEC has been given to the inhabitants at weekly and monthly intervals over long periods to reduce transmission. The drug has even been incorporated into table salt for continuous low-dose administration to the population. Unfortunately, substantial increases in microfilaremia in humans and higher infection rates in mosquitoes in these areas have been noted when mass DEC chemoprophylaxis has been stopped (19).

Ivermectin inhibits the exsheathment of microfilariae in mosquitoes (98). This action prevents biological

development within the mosquito, thereby disrupting the chain of transmission. Vaccine development strategies have focused on unique filarial proteins that are critical for biological functions; however, there are no vaccines in general use today (22, 50).

Brugia malayi

Microfilariae of *B. malayi* were first observed by Lichtenstein in blood films from natives in Indonesia, and Brug described the microfilariae as a new species in 1927. Rao and Maplestone recovered adult worms from the forearm of a patient in India in 1940, giving the first descriptions of *B. malayi* adults. The geographic distribution of *B. malayi* overlaps that of *W. bancrofti* in certain areas (Figure 12.1). Both species are considered to be lymphatic filariae; however, *Brugia* spp. are much more widely adapted to animal hosts other than humans.

Life Cycle and Morphology

Although the two species can be differentiated morphologically, the life cycle of *B. malayi* is similar to that of *W. bancrofti* (Figure 12.2). However, *Brugia* has a shorter development time in the mosquito vector and the time from infection to appearance of microfilariae may be as short as 3 to 4 months. The adult worms inhabit the lymphatics, and the females give birth to sheathed microfilariae. The microfilariae differ from those of *W. bancrofti* by having two terminal nuclei that are distinctly separated from the other nuclei in the tail (Figures 12.5 and 12.6). The last terminal nucleus is quite small and is found at the tip of the tail (Figures 12.9 and 12.10). The microfilariae range from 177 to 230 μm in length. The intermediate host is a mosquito that may be infected with a periodic or subperiodic strain, depending on the geographic area.

Figure 12.9 *Brugia malayi*. (Left) Head of microfilaria; note that the sheath is not that clearly visible. (Right) Tail of microfilaria; note the sheath and the two terminal tail nuclei.

Figure 12.10 *Brugia malayi*. Both images show the microfilarial tail. Note the sheath and two terminal tail nuclei with the bulge in the tail.

Clinical Disease

The clinical pathology of *B. malayi* infections in humans is similar to that of *W. bancrofti*. Clinical manifestations usually develop months or years after infection, and many of the patients are asymptomatic even when they have microfilaremia. Lymphangitis and filarial abscesses occur with a greater degree of frequency than in *W. bancrofti* infections. If elephantiasis occurs, the swelling is normally restricted to the lower extremities below the knee. Sclerotic cordlike lymphatics and enlarged nodes in the arms and legs are common; urogenital involvement with chyluria does not occur. In disease caused by *B. malayi*, episodes of prolonged fever, adenolymphangitis, abscesses of affected lymph nodes, and local residual scarring occur quite frequently. Chronic lymphedema or elephantiasis, as seen in bancroftian filariasis, does not occur frequently.

Cytokine analysis revealed that in an area where brugian filariasis is endemic, IFN- γ was most affected by the shifts in microfilarial densities; proliferative responses remained low throughout the study period in microfilaremic individuals; however, in those with no demonstrable microfilariae, the responses were inversely related to the microfilarial densities (104). In contrast, IL-4 responses showed little correlation with changes in parasite densities.

Diagnosis

The diagnostic methods are similar to those for *W. bancrofti* and include thin and thick blood films, wet preparations and concentrations, PCR, ultrasonography, and antigen and antibody detection. There are nocturnally periodic and nocturnally subperiodic strains, so travel history can be helpful in determining optimal specimen collection times. Giemsa stains the sheath of *B. malayi* (will stain pink) but does not stain the sheath of *B. timori*, a species found in the islands near Indonesia. Apparently, the sheath is absent in 50% of periodic microfilariae but in only 5%

of subperiodic microfilariae (Figures 12.5 and 12.6; Table 12.1; Algorithm 12.1). A DNA hybridization assay has been developed to identify microfilariae trapped on nitrocellulose membranes but has not been used in field trials (93).

Treatment

The frequency of severe reactions is greater in *B. malayi* infections than in *W. bancrofti* infections. Initiation of treatment with lower doses of DEC and use of anti-inflammatory drugs reduces the adverse reactions. Ivermectin has also been used to treat *B. malayi* infections. Side effects are attributed to host responses to the death of microfilariae rather than directly to the drug. Single doses are effective in clearing or reducing the microfilaremic burden for up to 6 months (107). However, a gradual decrease in microfilaria occurs over several weeks to 15 to 20% of pretreatment levels; this response is much slower than that seen with *W. bancrofti* and microfilaria clearance. The combination of DEC and albendazole, both well-tested drugs, offers a new option for countries such as India, where there is no onchocerciasis or loiasis and where ivermectin may not be readily available; the efficacy of albendazole against intestinal helminths would provide additional benefits (106). Since acute attacks of adenolymphangitis (ADL) contribute to the overall morbidity with brugian filariasis, studies now indicate that foot care seems to play the most important role in the prevention of ADL attacks. Benefits may accrue from local or systemic antibiotic use in patients with high grades of edema, whereas antifilarials are ineffective in the prevention of ADL attacks (108).

Epidemiology and Prevention

There are two types of *B. malayi*, one nocturnally periodic and the other nocturnally subperiodic. The periodic strains, which have no animal reservoirs, are widely distributed in Asia, whereas the subperiodic form has been noted in Malaysia, Indonesia, and the Philippines. The principal mosquito vectors are *Mansonia* spp.; however, in certain areas *Anopheles* and *Aedes* spp. may be important. There are a number of reservoir hosts for *B. malayi* infections, including humans, dogs, cats, and monkeys.

Any prevention program must consider reservoir hosts other than humans in the control of *B. malayi*. Measures used for control and prevention have been similar to those used for *W. bancrofti*.

Brugia timori

Human infections in the Indonesian island chain (Timor) were first reported in 1964, and the filarial worms were recognized in 1965 by David and Edeson as being

Figure 12.11 *Brugia timori* elephantiasis of the lower extremity. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of D. Dennis, Kuala Lumpur.)

distinctly different from *B. malayi* (24, 26). *B. timori* infections produce symptoms and pathology similar to those found in *W. bancrofti* and *B. malayi* infections, and the life cycle is similar. However, there appear to be more abscesses related to *B. timori* infections. As with *B. malayi* infections, if elephantiasis occurs, the swelling is normally restricted to the lower extremities below the knee (Figure 12.11).

The microfilariae have nocturnal periodicity and are transmitted by *Anopheles* mosquitoes. *B. timori* microfilariae are morphologically similar to *B. malayi* microfilariae, except that on average they are longer (310 versus 220 μm), the cephalic space (length from the tip of the microfilaria head to the first body nucleus) has a length/width ratio of 31 versus 21, and the sheath does not stain with Giemsa stain as well as the *B. malayi* sheath does (Table 12.1). Also, there tend to be five to eight, rather than four or five, contiguous nuclei

Figure 12.12 *Brugia timori* microfilarial tail. Note the two terminal tail nuclei with no bulge in the tail.

in the tail, and little to no bulge is seen in the cuticle (Figure 12.12).

The *Brugia* rapid test is an immunochromatographic dipstick test used to detect IgG4 antibodies that are reactive with a recombinant *B. malayi* antigen. This approach has been used successfully for the detection of *B. timori* antibodies and has been recommended as a monitoring tool for *B. timori* in the framework of the Global Program to Eliminate Lymphatic Filariasis (36, 113). Treatment is similar to that for *B. malayi* infections (36, 83).

Zoonotic *Brugia* Infections (American Brugian Filariasis)

A number of species of *Brugia* have been implicated in zoonotic transmission from animals to humans worldwide, including the United States. Some species normally infect dogs, cats, rabbits, and raccoons. Human infection with *Brugia* spp. is also referred to as brugian filariasis, zoonotic brugian filariasis, or brugian zoonosis. Mosquitoes may accidentally transmit the infective stages by feeding on an infected animal and then on a human approximately 2 weeks later (85, 86). Fewer than 50 cases have been reported, most of which have been documented since 1977. Most of the cases in the United States have been seen in the northeastern part of the country and have been due to *B. beaveri* from the raccoon (*Procyon lotor*) and possibly bobcat and mink and *B. leporis* from swamp rabbits (*Sylvilagus aquaticus*) and eastern cottontails (*Silvilagus floridanus alacer*) (71a). Cases have been reported from Malaysia, where differentiation of this infection from other endemic infections is difficult; reports of infections, most of which are probably due to *B. guyanensis* infecting the raccoon-like coatimundi (*Nasua nasua*) and the weasel-like grison (*Grison vittatus*), have also come from South America, specifically Colombia, Brazil, Ecuador, and Peru.

Patients with American brugian filariasis rarely exhibit any systemic symptoms. Usually patients present with a tender mass in the cervical, axillary, or inguinal region; the mass may have been present for a few weeks before the patient sought medical help. A number of different conditions may be suspected, including an enlarged lymph node, lymphoma, lipoma, and papilloma. Specific areas of the body that have been involved include the pulmonary artery, the groin, the area behind the ear, the chest wall, and the neck. Once the mass is removed and examined histologically, a nematode worm is often found lodged in a dilated lymphatic vessel in the capsule, cortex, or interior of the node. The worm is often living and the structure is well preserved; however, if the worm is dead, it is probably surrounded by a granulomatous

reaction. Once the mass is removed, no further treatment is required. *B. beaveri* and *B. leporis* are the only described species known to occur in the United States; they are commonly found in the raccoon in Louisiana, and microfilariae have been recovered from bobcats in Louisiana and Florida.

In Malaysia, *B. pahangi* is a common parasite of dogs and cats and has been implicated in cases of lymphangitis and lymphadenitis. It may be very difficult to differentiate infections with *B. pahangi* from endemic infections with *B. malayi*, particularly since they have the same mosquito vectors and the microfilariae are very similar to those of *B. malayi*.

Tropical Pulmonary Eosinophilia

Tropical pulmonary eosinophilia (TPE) is associated with *W. bancrofti* or *B. malayi* infections causing diffuse pulmonary infiltrates with significant local and systemic eosinophilia and high levels of polyclonal and parasite-specific IgE (60). Migration of microfilariae through the pulmonary blood vessels with subsequent allergic hypersensitivity responses is thought to be the cause of this syndrome. The epidemiology of this condition is not well understood, particularly since there can be other causes. It seems to occur in long-term residents but not in travelers or residents who have been in the area of endemicity for a short time or only a few years. TPE can also occur many years after susceptible individuals have left the area. The majority of cases have been reported in India, Pakistan, Sri Lanka, Brazil, Guyana, and Southeast Asia.

Studies have shown numerous pulmonary granulomas, possibly indicating trapping of the parasites within the lungs. Because no blood-borne microfilariae are present in these patients, the syndrome may be due to an intense inflammatory response to the migration of microfilariae through the pulmonary blood vessels. No apparent reason for this outcome in a small number of patients has yet been confirmed.

TPE usually occurs in young men, and the onset is gradual, progressing over a period of months. Patients present with a nonproductive cough, wheezing, fever, generalized malaise, fatigue, and weight loss. Symptoms tend to occur at night and may be associated with the release of microfilariae that have become trapped in the lungs. The chest X ray usually shows diffuse interstitial or reticulonodular infiltrates 1 to 3 mm in diameter; increased bronchovascular markings are also seen.

Diagnosis is based on clinical, epidemiologic, and laboratory findings. Successful resolution of symptoms after treatment with DEC generally confirms the diagnosis; the same dosage schedule as for bancroftian filariasis is

used. Failure to respond to DEC strongly suggests another diagnosis, including allergic granulomatosis with angitis, Wegener's granulomatosis, periarteritis nodosa, allergic bronchopulmonary aspergillosis, idiopathic hypereosinophilic syndrome, and severe asthma. TPE is an important diagnostic consideration in patients with eosinophilia, respiratory symptoms, and a history of exposure to this disease. Without therapy, TPE can lead to chronic and progressive respiratory disease and then to death. Prompt recognition and treatment with DEC is critical to patient outcome (15).

Loa loa

Loa loa, the African eye worm, was first noted in the eye of a Negro girl in the West Indies in 1770. In 1895, Argyll-Robertson described the adult worms that he extracted from the eye of a woman who had resided at Old Calabar in West Africa. The adult worms migrate through the subcutaneous tissues, producing intermittent "Calabar swellings," in addition to migrating beneath the conjunctiva. Approximately 13 million people are infected with *L. loa* in Central and West Africa. The vectors are biting flies (*Chrysops*) and are known as red flies in Africa.

Life Cycle and Morphology

The adult male and female worms live and migrate in the subcutaneous and deep connective tissues, and the microfilariae are found in the blood, where they can be ingested by mango flies or deerflies (*Chrysops* spp.) (Figure 12.13). Once ingested by the fly, the microfilariae of *L. loa* lose their sheaths, penetrate the gut wall, migrate to the fat body, undergo two molts, and become infective in approximately 10 to 12 days. Humans are infected when bitten by infected flies, and the infective larvae enter the skin through the bite wound. Development into adult worms takes about 6 to 12 months, and they can survive up to 17 years. The females measure 50 to 70 by 0.5 mm, while the males measure 30 to 35 by 0.3 to 0.4 mm. The microfilariae frequently are not detected in the blood until years after the adult worms are noted. The microfilariae have a diurnal periodicity whose peak occurs about midday; the remainder of the time they can be found in pulmonary capillaries. The microfilariae are sheathed and are 250 to 300 μm long. When stained, the body nuclei are continuous to the tip of the tail (Figures 12.5, 12.6, 12.14, and 12.15). The developmental cycle in the mango fly or deerfly is similar to the development of *W. bancrofti* in the mosquito.

Clinical Disease

The *Chrysops* bite results in erythema, swelling, and itching, symptoms which can worsen with the presence

Figure 12.13 Life cycle of *Loa loa*.

of infective larvae. The adult worms normally migrate through the subcutaneous tissue at a rate of about 1 cm/min. This migration is not painful and is seldom noticed unless the worm is passing over the bridge of the nose or through the conjunctiva of the eye (Figures 12.16 to 12.18). Many patients with active *L. loa* infections do not have a microfilaremia. The most common pathologic sequelae associated with *L. loa* infections are Calabar or fugitive swellings (angioedema). Calabar swellings are localized subcutaneous edemas, a type of inflammatory reaction brought about by a host response to the worm

Figure 12.14 *Loa loa* microfilariae in blood. Note the presence of the sheath and the tail nuclei positioned to the end of the tail.

Figure 12.15 *Loa loa*. (Left) Microfilarial tail; note that the tail nuclei go to the tip of the tail. (Right) Microfilarial tail enlarged; note that the tail nuclei go to the tip of the tail.

or its metabolic products. Calabar swellings may be found anywhere on the body but predominate on the extremities. The swellings develop rapidly over a few hours and may be preceded by localized pain, pruritus, and urticaria; the swellings usually last 1 to 3 days. Serious complications due to loiasis have included cardiomyopathy, encephalopathy, nephropathy, and pleural effusions. Even with low doses of DEC to initiate treatment of patients from the area of endemicity followed by gradually increasing doses combined with corticosteroids, microfilaremia encephalitis is frequently fatal (61). Host genetic factors appear to be involved in acquiring loiasis in areas of endemic infection, because individuals who are not microfilaremic by the age of 30 have a low probability of becoming positive later in life (46). A Th2-type immune response has been found in microfilaremic *L. loa*-infected patients (125), and IgE antibodies recognized more antigens in the microfilarial stage than in the adult worms (5).

Residents from areas of endemicity have been generally noted to have asymptomatic microfilaremia (90% of residents) and occasional episodic Calabar swellings (16% of residents), moderate eosinophilia, and variable antibody levels. Infections in nonresidents were more often symptomatic. Due to increased international travel, the diagnosis of loiasis must be considered in patients who have visited these areas and have a history of eosinophilia, migratory angioedema, and urticarial vasculitis (95). Approximately 10% are microfilaremic and have frequently recurring Calabar swellings, hypereosinophilia of over 70%, increased levels of IgE, and very high antibody titers (80). However, complications such as renal disease, encephalopathy, and cardiomyopathy have been found (80).

The most serious complications include meningoencephalitis, occurring in patients with large numbers of circulating microfilariae who have undergone treatment

Figure 12.16 *Loa loa*. Subconjunctival nematode. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of D. Gendelman.)

with DEC; immune complex glomerulonephritis; and endomyocardial fibrosis.

Diagnosis

Since the microfilariae of *L. loa* do not appear in the blood until years after the adult worms or the host

Figure 12.17 *Loa loa* beneath the conjunctiva of the eye. (Armed Forces Institute of Pathology photograph.)

Figure 12.18 *Loa loa* adult extracted from the eye. (Armed Forces Institute of Pathology photograph.)

reaction to infection is noted, the diagnosis is frequently made on the basis of clinical history (Calabar swellings, worm migrations through the eye, eosinophilia, and residence in an area of endemicity). Microfilariae can be detected in the blood by using methods similar to those used to detect *W. bancrofti* or *B. malayi*. Microfilariae are shed by the females on a random schedule; therefore, multiple samples over a period of days may have to be tested. Individuals not from the area of endemicity usually are amicrofilaremic (63). The microfilariae exhibit diurnal periodicity; therefore, blood samples should be collected during daytime, preferably between 10 a.m. and 3 p.m. The sheathed microfilariae must be differentiated from those of *W. bancrofti* and *B. malayi* (Figures 12.3 to 12.5, 12.14, 12.15, and 12.19; Table 12.1). Demonstration of the sheathed microfilariae with nuclei extending to the tip of the tail is sufficient for the diagnosis (Figures 12.14 and 12.15). The infection can also be diagnosed by detection or removal of adults from the eye (Algorithm 12.2)

Occasionally, in asymptomatic individuals, microfilariae can be recovered from peripheral blood films, urine, sputum, cerebrospinal fluid, cervicovaginal smears, blood vessel biopsy specimens, or autopsy specimens (71a). Although Giemsa stain does not reveal the sheath, Delafield's hematoxylin may do so and is recommended. Biopsy specimens of Calabar swellings prior to therapy rarely demonstrate the presence of adult worms.

Figure 12.19 *Loa loa* microfilaria in the capillaries of the dermis. (Armed Forces Institute of Pathology photograph.)

Treatment

Surgical removal of the adult worms as they are migrating across the bridge of the nose or through the conjunctiva is relatively simple (Figure 12.18). DEC is an effective treatment; however, in patients with a heavy microfilariaemia, anti-inflammatory drugs may also have to be administered to reduce severe side effects. The most serious sequelae are neurologic complications resembling the encephalitis that is commonly associated with a high micro-

Algorithm 12.2 Loiasis.

filaremia. If neurologic disorders develop, it is mandatory that therapy with DEC be stopped. Some individuals may require multiple courses of therapy to be clinically cured. Although DEC is curative in most individuals, relapses can occur within the first 12 months and up to 8 years after treatment (64). In areas of endemic infection, DEC at a prophylactic dose of 300 mg weekly is effective in preventing loiasis in long-term visitors (2). The occurrence of serious adverse effects following DEC treatment of onchocerciasis in areas where *L. loa* is endemic has been increasingly reported over the past decade. These include a severely disabling, and potentially fatal, encephalopathy, which appears to correlate with a high load of *L. loa* microfilariae (>30,000/ml).

Both mebendazole and ivermectin have been used to treat loiasis. The use of mebendazole is not promising, whereas ivermectin is effective in reducing microfilariaemia (57). Albendazole, a benzimidazole derivative related to mebendazole, is effective in reducing microfilariaemia, and there is a lower risk of encephalopathy; however, repeated courses of therapy may be required (2, 62). Individuals treated with albendazole have a significant reduction in the levels of eosinophils, antifilarial IgG, and IgG4. Although there were no cures, it is possible that albendazole directly affects the adult stages.

Epidemiology and Prevention

Loiasis is endemic to the Central and West African rain forests and may infect as many as 13 million people. Disease distribution depends on the vectors, which breed in wet mud at the side of streams under the rain forest canopy. Flies appear to be attracted by the movement of people or vehicles, as well as rising smoke. An excellent example of vector-host interactive sites would include rubber plantations with a dense high canopy and human workers. The *Chrysops* flies are more common in the rainy season, and exposure differences result in higher infection rates in adults rather than children. Although vector control is one means of prevention, the inaccessibility of breeding sites has proven to be a problem. Clearing of growth around houses and use of screens and protective clothing have all been helpful.

In general, control of loiasis also depends to a great degree on chemoprophylaxis with DEC. Although other therapeutic approaches have been tried, including mebendazole and ivermectin, problems remain with both options.

Mansonella ozzardi

Mansonella ozzardi infections are confined to the New World in Central and South America and the Caribbean islands. Areas of endemic infection in South America include northern Argentina, Bolivia, Brazil, Colombia,

Ecuador, and Peru. The infection was first noted by Ozzard in an Indian in South America and was described by Manson. Humans are the only known natural definitive hosts, and prevalence rates may reach 70% in certain areas.

Life Cycle and Morphology

The adult male and female worms live in the subcutaneous and connective tissues, and the microfilariae are found in the blood, where they can be ingested by *Culicoides* spp. (midges) or *Simulium* spp. (blackflies), the insect vectors. The microfilariae are nonperiodic and unshathed, with body nuclei that do not extend to the tip of the tail, and are 173 to 240 μm long (Figures 12.5, 12.6, and 12.20). Microfilariae of *M. ozzardi* resemble those of *M. perstans*; however, the tail of *M. ozzardi* tends to be pointed and slightly flexed and has a longer caudal space (Figure 12.20) (71a). Apparently, humans are the only recognized natural definitive hosts.

Clinical Disease

There is no definitive information available regarding the incubation period in humans. The infections generally produce no symptoms (West Indies); however, they may cause adenopathy in the lower extremities, knee and ankle pain, pruritus, urticaria, eosinophilia, and fever (Amazon region). Although the worms are generally found in the thoracic and peritoneal cavities and possibly the lymphatics, there is generally no inflammation. Microfilariae were detected in pericardial and pleural fluid from a patient with adenocarcinoma (103). It might be possible to find microfilariae throughout the body of an immunocompromised patient. A recent cross-sectional

Figure 12.20 *Mansonella ozzardi* microfilaria. Note that the microfilaria is unshathed and that the tail is pointed and slightly flexed and has a longer caudal space than *M. perstans*.

survey in the Chaco region of Bolivia showed that 26% (77 of 296) and 0.7% (2 of 298) of the rural populations of two village areas harbored *M. ozzardi* microfilariae. No sex differences were noted, and the lowest prevalence was in 0- to 14-year-old children. There was a sharp increase in 25- to 34-year-old adults, and the prevalence continued to increase in the older age groups. Microfilaremia also increased with age. No significant association between clinical symptoms (fever, skin rash, pruritus, headache, lymphedema, elephantiasis, and articular pain) and microfilaremia was seen (10).

Diagnosis

Methods similar to those used for *W. bancrofti* and *B. malayi* are used to detect microfilariae in the blood. The microfilariae are nonperiodic and must be differentiated from other blood-borne microfilariae (Figures 12.5, 12.6, and 12.20; Table 12.1). Since the microfilariae are nonperiodic, blood specimens can be taken at any time during the day.

Treatment

Asymptomatic patients need not be treated. Ivermectin has been successfully used to treat infections (57); however, DEC treatment may not be effective. The overall prognosis is excellent.

Epidemiology and Prevention

The infection is indigenous in the Caribbean islands and in Central and South America. *Culicoides* spp. (midges) are the main vectors except in the Amazon basin area of Brazil and Colombia, where blackflies (*Simulium* spp.) are the vectors. Humans are the only known reservoir hosts. The infection may be prevented by the use of insecticides to prevent fly bites. Because of the lack of public health significance of this infection, control programs have not been designed.

Mansonella perstans

Mansonella perstans was previously known as *Dipetalonema perstans* or *Acanthocheilonema perstans*. Manson discovered the microfilariae in a blood smear taken from an African patient, and Daniels described the adult worm collected from a South American Indian. In certain areas, infection rates of more than 50% have been reported.

Life Cycle and Morphology

Adult worms are found in the body cavities (peritoneal and pleural), and their microfilariae are found in the blood, where they are ingested by *Culicoides* spp. (midges), the insect vectors. The microfilariae are nonperiodic and unshathed, with body nuclei that extend to the tip of the tail, and are 190 to 200 μm long (Figures 12.5, 12.6, and

Figure 12.21 *Mansonella perstans* microfilaria. Note that the microfilaria is unshathed and that there is a cephalic space and very little caudal space.

12.21). There is no caudal space seen in microfilariae of *M. perstans*, and the posterior end tends to be blunt.

Clinical Disease

Even though the adult worms inhabit the body cavities, there is minimal literature on the pathology caused by this infection. Live adults appear to produce little or no host reaction; however, eosinophilia is common. Pruritus, abdominal pain, urticaria, and Calabar-like swellings on the arms, shoulders, and face have been described (77). *M. perstans* filariasis has been found in the bone marrow of a human immunodeficiency virus (HIV)-infected patient (74). Ocular symptoms include periorbital edema and conjunctival irritation. In Uganda, acute periorbital inflammation is common; this condition is known as bung-eye or bulge-eye (71a). These types of changes are also reported from Nigeria and Sudan.

Diagnosis

The methods used to detect microfilariae in the blood are similar to those used to detect *W. bancrofti* and *B. malayi* microfilariae. The microfilariae are nonperiodic and must be differentiated from other blood-borne microfilariae (Figures 12.5, 12.6, and 12.21; Table 12.1). Although these microfilariae are nonperiodic, larger numbers can be found in blood collected at night.

Treatment

Reports on the effectiveness of DEC are contradictory; the microfilariae are eliminated, but repeated therapy is re-

quired. However, mebendazole has been used effectively. Ivermectin is not effective in treating *M. perstans* infections (57). Dead worms release substances that are very antigenic and cause a dramatic immune response; the worms are surrounded by inflammatory exudates, and there may be abscesses, granulomas, and scarring. In a recent study, six different therapeutic protocols were undertaken for the treatment. DEC reduced microfilarial density but seldom eliminated the infection after a single treatment. Mebendazole was more effective than DEC in eliminating the infection, while ivermectin and praziquantel showed no modification of microfilarial concentration. Thiabendazole demonstrated a small but significant activity against the infection, while combination treatments with DEC and mebendazole showed significantly higher activity than did single drugs alone (17).

Epidemiology and Prevention

The infection occurs in tropical Africa, the West Indies, and along the Atlantic coast in Central and South America. *Culicoides* spp. (midges) are the insect vectors, and humans, gorillas, and monkeys are the known reservoir hosts. The intermediate host (*Culicoides* spp.) breeds in swamps and jungles, and so eradication or control measures are not practical. Insecticides can be used to prevent fly bites.

Mansonella streptocerca

Until recently, *M. streptocerca* was named *Dipetalonema streptocerca*. It was also previously called *Acanthocheilonema* or *Tetrapetalonema*. Microfilariae were first noted in skin snips obtained from a West African native in 1922, and the adult worms were described in the 1970s.

Life Cycle and Morphology

Adult female and male worms live in the dermal tissues, and the microfilariae are found in the skin, where they can be ingested by *Culicoides* spp. (midges), the insect vectors. The microfilariae are unshathed, with body nuclei that extend to the tip of the tail, and are 180 to 240 μm long (Figure 12.5). When they are immobile, the microfilariae curve the tail to assume a "shepherd's crook" configuration.

Clinical Disease

Although unconfirmed, the incubation period is suspected to be several months. There are limited reports on the symptoms and pathology associated with *M. streptocerca* infections, and many patients are asymptomatic. Pruritic dermatitis with hypopigmented macules on the skin and lymphadenopathy have been common complaints. Many patients have inguinal adenopathy.

In areas where leprosy is endemic, the hypopigmented dermal lesions of streptocerciasis are often misdiagnosed as leprosy; however, no sensory changes are seen, in contrast to leprosy. It is recommended that these lesions be examined histologically for confirmation of either filariasis, leprosy, or both.

Diagnosis

Any patient from the area of endemicity who presents with hypopigmented macules and pruritus should be suspected of having the infection. However, this appearance can be confused with leprosy, and some patients are misdiagnosed and inappropriately treated for leprosy for long periods. The diagnosis is made by the detection of microfilariae from skin snips taken over the scapula and examined as wet mounts. Orihel (84) noted that the microfilarial tails are split rather than blunt, as they were previously described. These microfilariae must be differentiated from *O. volvulus*, which also can be detected in the skin (Figure 12.5; Table 12.1).

Microfilaria can be found primarily in the upper third of the dermis in the dermal collagen. Changes in the skin include sclerosis of dermal papillae, edema, incontinence of melanin, fibrosis, and cellular infiltrates around blood vessels, and the lymphatics are frequently dilated. In untreated patients, adult worms are occasionally found in the dermis; they do not tend to cause an immune response when alive.

Treatment

The infection responds to treatment with DEC; however, a complaint from most patients is the intense pruritus that develops. The long-term effect of a single oral ivermectin dose of 150 µg/kg of body weight on *M. streptocerca* was studied in western Uganda. The results indicate that ivermectin is highly effective against *M. streptocerca*

and that a single dose leads to a sustained suppression of microfilariae in the skin. In Africa, ivermectin is used for mass treatment to control *O. volvulus* and *W. bancrofti*. Since these filarial infections are often coendemic with *M. streptocerca*, the treated population may receive suppression benefits for *M. streptocerca* microfilaria as well (37).

Epidemiology and Prevention

The infection has been found in western and central sub-Saharan Africa, as far east as western Uganda, and as far south as northern Angola. The incidence may reach 90% in certain areas of dense forests of equatorial Congo. Both monkeys and humans harbor the infection; however, there is speculation that the species infecting monkeys may differ from those infecting humans. Biting midges (*Culicoides* spp.) are the insect vectors. There are no control programs aimed specifically at *M. streptocerca* or *Culicoides* spp. Insecticides can be used to prevent fly bites.

Onchocerca volvulus

Onchocerca volvulus microfilariae were first found by O'Neil in 1875, and the adult worms were detected by Leuckart in 1893 in nodules removed from the scalp and chest of a West African native. Onchocerciasis, which is also known as river blindness, is a major public health problem because the infection is a leading cause of blindness in the world and may also cause significant disfigurement of the skin. Currently, 17.7 million people are infected with *O. volvulus*; of these, 270,000 are blind and 500,000 have severe visual impairment (52). Unfortunately, these figures are probably underestimates.

Life Cycle and Morphology

Adult female and male worms lie within fibrous tissue capsules in the dermis and subcutaneous tissues.

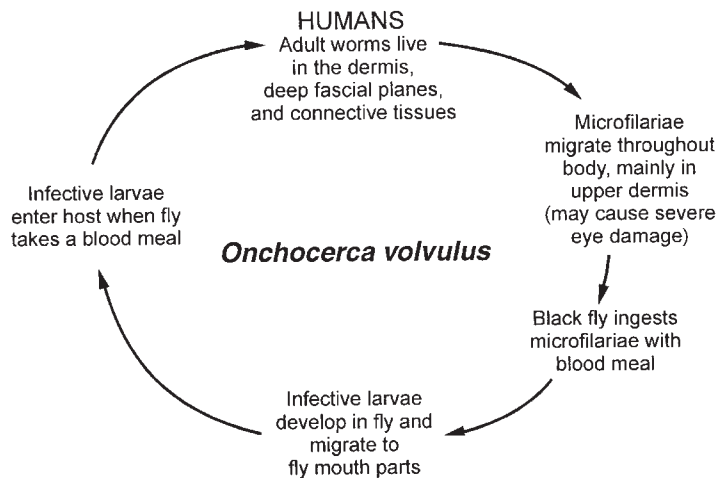

Figure 12.22 Life cycle of *Onchocerca volvulus*.

The female adult is very long and thin, measuring up to 50 cm by 0.3 mm, while the adult male is 2.5 to 5 cm by 125 to 200 μm . Gravid females produce microfilariae, which invade the subcutaneous tissues, skin, and eyes. The infection is transmitted by a species of *Simulium* (blackfly or buffalo gnat). Apparently the blackflies are pool feeders, and the saliva probably contains anticoagulants, as well as attractants for the skin-dwelling microfilariae (21). After being ingested, the microfilariae migrate to the flight muscles, become infective in about 6 to 12 days, and migrate to the proboscis, where they are transmitted when the next blood meal is taken. Humans are infected when bitten by the infected fly, and larvae are deposited into the bite site (Figure 12.22). Microfilariae are normally found in the dermis and rarely in the blood, sputum, or urine. They are unsheathed, with body nuclei that do not extend to the tail tip, and are 221 to 360 μm long (Figure 12.5). The infective larvae undergo two molts during the next 12 months prior to becoming mature adult worms. The gravid females produce thousands of microfilariae daily beginning about 12 to 15 months after infection. The mean reproductive life span of the adult worm is up to 15 years, with maximum reproduction during the first

Figure 12.23 *Onchocerca volvulus* microfilariae in the skin (cross section). (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 12.24 *Onchocerca volvulus* microfilariae in the dermis. (Armed Forces Institute of Pathology photograph.)

5 years of patency; the microfilariae may live for up to 15 years (71a).

Clinical Disease

The prepatent period in humans is 3 to 15 months. Light infections may produce no symptoms, and worms may be free in the tissue; however, in heavy infections, major disease manifestations include dermatitis, onchocercomas (subcutaneous nodules containing adult worms), lymphadenitis, and blindness. Even though there is an inflammatory reaction that causes the formation of a fibrotic capsule (onchocercoma) around the adult, the main pathology appears to be directed against the microfilariae (67) (Figures 12.23 and 12.24).

Onchocercomas. Light to moderate infection may produce an itchy rash, while heavy infections (up to 200 million microfilariae) may lead to severe sequelae. Heavy infections are the result of continued exposure to infective larvae over a period of many years. The onchocercoma is a firm, round, and nontender subcutaneous nodule that contains the adult worms. In Africa, the nodules are commonly found on the trunk (particularly the hip area) or limbs, while in Mexico and Guatemala, they are frequently found on the scalp (Figures 12.25 to 12.27).

Skin Changes. Some individuals with onchocerciasis have clinically normal skin, whereas others have pruritus and disfiguring skin lesions. The pruritus may be so severe as to cause sleeplessness, fatigue, and weakness, symptoms that may affect the individual's ability to work and interact socially. Scratching often leads to ulcers, bleeding,

Figure 12.25 Onchocerciasis. The nodule on the patient's head contains adult worms of *Onchocerca volvulus*. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 12.26 Onchocerciasis. Nodules on the back prior to surgical removal. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

and secondary bacterial and/or fungal infections. The skin may be painful, hot, and edematous. This inflammatory condition may recur numerous times, eventually resulting in permanent thickening of the skin. Acute attacks of onchodermatitis have resulted in a purplish skin discoloration on the trunk and upper limbs known as mal morado in Central America. Chronically infected skin loses its elasticity and becomes hypertrophic or thickened. As a result of atrophy and loss of skin elasticity, patients may develop premature exaggerated wrinkling of the skin (Figure 12.28). In Central America, these skin changes are frequently seen as noticeable thickening of the earlobes and thickening of facial skin to mimic leonine facies (seen in lepromatous leprosy). In Africa, the same skin changes occurring in the hip region, usually around the inguinal lymph nodes, produce a condition known as hanging groin, which may predispose infected individuals to inguinal and femoral hernias. Lymphadenopathy in the inguinal and femoral areas is common among Africans (Figure 12.29).

Skin may become hypo- or hyperpigmented. In Africa, patients may exhibit localized areas of spotty depigmentation surrounded by slightly hyperpigmented zones occurring mainly on the shins; this condition is known as leopard skin (Figure 12.30). These white areas have an absence of melanin, and the prevalence of skin depigmentation has been proposed as a marker for endemic onchocerciasis.

Sowda is a chronic hyperreactive form of onchocerciasis occurring in a subset of infected individuals, usually in Arabia, Ecuador, Guatemala, Sudan, and West

Africa. It is characterized by a severe papular dermatitis usually localized to one limb, typically a leg, with darkening of the skin. The number of microfilariae in the skin is extremely small, and there is extensive follicular hyperplasia of the regional lymph nodes. Individuals with sowda have significantly higher antibody titers, including IgE and antigen-specific IgG, than do individuals with generalized onchocerciasis (45). These skin lesions improve after therapy. It is possible that this form of onchocerciasis is linked to the formation of autoantibodies to defensins and the hyperimmune response to the parasite.

Ocular Involvement. A major complication of onchocerciasis has been ocular lesions leading to bilateral blindness. The prevalence of blindness depends on the organism strain and the prevalence of disease within an area, while the degree of eye involvement depends on the duration and severity of infection (Figure 12.31). Visual problems can include fluffy corneal opacities, sclerosing keratitis, and iridocyclitis leading to glaucoma and cataracts; chorioretinitis and optic atrophy also occur. Eye damage is caused by living and dead microfilariae in the cornea, anterior and posterior chambers, iris, retroental space, vitreous, choroid, retina, sclera, and optic nerve.

Figure 12.27 Onchocerciasis. Surgical removal of a nodule on the back. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

Progressive pathology generally develops over time, with resulting blindness seen in adults.

Ocular lesions are a result of the host immune response to the microfilariae. Circulating antibodies to retinal antigens have been found in patients with onchocercal retinopathy (102, 126). Whether these autoantibodies play an appreciable role in ocular pathology is unknown. Chorioretinal changes have been noted in 75% of the population in areas of West Africa where the infection is endemic.

In West Africa, the severity of ocular pathology is based on strain differences as confirmed by DNA sequence determination. Classification of these strains based on sequence differences correlates very well with pathologic differences. PCR testing has been used to map the distribution of the blinding and nonblinding strains in Nigeria (52, 81). Preliminary studies indicated that certain species of blackfly transmitted the different strains; delineation of these transmission zones has become more difficult, and transition zones appear to contain both strains and/or hybrids. Ocular problems such as severe sclerosing keratitis, anterior uveitis, and blindness are more prevalent in the savanna regions of West Africa but much less common in the rain forest areas.

Immune System Effects. In individuals with microfilaridemia, there is a lack of a cellular immune response;

Figure 12.28 Wrinkling of the skin due to onchocerciasis. (Armed Forces Institute of Pathology photograph; published in D. H. Connor, N. E. Morrison, F. Kerdel-Vegas, H. A. Berkoff, F. Johnson, R. Tunnicliffe, F. C. Failings, L. N. Hale, and K. Lindquist, *Hum. Pathol.* 1:553–579, 1970.)

however, there is a Th2 response, which is most rigorous in patients with the sowda form of onchocercal dermatitis. Individuals with chronic onchocerciasis have an abundance of T cells producing IL-4 and IL-5, and they have markedly high levels of antigen-specific IgE and IgG4 antibodies and eosinophilia (47, 88).

Figure 12.29 Hanging groin due to *Onchocerca volvulus* femoral lymphadenitis. (Armed Forces Institute of Pathology photograph.)

Figure 12.30 Depigmentation due to onchocerciasis. (Armed Forces Institute of Pathology photograph.)

Recent studies suggest a role for mast cells and tissue basophiles in the pathogenesis of onchocerciasis. The IgE bound to the plasma membrane of these mediator-rich cells could contribute to the inflammatory reaction; parasite-soluble components and cuticular proteins are inducers of histamine release. Possible recognition of cuticle internal matrix could occur during molting and after attack by immune responses directed against other targets. If this is true, histamine-containing cells could participate in the body's response to the parasite. The

Figure 12.31 Keratitis due to onchocerciasis. (Armed Forces Institute of Pathology photograph.)

chronic inflammatory reaction seen in onchocerciasis may be mediated by mechanisms involving IgE. Product release from basophiles or mast cells acting on eosinophils could be very relevant to the outcome of the infection (48). It also appears that the eosinophil chemokine eotaxin plays a role in recruitment of eosinophils to the dermis in early-stage onchocercal skin disease (91).

In Uganda, as well as in other areas of Africa, *O. volvulus* and HIV are two immunocompromising infectious agents of major health concern. Cellular immune responses in patients coinfecting with these two agents suggest an HIV-related lack of specific reactivity to *O. volvulus* antigen and impairment of IL-4 and IL-5 production in addition to the lack of an IFN- γ response to antigenic stimulation (105).

Diagnosis

In areas of endemic infection, the clinical diagnosis of onchocerciasis is not difficult when individuals present with typical features such as hanging groin, leopard skin, skin atrophy, or subcutaneous nodules. However, skin lesions must be differentiated from scabies, insect bites, streptocerciasis, contact dermatitis, hypersensitivity reactions, traumatic or inflammatory depigmentation, tuberculoid leprosy, dermatomycoses, and treponematoses.

Microfilariae are commonly detected in the skin and must be differentiated from *M. streptocerca* microfilariae, which are also found in the skin (Figure 12.5; Table 12.1). Multiple skin snips are recommended, with the sensitivity of six snips per person being estimated at 91.6% (115). Infrequently, microfilariae are found in the urine, blood, or sputum, particularly after initiation of DEC treatment. Skin snips should be examined 3 to 6 months after therapy to determine whether the treatment was successful (Algorithm 12.3). PCR has been used successfully with skin snips to detect infections. The PCR method is significantly more sensitive than routine microscopic methods in detecting microfilariae in skin snips and would be more reliable in detecting active infections than are serologic assays (128). Microscopic examination of skin snips cannot detect prepatent or low-level infections.

The diagnosis can also be confirmed by finding onchocercomas and adult worms within fibrotic tissues. Ultrasonography can distinguish onchocercomas from lymph nodes, lipomas, fibromas, and a foreign-body granuloma. A typical nodule appears as a central homogeneous area containing some dense particles with a lateral acoustic shadow.

In addition, slit-lamp examination of the eye to detect and visualize microfilariae in the anterior chamber or retroillumination to detect corneal microfilariae can be performed. Patients are instructed to place their heads

Algorithm 12.3 Onchocerciasis.

between their knees for about 10 min. Once they sit up, the microfilariae become concentrated behind the central cornea and are easier to see and count.

The Mazzotti test can be used when results with skin snips are negative; however, there may be severe reactions in patients with heavy microfilarial burdens. A single oral dose of 25 to 50 mg of DEC is given; individuals often develop intense pruritus within a few hours. The itching can be severe and may be accompanied by erythema, edema, and papules; it usually subsides within a few days. Topical application of DEC in a patch test eliminates some of these problems; the appearance of a localized inflammatory reaction at the site of the patch indicates a positive test. The Mazzotti test should be limited to patients with light infections who have no microfilariae in the eyes.

The use of recombinant antigens for serologic diagnosis can help overcome the problems associated with poor sensitivity and specificity, particularly in areas where other human filarial infections overlap with those caused by *O. volvulus* (114). A cocktail of recombinant *O. volvulus* antigens for serologic diagnosis with the potential to predict the endemicity of onchocerciasis infection has been developed (16). When a sentinel population of 5- to 15-

year-old children was used to compare communities, the serologic index was sufficiently sensitive to measure the changes in endemicity that would be required for control programs. However, serologic testing cannot distinguish between current and past infection and tends to be more important in monitoring specific groups.

Treatment

Surgical removal of detectable nodules, especially in the head region, is simple and easy to perform. Nodule removal from the head, particularly in children, reduces the risk and severity of ocular complications. Removal of adult worms decreases the exposure of the host to microfilariae, which helps decrease the risk of complications. Because many nodules are nonpalpable or the adults may be freely migrating, the removal of nodules may have little effect on the total microfilarial or worm burden. Removal of enlarged regional lymph glands has been traditional therapy for sowda in Yemen.

Ivermectin is the drug of choice for treating onchocerciasis (100). It markedly reduces microfilaria numbers within 48 h and blocks the release of microfilariae from the uterus of the adult female worm for up to 6 months.

Following treatment, microfilariae disappear from the skin and can be detected in large numbers in the regional lymph nodes, where there is a high concentration of eosinophils. Ivermectin is well tolerated, but its side effects include pruritus, skin edema, and arthralgia; however, these effects are not as severe as those noted with DEC treatment. Ivermectin can also cause renal glomerular and tubular disturbances in patients with onchocerciasis; however, these are minor and do not seem to be clinically relevant (18). Although ivermectin significantly reduces the microfilarial burden in the host, thereby reducing dermatitis, it has no effect on depigmentation and scarring. Ivermectin treatment even in single doses reduces the prevalence of ocular microfilariae, including the number found in the anterior chamber of the eye, resulting in improvement of ocular lesions and visual acuity. When used in multiple doses, ivermectin is not only microfilaricidal but also macrofilaricidal (i.e., it kills adult worms). However, total doses of ivermectin up to 1,600 µg/kg are not significantly more effective than 150 µg/kg in killing the adult worms; more effective drugs against the adult worms are still needed (8). Ivermectin is contraindicated for pregnant women, children younger than 5 years, children weighing less than 33 lbs (15 kg), and patients with concurrent illness. Even though pruritus was frequent, no ocular or systemic complications were noted.

DEC is an effective microfilaricidal drug, but it may precipitate serious dermal and systemic complications as well as ocular damage in heavily infected patients. It has little or no effect on adult worms. The side effects resulting from the death of the microfilariae can be reduced by the use of anti-inflammatory drugs. Another method commonly employed is to gradually increase the DEC doses to therapeutic levels.

Suramin is effective in eliminating adult filarial worms as well as the microfilariae; however, it must be administered systemically and is very nephrotoxic. DEC and suramin in combination have been effective and well tolerated.

Amocarzine (CGP 6140) is a methylpiperazine derivative of amoscanate. Individuals treated with amocarzine had a rapid drop in the number of skin microfilariae, and the low level was maintained for over 2 years. A large number of adult female worms (65 to 73%) either were killed or became moribund (127). Amocarzine affects both mitochondrial function, by blocking NADH-dependent respiration, and acetylcholinesterase activity. Toxicity associated with amocarzine treatment included dizziness, impaired coordination, and Mazzotti-type reactions consisting mainly of pruritus and rash.

Mebendazole and flubendazole (benzimidazole derivatives) are effective microfilaricidal drugs; they are useful alternatives to DEC, and fewer ocular side effects were noted. Mebendazole is poorly absorbed and requires

multiple doses. It is teratogenic and embryotoxic in laboratory animals and is contraindicated in pregnancy. Although flubendazole is not teratogenic, a complication is ulceration of the injection site (121).

Epidemiology and Prevention

Onchocerciasis is widely distributed throughout Central Africa, occurs in Saudi Arabia and Yemen, and is found in areas of Brazil, Colombia, Venezuela, Ecuador, Guatemala, and Mexico. An estimated 85.6 million people are considered at risk for onchocerciasis worldwide. There appear to be no known important animal reservoirs, although natural infections in gorillas have been found in Africa.

Simulium spp. (blackfly or buffalo gnat) are the insect vectors, and they are usually found near rivers and streams. Many species require fast-flowing streams for larval development. River blindness is the common name for onchocerciasis as a result of the frequency of blindness in people living along rivers and streams in areas of endemic infection. In some areas, control programs may be misdirected because of the inability to distinguish animal from human onchocercal larval forms in infected flies. DNA probes to distinguish larval forms could help in targeting the areas where human infections are most frequent. Pool screen PCR for estimating the prevalence of *O. volvulus* infection in the vectors has been used in epidemiologic surveillance for infection (127).

Treatment of streams and rivers with insecticides has successfully reduced or eliminated transmission. A significant problem in vector control has been the development of resistance to larvicides. A solution to this problem is the rotational use of different larvicides during the treatment campaign. Because of the long life span of the adult worms (15 years or more), campaigns must be continued for extended periods.

In areas where application of insecticides would be difficult, surgical removal of nodules has been used as a means of controlling as well as preventing blindness. Chemotherapy as a means of control has not been previously used because of severe side effects from microfilarial death. Because ivermectin can be given orally, the number of doses is limited in comparison with DEC, and compliance is better than with DEC because ivermectin has fewer side effects. Ivermectin therapy could be used as a control measure to reduce transmission in areas of endemicity. The disadvantages of this approach are cost, the fact that ivermectin is not effective against adult worms unless used in multiple doses, and the finding that in areas where *L. loa* also exists, treatment may induce encephalitis in *L. loa*-infected individuals. In communities where ivermectin has been used on a large scale with multiple doses over time, significant reductions in the number of infected flies

Figure 12.32 Adult *Dirofilaria immitis*. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

and the number of infective larvae transmitted have been noted. Significant decreases in the prevalence of onchocerciasis in children have been noted when mass treatment with ivermectin has been carried out in areas of endemic infection. The use of ivermectin in control and eradication programs holds considerable promise. A search for vaccine candidate immunogens is under way.

Dirofilaria *Dirofilaria* and *Dirofilaria* *Nochtiella* spp.

Currently, there are two subgenera, *Dirofilaria* *Dirofilaria* and *Dirofilaria* *Nochtiella*, based on the presence or absence of external longitudinal cuticular ridges (71a). *D. Dirofilaria immitis* is referred to in this volume as *D. immitis*. The others in the *Dirofilaria* *Nochtiella* species are designated *Dirofilaria* and the species name. A number of these species, such as *D. tenuis*, *D. repens*, *D. ursi*, *D. striata*, and *D. subdermata*, as well as *Brugia* spp., are animal filariae causing subcutaneous or conjunctival nodules in humans (9, 14, 44, 51, 54, 86, 87). Almost all of the worms detected in humans have been nongravid, with the exception of *Brugia* spp. detected in immunodeficient patients and in the right cervical lymph node lymphatic vessel of a normal human and a *Dirofilaria* sp. found in the right lung of a patient with lymphoid leukemia (9, 13). It is possible that the release of microfilariae into the vascular system is suppressed in normal human hosts.

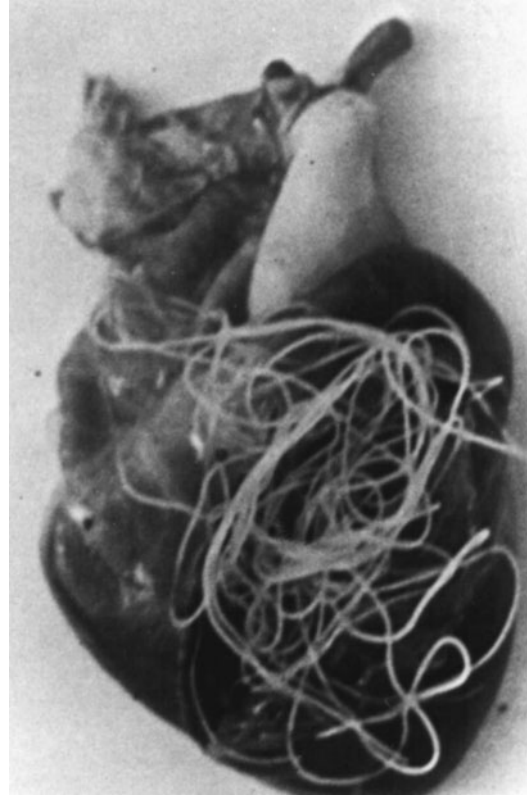

Figure 12.33 Adult *Dirofilaria immitis* within a canine heart. (Original photograph by S. Kume; from A Pictorial Presentation of Parasites: A cooperative collection prepared and/or by H. Zaiman.)

D. immitis, the dog heartworm, causes a common zoonotic filarial infection in dogs in the tropical, subtropical, and warm temperate regions of the world. The infection was prevalent predominantly in the southern coastal and southeastern United States; however, the zone of endemicity has been increasing northward and to the west. Pulmonary lesions are the most common findings in humans infected with *D. immitis*. *D. tenuis* is a parasite of the raccoon within the United States; *D. repens* is found in dogs and cats in Europe, Africa, and Asia and is the cause of human infections in these geographic areas; *D. ursi* infects bears in Canada, the northern United States, and Japan; *D. subdermata* infects porcupines in North America; and *D. striata* infects wild cats such as bobcats, Florida panthers, ocelots, and margays in North and South America. (Table 12.3).

Life Cycle and Morphology

Adult female and male worms reside in the right heart of dogs, and microfilariae are found in the blood, where they are ingested by mosquitoes or, in the case of *D. ursi*, *Simulium* blackflies (Figures 12.32 and 12.33). After biological development of the larvae in the mosquito,

Table 12.3 *Dirofilaria* species infecting humans

Species	Length and diam		Geographic area	Clinical findings	Comments
	Females	Males			
<i>D. immitis</i>	230–310 mm, 350 μm	120–190 mm, 300 μm	Throughout the world; tropics to temperate areas	Small pulmonary infarcts usually asymptomatic and appear as “coin lesions”— usually only a single lesion	Humans most often infected in United States, Japan, Europe, Australia; no external longitudi- nal cuticular ridges
<i>D. tenuis</i>	80–130 mm, 260–360 μm	40–48 mm, 190–260 μm	Subcutaneous parasite of raccoon in United States	Gravid worm in thigh and abdominal wall (2 patients)	External longitudinal cuticular ridges; usually low and rounded
<i>D. repens</i>	100–170 mm, 460–650 μm	50–70 mm, 370–450 μm	Subcutaneous parasite of dogs, cats in Europe, Africa, Asia	Can cause pulmonary disease as with <i>D. immitis</i> ; also recovered from subcu- taneous tissue; subcutane- ous (normally nodular) and the submucosa (nodu- lar or not)	The most commonly affected areas are the head, the thoracic wall, and the upper limbs; most infections seen in Italy; many cases probably not diagnosed, and patients recover spontaneously; external ridges appear beaded
<i>D. ursi</i>	117–224 mm, 460–700 μm	51–86 mm, 330–480 μm	Parasitizes bears in Canada, northern United States, and Japan	Usual location of nodules containing the worms was the scalp or a covered part of the upper body where blackflies, the intermediate hosts of <i>D. ursi</i> , normally feed; 5 reports from along U.S.-Canadian border	Case reports indicate worms like either <i>D. ursi</i> or <i>D. subdermata</i> ; distinct longitudinal cuticular ridges; cuticular ridges fewer and farther apart, regularly and widely spaced on the outer sur- face, usually evident even when the worms are necrotic
<i>D. subdermata</i>	117–185 mm, 440–660 μm	41–66 mm, 280–420 μm	Infects porcupines in North America	May see inflamed subcu- taneous nodules (painful, erythematous, sometimes migratory)	Very difficult to differentiate female <i>D. ursi</i> from <i>D. subder- mata</i> ; now called <i>D. ursi</i> -like
<i>D. striata</i>	250–360 mm, 440–500 μm	80–120 mm, 350–380 μm	Bobcats in Florida, panthers, ocelots, margays in North and South America	Rare, but produces subcu- taneous lesions; also recov- ered from eye in one child	Ridges may mimic lateral alae

dogs and humans may be infected with the infective larvae when the mosquito takes a blood meal. Development to a mature adult takes approximately 180 days in the dog. In humans, the worms do not reach maturity and no microfilariae can be detected.

Adult worms in the *Nochtiella* subgenus live in the subcutaneous tissues of their hosts, although in some cases the worms migrate to the pulmonary vessels. There is often only a single worm; therefore, there is no production of microfilariae.

Clinical Disease

The first reported case in humans was recorded in 1941. Many of the patients were asymptomatic, and pulmonary nodules (coin lesions) were noted on routine X-ray examinations or at autopsy (75). Symptomatic patients exhibited signs and symptoms leading to chest examination, with common findings of chest discomfort,

cough, fever, chills, malaise, and occasional hemoptysis. Infections were more frequent in males than in females, and most individuals were 40 to 60 years old.

When the worms lodge in the pulmonary artery branches, they cause an infarct. These lesions are usually on the periphery of the lungs and are sharply defined (coin lesion). There is a central necrotic area surrounded by a granulomatous inflammation and a fibrous wall. Dead or dying worms may be found in the lesion (Figures 12.34 and 12.35).

In one review, 39 patients were discussed. All were Americans between 8 and 80 years old and included 23 men and 16 women (38). Twenty-two of the patients (56%) were asymptomatic, and the pulmonary nodule was discovered on chest X rays during a routine physical examination. Seventeen patients (44%) presented with general complaints or respiratory symptoms. Only 10% of the patients had a peripheral eosinophilia. Most lesions (76%) were seen in the right lung, with a predilection for the lower lobe. Five

Figure 12.34 Pulmonary nodule with *Dirofilaria immitis* (cross section). (Original photograph by G. Healy; from *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

patients had multifocal nodules. All patients underwent thoracotomy with excisional lung biopsy or lobectomy. In all cases, histology revealed a histiocyte-rimmed necrotic nodule containing fragments of a partially degenerated *D. immitis* worm, while adjacent lung parenchyma showed morphological features consistent with other pulmonary processes such as extrinsic allergic alveolitis and/or pulmonary vasculitis syndromes. This group of cases highlights the morphologic variation seen in human pulmonary dirofilariasis and emphasizes the need to consider this diagnosis in all cases of necrotizing granulomas of the lung.

Diagnosis

Microfilariae cannot be found in the blood or tissues, and serologic results are of little value because of the lack of sensitivity and specificity of this method. Some patients have a moderate eosinophilia. Diagnosis can be confirmed by the identification of worms in surgical or autopsy specimens. Because the immature larvae may be detected in only a few microscopic sections, careful histologic examination is necessary. The cuticle of nematodes contains chitin, which

Figure 12.35 Dirofilariasis. (Upper) Computed tomogram image with fine needle in left pulmonary round focus; round focus in right lung periphery. (Lower) Histology of resected “coin lesion” with immature *Dirofilaria* in the peripheral pulmonary artery; silver methenamine stain. (From R. Fueter and J.-O. Gebbers, *Schweiz. Med. Wochenschr.* 127:2014, 1997, with permission).

can be stained with nonspecific whiteners such as calcofluor white. *Dirofilaria* larvae stained with calcofluor white can be easily recognized in tissue sections, whereas the parasite may be difficult to identify using routine histologic stains.

In a very extensive study of over 90 cases of human infection with *D. repens*, the authors commented on the diagnostic difficulties involved with histologic diagnosis (89). As the worms begin to die within the nodule, the invasion of inflammatory cells begins at the worm’s orifices (mouth, vulva, anus, and cloaca) and gradually spreads throughout its body. It is recommended that the nodule be sectioned at different points in order to review morphologic features that may still be recognizable. This review also contains a series of color photographs in which the nematodes are in an excellent state of preservation, while other photographs illustrate the range of disintegration of the worm within the nodule (Figure 12.36).

Figure 12.36 *Dirofilaria tenuis*. (Upper) Cross section from right flank muscle. (Lower) Cross section enlarged. Note the key characteristics: thick cuticle; low, rounded, wavy external longitudinal cuticular ridges; prominent lateral chords; prominent somatic musculature; and location within soft tissue. (Photographs courtesy of Marjorie R. Fowler, with permission.)

Treatment

Lesions identified in the lungs are frequently removed when cancer is suspected (39). The correct diagnosis can be confirmed by examination of histologic preparations after surgery. Identification of the worm in biopsy specimens or extraction of the worm from the lesion will confirm the diagnosis. Surgical removal of the worms is the only known treatment. No chemotherapeutic agents are used, since they appear to be ineffective.

Epidemiology and Prevention

Although at least 15 species of mosquitoes can carry the infective forms and the infection is considered an emerging zoonosis, probably fewer than 1,000 cases of human infection have been described. However, it is quite possible that many infections go undiagnosed and the number of cases is larger than documented. Canines, cats, foxes, muskrats, otters, and sea lions are natural hosts. The infection in animals has been noted in the United States, Africa, Mediterranean countries, Southeast Asia, and the Pacific Islands. The prevalence of infection in dogs in the southeastern United States may be as high as 40%.

Intestinal Cestodes

Diphyllobothrium latum

Taenia solium

Taenia saginata

Taenia saginata asiatica (Asian *Taenia*
or *Taenia asiatica*)

Hymenolepis nana

Hymenolepis diminuta

Dipylidium caninum

Adult cestodes, or tapeworms, live attached to the mucosa in the small intestine and absorb food from the host intestine. The attachment organ is called the scolex, to which is attached a chain of segments or proglottids called the strobila. Each proglottid contains a male and female reproductive system. The proglottids are classified as immature, mature, or gravid (the latter are found at the end of the strobila and contain the fully developed uterus full of eggs). The uterine structure in the gravid proglottids is often used as the main criterion for identification. The eggs and/or scolex can also be used to identify a cestode to the species level (Algorithm 13.1).

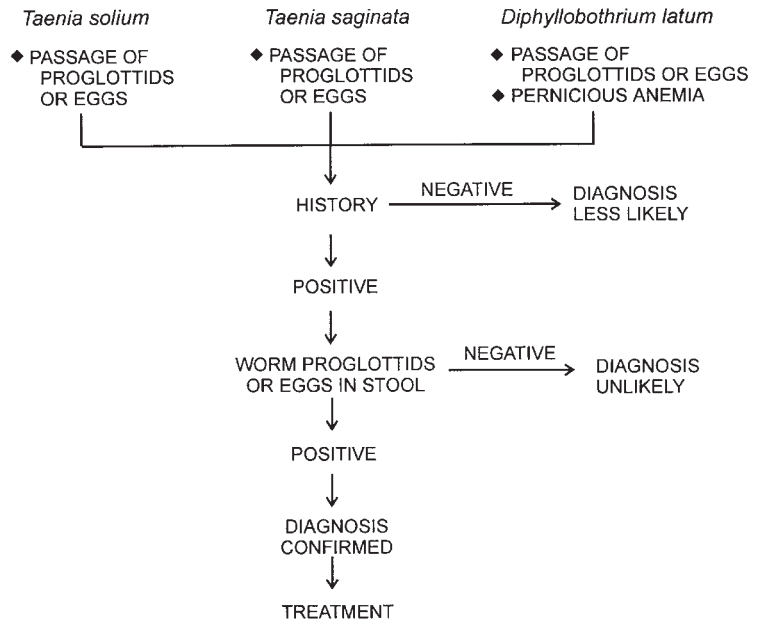

Cestodes have complex life cycles that usually involve both the intermediate and definitive hosts. In some infections, humans serve as only the definitive hosts, with the adult worm in the intestine (*Diphyllobothrium latum*, *Taenia saginata*, *Hymenolepis diminuta*, and *Dipylidium caninum*). In other cases, humans can serve as both the definitive and intermediate hosts (*T. solium* and *H. nana*).

Tapeworms have been recorded in writings from about 1500 BC and are among the earliest known human parasites. Galen, in the second century, recognized *Taenia*, and other tapeworms have been recognized since the late 1500s (3). Apparently, eggs of *Diphyllobothrium* spp. have been found in Alaska and date from the 13th and 17th centuries (8). It was not until 1993 that a new human species was identified and described, *Taenia asiatica*; however, there is some discussion regarding whether this is actually a separate species or a subspecies of *T. saginata*.

The exact prevalence of human intestinal tapeworms is not really known, but estimates are that as many as 100 million people are infected with *T. saginata* and *T. solium* while approximately 75 million are probably infected with *H. nana*. Certainly, the presence of adult tapeworms in the intestinal tract is not life-threatening; however, infection with larval tapeworms can be very serious and can lead to death.

Diphyllobothrium latum

D. latum belongs to the pseudophyllidean tapeworm group, which is characterized by having a scolex with two bothria (sucking organs) rather than the typical four suckers seen in the *Taenia* tapeworms. The distribution of this worm

Algorithm 13.1 *Taenia solium*, *T. saginata*, and *Diphyllbothrium latum*.

is worldwide, with various increased outbreaks reported from time to time. Areas of the world where a high incidence of infection with *Diphyllbothrium* spp. has been reported to occur include the Baltic countries, countries within the former USSR, and, especially, Finland; infections are also present in tropical Africa and parts of Asia, as well as North and South America. *Diphyllbothrium* spp. are not host specific. *D. dendriticum* occurs in fish-eating birds and mammals and can be found in certain human populations in Alaska, while *D. ursi* occurs in bears and humans in Alaska and Canada. Occasionally, *D. pacificum* is found in humans, although it is normally found in pinnipeds off the coast of Peru. Infections have also been found in New Guinea and Australia. Currently there are 13 species in the genus, most of which can infect humans.

In reviewing data from Europe during the last 20 years, results indicate that several dozen cases of diphyllbothriasis have been reported each year from Finland and Sweden, that there have been numerous cases in the French- or Italian-speaking areas around subalpine lakes, and that sporadic cases have been observed in Austria, Spain, Greece, Romania, Poland, and Norway. Over 30 cases have been identified on the Swiss shores of Lake Maggiore since 1990, and 70 cases have been reported on the Swiss and French shores of Lake Lemman between 1993 and 2002. Between 8 and 12% of perch fillets from Lake Lemman and 7.8% of perch from Lake Maggiore were found to contain larvae. Sources of infection include marinated fish fillets in northern Europe, “carpaccio di persico” in northern Italy, and perch and charr consumed raw or undercooked around Lake Lemman (20).

The infection is acquired by the ingestion of raw, poorly cooked, or pickled freshwater fish and has been associated with a condition similar to pernicious anemia (Table 13.1).

Life Cycle and Morphology

The life cycle can be seen in Figure 13.1. Infection with the adult worm is acquired by the ingestion of raw, poorly cooked, or pickled freshwater fish (pike, perch, lawyer, salmon, trout, whitefish, grayling, ruff, turbot, etc.) containing the encysted plerocercoid larvae. After ingestion, the worm matures, with egg production beginning in about the fifth or sixth week. The adult worm reaches a length of 10 m or more and may contain up to 3,000 proglottids.

The scolex of *D. latum* is elongate and spoon shaped and has two long sucking grooves, one on the dorsal surface and the other on the ventral surface (Figure 13.2). The mature and gravid proglottids are wider than they are long, with the main reproductive structures (mainly the uterus) located in the center of the gravid proglottid. This configuration of the uterine structure has been called a rosette (Figures 13.3 and 13.4). Identification to the species level is usually based on this typical morphology of the gravid proglottids. Both eggs and proglottids may be found in the stool. Often, a partial chain of proglottids may be passed (a few inches to several feet).

The eggs are broadly oval and operculated and measure 58 to 75 μm by 40 to 50 μm (Figure 13.5). After developing for 2 weeks in freshwater, the eggs hatch and the ciliated, coracidium larvae are ingested by the first intermediate host, the copepod (Figure 13.6). The copepods, containing the second larval stage (proceroid), are then ingested by

Characteristic	<i>Diphyllobothrium latum</i>	<i>Taenia saginata</i>	<i>Taenia saginata asiatica</i>	<i>Taenia solium</i>	<i>Hymenolepis nana</i>	<i>Hymenolepis diminuta</i>	<i>Dipylidium caninum</i>
Diagnostic problems or notes	Eggs are sometimes confused with eggs of <i>Paragonimus</i> spp.; eggs are unembryonated when passed in feces	Eggs are identical to those of <i>T. solium</i> ; ordinarily can distinguish between species only by examination of gravid proglottids; eggs can be confused with pollen grains (handle all proglottids with extreme care)	Eggs are identical to those of <i>T. solium</i> and <i>T. saginata</i> ; ordinarily can distinguish between species only by examination of gravid proglottids; proglottids much smaller than those of <i>T. saginata</i> or <i>T. solium</i> ; eggs can be confused with pollen grains (handle all proglottids with extreme care)	Eggs are identical to those of <i>T. saginata</i> ; eggs less likely to be found in feces than with <i>T. saginata</i> (handle all proglottids with extreme care as <i>T. solium</i> eggs are infective to humans)	Sometimes confused with eggs of <i>H. diminuta</i> ; rodents serve as reservoir hosts	Should not be confused with <i>H. nana</i> , as eggs lack polar filaments; rodents serve as reservoir hosts	Gravid proglottids resemble rice grains (dry) or cucumber seeds (moist); dogs and cats serve as reservoir hosts

fish, which may be ingested by larger fish. In this situation, the final fish intermediate host may contain many plerocercoid larvae, which initiate the infection with the adult worm when ingested by humans (Figure 13.7).

Clinical Disease

Symptoms depend on a number of variables: the number of worms present, the amounts and types of by-products produced by the worm, the patient’s reaction to such by-products, and the absorption of various metabolites by the worms. Occasionally intestinal obstruction, diarrhea, abdominal pain, or anemia occurs. If the worm is attached at the jejunal level, there may be a vitamin B₁₂ deficiency, which resembles pernicious anemia and develops in a very small percentage of persons harboring the tapeworm. Heavy or long-term infections with *D. latum* may cause megaloblastic anemia due to parasite-mediated dissociation of the vitamin B₁₂-intrinsic factor complex within the gut lumen, making B₁₂ unavailable to the host (46). This clinical picture is seen most frequently in Finland, where individuals tend to have a genetic predisposition to pernicious anemia. In patients without this genetic predisposition, symptoms of a *D. latum* infection may be absent or minimal, consisting of a slight leukocytosis with eosinophilia.

Most patients are actually asymptomatic; however, the following symptoms were found more frequently in those who were infected than in the control group: fatigue, diarrhea, dizziness, weakness, numbness of extremities, and a sensation of hunger. No differences were found in terms of abdominal pain. Symptoms occur in approximately 22% of infections. No proglottids are routinely passed in the stool as is seen with *Taenia* infections, although occasionally a string of proglottids is passed or vomited.

About 40% of patients infected with *D. latum* have reduced vitamin B₁₂ levels, but fewer than 2% develop anemia. In cases of severe anemia, there may be neurologic symptoms such as weakness, numbness, paresthesia, movement and coordination problems, and impairment of deep sensibilities. Both the anemia and neurologic problems are reversed by administration of vitamin B₁₂ and do not reoccur after the worm has been eliminated. This type of severe anemia is rarely seen, probably as a result of overall improvements in general nutrition of the population in the area of endemic infection.

Diagnosis

Diagnosis is usually based on the recovery and identification of the characteristic eggs or proglottids. If the egg operculum is difficult to see, the coverslip of the wet preparation can be tapped and the pressure may cause the operculum to pop open, thus making it more visible. The eggs are unembryonated at the time they are passed in the stool. Proglottids are often passed in chains (a few inches to several feet), and this is a clue to *D. latum*. The overall

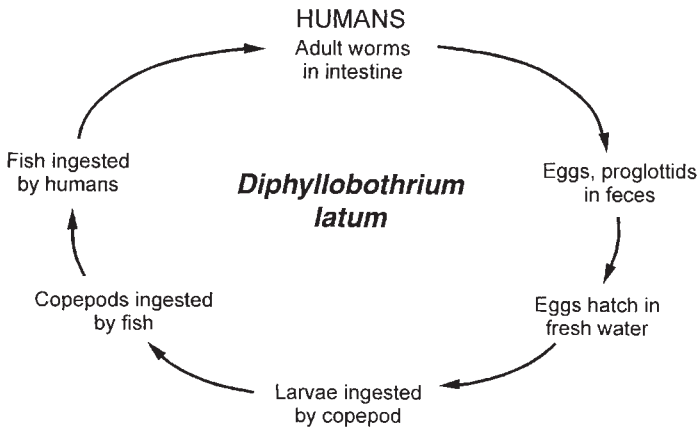

Figure 13.1 Life cycle of *Diphyllbothrium latum*.

proglottid morphology with the rosette uterine structure also facilitates identification.

Although differentiation is not generally a problem, the eggs of *D. latum* look very much like those of *Nanophyetus salmincola*, a trematode that is commonly found in the Pacific Northwest region of the United States and in eastern Siberia. *N. salmincola* eggs have been described as being broadly oval, operculate, relatively thick-shelled, and yellowish; they measure 60 to 80 μm by 34 to 50 μm , a direct overlap with the size range of *D. latum*. However, human infection with *N. salmincola* is generally incidental and uncommon.

KEY POINTS—LABORATORY DIAGNOSIS

Diphyllbothrium latum

- Careful examination of the eggs should reveal the operculum. If it is difficult to see, it can sometimes be popped open by tapping on the coverslip of the wet preparation. The light should be somewhat reduced to allow the operculum to be seen more easily.

Figure 13.2 Scolex of *Diphyllbothrium latum*.

- Often, the proglottids are passed in chains (a few inches to a few feet). Also, the gravid proglottids are much wider than long, with the uterine structure being seen in the middle of the proglottid (rosette).
- Handling of the specimens presents no danger in terms of cysticercosis; however, all fecal specimens should be considered potentially infectious (with other organisms).

Treatment

The use of both praziquantel and niclosamide has been recommended (see chapter 25). A single dose of praziquantel (5 to 10 mg/kg of body weight) for both adults and children eliminates the infection in >90% of patients. Niclosamide is given as a single dose of 2 g (four tablets chewed thoroughly). A single dose of 50 mg/kg is recommended for children. Niclosamide may not be available within the United States. After therapy, if the worm has not been spontaneously passed within 2 h, a saline purgation can be used.

Epidemiology and Prevention

Although *D. latum* infections have been detected in other mammals, in areas where human infection has become

Figure 13.3 Gravid proglottids. (1) *Taenia saginata*; (2) *T. solium*; (3) *Diphyllbothrium latum*; (4) *Dipylidium caninum*.

Figure 13.4 Gravid proglottids of *Diphyllbothrium latum*. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*. Slides from J. F. Mueller.)

rare, the natural transmission cycle from mammals other than humans does not seem to be sustained. It is quite possible to acquire the infection from the ingestion of infected raw freshwater fish that has been shipped under refrigeration to areas where the infection is not endemic. Preventive measures would include thorough cooking of all freshwater fish or freezing for 24 to 48 h at -18°C . This infection has been called the Jewish housewives' disease, since the individual preparing the food may sample the dish (e.g., gefilte fish) prior to cooking and acquire the infection. Other groups who tend to eat raw or insufficiently cooked fish include the Russians, Finns, and Scandinavians (7). Raw fish marinated in lime juice (ceviche) is also a source of infection (*D. pacificum*) in Latin America. Since the domestic dog can serve as a reservoir host, infected dogs should be periodically treated. Other factors contributing to the parasitic cycle include the continued dumping of wastewater into lakes and possible animal reservoirs.

Figure 13.5 *Diphyllbothrium latum* eggs. Note the small knob at the abopercular end (end opposite the operculum); also note that the operculum does not fit into "shoulders" like the *Paragonimus* eggs but presents a smooth outline on the egg shell.

Taenia solium

T. solium infection may have been recognized since biblical times, and the life cycle was delineated in the mid-1850s (7). The tapeworm is found in many parts of the world and is considered an important human parasite where raw or poorly cooked pork is eaten (Table 13.1).

Cysticercosis infections with *T. solium* larvae are relatively common in certain parts of the world. However, cysticercosis is becoming more common within the United States; the infection is associated with Hispanic ethnicity, immigrant status, exposure to areas where neurocysticercosis is endemic, and the American Southwest (15, 43, 50, 58). Serum immunoblotting shows that the seroprevalence of cysticercosis and infection with the adult tapeworm in a

Figure 13.6 Copepod. (Illustration by Sharon Belkin.)

rural southern California population approximates the prevalence in some areas of Latin America where the infection is endemic (15). Also, an increasing number of cases has been reported in the United States over the past 50 years (58). This extraintestinal form of the infection is far more serious than the presence of the adult worm in the intestine.

Life Cycle and Morphology

The life cycle can be seen in Figure 13.8. Infection with the adult worm is initiated by the ingestion of raw or poorly cooked pork containing encysted *T. solium* larvae (Figure 13.9). The larva is digested out of the meat in the stomach, and the tapeworm head evaginates in the upper small intestine, attaches to the intestinal mucosa, and grows to the adult worm within 5 to 12 weeks. Although usually a single worm is present in the intestine, multiple worms may occur. The adult worm reaches a length of 2 to 7 m and may survive for 25 years or more (7).

Figure 13.7 *Diphyllobothrium latum*, encysted pleurocercoids in cherry salmon fillet. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of T. Oshima, Yokohama City University.)

The attachment organ, or scolex, has four large suckers with a rounded rostellum containing a double row of 25 to 30 small hooks (Figure 13.10). The neck region is short and about half the width of the scolex. The total number of proglottids is less than 1,000, with the immature proglottids being wider than long, the mature proglottids being approximately square, and the gravid segments being longer than wide.

Identification to the species level is usually based on the number of lateral uterine branches in the gravid proglottid (Figures 13.3 and 13.11). The main lateral branches should be counted where they come off the main central stem. Only one side is counted, and there are between 7 and 13 branches, with an average of 9.

The terminal gravid proglottids break off from the main strobila and are passed out in the stool or actually migrate out of the bowel. In some cases, three or four attached proglottids pass out in the stool. Eggs usually pass from the uterus through the ruptured wall, where the proglottids break off from the strobila. The eggs are round or slightly oval (31 to 43 μm), have a thick, striated shell, and contain a six-hooked embryo or oncosphere (Figure 13.12). These eggs may remain viable in the soil for weeks.

On ingestion by hogs or humans, the eggs hatch in the duodenum or jejunum after exposure to gastric juice in the stomach. The released oncospheres penetrate the intestinal wall, are carried via the mesenteric venules throughout the body, and are filtered out in the subcutaneous and intramuscular tissues, the eyes, the brain, and other body sites. This cysticercus is an ovoid, milky-white bladder with the head invaginated into the bladder (Figure 13.13). The bladder worms measure 5 mm long by 8 to 10 mm wide; however, in the brain, they may reach a volume of 60 ml. The host generally produces a fibrous capsule around the bladders, unless they are located in the brain, particularly the ventricles.

Clinical Disease

Adult Worm. The presence of the adult worm usually causes no problems other than slight irritation at the site of attachment or vague abdominal symptoms (hunger pains, indigestion, diarrhea, and/or constipation). There may be a low-grade eosinophilia, usually under 15%, and increased levels of immunoglobulin E (IgE) in serum.

Cysticercosis. The larval forms of *T. solium* have been called *Cysticercus cellulosae*; however, this term is not taxonomically correct and is used infrequently. These cysticerci have been recovered from all areas of the body, and symptoms depend on the particular body site involved. The presence of cysticerci in the brain represents the most frequent parasitic infection of the human nervous system and

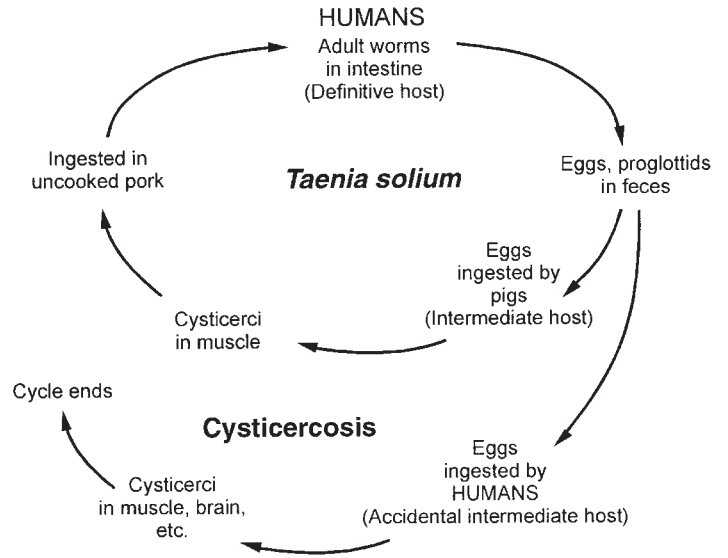

Figure 13.8 Life cycle of *Taenia solium*.

Figure 13.9 (A) Cysticerci in muscle (pork). (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (B) Cysticerci in muscle (dog). (Courtesy of W. Jann Brown and Marietta Voge, University of California, Los Angeles.)

the most common cause of adult-onset epilepsy throughout the world (13, 26, 43). For unknown reasons, in Latin America it is unusual for both brain and muscle cysticercosis to occur in the same patient, with fewer than 6% of patients having cysticerci in both sites. However, elsewhere in the world, subcutaneous involvement by *T. solium* cysticerci has been detected in as many as 78.5% of patients with cerebral cysticercosis (12). Possible reasons for such differences may include (i) the immune status of the patient, (ii) the human leukocyte antigen type, (iii) the nutritional status of the patient, (iv) the burden of eggs infecting the patient, and (v) a difference in the strains of *T. solium*. It is also rare for a patient with cysticercosis to harbor adult *T. solium* worms in the intestine. Neurocysticercosis

Figure 13.10 Scolex of *Taenia solium*.

Figure 13.11 Gravid proglottid of *Taenia solium*.

usually affects males and females of all ages, with a peak incidence between 30 and 50 years of age.

Neurocysticercosis is the most common parasitic disease of the central nervous system; in some countries the prevalence exceeds 10% and is responsible for up to 50% of late-onset epilepsy cases (43). Factors related to neurocysticercosis pathology include (i) the individual immune response to the presence of the parasite, from tolerance to a severe inflammatory response; (ii) the location of the parasite in the brain; (iii) the number of cysticerci present; and (iv) the stage or age of the lesions (live cysts, inflammatory exudates, granulomas, calcifications, and residual fibrosis).

When the larvae are found in the brain, symptoms can result from actual larval invasion of the brain tissue and/or death of the organism, which stimulates tissue reactions around the larvae (Figure 13.14). It has been recommended that in every case of epilepsy occurring in a patient with no family history of fits and no personal history of fits in childhood, the probability of cysticercosis should be entertained (39). Although studies indicate the presence of epileptiform seizures in patients with cysticercosis, other symptoms, including abnormal behavior, transient paresis, intermittent obstructive hydrocephalus, disequilibrium, meningoencephalitis, and visual problems, may also be present. Spinal fluid from patients with cerebral cysticercosis shows possible eosinophilia and pleocytosis (the most common cell type is the lymphocyte), with atypical mononuclear lymphoid cells. The most distinctive features of the infection in the spinal fluid are atypical, reactive lymphoid cells with a mixed cellular population. A study by Sotelo et al. (54) of 753 cases of neurocysticercosis reviewed inactive and active disease, the frequency of signs and symptoms, and cerebrospinal fluid (CSF) findings. More than 50% of all patients exhibit at least two of these clinical presentations (54) (Table 13.2). Although rare, the

Figure 13.12 *Taenia* eggs. Note the striated shell and the presence of the six-hooked oncosphere within the thick egg shell. The hooks may not be visible in every egg, particularly in specimens that have been stored for long periods in preservatives; however, in clinical specimens submitted to the laboratory in fixatives for timely examination, the hooklets are generally visible within the egg shell. Without special staining, the eggs of *Taenia* spp. cannot be identified to the species level (*T. solium*, *T. saginata*, *T. asiatica*).

occurrence of secondary parkinsonian tremors in previously shunted patients with cysticercosis suggests obstruction and requires immediate evaluation (33).

In a study from Mexico, the frequency of cerebral arteritis in subarachnoid cysticercosis was higher than previously reported. Involvement of middle-sized vessels is a common occurrence, even in patients without clinical evidence of ischemia (6).

Although rare, a case of acute leukemia and massive cardiopulmonary cysticercosis has been reported (38). In this case, pulmonary cysticercosis may have been caused by the immunosuppression.

Figure 13.13 (A) Cysticercus with head invaginated into the bladder. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*) (B) Scanning electron micrograph of scolex from cysticercus. (Photograph courtesy of U.S. Department of Agriculture).

Cysticerci in the eye can be found in various areas, including in the eyelid and under the conjunctiva. The larvae are unencapsulated when found in the vitreous or anterior chamber and will actively change shape, casting

Figure 13.14 Gross specimen of brain containing many cysticerci. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

shadows in front of the retina (Figure 13.15). Unless the organism is removed, permanent eye damage may occur, particularly if the parasite dies, thus stimulating an intense inflammatory reaction.

A single case of cysticercosis involving the scrotum has been reported; the patient's presentation was that of testicular torsion requiring surgical exploration. The patient was a 9-year-old Hispanic boy who was born and raised in the United States and had no history of foreign travel. Histologic testing was confirmatory, as were the serologic results (4).

Based on fine-needle aspiration cytology, five cases of cysticercosis of the tongue and buccal mucosa in children have been reported. Symptoms included gradually increasing nodular swelling; cysticercosis was not

^b Inflammation of the intermediate membrane (between pia mater and dura mater) which encloses the brain and spinal cord.

^c Increased accumulation of cerebrospinal fluid within the ventricles of the brain, usually caused by interference with normal circulation of fluid.

^d Paralysis of conjugate upward movement of the eyes without paralysis of convergence; associated with lesions of the midbrain.

Figure 13.15 Cysticercus in the eye. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*. Photograph courtesy of R. Delgado y Garnica, Hospital Infantil de Tacubaya, Arq. Carlos Laxo y Gaviota, Mexico D.F.)

considered in any of these cases. Since patients with these lesions may be seen by a dentist rather than a physician, cysticercosis should be included in the differential diagnosis of solitary nodular lesions in the oral cavity, particularly in young patients, in areas of endemic infection (48).

There appear to be cases where reactivation of neurocysticercosis occurs, often several years after the patient was considered cured. Several years earlier, one patient had undergone treatment and was presumed to be cured of active disease. Computed tomographic (CT) and magnetic resonance imaging (MRI) studies performed 3 months prior to presentation revealed multiple intracerebral calcified lesions consistent with resolved neurocysticercosis. The patient presented with frontal headaches that occurred intermittently and were associated with vomiting, slowed mentation, and episodic visual scintillations. On presentation, additional imaging studies were performed and showed the same calcified lesions; however, these lesions were now surrounded by large areas of edema (52). Although this patient's symptoms resolved spontaneously within several days, she received a 28-day course of albendazole, cimetidine, and dexamethasone, with subsequent resolution of the cerebral edema. Another earlier report describes five patients whose CT scans showed an area of brain swelling surrounding previously inactive calcifications (16). There are several possible explanations for these relapse cases. Cerebral edema may have resulted from the death of worms that were incompletely calcified and still

viable. There may have been antigen release from dead, calcified parasites. Another explanation, which might be more realistic, suggests that a spontaneous increase in the immune response could have been triggered by antigen release from live or dying parasites. Based on these cases, it is important to remember that patients with calcified lesions may present with late-onset symptoms associated with marked inflammation and cerebral edema surrounding these lesions (26). Retreatment with anthelmintics may or may not be required; corticosteroid therapy may be sufficient.

Larger numbers of cysticerci usually correlate with more serious disease. In general, patients with <20 cysticerci within the parenchyma and the absence of hydrocephalus have a more positive prognosis than do patients who have many basal or ventricular lesions accompanied by hydrocephalus. Also, it is not clear how many asymptomatic patients with intracranial cysticerci eventually develop symptoms or how many symptomatic patients spontaneously recover.

Cysticercus, Racemose Type. The racemose, or proliferating, form of the cysticercus is composed of several bladders that are connected and are often found in the brain, particularly the fourth ventricle and subarachnoid space (Figures 13.16 and 13.17). Within these bladders, no scolices are found and the growth may resemble that of a metastatic tumor. Other larval cestodes may also have a racemose growth pattern, and it may be very difficult to differentiate a *T. solium* racemose cysticercus from other types histologically. The prognosis for such infections is very poor. Racemose cysticerci are usually not found in infected children and may be either a degenerative form or formed in response to infection at a different anatomic

Figure 13.16 Racemose form of *Taenia solium* cysticercus, left temporal lobe (filmy, white material). (Courtesy of W. Jann Brown and Marietta Voge, University of California, Los Angeles.)

site. Cervical spinal cysticercosis is usually associated with the racemose type within the posterior fossa.

Although infection with both human immunodeficiency virus (HIV) and *T. solium* would be expected to occur more frequently due to the increased frequency of HIV in areas where cysticercosis is endemic, very little is known about the impact of HIV on the racemose type of cysticercosis. Very large cysts and the racemose type of neurocysticercosis appear to be more frequent in HIV-positive patients; these findings may be related to an impaired cell-mediated immune response (18).

Diagnosis

Adult Worms. Identification of adult worms to the species level is not possible from the eggs because *T. solium* and *T. saginata* eggs look identical. Identification is usually based on the recovery and examination of the gravid proglottids, in which the main uterine lateral branches are counted after India ink injection staining or some other clearing mechanism (7 to 13 branches for *T. solium* and 15 to 20 for *T. saginata*) (Figure 13.3). If the scolex is recovered after therapy (purgation may be necessary to recover the intact attachment organ), the presence of the

four suckers and the armed rostellum with hooks will differentiate the worm from *T. saginata*. There are some other differences in the mature proglottids; however, these require staining and clearing of the proglottid and may be much more difficult to see.

It is well known that the proglottids of *T. saginata* can actively migrate from the anus. However, proglottids of *T. solium* are actively motile in the stool, so they would appear to be capable of migrating from the anus as well. Since these proglottids contain infective eggs and cannot be identified to the species level at first glance, it is very important that personnel use precautions to prevent accidental infection with *T. solium* eggs, which may lead to cysticercosis. It is also very important that all patients be instructed to use good personal hygiene if they are found to have *Taenia* tapeworm infection, since there may be a time lag between diagnosis and initiation of therapy and a danger of autoinfection with the eggs or possible infection of others.

Using DNA differential diagnosis by base excision sequence scanning thymine-base reader analysis with mitochondrial genes, four distinct *Taenia* spp. can be identified: *T. saginata*, *T. asiatica*, and two genotypes of *T. solium*. Thus, if nucleotide databases are available, this system provides a useful tool for the identification of taeniid specimens from patients and for the study of genetic variations of these helminths (61).

Coproantigen Detection. Preliminary enzyme-linked immunosorbent assay (ELISA) studies for the diagnostic detection of *T. solium* and *T. saginata* coproantigens appear to be very promising (1, 2, 19, 36). The ability to detect human taeniasis by coproantigen ELISA in the absence of eggs in the stool would represent a significant advance in diagnosis. Also, the ability to reliably identify *Taenia* carriers in areas where infections are endemic would improve epidemiologic studies (47, 59). High concentrations of coproantigens are present until approximately 6 to 17 days after treatment. With the newer immunologic and biological methods available, test kits applicable under laboratory and field conditions may be developed and refined in the near future. By using *T. solium* and *T. saginata* DNA probes, a rapid, highly sensitive and specific dot blot assay for the detection of *T. solium* has been developed (11).

Cysticercosis. The diagnosis of cysticercosis usually depends on surgical removal of the parasite and microscopic examination for the presence of suckers and hooks on the scolex. Multiple larvae are frequently present, and the presence of cysticerci in the subcutaneous or muscle tissues indicates that the brain is probably also involved. The calcified larvae can be readily seen on X-ray examination (Figure 13.18). CT scans or MRI

Figure 13.18 Calcified cysticerci in tissue. (Armed Forces Institute of Pathology photograph.)

may reveal the presence of lesions in the brain (Figure 13.19). Although neurocysticercosis may be suspected, particularly in a patient living in an area of endemicity, the multiple neurologic syndromes and the various clinical presentations make it difficult to confirm the diagnosis, even with CT or MRI techniques. The primary consideration may be brain tumor. If the racemose form is present in the brain, the CT scan cannot distinguish the lesion from that caused by other tumors. Ultrafast CT has been used successfully to diagnose a case of cysticercosis involving the myocardium (14). Ocular cysticercosis can usually be diagnosed by visual identification of the movements and morphology of the larval worm.

Fine-needle aspiration cytology has also been recommended as a cost-effective procedure, since it eliminates the need for open biopsy (32, 48). The characteristic cytomorphology of parasitic tegument and parenchyma has proven to be very helpful. Review of fine-needle aspiration smears from 258 patients with cysticercosis showed that Charcot-Leyden crystals were conspicuous by their absence, although cholesterol crystals were often seen (5). Absence of Charcot-Leyden crystals in cysticercosis could be attributed to the high lipid content of these lesions, as indicated by the frequent occurrence of cholesterol crystals.

Cysticercosis Serologic Testing. The immunoblot assay for neurocysticercosis has been a definite improvement in antibody detection and is available at the Centers

Figure 13.19 Neurocysticercosis. Scanning images of cysticerci in brain. (Upper, adapted from the Public Health Image Library, Centers for Disease Control and Prevention; lower, from A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

for Disease Control and Prevention (29, 37). A semipurified abstract of *T. solium* cysticerci is used as the antigen, with seven major glycoprotein bands (50 to 13 kDa); a serum reaction with any one of these bands is indicative of cysticercosis. The sensitivity is 98%, and the specificity is 100% (37). Both a single parietal cyst and subcutaneous infections without neurologic involvement are usually detected by this procedure. This test is more sensitive than the ELISA procedure, especially when using serum (45). However, in another study using cerebrospinal fluid, the ELISA results were positive for 22 of 24 patients with active neurocysticercosis; however, six cases with calcified cysts and one case in transition were both negative. Thus, a significant difference was seen between active and inactive neurocysticercosis (41).

An enzyme-linked immunoelectrotransfer blot (EITB) assay using blood dried on filter paper has proven to be a convenient, economical way of handling field samples for epidemiologic surveys of cysticercosis, particularly in underdeveloped countries, where refrigeration and venipuncture represent problems with specimen collection and handling. There is no decrease in sensitivity compared with traditional serum samples used in the EITB assay (30).

Using the EITB assay on CSF samples, the sensitivity of a recent study was 86% (27). Patients with hydrocephalus had higher levels of circulating antigen, and there was no difference between antigen levels in CSF taken before and 14 days after therapy. There was a high correlation between the number of live cysts detected by CT and the number and intensity of antibody reactions. In contrast, there was a negative correlation with the number of enhancing lesions seen using CT, supporting the hypothesis that enhancing lesions correspond to the dead stage of the parasite.

KEY POINTS—LABORATORY DIAGNOSIS

Taenia solium

1. Preliminary examination of the proglottid may not allow identification without clearing or injection of the uterine branches with India ink.
Note. Because of the possible danger of egg ingestion, specimens and proglottids should be handled with extreme care. The proglottid uterine structure will be packed with viable, infectious eggs, even if the proglottids are received in fixative.
2. The eggs look identical to those of *T. saginata*, and no identification to the species level can be performed with eggs alone without special procedures.
3. *Any patient with Taenia eggs recovered in the stool should be cautioned to use good hygiene. These patients should be treated as soon as possible to avoid the potential danger of accidental infection with the eggs, which may lead to cysticercosis (T. solium).*
4. Although serologic reagents for antibody detection and antigen detection tests have been developed, not all reagents produce sensitive and specific results. Consultation with the Centers for Disease Control and Prevention and/or your state public health laboratories may be helpful. Efforts made to use the immunodominant bands in ELISA are expected to yield a sensitive but easier and cheaper test for neurocysticercosis (55).

Treatment

Adult Worm. The use of praziquantel or niclosamide has been recommended (see chapter 25). Since there is

always the possibility of cysticercosis via autoinfection, patients should be treated as soon as they are diagnosed.

Cysticercosis. Surgical removal is recommended when possible. In patients with ocular cysticercosis, cyst removal rather than enucleation is recommended. To prevent loss of the eye, it is recommended that the cysticercus be removed while it is still living; antiparasitic drugs may lead to a loss of vision secondary to intraocular inflammatory reaction. Excisional biopsy is recommended for subconjunctival cysticercosis. Idiopathic cystic myositis can present like extraocular muscle cysticercosis but can be differentiated by resolution with corticosteroid treatment. Therapy for orbital cysticercosis with oral albendazole and corticosteroids can prevent recurrent inflammation and improve ocular mobility (51).

The introduction of new drugs for cysticercosis has significantly changed the approach to patient management. Two drugs, praziquantel and albendazole, are effective against the cysticerci (53, 55). Praziquantel is rapidly absorbed and reaches its peak concentration in plasma in 1.5 to 2 h; it can cross the blood-brain barrier, and the concentration in CSF is approximately 24% of that obtained in the plasma (55). Apparently, the drug action damages the worm tegument to produce spastic paralysis of the scolex. Albendazole is a broad-spectrum anthelmintic drug; the anticysticercal impact is by inhibition of glucose uptake by parasitic membranes. In a study of 114 patients with parenchymal brain cysticercosis, albendazole was found to be more effective than praziquantel for both a full and a short course of therapy. Also, the length of albendazole therapy could be shortened without loss of efficacy; in contrast, a short course of praziquantel caused a 12% reduction in drug effectiveness. From the results of this study, an 8-day course of albendazole is recommended as treatment for parenchymal brain cysticercosis; a 15-day course of praziquantel could subsequently be used in patients demonstrating partial response to albendazole (53). The issue of medical or surgical therapy for subarachnoid or ventricular cysticercosis is controversial; however, successful therapy with albendazole has been reported for a patient with cysticerci in both subarachnoid and ventricular locations (17).

The prognosis for the patient is excellent when the adult worm is present, good when the cysticerci can be surgically removed or medically treated, and poor when the racemose form of the parasite is present, particularly in the brain. However, treatment of hydrocephalus secondary to cerebral racemose cysticercosis using endoscopic third ventriculostomy appears to be an effective and safe technique; the efficacy of endoscopic third ventriculostomy will be evaluated in additional studies (34).

Epidemiology and Prevention

Although other animals occasionally harbor the cysticercus stage, poorly cooked or raw pork is the usual source of human infection for the development of the adult worm. Three cases of cysticercosis in black bears in three northern California counties have been confirmed as due to *T. solium* (56). The number and geographic separation of the cases indicate that infection was not due to a single contaminated source but to human fecal material contaminated with *T. solium* eggs. How much of a threat this human-to-bear transmission poses to the bear population and/or to hunters (cysticercosis) is unknown, as is the reverse situation, bear-to-human transmission (adult worm). Human infection with cysticerci can involve thousands of organisms obtained from various sources: ingestion of *T. solium* eggs in contaminated food or water; self-infection from the presence of the adult worm in the intestine; and possibly internal autoinfection, in which the eggs come in contact with the stomach acid, thus possibly allowing hatching and penetration of the larvae into the tissues.

Prevention involves awareness of the infection route and the use of good sanitary and personal hygiene measures. The ingestion of vegetables fertilized with sewage should also be avoided. Adequate requirements for human sewage disposal should be followed. One of the most important means of prevention is the adequate cooking of pork and pork products; thorough cooking at 65°C kills the cysticerci; however, salting or pickling of the meat is usually not effective. In pig carcasses held at 4°C, more than 80% of the cysticerci were viable between days 1 and 25 (24). These findings confirm that eating raw or undercooked pork or viscera of pigs following refrigeration at 4°C for less than 30 days can lead to infection with *T. solium*. Effective immune protection of pigs against cysticercosis through vaccination has also been reported (42). The use of the EITB assay in sentinel piglets has been used to determine environmental contamination with *T. solium* eggs. This approach permits an indirect assessment of human risk and could be useful in monitoring the efficacy of intervention programs (28).

For a number of reasons, *T. solium* is a candidate for control: (i) neurocysticercosis has a tremendous impact on human health; (ii) since *T. solium* is the only source of cysticercosis for both humans and pigs, it may be epidemiologically controllable; (iii) effective and practical therapeutic intervention is available; (iv) international commitment to the use of control measures is present; and (v) the cost is acceptable. Through education, allocation of funds, recognition of both the human and veterinary issues, implementation of control measures, and chemotherapy, morbidity and mortality may be drastically reduced throughout the world (10, 44, 49).

Taenia saginata

T. saginata was apparently differentiated from *T. solium* in the late 1700s; however, cattle were not identified as the intermediate host until 1863. This infection has a worldwide distribution and is generally much more common than *T. solium* infection, particularly in the United States (Table 13.1). The overall impact on human health is much smaller than that seen with *T. solium*, since cysticercosis with *T. saginata* is apparently quite rare.

Life Cycle and Morphology

The life cycle is very similar to that of *T. solium* (Figure 13.20). Infection with the adult worm is initiated by the ingestion of raw or poorly cooked beef containing encysted *T. saginata* larvae. As with *T. solium*, the larva is digested out of the meat in the stomach, and the tapeworm evaginates in the upper small intestine and attaches to the intestinal mucosa, where the adult worm matures within 5 to 12 weeks. The adult worm can reach 25 m but often measures only about half this length. Although a single worm is usually found, multiple worms can be present.

The scolex is “unarmed” and has four suckers with no hooks (Figure 13.21). The proglottids usually number 1,000 to 2,000, with the mature proglottids being broader than long and the gravid proglottids being narrower and longer. Identification to the species level is usually based on the

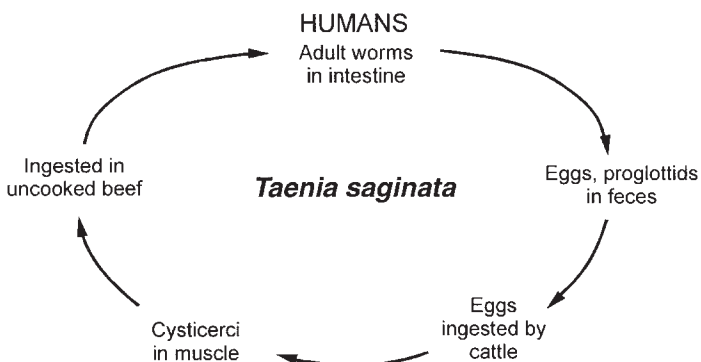

Figure 13.20 Life cycle of *Taenia saginata*. The same life cycle is applicable to *T. asiatica* (except that the eggs are contained primarily in the liver of the pig).

Figure 13.21 Scolex of *Taenia saginata*.

number of main uterine lateral branches, which are counted on one side of the gravid proglottid. There are between 15 and 20 branches, with an average of 18 (Figure 13.22).

Gravid proglottids often crawl from the anus during the day, when the host is most active. These proglottids may crawl under the stool when a specimen is submitted unpreserved in the stool collection carton. The eggs cannot be distinguished from those of *T. solium*. They are round to slightly oval, measure 31 to 43 μm , have a thick, striated shell, and contain the six-hooked embryo (oncosphere) (Figure 13.12). The eggs can remain viable in the soil for days to weeks.

On ingestion by cattle, the oncospheres hatch in the duodenum, penetrate the intestinal wall, and are carried via the lymphatics or bloodstream, where they are filtered out in the striated muscle. They then develop into the bladder worm or cysticercus within approximately 70 days. The mature cysticercus measures 7.5 to 10 mm wide by 4 to 6 mm long and contains the immature scolex, which has no hooks (unarmed). Other animals found to harbor cysticerci include the buffalo, giraffe, llama, and possibly reindeer (7). Actual cases of human cysticercosis with *T. saginata*

Figure 13.22 Gravid proglottid of *Taenia saginata*.

are rare in the literature, and there is speculation that some reported cases have been inaccurately diagnosed.

Clinical Disease

There are usually few symptoms associated with the presence of the adult worm in the intestine. Although rare symptoms (obstruction, diarrhea, hunger pains, weight loss, and appendicitis) have been reported, the most common complaint is the discomfort and embarrassment caused by the proglottids crawling from the anus. This occurrence may be the first clue that the patient has a tapeworm infection. Occasionally, the proglottids are also seen on the surface of the stool after it is passed.

Diagnosis

Since the eggs of *T. saginata* and *T. solium* look identical, identification to the species level is normally based on the recovery and examination of gravid proglottids, in which the main uterine lateral branches are counted (15 to 20 for *T. saginata* and 7 to 13 for *T. solium*). Often, the gravid proglottids of *T. saginata* are somewhat larger than those of *T. solium*; however, this difference may be minimal or impossible to detect when looking at fresh or preserved proglottids. If the scolex is recovered after therapy (which may require purgation), there will be four suckers and no hooks (Figure 13.21).

KEY POINTS—LABORATORY DIAGNOSIS

Taenia saginata

1. Preliminary examination of the gravid proglottid may not allow identification without clearing or injection of the uterine branches with India ink.

Note. Since there is always the possible danger that the proglottid is *T. solium*, with the inherent problem of egg ingestion and cysticercosis, all specimens should be handled with extreme caution.
2. The eggs look identical to those of *T. solium*, so identification to the species level cannot be performed with eggs alone.
3. Although gravid proglottids of *T. saginata* are often somewhat larger than those of *T. solium*, this difference may be very minimal or impossible to detect.
4. Any patient with *Taenia* eggs recovered in the stool should be cautioned to use good hygiene. These patients should be treated as soon as possible to avoid the potential danger of accidental infection with the eggs, which may lead to cysticercosis (*T. solium*).

Treatment

The use of praziquantel or niclosamide has been recommended (see chapter 25). The same general approach used

for *T. solium* is used to eradicate the adult worm. Therapy is usually very effective; however, if the proglottids begin to reappear in the stool or crawl from the anus, retreatment is necessary.

Epidemiology and Prevention

Since human infection is acquired from the ingestion of raw or poorly cooked beef, all beef prepared for human consumption should be inspected for the presence of cysticerci. Thorough cooking of beef provides complete protection. A reliable method to detect infected cattle is needed, particularly because of public health concerns. The method of choice for routine serologic surveillance of cysticercosis is probably ELISA; however, previous antigenic reagents have lacked the necessary sensitivity and/or specificity. To improve the sensitivity and specificity of an existing IgM monoclonal antibody (MAB)-based ELISA for the detection of circulating antigen in the sera of cattle infected with *T. saginata* metacestodes, a modified sandwich ELISA was developed. When the original IgM MAB-based ELISA was compared with the IgG MAB-based ELISA using heat-treated sera from animals harboring more than 50 living metacestodes of *T. saginata*, the sensitivity increased from 56% with the former assay to 92% with the latter. Only a few animals carrying fewer than 50 cysts were detected by both the ELISA using IgG MABs and that using IgM MABs. The specificity of the IgM and IgG MAB-based ELISAs was 93.4 and 98.7%, respectively (57). To minimize the chance of infection, cattle should not be allowed to graze on ground contaminated by human sewage. Egg viability can range from a couple of weeks in untreated sewage to approximately 5 months on grass. According to Beaver et al. (7), the rate of bovine cysticercosis in the United States reached 0.37% in 1930 and has remained around this level in federally inspected cattle.

Taenia saginata asiatica (Asian *Taenia* or *Taenia asiatica*)

Recent epidemiologic studies of taeniasis in Southeast Asia indicate the presence of a third form of human *Taenia* spp. which can be distinguished from *T. saginata* and *T. solium*. This newly recognized cestode was originally called the Taiwan *Taenia* sp. and was first detected in Taiwanese aboriginals. However, it is now referred to as the Asian *Taenia* sp. or *T. asiatica* since it has also been found in a number of other Asian countries. Genetic studies have been used to determine whether the Asian *Taenia* sp. should be considered a new species or a subspecies, strain, or variant of *T. saginata*, which it closely resembles. The use of PCR-restriction fragment length polymorphism determined the cestode to be different from either *T. solium* or *T. saginata*. However, mitochondrial

and nuclear sequence comparisons indicate that the Asian *Taenia* sp. is more closely related to *T. saginata*. These results support earlier conclusions that the Asian *Taenia* sp. is a genetically distinct entity but is closely related to *T. saginata*. Although there is no total agreement, its taxonomic classification as a subspecies or strain of *T. saginata* may be changed to a new species designation (9, 21, 22, 25, 31). Because of this close relationship with *T. saginata*, any public health significance would be unlikely, since human cysticercosis is caused almost exclusively by *T. solium*.

Life Cycle and Morphology

The life cycle is similar to that of *T. saginata* (Figure 13.20). However, cysticerci of *T. asiatica* develop in the liver of pigs, cattle, and goats, rather than the muscles of cattle. The cysticerci are much smaller than those of *T. saginata* or *T. solium* and measure approximately 0.5 to 1.7 mm by 0.5 to 2.0 mm. The protoscolex is armed, but the hooklets are lost in the mature worm (Figure 13.23). The adult worm matures in 10 to 12 weeks, like *T. saginata*, but is smaller, measuring 4 to 8 m long, and contains 300 to 1,000 proglottids (Figure 13.24). In some indigenous populations in Taiwan, 10 to 20% of the people are infected, primarily from the ingestion of pork meat and viscera. Another difference appears to be the presence of multiple worms, whereas infections with *T. saginata* are usually limited to a single worm (23). In one area of Taiwan during the late 1990s, the rate of *T. asiatica* infection was 11% and the annual economic loss was calculated at US\$18,673,495. These and other figures suggest that taeniasis not only is a

Figure 13.23 *Taenia saginata asiatica* (*Taenia asiatica*). (Left) Scolex (unarmed, no hooks) from cysticercus; (right) scolex from adult worm. (Photographs courtesy of Ping-Chin Fan, with permission.)

Figure 13.24 *Taenia saginata asiatica* (*Taenia asiatica*). (Upper) Gravid proglottid. (Lower) Gravid proglottid (note the large number of uterine branches and the similarity of this proglottid to the one of *Taenia saginata* in Figure 13.22). (Photographs courtesy of Ping-Chin Fan, with permission.)

significant public health problem, but also leads to severe economic losses in East Asia.

Clinical Disease

Infected individuals may not be aware of the infection and may remain asymptomatic. However, they may complain of having abdominal pain, nausea, weakness, weight loss, changes in appetite, and headache. These symptoms suggest that the tapeworm causes irritation; biopsies of the mucosa may reveal inflammatory changes. Eosinophilia is seen in some patients.

Diagnosis

Since the morphologies of *T. asiatica* and *T. saginata* are so similar, the diagnosis may rely on the patient's history. Have they ingested undercooked or raw beef (*T. saginata*) or raw pig liver (*T. asiatica*)? Although wartlike formations can be found on the surface of the larval worm, they are not always visible in sections (Figure 13.25).

Treatment

The use of praziquantel or niclosamide has been recommended (see chapter 25). The same general approach used for *T. solium* and *T. saginata* is used to eradicate the adult worm. Therapy is usually very effective; however, if the

Figure 13.25 *Taenia saginata asiatica* (*Taenia asiatica*). Cross section of cysticercus. (Photograph courtesy of Ping-Chin Fan, with permission.)

proglottids begin to reappear in the stool or crawl from the anus, retreatment is necessary.

Epidemiology and Prevention

In areas where *Taenia* tapeworms are endemic in Korea, *T. saginata* is dominant over *T. solium*; however, pig consumption is considerably higher than beef consumption. By examination of data published between 1963 and 1999, the ratio of armed versus unarmed tapeworms in humans was estimated at approximately 1:5. The ratio of pig eaters versus cattle eaters, however, was approximately 5:1. This inconsistency was explained with the recently described *T. asiatica*, which infects humans through the eating of raw pig viscera, primarily liver. Considering that the scolex of *T. asiatica* is unarmed and the consumption of visceral organs of pigs is higher than beef consumption, this information provides a clearer understanding of *T. asiatica* infection together with coexisting *T. saginata* and *T. solium* infection in Korea (22). Prevention depends on a thorough understanding of the epidemiology of this infection.

Hymenolepis nana

H. nana has been called the dwarf tapeworm and has a worldwide distribution. The fact that an intermediate host is not required in the life cycle was determined in the late 1800s by Grassi and Rovelli (7). For this reason, *H. nana* has been considered to be the most common tapeworm throughout the world, and it is estimated that 50 million to 75 million people worldwide are infected. The infection is most commonly seen in children, although adults are also infected (Table 13.1). There has been some discussion regarding placing *H. nana* in the genus *Rodentolepis*.

Life Cycle and Morphology

The life cycle can be seen in Figure 13.26. Infection is usually acquired by the ingestion of infective *H. nana* eggs, primarily from human stool (direct life cycle). The eggs hatch in the stomach or small intestine, and the liberated larvae, or oncospheres, penetrate the villi in the upper small intestine. The larvae develop into the cysticercoid stage in the tissue and migrate back into the lumen of the small intestine, where they attach to the mucosa (Figure 13.27). The adult worms mature within several weeks. They are very small compared with worms of the *Taenia* species and measure up to 40 mm long. The more worms that are present, the shorter the total length of each worm. Insect intermediate hosts include grain- and flour-eating beetles such as *Tribolium* and *Tenebrio*; fleas such as *Pulex irritans*, *Xenopsylla cheopis*, and *Ctenocephalides canis*; and moths. The indirect life cycle is initiated when the insect ingests an infective *H. nana* egg. Within the insect body cavity, the oncosphere contained within the egg becomes free of the egg membranes and transforms into the cysticercoid larval form, which is infective when the insect is ingested by the human host.

The scolex has four suckers and a retractable, prominent rostellum with hooks. The adult worm is rarely seen in the stool. The eggs are released by disintegration of the gravid proglottids, pass out in the stool, and are immediately infectious. They are round to oval with a thin shell and measure 30 to 47 μm in diameter. The oncosphere has two polar thickenings from which arise polar filaments that lie between the oncosphere and the shell (Figure 13.28). Although accidental ingestion of the insect intermediate host can result in development of the adult worms, this mode of infection is probably rare. There is evidence that auto- or hyperinfection occurs when eggs spontaneously hatch in the small intestine and initiate a new life cycle. Although adult worms live for only about a year, some patients can carry a large worm burden for many years, possibly due to the autoinfection capability within the life cycle or repeated reinfection.

Figure 13.26 Life cycle of *Hymenolepis nana*.

Figure 13.27 *Hymenolepis nana*. (Upper) Diagram of both a cysticercoid and adult worm in the small intestine. (Illustration by Sharon Belkin.) (Lower) Cysticercoids of *H. nana* in the villi of the small intestine. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

Clinical Disease

Within the human host, the adult worms tend to be located in the upper portion of the ileum. An infection with *H. nana* may cause no symptoms, even with a heavy worm burden. Some patients complain of headache, dizziness, anorexia, abdominal pain, diarrhea, or possibly irritability, particularly if the worm burden is 1,000 to 2,000 worms. Some patients have a low-grade eosinophilia of 5% or more. When young children have heavy infections, they may have loose stools or even diarrhea containing mucus. Persistent, diffuse abdominal pain seems to be the most common symptom.

Heavy human infection may be attributed to internal autoinfection, in which the eggs hatch in the intestine and follow the normal life cycle to the adult worm. This autoinfection feature of the life cycle may lead to complications in immunocompromised patients (35).

Diagnosis

Since the adult worm or proglottids are rarely seen in the stool, the diagnosis is based on recovery and identification of the characteristic eggs containing polar filaments (Figure 13.28). They are most easily seen and identified from fresh specimens or those preserved in formalin-based fixatives. Specimens preserved in polyvinyl alcohol contain eggs that do not exhibit morphologic characteristics that are as well delineated as those seen in formalin-fixed specimens. These thin-shelled eggs also tend to collapse on the permanent stained smear and may be difficult to identify in this type of preparation; the direct wet film or concentration wet mount is recommended.

KEY POINTS—LABORATORY DIAGNOSIS

Hymenolepis nana

1. Adult worms or proglottids are rarely seen in the stool.
2. Eggs with the characteristic thin shell, six-hooked oncosphere, and polar filaments are diagnostic.
3. Egg morphology is more easily seen in fresh specimens or those preserved in formalin-based fixatives.
4. The eggs are infectious, and unpreserved stools should be handled with caution.

Treatment

Niclosamide has been widely used for years. However, the use of praziquantel in a single oral dose is apparently more effective and kills the cysticercoid as well as the adult worm. The recommended dose for adults and children is 25 mg/kg in a single dose (see chapter 25).

Figure 13.28 (Left) Egg of *Hymenolepis nana* (note the thin egg shell, the six-hooked oncosphere, and the polar filaments that lie between the oncosphere and egg shell). (Right) Egg of *Hymenolepis diminuta* (note the thin egg shell, the six-hooked oncosphere, and the lack of polar filaments.)

Epidemiology and Prevention

H. nana is the only human tapeworm in which an intermediate host is not necessary and transmission is from person to person. Children are usually infected more often than adults. Since infection is from person to person via the eggs, good personal hygiene is an important preventive measure. Infection from rats and mice is always a possibility, as is the accidental ingestion of infective insect intermediate hosts.

Hymenolepis diminuta

Although *H. diminuta* is commonly found in rats and mice, it is infrequently found in humans. It has a worldwide distribution in normal hosts, and fewer than 500 human cases, primarily from India, the former Soviet Union, Japan, Italy, and certain areas of the southern United States (Tennessee, Georgia, and Texas), have been reported (7, 60) (Table 13.1).

Life Cycle and Morphology

The life cycle is very similar to the indirect life cycle of *H. nana*, and the infection is considered a true zoonosis; the arthropod intermediate host is not optional but obligatory (Figure 13.29). A number of different arthropods (lepidopterans, earwigs, myriapods, larval fleas, and various beetles) can serve as intermediate hosts. After egg ingestion by the arthropods, the cysticercoid stage forms, which is similar in morphology to the cysticercoid stage of *H. nana*. Infection by accidental ingestion of the infected arthropod containing cysticercoids results in development of the adult worm in the intestine of the human host. In contrast to *H. nana*, the scolex of *H. diminuta* has no hooks on the rostellum. Multiple worms may be present, each being shorter than if a single worm were present. Although some of the adult worms (measuring 20 to 60 cm long) are occasionally spontaneously passed in the stool, usually the eggs are recovered and identified. They are morphologically similar to the eggs of *H. nana* and measure from 60 to 79 μm . They contain the six-hooked oncosphere and a clear area between the oncosphere and the shell. This area contains a gelatinous matrix that does not have polar filaments arising from the polar thickenings, as is seen in *H. nana* (Figure 13.28).

Clinical Disease

As with most tapeworms, the infection is usually tolerated very well by the host, with few if any symptoms. Most infections have been reported from children younger than 3 years; however, infected adults have also been reported. Symptoms that have been reported include diarrhea, anorexia, nausea, headache, and dizziness; they are most likely to be seen in infected children with a heavy infection.

Figure 13.29 Life cycle of *Hymenolepis diminuta*.

Diagnosis

Since the proglottids usually disintegrate in the gut, diagnosis is based on recovery and identification of the characteristic eggs. The similarity to *H. nana* eggs is striking; however, there are no polar filaments in the eggs of *H. diminuta* (Figure 13.28).

KEY POINTS—LABORATORY DIAGNOSIS

Hymenolepis diminuta

1. Although human infection is rare, diagnosis can be based on recovery and identification of the characteristic eggs (thin shell, presence of six-hooked oncosphere, and no polar filaments).
2. The eggs are occasionally submitted to laboratories for identification as a part of various proficiency testing programs. The important point is to be able to differentiate these eggs from those of *H. nana*.
3. Unlike *H. nana* eggs, the eggs of *H. diminuta* are not infectious from person to person.

Treatment

Praziquantel is recommended as a single dose of 5 to 10 mg/kg of body weight (see chapter 25).

Epidemiology and Prevention

Since the infection is acquired from accidental ingestion of the infected intermediate arthropod hosts, avoidance of this type of exposure is recommended. Possible situations include swallowing ectoparasites from the rodent host or accidentally ingesting beetles in precooked cereals. Rat control programs might also decrease the possibility of human exposure.

Dipylidium caninum

D. caninum is commonly found throughout the world in dogs and cats, both domestic and wild. Human infections have also been reported from many areas of the world, including the United States. Most reported infections

have been in children (Table 13.1). A case reported in 2003 appears to be the first case reported in the American pathology literature during the last 36 years (MEDLINE database, 1966 to 2002) (40).

Life Cycle and Morphology

The life cycle is very similar to that of *H. diminuta*, in which the arthropod is an obligatory intermediate host (Figure 13.30). The adult worms are found in the dog or cat intestine, and gravid proglottids separate from the strobila and may migrate singly or in short chains out of the anus. The adult worms measure 10 to 70 cm long and have a scolex with four suckers and an armed rostellum. The single proglottids have been described as looking like cucumber seeds when moist and like rice grains when dry (Figure 13.31). Groups of eggs (egg packets) may be found in the stool (Figure 13.32). Each egg measures from 25 to 40 μm and contains the six-hooked oncosphere. The eggs are ingested by the larval stages of the dog, cat, or human flea, in which they develop into cysticercoid larvae. When these fleas are then ingested by the definitive host (dogs, cats, or humans), the adult worm develops within 3 to 4 weeks.

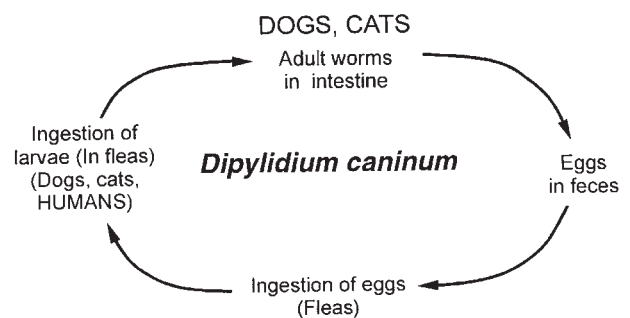

Clinical Disease

The symptoms are related to worm burden; however, in most patients (usually children), complaints may consist of indigestion and appetite loss. The infection may first be noticed when proglottids migrate from the anus. Symptoms have been reported and can include abdominal pain, diarrhea, urticaria, and pruritus ani. A moderate eosinophilia may also be present.

Diagnosis

Diagnosis depends on the recovery and identification of the characteristic egg packets or the proglottids. The proglottids appear like white cucumber seeds when fresh and rice grains when dry.

Figure 13.30 Life cycle of *Dipylidium caninum*.

Figure 13.31 Proglottids of *Dipylidium caninum*. (Upper) Fresh proglottid that may resemble a cucumber seed (note the shape and light color); when the proglottids dry, they may resemble rice grains. (Lower) Stained proglottid. (Photographs from the Centers for Disease Control and Prevention Program: Laboratory Identification of Parasites of Public Health Concern.)

Figure 13.32 *Dipylidium caninum* egg packets. (Upper) Diagram showing the packet of *Taenia*-like eggs. (Lower) Egg packet in wet mount preparation.

KEY POINTS—LABORATORY DIAGNOSIS

Dipylidium caninum

1. The egg packets are very characteristic and are frequently used to make the diagnosis.
2. Proglottids can be identified on the basis of shape (cucumber seeds when fresh, rice grains when dry) and the presence of egg packets that can be recovered from a ruptured proglottid.

Treatment

A single dose of praziquantel (10 mg/kg of body weight) for both adults and children is recommended (see chapter 25).

Epidemiology and Prevention

Most human cases have been in children, indicating that children may be more likely to accidentally swallow the infected fleas or may be more susceptible to infection. Periodic administration of anthelmintic agents to dogs and cats and use of flea powders will help reduce the risk of infection.

Tissue Cestodes: Larval Forms

Echinococcus granulosus (cystic disease, hydatid disease)

Echinococcus multilocularis (alveolar disease, hydatid disease)

Echinococcus oligarthrus and *Echinococcus vogeli* (polycystic hydatid disease)

Taenia (Multiceps) spp. (*Taenia multiceps*, *Taenia serialis*) (coenurosis)

Spirometra mansonoides and *Diphyllobothrium* spp. (sparganosis)

NOTE: *Taenia solium* (cysticercosis) is discussed in chapter 13.

Echinococcus granulosus (Cystic Disease, Hydatid Disease)

Currently, four species are recognized within the genus *Echinococcus*: *E. granulosus* (which causes cystic disease), *E. multilocularis* (which causes alveolar disease), *E. vogeli* (which causes polycystic disease), and *E. oligarthrus* (which causes polycystic disease) (Table 14.1). There is clear evidence of strain variation in *E. granulosus*, and 10 different strains have now been identified (Table 14.2) (33, 34, 71). However, evidence for strain variation for the other species of *Echinococcus* does not exist. Based on historical information, hydatid cysts were recognized by Hippocrates, Aretaeus, and Galen. There was speculation concerning the possible relationship between human and animal hydatid cysts during the 1600s and 1700s. The adult worms and various aspects of the life cycle were studied in the late 1800s.

The areas of the world involved in sheep and cattle raising tend to be the areas where infections are endemic; they even include the Basque sheep farmers in California. The number of infections in both animals and humans has decreased over the years as a result of education and various control measures. However, figures suggest that the surgical incidence in some areas in Central Asia is now greater than 10 in 100,000 (up to 27 in 100,000 in Tadjikistan), and many of the cases are in children and the unemployed (131). The rates of infection in major livestock species such as sheep have also increased, with a doubling of prevalence, to a figure approaching 25% in some areas.

There is also evidence to indicate a reemergence of canine *E. granulosus* infection in Wales. This has been associated with the large-scale outdoor slaughter of sheep during the 2001 foot-and-mouth disease outbreak in the United Kingdom and the suspected increased risk for transmission between sheep and dogs. The data suggest that allowing dogs to roam free and infrequent dosing of dogs with praziquantel has contributed to the increase; thus, increased transmission to humans appears probable in this setting (16).

Life Cycle and Morphology

The life cycle of *E. granulosus* is presented in Figure 14.1. The adult worms are very small (3 to 6 mm long) and consist of a scolex, a neck, and only a single proglottid at each stage of development (immature, mature, and gravid) (Figure 14.2). There may be several hundred worms in the intestine of the

Table 14.1 Tissue cestodes

Characteristic	<i>Echinococcus granulosus</i>	<i>Echinococcus multilocularis</i>	<i>Echinococcus vogeli</i> , <i>E. oligarthrus</i>	<i>Taenia (Multiceps)</i> spp.	<i>Spirometra</i> and <i>Diphyllobothrium</i> spp.
Disease	Hydatid disease (cystic)	Hydatid disease (alveolar)	Hydatid disease (polycystic)	Coenurosis	Sparganosis
Geographic location of the parasite	Worldwide	North America, northern and central Eurasia	Central and South America (85%) in Brazil, Colombia, Ecuador, Argentina	Worldwide	Worldwide; more common in China, Japan, Southeast Asia
Definitive host(s)	Domestic dog, wild canids (coyote, dingo, red fox, etc.)	Red fox, Arctic fox, raccoon dog, coyote, domestic dog, cat	Bush dog, domestic dog	Dogs, other canids	Dogs, cats
Acquired by	Egg ingestion (dogs)	Egg ingestion (foxes, cats)	Egg ingestion (dogs [<i>E. vogeli</i>], felids [<i>E. oligarthrus</i>])	Egg ingestion (dogs, other canids)	(i) Ingestion of infected <i>Cyclops</i> spp. (proceroid); (ii) ingestion of raw infected flesh of amphibians, reptiles, birds, mammals (spargana); (iii) local application of raw infected flesh as a poultice (spargana)
Intermediate host(s)	Primarily ungulates (sheep, cattle, swine, horses); also marsupials	Rodents (voles, lemmings, shrews, mice), other small mammals	Paca, agouti, spiny rat	Sheep, goats, cattle, horses, lagomorphs, rodents	Frogs, mammals
Stage of organism found in tissue	Larval form (fluid-filled unilocular hydatid cyst), contains protoscolices and daughter cysts, limiting membrane; 1–>15 cm; visceral, primarily liver and lungs	Larval form (alveolar hydatid cyst), no limiting membrane, usually sterile with no protoscolices; visceral, primarily liver	Larval form (fluid-filled polycystic hydatid cyst), scolex visible in wet mounts, large hooklets (38–46 µm long) and small hooklets (30–37 µm long); visceral, liver, abdomen, lungs (<i>E. vogeli</i>); orbits, heart (<i>E. oligarthrus</i>), vesicles partitioned by septa, protoscolices present	Larval form (intermediate between cysticercus and hydatid cyst)	(i) Proceroid; (ii) spargana; (iii) spargana (see above)
Type of growth in humans	Concentric expansion	Exogenous proliferation, tumorlike, similar to metastatic growth	Exogenous and endogenous proliferation (<i>E. vogeli</i>); expansive, no indication of exogenous proliferation (<i>E. oligarthrus</i>)	Multiple scolices, but no daughter cysts	More elongate, wormlike structure, no suckers or hooks; resemble narrow tapeworm proglottids, motile
Location in body	Liver (60%), lungs (20%), kidneys (4%), muscle (4%), spleen (3%), soft tissues (3%), brain (3%), bones (2%), other (1%)	All sites as for <i>E. granulosus</i> ; most common site is liver, metastases in lungs, brain, bones, etc.	Liver, lungs (15%) (<i>E. vogeli</i>); eye and heart (<i>E. oligarthrus</i>)	Most often in central nervous system	Most tissues have been involved; depends on the site of the poultice application
Symptoms	Depends on cyst location, usually mechanical from enlarging cyst; may also be allergic reactions from cyst fluid leakage	Hepatic disease resembles slow growing mucoid carcinoma (no fever); hepato- and splenomegaly, jaundice, ascites	Hepatomegaly, palpable peritoneal masses, jaundice (<i>E. vogeli</i>)	Like space-occupying lesion in the central nervous system, similar to tumor, rarely muscles or subcutaneous tissues	Edema, pain, irritation, inflammation, toxemia, eye damage, elephantiasis if lymphatics involved, slowly growing, tender, subcutaneous nodules (may be migratory), ocular sparganosis
Treatment	Surgical removal, albendazole, praziquantel	Albendazole, praziquantel; surgery not recommended	Surgery plus albendazole; difficult to treat	Rarely diagnosed preoperatively	Surgical removal and drainage

Table 14.2 *Echinococcus granulosus* strains^a

Strain (genotype, G)	Geographic distribution	Definitive host	Intermediate host	Infective for humans
G1: common sheep strain	Europe, Middle East, Africa, Iran, India, Nepal, China, Russia, Australian mainland, Tasmania, New Zealand, United States, South America, Sardinia	Dog, fox, dingo, jackal, hyena	Sheep, cattle, pig, camel, goat, macropods	Yes
G2: Tasmanian sheep strain	Tasmania, Argentina, Europe	Dog, fox	Sheep, cattle?	Yes
G3: buffalo strain	Asia	Dog, fox?	Buffalo, cattle?	?
G4: horse strain (<i>E. equinus</i>)	Europe, Middle East, South Africa (New Zealand?, United States?)	Dog	Horse, other equines	No?
G5: cattle strain (<i>E. ortleppi</i>)	Europe, South Africa, India, Nepal, Sri Lanka, Russia, South America?	Dog	Cattle, buffalo, sheep, goat	Yes
G6: camel strain	Middle East, Iran, Africa, China, Nepal, Argentina	Dog	Camel, goat, cattle	Yes
G7: pig strain	Poland, Slovakia, Ukraine, Russia, Argentina, Europe, Sardinia	Dog	Pig	Yes
G8: cervid strain	North America, Eurasia	Wolf, dog	Cervids	Yes
G9: ?	Poland	?	?	?
G?	Africa	Lion	Zebra, wildebeest, warthog, bushpig, buffalo, various antelope species, giraffe?, hippopotamus?	?
G10: Fennoscandian cervid strain	Finland	Wolf, dog	Cervids; closely related to G5, G6, and G7 strains	Probably

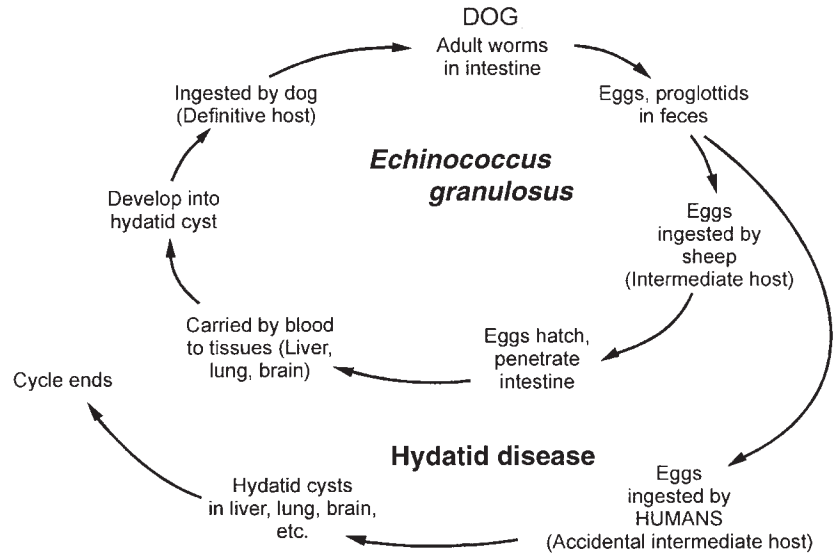

Figure 14.1 Life cycle of *Echinococcus granulosus* (cystic echinococcosis).

Figure 14.2 Adult worm of *Echinococcus granulosus*. (A) Diagram. (B) Whole mount (note that only three proglottids are present in the adult worm).

canine host (usually the dog). The worms may survive in the host for up to 20 months, and each gravid proglottid contains few eggs (100 to 1,500), which are much larger than those of some of the other tapeworms. After the gravid proglottids and eggs are passed in the feces, they may be swallowed by an intermediate host, including humans. After exposure to gastric and intestinal enzymes, the eggs hatch in the duodenum. The released oncospheres penetrate the intestine and are carried via the bloodstream, where they are filtered out in the various organs. The most common site in humans is the liver (60 to 70% of cases). Although not all oncospheres survive this passage through the body, those that do survive begin to grow and develop. Usually by the fifth month, the wall of the hydatid cyst has become differentiated into an outer friable, laminated, nonnucleated layer and an inner nucleated germinal layer. Various daughter cysts (brood capsules) bud off from the inner germinal layer and may remain attached or float free in the interior of the fluid-filled cyst. The individual scolices bud off from the inner wall of the daughter cysts; these scolices and free daughter cysts are called hydatid sand. Each scolex normally invaginates to protect the hooklets (Figures 14.3 and 14.4). Although not every cyst produces daughter cysts and/or scolices, this general tissue organization is called a unilocular cyst, in which the cyst contents are held within a single limiting cyst wall. On average, the cysts increase in size by about 1 cm per month; this growth rate was reported for a series of multiple intracranial hydatid cysts caused by *E. granulosus* (37).

When animals that serve as intermediate hosts are slaughtered, the viscera may not be disposed of properly and may be consumed by animals that serve as definitive hosts. The adult worms then develop in the intestine of the definitive host.

Figure 14.3 *Echinococcus granulosus*. (Top) Daughter cyst within the main cyst wall. (Middle) Hydatid sand (immature scolices). (Bottom) Individual hooklets. (Top image from *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

Based on differences in the host specificity of the larval stage, at least 10 different strains of *E. granulosus* have been identified (Table 14.2). The strains differ in their intermediate host spectrum, geographic distribution, adult and larval stage morphologies, and protoscolex production. Also, at least seven of the strains are infective for humans. The northern form is found in the holarctic zones of the tundra and boreal forest of North America and Eurasia. The larval stage occurs primarily in moose, elk, and reindeer, while the adult worm is found in wolves and sometimes in dogs and other wild canids. The European form of *E. granulosus* includes domestic animals, primarily sheep as the main intermediate host and dogs as the main definitive host. Although mixed infections with *E. granulosus* and *E. multilocularis* are rare, they have been reported from areas in China, a recognized area where echinococcosis is hyperendemic (143).

The risk of infection depends to a high degree on the association between humans and dogs, with the exception of the lion strain. Those at high risk include populations where dogs are used to herd sheep and are also intimate members of the family, often having unrestricted access to the house and family members. Cystic echinococcosis has been recorded in 21 of China's 31 provinces, autonomous regions, and municipalities (approximately 87% of the territory). This infection constitutes one of the major health problems in this part of the world. Hydatid disease caused by *E. granulosus* is a zoonosis of major public health concern throughout Latin America, particularly in the Andean and South Cone regions. Cystic echinococcosis is also widely found throughout the region comprising Arab North Africa and the Middle East. In areas of endemic infection around the world, the practice of giving raw viscera of slaughtered livestock to the dogs enhances transmission; in areas where this practice has been curtailed, prevalence figures have decreased.

Clinical Disease

Hydatid disease in humans is potentially dangerous; however, cyst size and organ location greatly influence the outcome. Clinical symptoms may appear after an incubation period of several months to years.

Liver Cysts. The majority of hydatid cysts occur in the liver, causing symptoms that may include chronic abdominal discomfort, occasionally with a palpable or visible abdominal mass. Liver cysts tend to occur more frequently in the right lobe. Symptoms can include pain, hepatomegaly, cholestasis, biliary cirrhosis, portal hypertension, and ascites. If a cyst becomes infected with bacteria, it resembles an abscess. Severe symptoms can occur if the cyst ruptures spontaneously, from trauma, or during surgery. In addition to the spread of tissue from which additional hydatid cysts can grow, there may be serious allergic reactions,

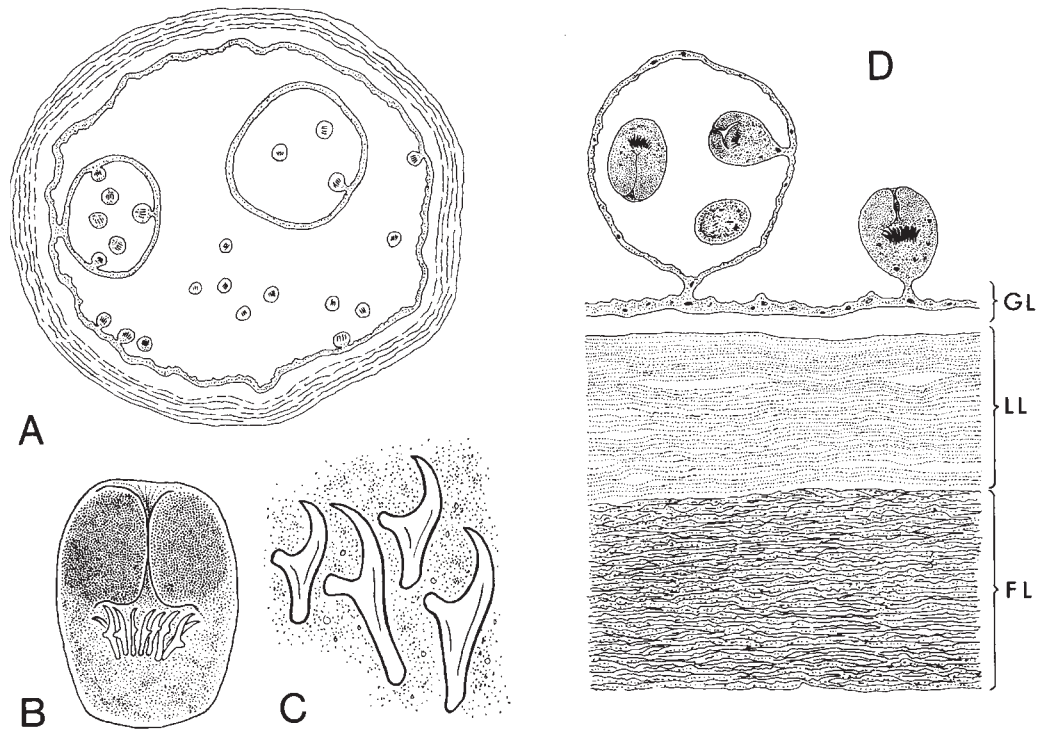

Figure 14.4 *Echinococcus granulosus* hydatid cyst. (A) Diagram of unilocular cyst (limiting membrane). (B) Diagram of single immature worm. (C) Diagram of hooklets. (D) Diagram of laminated layers, daughter cysts, and scolices. (Illustration by Sharon Belkin.) GL, germinal layer; LL, laminated layer; FL, fibrous layer.

including rash, anaphylactic shock, or death. Cyst rupture can also lead to cholangitis and cholestasis (9). Morbidity and mortality rates associated with perforated hydatid cysts are higher than those associated with nonperforated cysts. Specific disease sites and complications can be seen in Table 14.3. Some unilocular cysts may remain undetected for many years until they become large enough to crowd other organs (Figure 14.5).

Lung Cysts. Cysts in the lungs are usually asymptomatic until they become large enough to cause chronic cough, shortness of breath, or chest pain (Figure 14.6). Cyst rupture can lead to expectoration of hydatid fluid or membranes, followed by the development of infection and a lung abscess. If the rupture occurs into the lung, it may cause pneumothorax and empyema, allergic reactions, and even anaphylactic shock.

Other Sites. The spleen and kidneys are the next most common intra-abdominal organs, occurring in 3 to 5% of patients, and cardiac and cerebral cysts have been found in about 1 to 1.5% of patients (70). Even relatively small cysts can cause severe damage if they are located in a vital area or in bone (osseous cysts). Diagnostic procedures for

the detection of liver or lung cysts should always be considered when cysts are detected in more unusual or rare body sites (Figure 14.7).

Cyst Location Related to Patient Age. It is well known that hydatid cysts are most commonly found in the liver and lungs, but certain locations have been reported to be more prevalent in children and/or young adults. Lung, brain, spinal, and orbital hydatid cysts have been more commonly seen in younger patients. It is thought that age somehow alters the host-parasite relationship and thus affects the organ distribution of the cysts (148).

Hydatid Disease and Cancer. The simultaneous occurrence of hydatid disease and cancer is relatively rare. In a patient who had liver disease as well as acute leukemia, therapy for his leukemia over a 3-month time frame had no effect on the size and contents of the liver hydatid cyst. The hydatid serologic titers remained unchanged, and the cyst classification remained the same (4). Hodgkin's lymphoma and cystic hydatid disease as a dual infection has been reported; however, no residual and/or new cyst formation was seen on follow-up after surgery and subsequent therapy for the lymphoma (145).

Table 14.3 Examples of hydatid disease, complications, and/or outcomes

Body site, description	Comments	Reference(s)
Liver, asymptomatic disease	Despite a limited number of cases, most asymptomatic liver hydatid patients (75%) remain symptom free for >10 yr, regardless of cyst size or type. Such carriers are probably at low risk for developing complications.	39
Liver, surgical treatment and review of 304 cases	238 had cyst in right lobe, 41 in left lobe, 25 in both lobes; 45 had multiple hepatic cysts, 18 had coexisting cysts in other intra-abdominal sites. For management of infection, capitonnage, omentoplasty, cyst excision, segmentectomy, or cystoenterostomy are all superior to tube drainage.	6
Liver, right hepatic vein	Defect on wall of right hepatic vein, as well as 3 ruptures into the bile duct. Unusual presentation.	22
Liver, spontaneous rupture of cyst into biliary tract	Resolution of hydatid cyst by spontaneous rupture into the biliary tract; impaction of hydatid material into common bile duct was relieved endoscopically; patient was treated with 2 courses of mebendazole.	5, 69
Liver, intrabiliary rupture of cyst	Ideal treatment is traditional lavage of biliary tree followed by radical treatment of cyst and free drainage of bile ducts; hepatectomy and cystojejunostomy can be avoided.	65
Liver, cyst rupture directly into the left colon	Rupture of hydatid cyst into a hollow area such as the colon is extremely rare; partial drainage of the cyst was demonstrated by creation of an air-fluid level.	76
Intra-abdominal organs, spontaneous cyst rupture	Two case reports with severe spontaneous systemic anaphylactic reaction due to cyst rupture (without known precipitating factors such as trauma, accidental). Emphasizes importance of high index of suspicion for hydatid etiology for idiopathic anaphylactic reactions in areas of endemic infection.	88
Pancreas, rupture into main pancreatic duct	Reports a case of recurrent pancreatitis due to rupture of a solitary hydatid cyst of the pancreas into the main pancreatic duct.	121
Lung, mean age of patients with giant hydatid cysts younger than patients with normal-size cysts	Increase in cyst diameter correlated with higher lung tissue elasticity and delay in diagnosis due to delayed symptoms; review of 47 patients.	47
Lung, secondary pleural disease (usually primary, not secondary)	Presented 4 yr after treatment for a pyopneumothorax caused by rupture of pulmonary cyst near the pleural space; treatment with albendazole; surgery ruled out due to severe chronic obstructive pulmonary disease.	1
Unusual intrathoracic, extrapulmonary hydatid cysts	Sites included fissure, pleural cavity, chest wall, mediastinum, myocardium, diaphragm; total resection in 18/22 patients; no deaths after 1 yr.	94
Aorta, causing occlusion of aorta and both iliac arteries	Patient had previous surgery for a paraspinal hydatid cyst; presented with intermittent limping. CT and MRI showed multiple cysts in soft tissues of the back, retroperitoneum, and lumen of aorta and iliac arteries.	86
Heart, causing tamponade	Patient complained of severe dyspnea, thoracic pain, dizziness, short period of unconsciousness. Preliminary serology negative, low eosinophilia (5%); hydatid dismissed. Later, positive serology and eosinophilia of 59% found. Surgery and therapy with albendazole were used. With "cardiac tumor," negative serology and absence of eosinophilia do not rule out hydatid disease.	13
Heart, death caused by hydatid embolism	Rare case, limited to the heart; asymptomatic course until sudden death caused by arterial embolism. Note: no antibodies were detected by indirect hemagglutination.	57
Heart, cardiac involvement is usually by only 0.5 to 3% of hydatid cysts	Patient evaluated for intracardiac cyst; surgically excised; diagnosis confirmed by Giemsa staining of hooklets and scolices in cyst fluid. Patient was young (4-yr-old male).	77

(continued)

Table 14.3 Examples of hydatid disease, complications, and/or outcomes (*continued*)

Body site, description	Comments	Reference(s)
Heart, in the septum interventriculare	Unusual location for hydatid cyst; positive serology, surgery rejected due to severe underlying hypertensive cardiopathy (60-yr-old man).	14
Heart (primary cyst), cerebral cysts (secondary cysts)	Rare case in 7-yr-old child; symptoms of raised intracranial pressure; underwent 9 operations over 8 years because primary ruptured cyst in myocardium of left ventricle was detected; concurrent therapy with mebendazole (would not have been successful without removal of intracardiac hydatid cyst).	134
Heart, cyst located in septum and right ventricular cavity	Cyst located exclusively in the heart, first manifested as anaphylactic shock of unknown origin, required immediate surgical treatment due to severe hemodynamic compromise.	69
Orbital hydatid cyst	Emphasis on the superiority of MRI over CT for orbital cysts.	43
Central nervous system	Multiple hydatid cysts in cerebral subarachnoid space; based on clinical findings, latex test results, cerebrospinal fluid exam, and MRI findings.	132
Spine, progressive paraplegia	Rare hydatid disease manifestation. Disease misdiagnosed as tuberculous spondylitis. Patient presented with increasing weakness in lower limbs; treated for tuberculous spondylitis. Presented 1.5 yr later and underwent surgery and chemotherapy, paraparesis resolved. Early decompressive surgery with stabilization of the spine plus chemotherapy is treatment of choice.	11
Spine, uncommon but significant	Review of 28 reports; only 14 patients had pulmonary or other organ involvement; most patients misdiagnosed as Pott's disease (tuberculous spondylitis); surgical intervention followed by chemotherapy; hydatid disease should be considered when radiologic findings suggest spinal infections or tumors.	133
Spine, rare case	Intraspinal extradural hydatid disease of the thoracic region with spinal cord compression; diagnosis on MRI findings; patient recovered completely after surgery.	10
Gluteus muscle	Unusual location for hydatid cyst.	18
Ovary	Asymptomatic right adnexal mass; vaginal ultrasound revealed cyst in posterior cul-de-sac adjacent to the right ovary, with internal septa resembling a maze or an onion slide structure. Color Doppler revealed simple echogenic pattern; in contrast, ovarian carcinomas have a complex internal structure.	27
Tongue	Unusual site (5 reported cases in the literature); additional liver and cyst lesions found and treated with albendazole.	111

Immune Reactions. During the life of the cyst, there may be small fluid leaks into the systemic circulation that sensitize the patient. Later, if the cyst should burst or if there is a large fluid leak, serious allergic sequelae, including anaphylactic reactions, may occur. Release of cyst tissue may lead to abscess formation, emboli, and/or the development of additional young cysts at secondary sites.

Although publications have described autoimmune phenomena in patients with hydatid cysts, apparently there is no association between hydatid infection and the level of autoantibodies to a broad range of self antigens such as antinuclear antibodies, tissue-specific autoantibodies, and rheumatoid factor. No significant differences have been found between autoantibody levels in the sera from patients and from controls.

Echinococcus-specific immunoglobulin E (IgE) is present in most of the patients and is associated with the severity of disease. Specific histamine release by circulating basophils stimulated with *E. granulosus* antigens is present in all patients with cystic echinococcosis and alveolar echinococcosis. *Echinococcus* allergens include (i) AgB 12-kDa subunit, a protease inhibitor and a potent Th2 inducer; (ii) Ag5, a serine protease; (iii) EA 21, a specific cyclophilin, with homology to other types of cyclophilins; and (iv) Eg EF-1 beta/delta, an elongation factor with homology to *Strongyloides stercoralis* EF, which has the same IgE epitope. Clarification of the immunology of echinococcosis in humans has led to new therapy options, such as immunomodulation using alpha interferon. Also, a Th2-driven immunological response and an interleukin-10

Figure 14.5 Hydatid cysts in liver. This patient had three cysts (marked by arrows) in the right lobe. Two were completely calcified, and the large one in the background was partially calcified. (From V. Zaman, *Atlas of Medical Parasitology*, Lea & Febiger, Philadelphia, Pa., 1979.)

Figure 14.6 Hydatid cyst in the lung. This patient had a single large cyst in the left lung. There was collapse and consolidation in part of the left lung as a result of pressure on the bronchus. Partial pneumonectomy was required to remove the cyst. (From V. Zaman, *Atlas of Medical Parasitology*, Lea & Febiger, Philadelphia, Pa., 1979.)

(IL-10)-related tolerance state are common characteristics of atopic allergy and echinococcosis (138).

Diagnosis

In an area of endemic infection, exposure to sheepdogs, the presence of an enlarged liver, the presence of a palpable mass in the right upper quadrant of the abdomen, expectoration of a salty-tasting fluid with hemoptysis, and a round lesion on chest radiographs all support the presumptive diagnosis of hydatid disease in either the liver or the lungs. Hydatid cysts in the liver may be confused with congenital liver cysts, amebic abscess, or hepatic tumors. Pulmonary symptoms may be confused with tuberculosis.

Hydatid cysts should be considered in patients with abdominal masses with no clearly defined diagnosis. Although eosinophilia is present in 20 to 25% of patients, it is merely suggestive. Many asymptomatic cysts are first discovered after radiologic studies. The cyst usually has a well-defined margin with occasional fluid level markings. These studies can also be helpful in diagnosing osseous involvement. Scans may also demonstrate a space-occupying lesion, particularly in the liver. If the cyst is large and located in the abdomen, a thrill is sometimes detected.

Serologic tests are available, including the enzyme-linked immunotransfer blot (EITB) test, which apparently offers greater sensitivity and specificity than do the

enzyme-linked immunosorbent assay (ELISA) and arc-5 double-diffusion assay (DD5); when the tests were run simultaneously, the largest number of cases was detected by a combination of the EITB and DD5 tests (136). Newer enzyme immunoassay procedures appear to provide greater than 90% sensitivity and specificity compared with EITB (125). Specific antibodies in serum samples from patients with hydatid disease have been recognized by immunoblotting; recognition of 8- and 116-kDa hydatid antigens by a patient's serum sample seems to be a specific test confirming a clinical diagnosis (56). Evaluation of a monoclonal antibody-based competition ELISA for the diagnosis of human hydatidosis also provides a highly sensitive (92.8%) and specific screening system for human hydatid disease diagnosis (75). The use of recombinant antigens for immunodiagnosis of cystic echinococcosis has yielded an overall sensitivity of 92.2% and a specificity of 95.4%, excellent levels considering that the study was undertaken with a large panel of 896 human sera (Table 14.4) (75). Additional information is provided in chapter 22.

Figure 14.7 *Echinococcus granulosus* calcified liver cyst. The cyst is visible at the upper edge of the right pelvis; the dense pearlike structure is the gallbladder. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

A newer method, the hydatid antigen dot immunobinding assay, consists of incubation of a serum sample with a textile colloidal dye and a nitrocellulose stick to which the hydatid antigen has been bound. The presence of parasite-specific antibodies leads to dyeing of the stick reactive area, and a colored spot appears. This method showed good correlation with other available methods (87).

Serologic differentiation between cystic and alveolar echinococcosis, involving recombinant larval antigens, has also been used (50). Studies show good correlation between radiologic and serologic detection; however, serologic detection is more specific but less sensitive than imagery (5).

Once the cyst is discovered and surgical removal is selected as the approach, some of the cyst fluid can be aspirated and submitted for microscopic examination to detect the presence of hydatid sand, thus confirming the diagnosis. This procedure is definitely not without risk because of possible fluid and/or tissue leakage or dissemination. Cyst aspiration is usually performed at the time of surgery.

Hydatid sand is not always present. Also, if the cyst is old, the daughter cysts and/or scolices may have disintegrated, so that only the hooklets are left. These may be difficult to find and identify if there is debris within the cyst (Figure 14.3).

To detect hydatid sand, a drop of centrifuged fluid is placed on a slide and then another slide is placed on top of the drop. The two slides are then rubbed back and forth over the fluid. The grating of the hooks on the glass may be felt and heard (hydatid sand sounds like glass grating on sand grains). Of course, if the individual scolices are intact, routine microscopic examination of the centrifuged fluid as

Table 14.4 Antibody detection tests for human cystic and alveolar echinococcosis^a

Type of echinococcosis test	Antigen	Sensitivity (%)	Specificity (%)	Cross-reactions	
Cystic echinococcosis	IgG ELISA	80–>99	61.7	Cestodes (89%), trematodes (30%), nematodes (39%)	
	IgG4 ELISA EITB	Crude <i>E. granulosus</i> cyst fluid	85–93	Alveolar echinococcosis	
		Antigen B (native or synthetic peptide)	>99	Alveolar echinococcosis only	
		Crude cyst fluid	>98 ^b	<i>T. solium</i> cysticercosis only	
		Crude cyst fluid	71	None	
Alveolar echinococcosis	IgG ELISA	Antigen B fraction	100	See above	
		Antigen B subunit	>90	Cystic echinococcosis (25%)	
	IgG4 ELISA	Crude cyst fluid	97.1	61.7	Cystic echinococcosis (25%)
		<i>E. multilocularis</i> PLUS	97.1	98.9	Cystic echinococcosis (5.6%)
		Em2/Em2G11	89.3	100	Cystic echinococcosis (6.5%)
	EITB	EmII/3-10	86.4	98.4	Cystic echinococcosis

		Em18	97	100	None
		Glycoproteins	70–90	>95	None

^a Adapted from references 44–46, 82, 106, 124, 142, and 150.

^b Tested with 80 to 184 sera from patients with different parasitic infections (excluding *Echinococcus*-infected patients).

a wet mount will confirm the diagnosis. If the cyst is sterile (no daughter cysts or scolices), the diagnosis could be confirmed histologically from the cyst wall. Refer to Algorithm 14.1 and Tables 14.4 and 14.5. If the material is purulent, place a few milliliters of fluid into a tube and add concentrated hydrochloric acid (HCl). Either boil for 10 min or leave at room temperature for approximately 1 h until the material is quite fluid. Centrifuge and examine the material thoroughly for the refractile hooklets, which survive the HCl treatment intact. Along with the cellular and other mucoid material, the scolices are destroyed; however, the hooklets are liberated and can be seen and identified (personal communication from Graeme Paltridge). Additional information on diagnostic methods can be seen in Table 14.5.

KEY POINTS—LABORATORY DIAGNOSIS

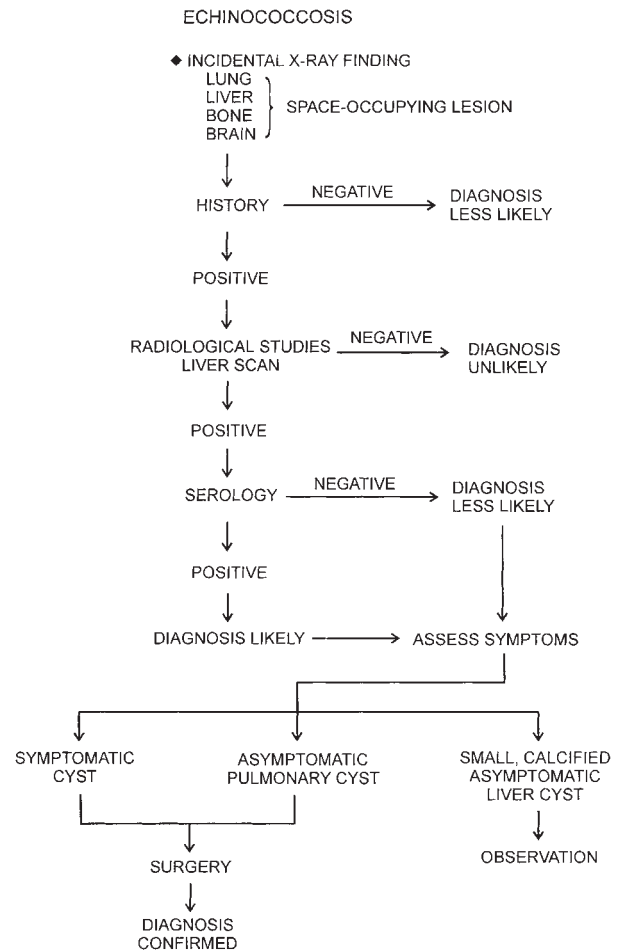

Echinococcus granulosus (Cystic Disease)

1. Presumptive diagnosis may be based on history, radiographic studies, or scans.
2. Additional supportive data may be acquired from immunologic tests.
3. Microscopic examination of hydatid cyst fluid may reveal the hydatid sand or, under certain circumstances, just the hooklets.
4. If the cyst fluid is thick or purulent, it may have to be subjected to a digestion procedure prior to examination; the hooklets survive this treatment and can then be seen and identified.
5. Light, fluorescence, and epifluorescence microscopy can be used to visualize the hooklets; some approaches require staining, and some do not.

Treatment

A number of options are available for treatment of cystic echinococcosis, including surgery, puncture-aspiration-injection-reaspiration (PAIR), and chemotherapy. Surgery is generally considered the treatment of choice for a complete cure, although this approach is limited to unilocular cysts in operable body sites. In cases where multiple cysts are present in several different sites or in patients with a high surgical risk, PAIR and chemotherapy are considered appropriate options, either together or separately.

Surgery. Because there is always the risk of cyst fluid spillage during surgery, pre- and/or postoperative use of chemotherapy may be appropriate. Chemotherapy with albendazole or mebendazole offers the advantage of reducing the risk of disease recurrence and intraperitoneal seeding of infection that may develop via cyst rupture and spillage occurring spontaneously or during surgery or needle drainage. Surgery is normally reserved for patients with hydatid

Algorithm 14.1 Echinococcosis.

cysts refractory to PAIR due to advanced hydatid disease or secondary bacterial infection or for patients with cyst-biliary communication or obstruction. Histologic images of cystic echinococcosis can be seen in chapter 23.

Puncture-Aspiration-Injection-Reaspiration. PAIR is minimally invasive and includes the following steps: (i) under ultrasonographic guidance, percutaneous puncture of the cyst; (ii) aspiration of 10 to 15 ml of the cyst fluid; (iii) injection of a parasitocidal solution (95% ethanol in a volume one-third the amount of fluid aspirated); and (iv) reaspiration of the fluid after 5 min (33). Although hypertonic NaCl (15% [final concentration] in the cyst fluid) can be used instead of 95% ethanol, reaspiration of the fluid should not be performed until after 15 to 20 min. PAIR appears to have a higher incidence of cure, lower rates of complications, mortality, and disease recurrence, and fewer hospitalization days compared with surgery (126). Also, for patients with hepatic echinococcosis who fail to respond to chemotherapy alone, PAIR

Table 14.5 Procedures for the diagnosis of echinococcosis

Procedure	Comments	Reference
Cellular and humoral responses to purified antigens	Lymphoproliferative assay could be used as an additional tool for the diagnosis of hydatid disease, particularly in seronegative cases; unsuitable for effective monitoring of treatment or surgery.	62
<i>E. granulosus</i> hydatid fluid antigen-ELISA	Diagnostic sensitivity, 91%; specificity, 82% (with cross-reactions in tumor patients [6%] and in patients with other parasitic diseases). Immunoblotting (8, 29, or 34 kDa) provided a 99% discrimination between seropositive cystic hydatid disease cases and noncestode parasitic infections or malignancies.	100
<i>E. granulosus</i> (cystic hydatid disease) cyst fluid (antigen B-rich fraction), <i>E. multilocularis</i> (alveolar hydatid disease), protoscolex extract (Em18-rich fraction)	Antigen B (8 kDa) not species specific for <i>E. granulosus</i> (genus specific; Em18 antigen is a serologic marker for differentiation of <i>E. granulosus</i> and <i>E. multilocularis</i>)	52
Enzyme-linked immunotransfer blot (EITB)	Utility of discriminant analysis applied to the serologic results was more sensitive than conventional serologic diagnosis; detected 100% of patients with active hydatid cyst with a specificity of 100%. However, failed to detect 1 case of uncomplicated hyaline pulmonary hydatid cyst.	40
Pre- and posttreatment sera tested for circulating hydatid antigen using coagglutination and countercurrent immunoelectrophoresis and for antibody using indirect hemagglutination	Serial pre- and postoperative or chemotherapy estimation of antigen valuable as an index of cure or of continuing hydatid infection.	102
Countercurrent immunoelectrophoresis of urine for hydatid antigen	Antigen detected in 44% with surgically confirmed disease, 40% with ultrasonography-proven disease, and 57% with presumptive disease. No cross-reactivity, but 8% false positives. Simple, rapid, and noninvasive method of diagnosis.	96
Countercurrent immunoelectrophoresis of hydatid fluid	Test is moderately sensitive (79%) and 100% specific; although sensitivity is not very high, test is simple, inexpensive, and rapid.	102
Coagglutination for detection of hydatid antigen in fluid aspirated from hydatid cysts	Scolices and hooklets seen in <50% of aspirated samples; hydatid antigen demonstrated in all samples with 100% sensitivity; provides alternative to microscopy for confirmation of hydatid etiology.	96
FNA biopsy; detection of <i>E. granulosus</i> antigen 5 in liver cyst biopsy specimens	Sensitivity of microscopy after FNA biopsy, 64% (16/25); antigen 5 results were positive in those who were microscopy positive (confirmed) but in only 11% of suspected patients.	97
Fiber-optic bronchoscopy in diagnosis of complicated pulmonary unilocular cystic hydatidosis	Review of 1,726 cases. While clinical, radiologic, and laboratory findings are presumptive, fiber-optic bronchoscopy and cytologic-histopathologic exam of material obtained are conclusive for diagnosis.	117
Dark-field microscopy compared with cytochemical stains for diagnosis of complicated pulmonary unilocular cystic hydatidosis	Superior to cytochemical stains, providing increased sensitivity of cytologic detection of true hydatid elements such as hooklets and laminated membrane fragments.	95
Visualization of hydatid elements; several methods	Ryan and modified Baxby (steaming-hot 1% safranin for 2 min, malachite green for 30 s) stains recommended for examination under transmitted light; Ziehl-Neelsen stain under green excitation light (excitation, 546 nm; long pass, 590 nm) or violet light with no staining for fluorescence; epifluorescence microscopy convenient for samples concentrated by filtration.	20
Sandwich ELISA for coproantigen in formalin- and heat-treated fecal material from dogs	Sensitivity of 100% and specificity of 96%.	81

is a safe and effective procedure. It is recommended for treatment of hepatic cysts of ≥ 5 cm in diameter, for cysts with daughter cysts, for cysts with detached membranes, and for multiple cysts accessible to puncture. Contraindications are for cysts communicating with the biliary tree, hepatic cysts with high surgical risk or in inaccessible locations, cysts free in the abdominal cavity, and cysts in the lungs, heart, brain, or spine (33).

To prevent chemical cholangitis, it is critical that PAIR not be used to treat cysts with biliary communication. Cyst aspirates must be checked for traces of bilirubin; if it is found in the cyst fluid, the PAIR protocol must be stopped immediately.

Percutaneous Thermal Ablation. Percutaneous thermal ablation of the cyst germinal layer using a radiofrequency ablation device has proven to be a newer option that may find greater use in the future (33). One advantage of this approach is that it avoids injection of parasitocidal fluids into the hydatid cyst.

Chemotherapy. During the last few years, experience with the benzimidazole derivatives mebendazole and albendazole suggests that under certain circumstances, chemotherapy may replace surgery. This approach is recommended for patients with inoperable cystic disease and those with multiple cysts in several body sites; however, chemotherapy for bone disease is less effective. Although relapses after chemotherapy have been reported, patients are usually sensitive to retreatment (3, 33, 98). In general, side effects are mild.

Immunologic markers indicating the effectiveness of pharmacologic treatments with albendazole and mebendazole in human hydatid disease have been reviewed. These studies show that IgE may be a useful marker of therapeutic success in patients with pretreatment specific IgE antibodies, since the levels of these antibodies decrease rapidly in those who respond fully to therapy. IgG subclass responses and differential immunoglobulin in subclass binding pattern to hydatid antigens may also be useful (105). Specific dosage information is provided in chapter 25 (Table 14.6).

Epidemiology and Prevention

The percentage of infected hosts varies throughout the world, but human infection is still much less common than infection of any of the reservoir hosts. Areas of endemicity of growing concern are the sheep- and cattle-raising areas of Argentina, Uruguay, southern Brazil, and Chile (8) (Table 14.7). There are two life cycles of *E. granulosus*, the first of which can be domestic, involving the domestic dog as the definitive host and various species of domestic ungulates as intermediate hosts.

The second type of life cycle is sylvatic, in which wild carnivores serve as definitive hosts and wild ungulates serve as intermediate hosts. The dog-sheep strain is the most common and important throughout the world. There are often overlapping domestic and sylvatic cycles, all of which present special situations and challenges related to disease control.

Most human hydatid cysts are probably acquired in childhood and may continue to grow undetected for many years. Several preventive measures are considered mandatory if the incidence is to decrease. First, all infected viscera from slaughtered animals (intermediate hosts containing hydatid cysts) must be disposed of so that dogs do not have access to this material. Also, personal hygiene must be emphasized to prevent accidental ingestion of the infective eggs from soil contaminated with dog feces, particularly since the eggs are very resistant to disinfectants. In many areas, extensive control measures have also been taken to reduce hydatid disease (Table 14.8). Certainly, educational programs are also very important.

ELISAs for *Echinococcus* coproantigen have been developed to detect infection in animals (33). Antigen could be detected for 6 months in fecal samples stored in 5% formalin. Improvements in sensitivity in patients with low worm burdens and modifications for field application may prove to be very helpful in future epidemiologic studies.

Echinococcus multilocularis (Alveolar Disease, Hydatid Disease)

For many years, pathologists recognized the difference between the unilocular type of human hydatid cyst and the alveolar form. Some workers thought that the alveolar form was a variant species, while others thought that it might arise from an early unilocular cyst. Investigations in Alaska and Germany served to define the characteristics of alveolar hydatid disease caused by *E. multilocularis* (Table 14.1). Alveolar hydatid disease is the most lethal of helminthic diseases, with radical surgery still being the only curative therapy. However, resection has been possible in only 25 to 57% of patients. Most cases are diagnosed in rural residents, suggesting direct or indirect contact with fecal material from infected foxes or dogs. The spread of infections and the increasing numbers of documented cases in the former USSR, China, Japan, and Alaska are causing concern among public health personnel in these regions. There is some variation among isolates from North America and Eurasia; however, there appear to be no actual genetic strain differences (46).

Table 14.6 Additional information on therapy for hydatid disease

Therapy	Comments	Reference
Albendazole vs. mebendazole (3–6 month continuous cycles)	448 patients with 929 hydatid cysts; 74% of cysts showed degenerative changes at the end of therapy, more frequent in albendazole-treated than mebendazole-treated patients (82 and 56%, respectively). Relapse percentages similar. Cysts recurred most often within 2 yr after therapy.	38
Albendazole vs. placebo	20 patients with 179 pulmonary cysts; 800 mg of albendazole daily in 3 cycles of 6 wk (2 wk between cycles); 91% (10/11) of treatment group showed cure (5) or improvement (5); 25% of placebo group showed improvement but no cure; 71% of cysts in treatment group (88/124) showed improvement compared to 15% (4/26) in placebo group.	61
Albendazole	12 patients, cystic hydatid disease of liver, continuous treatment for 6 courses of 4 wk with a 2-wk drug-free interval between cycles; at 24 mo, continuous therapy better than discontinuous therapy.	78
Albendazole, cerebral cyst	Cerebral cyst treated with albendazole; follow-up showed complete disappearance of the cysts with residual focal calcification on CT and presumed gliosis on MRI.	55
Mebendazole, dosage and duration	53 patients, single-, multiple-, and/or multiorgan hydatid cysts (30–70 mg/kg/day) over various periods (6–24 mo); treatment failure in 40%, cure in 38%, intermediate result in 23%; cure rates increased both with dosage and duration; daily dosages of 60–70, 50, and 30–40 mg/kg cured 48, 33, and 25%, respectively.	139
Mebendazole, intracystic application of solution	2 patients with liver cyst; first report of paired therapy; concentration of 2.4 µg/ml injected into cyst plus 50 mg/kg/day oral treatment; at end of 6- to 9-mo period, total recovery observed.	36
Surgery vs. percutaneous drainage or prolonged chemotherapy	63 patients; if CT findings include evidence of exophytic (growth out from the original lesion or dilated ducts in the vicinity of the cyst), surgery is indicated and should not be delayed when either sign is encountered.	72
Percutaneous drainage combined with albendazole	Percutaneous drainage, combined with albendazole therapy, is an effective and safe alternative to surgery for treatment of uncomplicated hydatid cysts of the liver; requires shorter hospital stay.	63
Laparoscopic partial pericystectomy	Laparoscopic partial pericystectomy is a promising new surgical approach to hepatic hydatid disease; practical without increasing the risk of intra-abdominal spillage of scolices; some cysts may not be accessible by this procedure; approach not possible for <i>E. multilocularis</i> .	128
Pulmonary cyst; percutaneous drainage and albendazole treatment	Aspiration plus chemotherapy common for liver cysts; not as commonly reported for pulmonary cysts; other options for pulmonary cysts should also be considered.	83
One-stage surgical approach for bilateral lung and liver hydatid cysts	Simultaneous combined resection of hydatid cysts in one stage through midsternotomy along with laparotomy or transdiaphragmatic removal of liver cysts.	25
Endoscopic stenting for postoperative biliary strictures	13 cases; endoscopic stenting is safe in treatment of postoperative benign biliary strictures secondary to hepatic hydatid disease.	146
Orbital hydatid cyst; percutaneous treatment	The cyst was treated percutaneously under ultrasonographic guidance with aspiration, 15% hypertonic saline injection, and reaspiration; no complications; patient asymptomatic after 9 mo; same follow-up at 21 mo; approach may be a safe and effective alternative to surgery.	2
Cardiac and pericardiac disease	14 patients; intraoperative surface echocardiography is critical for diagnosis and planning management of successful surgery; definitive treatment is surgical removal of the cyst.	12
Pancreas	Patient with primary hydatid cyst in head of the pancreas, with obstructive jaundice due to extrinsic compression of the intrapancreatic portion of the bile duct; percutaneous drainage used with hypertonic (20%) saline.	144
Evaluation of scolicidal agents in experimental model	Mouse model; hydrogen peroxide and povidone iodine show a greater protoscolicidal effect than does simple cleansing with physiological saline, hypertonic saline, or praziquantel.	41

Table 14.7 Examples of epidemiology of cystic hydatid disease (*E. granulosus*)

Geographic location	Comments	Reference(s)
Northern Libya	20,220 people screened; use of ultrasonography combined with serology as a mass screening approach; of ultrasonography-positive cases, 69% seropositive (ELISA with hydatid cyst fluid antigen B); cystic echinococcosis increased significantly with age; 25% of ultrasonography-negative members of families with an index case were seropositive.	122
Iran	Majority of <i>E. granulosus</i> -infected livestock animals can potentially act as reservoirs of human infection; important implications for hydatid control and public health.	149
Turkana, Kenya	Ultrasonography of 260 sheep and 320 goats; 9.2% of sheep and 2.5% of goats positive.	84
Turkana, Kenya	Ultrasonography of 16 sheep and 284 goats; sensitivity and specificity of ultrasonography in sheep and goats were 54 and 98%, respectively.	112
Argentina	PCR-restriction fragment length polymorphism characterized 4 distinct genotypes of 33 isolates; first report of G2 and G6 genotypes in humans—may have consequences for human health.	109
Peru	High prevalence of human and animal echinococcosis in village in central Peruvian Andes; field studies include coproantigen enzyme immunoassay and arecoline purging used for study of canine disease; EITB used in sheep; overall prevalence was 9.3% in humans, 46% in canines, and 65% in sheep.	89, 90
La Paloma, Central Uruguay	Prevalence of human infection was 5.6%; almost 20% of dogs were infected; human cystic echinococcosis highly endemic in Uruguay, one of the highest prevalence rates in the world; mass screening by ultrasonographic scanning with confirmatory serologic testing is an effective approach to detection at community level.	21
Florida, Uruguay	Ultrasonography of 9,515 patients with liver lesions revealed 156 positive; sensitivity of ELISA and latex agglutination serology compared with ultrasonography was 48 and 28%, respectively; specificity was >85%. No correlation with dog ownership or home slaughter of sheep, but offal disposal was important.	17
Northern Israel	IgG ELISA, using both crude and purified antigens, very useful for seroepidemiologic screening for hydatid disease; the condition is an emerging disease in this area.	35
Bulgaria	Review of control measures over periods spanning 46 yr. After a period of effective control measures, economic changes led to removal of control structures; the incidence rose, providing convincing evidence that cessation of control measures can lead to intensification in the transmission of <i>E. granulosus</i> and to resurgence of disease to former levels.	130

Table 14.8 Control measures for cystic hydatid disease

Approach	Comments	Reference
Vaccination of intermediate host (sheep)	Immunization of sheep with specific purified protein results in 92% resistance; immunization using fusion protein has given 97 and 98% resistance to a challenge infection; shelf life is 12 mo; 2 injections given 1 mo apart effective for at least 12 mo.	48
Vaccination of intermediate host (sheep)	Cloned recombinant antigen from parasite oncosphere; sheep protected (mean, 96–98%); potential for human vaccination.	74
Vaccination of intermediate host (sheep)	EG95 recombinant vaccine; 86% of vaccinated sheep completely free of viable hydatid cysts approximately 1 yr after challenge infection; number of viable cysts reduced by 99% compared with unvaccinated controls.	73
Treatment of sheep with oxfendazole	215 adult sheep; in daily, weekly, and monthly groups receiving treatment, 100, 97, and 78% of sheep, respectively, were cured or improved compared with 35% in the control group; daily dosing at 30 mg of oxfendazole per kg proved highly toxic (24% death rate in daily group).	31

Life Cycle and Morphology

The life cycle is essentially identical to that of *E. granulosus*, with the following exceptions: the definitive hosts in the sylvatic cycle tend to be dogs, cats, wolves, and foxes while the intermediate hosts have been identified as voles, field mice, house mice, ground squirrels, and shrews (Figure 14.8). Laboratory infections have also been maintained in deer mice and gerbils.

The adult worms are smaller than those of *E. granulosus* (1.2 to 3.7 mm versus 3.0 to 6.0 mm long). Also, the eggs are *Taenia*-like and very resistant to cold.

The cyst itself is composed of many irregular cavities with little or no fluid, rare or no free scolices, and often central necrosis and cavitation of the lesion (Figure 14.9). The human lesion is an example of persistent parasitic growth at a low level rather than active growth or malignancy.

Clinical Disease

Although the alveolar form of hydatid disease has been found in other tissues, the liver is the most common site. The disease may resemble a slowly growing carcinoma and may cause symptoms of intrahepatic portal hypertension. In humans there are several stages of the infection; they have been described as initial, progressive, advanced, stable, and abortive course (33) (Table 14.9).

Proliferation of the cyst is most active at the advancing margin, while the interior of the cyst structure may deteriorate and appear to be a necrotic abscess filled with pus. The lesions tend to spread by direct extension into the surrounding tissues and can also be transported to other body sites via the lymphatic or hematogenous routes. In about 2% of cases, pieces of the germinal membrane can metastasize to other body sites, including the brain, lungs, and mediastinum. Since the human is not a normal host,

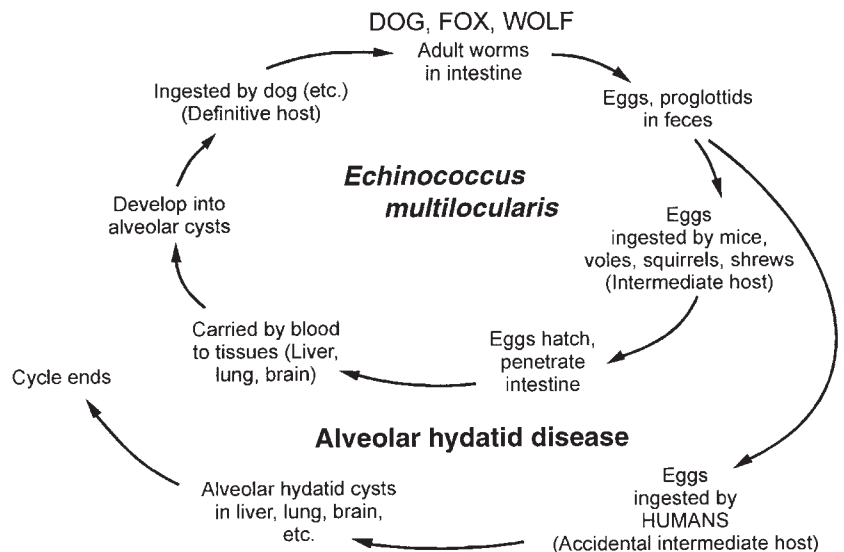

the typical brood capsules, scolices, and calcareous corpuscles may not develop (Figure 14.9). In the human, the laminated membrane may surround vesicles that are void of scolices and other internal structures. The lesions caused by *E. multilocularis* may appear as firm, solid, cancerlike masses, and the outer layer has a poorly defined margin that continues to grow and spread throughout the tissue.

In well-established disease, there may be hepatomegaly, splenomegaly, and finally jaundice and ascites. Patient symptoms include right upper quadrant pain and the presence of a palpable hepatic mass. There may also be shortness of breath, as well as central nervous system symptoms from brain metastases. Because the growth of the alveolar cyst is very slow, some patients may be infected for 20 or 30 years before exhibiting any symptoms. In patients who remain untreated, the mortality rate can exceed 90% (80).

Studies directed at the metacestode developmental stage of *E. multilocularis* have confirmed that the 14-3-3 protein is found in the germinal layer and is expressed about 10-fold in this stage compared with the adult worm. These results, taken together with current knowledge of the 14-3-3 protein family, suggest that this parasite molecule may contribute to the promotion of the progressive, potentially unlimited growth behavior of the organism within the host tissue (123). Studies also suggest that viable *E. multilocularis* vesicles induce significant cellular production of cytokines and chemokines. In patients with viable alveolar hydatid disease, these immune mediators may enhance antibody-dependent cellular effector mechanisms against proliferating metacestodes (30).

Both humoral and cell-mediated immune responses occur. In the mouse model, there is an initial Th1-dominant cytokine response, including IL-2 and gamma interferon

Figure 14.8 Life cycle of *Echinococcus multilocularis* (alveolar hydatid disease).

Figure 14.9 *Echinococcus multilocularis*. (A) Entire cyst. (B) Multicystic nature of the parasite in an experimental infection in a muskrat. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*. Photograph courtesy of R. L. Rausche.) (C) Diagram of a histologic section (the left side represents the normal animal intermediate host in which scoleces are found; the right side demonstrates the cyst structure within the human accidental intermediate host in which the scoleces may not develop). (D) Histologic section. (Illustration by Sharon Belkin.)

Table 14.9 Infection phases: alveolar echinococcosis

Disease phase	Symptoms	Comments
Initial	Asymptomatic	Spontaneous cure or become progressive: incubation period 5–15 yr
Progressive	Abdominal pain, jaundice, hepatomegaly, fever, anemia, weight loss, pleural pain	Symptoms occur when metacestode infiltrates larger parts of liver or impacts organ functions
Advanced	Severe hepatic dysfunction, portal hypertension	Disease duration variable between weeks and years; mortality in both treated and untreated patients can be high
Stable	Patients on long-term chemotherapy	Parasite growth inhibited
Abortive	Seen in asymptomatic patients	Parasite dies and the cyst is calcified

(IFN- γ). This response is associated with diminished parasite growth. Rapid organism growth was associated with secretion of Th1- and Th2-type cytokines including IL-5 and IL-10. In patients with progressive disease, IL-10 was more pronounced and IL-10 levels in serum were higher than in patients with the abortive form (42).

Diagnosis

Imaging Techniques. Ultrasonography, in association with computed tomography (CT), is recommended; magnetic resonance imaging (MRI) can also be helpful. These imaging options can detect the majority of lesions, including those that have calcified. In a recent study, contrast-enhanced power Doppler ultrasonography was compared with CT for the diagnosis of alveolar echinococcosis. The three-phase helical CT was able to visualize the vascularization associated with *E. multilocularis* lesions in the liver, while neither unenhanced nor contrast-enhanced ultrasonography in power mode was suitable for this purpose (66).

Immunodiagnostic Tests. The diagnosis of alveolar hydatid disease may be difficult unless there is a presumptive diagnosis based on history. Often, the correct diagnosis is missed even at autopsy. Serologic procedures used for unilocular hydatid disease may be helpful (Table 14.4) (33, 150). The metacestodes of *E. multilocularis* contain glycolipids which are recognized by serum antibodies from patients with alveolar hydatid disease. The ELISA procedure results were confirmed by immunostaining on

thin-layer chromatography (99). This approach may also provide another procedure for the diagnosis of alveolar hydatid disease. The use of monoclonal antibodies in a sandwich ELISA has also proven valuable in the diagnosis of alveolar hydatid disease, particularly when one is distinguishing this infection from those caused by other helminths. In general, one of the difficulties with any complex parasite involves the cross-reactivity seen when crude antigen extracts or antigen fractions from different isolates are used for immunodiagnosis. This approach results in a lack of test standardization and inability to interpret and compare test results. Because serodiagnosis fails in 5 to 10% of cases and radiologic techniques are difficult to interpret in some cases, PCR has been developed for the detection of *Echinococcus*-specific mRNA from fine-needle aspiration (FNA) biopsy specimens (60).

Fine-Needle Aspiration. FNA biopsy findings for hepatic *E. multilocularis* have been reviewed; there appear to be some basic diagnostic criteria for this approach (19). Cytologic smears were stained with May-Grunwald-Giemsa and periodic acid-Schiff (PAS) stains. Tissue sections were stained with hematoxylin and eosin and with PAS. In tissue sections, homogeneous, thin cystic structures of various dimensions were strongly PAS positive. Mucoïd material within the cystic structures was also PAS positive. Wide coagulative necrosis was seen in all cases, and there were foreign-body-type giant cells at the periphery of the lesion in some cases. In all of the cytologic smears, there were necrotic ground, PAS-positive hyaline cuticular structures, and mucoïd globules; in some smears, there were also foreign-body-type giant cells.

In another case where the patient presented with a multicystic mass in the pancreas, FNA biopsy revealed some scolices, free hooklets, and fragments of the laminated layer, findings which are pathognomonic for echinococcosis. In this case, the patient had pancreatic alveolar hydatid disease (28). Serologic testing using an ELISA with Em2(plus) antigen showed high antibody reactivity with the patient serum, a finding indicative of an *E. multilocularis* infection. Diagnosis was confirmed by molecular analysis of the cytologic material using PCR and a direct fluorescent-antibody assay.

KEY POINTS—LABORATORY DIAGNOSIS

Echinococcus multilocularis (Alveolar Disease, Hydatid Disease)

1. Serologic results may be helpful (the same procedures as used for unilocular disease).
2. Histologic identification may be unsuccessful at both the biopsy and autopsy phases of the diagnosis

as a result of nonrecognition of the etiologic agent or insufficient tissue.

3. Imaging techniques can be very helpful, particularly when coupled with immunodiagnostic tests for confirmation.

Treatment

Surgery. Total surgical removal of an alveolar hydatid cyst is almost impossible, since the cyst morphology does not have a limiting capsule. However, in cases diagnosed in the early stages, radical surgery may result in a cure. In more advanced cases of alveolar disease, the effectiveness of radical surgery drops dramatically. Liver transplantation is generally not recommended, and there remains a risk of metastasis after surgery.

Chemotherapy. In addition to surgery, the same drugs that have been used for *E. granulosus* have been tried. Mebendazole and albendazole are the drugs of choice for treating alveolar echinococcosis. However, if one considers cost, albendazole reduces costs by about 40% and is easier for patients to take (104). In some situations, the data indicate that mebendazole therapy is parasitostatic rather than parasitocidal; however, even with recurrence, the patients responded favorably to reintroduction of chemotherapy. Because IFN- γ and IFN- α levels are decreased in patients with echinococcosis, the addition of IFN- γ to standard therapy with mebendazole has been reported to halt disease progression (120). Specific drug information is provided in chapter 25. The overall prognosis for this infection is usually very grave. However, spontaneous death of *E. multilocularis* cysts in humans has been reported. Additional information can be found in Table 14.10.

Assessment of chemotherapy can be difficult and is usually based on the following criteria: (i) long-term patient survival rates, (ii) lack of disease progression, (iii) improved clinical status, (iv) slowed or stopped parasite proliferation, and (v) absence of disease recurrence (32).

Epidemiology and Prevention

A number of variables play roles in the epidemiology of *E. multilocularis* infection (Table 14.11). Also, there are serious questions regarding the emergence and geographic spread of this infection. It is found in at least 30 countries, including Russia, Kazakhstan, China, parts of Europe, and North America. Although it appears that areas of endemic infection are increasing in size, it is difficult to tell whether the data reflect actual changes in the parasite range or merely clarification of range extensions that were already present but unrecognized (59, 127).

Handling of infective definitive hosts or ingestion of contaminated food or water probably initiates the infection, while accidental ingestion of soil, berries, or other vegetables contaminated with eggs may be less important in transmission. However, it is important that the dangers of playing in the woods, picking berries, etc., in areas of endemicity that are frequented by wolves, foxes, and dogs be recognized, although routes of infection are difficult to prove due to the long incubation periods for the infection and lack of detailed information (32, 67, 108, 129, 137). Educational programs should be initiated early with children, since most infections are presumed to be acquired in childhood. There are probably additional factors that influence human infections but remain unknown (59, 68).

The use of coproantigen testing by a sandwich ELISA method to detect infection in foxes is more sensitive than routine egg detection assays and has been recommended for diagnosis in the definitive host of *E. multilocularis* (24, 92, 93). Coprodiagnosis by PCR is an excellent alternative to necropsy, since the sensitivity of necropsy is no higher than 76%. The PCR system is an alternative, sensitive method for the routine diagnosis of *E. multilocularis* in carnivores (29).

Chemotherapy with praziquantel has the potential to reduce the prevalence of *E. multilocularis* in wild foxes. However, the question of its long-term efficacy and other unresolved problems such as cost need to be addressed by additional studies before routine application of this baiting method can be recommended (49, 118, 140).

Echinococcus oligarthrus and *Echinococcus vogeli* (Polycystic Hydatid Disease)

Life Cycle and Morphology

E. oligarthrus and *E. vogeli* are the only indigenous species known in the neotropical area of the New World (101). The *E. oligarthrus* life cycle involves wild felids such as pumas, jaguars, and wild cats as definitive hosts, while the intermediate hosts harboring the larval forms (hydatid cysts) include the paca, agouti, spiny rats, and opossums. Further studies to determine which other wild animals might be involved in the life cycle are under way. The definitive hosts of *E. vogeli* include the bush dog, while the intermediate hosts are the same as for *E. oligarthrus*.

Clinical Disease

In a case of human hydatid disease caused by *E. oligarthrus* (26), the patient presented with proptosis of the left eye and persistent headache; a CT scan revealed a single orbital, retro-ocular cyst approximately the same

Table 14.10 Additional information on therapy for alveolar hydatid disease

Therapy	Comments	Reference
Gamma knife radiosurgery and albendazole	Patient had inoperable cerebral alveolar hydatid cysts; procedure performed in 2 sessions; repeated courses of albendazole given concurrently; MRI follow-up showed marked shrinkage of the irradiated cystic structures and initially increased perifocal edema; at 3-yr follow-up, the lesion, perifocal edema, and neurologic symptoms all decreased; patient now stable with minimal neurologic symptoms.	119
Albendazole plus dipeptide methyl ester (Phe-Phe-OMe)	Animal model (gerbils); histologic and ultrastructural studies showed that Phe-Phe-OMe increases the effect of albendazole; dipeptide has a low acute toxicity and is available at a low cost; studies under way to optimize the combination of Phe-Phe-OMe and albendazole.	116
Liver transplantation	21 patients received liver transplants for incurable alveolar echinococcosis; primary-disease recurrence is not rare after this treatment; immunosuppressive therapy may favor larval growth in extrahepatic sites, requiring extensive extrahepatic radiological checkup prior to transplantation; benzimidazole seems to stabilize residual foci; anti-Em2 ELISA did not appear useful in detecting recurrence, but ELISA using crude heterologous antigen (<i>E. granulosus</i>) allowed early diagnosis of residual disease.	15
Follow-up after treatment	11 patients with nonresectable lesions, treated with albendazole for 17–69 mo; various responses (2 cures, 5 stabilized, 3 with recurrences, 1 treatment failure); serum follow-up using Em2(plus)-ELISA and Em18-Western blot was useful in evaluating and predicting efficacy of chemotherapy.	79
Follow-up after treatment	Group of patients (cured, stabilized, aggravated) receiving therapy (mebendazole, albendazole, and isoprinosine); purified alkaline phosphatase antigen (pAP-Ag) is recommended for diagnosis and follow-up.	115
Amphotericin B	Used for benzimidazole intolerance or treatment failure (mebendazole, albendazole); may be used as salvage treatment, suppresses parasite growth; long-term treatment required.	103

size as the eye and thought to be a tumor. During surgery, fluid and internal tissues were taken from the cyst, which was also later removed. A few protoscolices and hooklets were found, and *E. oligarthrus* was identified (Figure 14.10). The first three known cases of *E. oligarthrus* have been documented, with the first two involving infection in the eye and the third involving infection in the heart.

E. vogeli is the etiologic agent of polycystic disease in humans in areas such as Brazil, Colombia, Venezuela, Panama, and Ecuador. Nine patients from Brazil were found to have polycystic hydatid disease, and the diagnosis was based on the shape and dimensions of the rostellar hooks. The liver was the most common site, followed by the lungs, mesentery, spleen, and pancreas. The main symptoms included abdominal pain, hepatomegaly, jaundice, weight loss, anemia, fever, hemoptysis, palpable abdominal masses, and signs of portal hypertension. The most common clinical presentation involved the abdomen, with hard, round masses in or connected to the liver. In 25% of cases, there were also signs of portal hypertension; all of these patients died, either from the disease or from surgical complications. Asymptomatic

individuals accounted for 10% of the cases. Hepatic calcifications were seen in four patients. Patients may have calcified, round structures in the liver, suggestive of calcified polycystic hydatids. This disease is chronic and can last for over 20 years; in advanced cases the mortality is high.

Fewer cases of *E. oligarthrus* infection in humans have been documented; to date, four cases have been published, three orbital and one cardiac (33, 91).

To date, approximately 80 cases of polycystic hydatid disease have been recorded, with more than 85% occurring in Brazil, Colombia, Ecuador, and Argentina. Patient ages have ranged from 6 to 78 years (median, 44 years), with one-third of the patients being younger than 22 years (23).

Diagnosis

In 80% of the patients, the lesions were in the liver alone or in both the liver and other organs. In the remainder of the cases, they were located in the lung or other single sites. Patients were diagnosed by various imaging techniques (radiography, ultrasonography, CT scan). Serologic tests did not always confirm the

Table 14.11 Variables in the epidemiology of alveolar echinococcosis^a

Life cycle phase	Epidemiologic factors	Comments
Definitive hosts, adult form of the parasite	Animal species: Distribution, population size, interactions with prey animals, feeding habits, behavior, habitat characteristics, relation to human habits Parasite: Prevalence, intensity and duration of infection, egg production, host immunity	Arctic region: Arctic fox is the sole definitive host (highly susceptible); voles are a major intermediate host and prey of foxes (infection prevalence in voles can reach 40%) Sub-Arctic region: Landscape, biotopes, climate more varied; more intermediate hosts, more than one definitive host
Parasite egg survival	Survival and dispersal of eggs, climate and weather conditions	Detailed knowledge of egg production, survival, dispersal not clearly defined; eggs infective for about 1 yr if kept moist and cool; -70°C for 4 days or -80°C for 3 days required for egg inactivation
Intermediate hosts, metacestode	Animal species: Longevity, distribution, population size, feeding habits, role as prey animals, habitat Parasite: Prevalence, level of infection, protoscolex production, host immunity	Transmission highest if one or two species of rodents are dominant, populations reach high densities, rodents are prey animals for foxes; areas of permanent grasslands are important
Humans, other hosts	Egg exposure, hygienic behavior, relationship to carnivores, susceptibility, resistance, immunity	Handling infected definitive hosts, ingestion of contaminated food or water

^a Adapted from references 32, 33, 58, and 59.

Figure 14.10 Polycystic hydatid disease.

infection; species identifications were based on morphological characteristics of the hooklets from protoscolices. Aspiration cytology has also been reported and can be very helpful in confirming the cause of the “mass” (64). Another option is DNA analysis by PCR using protoscolices. In cases where the organism was identified to the species level, the ratio of *E. vogeli* to *E. oligarthrus* was approximately 10:1.

Treatment

Albendazole therapy has resulted in clinical improvement, with resolution or reduction in the size of the cysts. Because surgical resection is difficult at best, some physicians think that albendazole therapy should be tried prior to surgical intervention. However, a combination of surgery and albendazole therapy has also been advocated.

Epidemiology and Prevention

Human polycystic echinococcosis is now recognized as a distinct disease entity. Although the cestodes that cause polycystic hydatid disease are indigenous to the humid tropical forests in Central and northern South America, *E. oligarthrus* has now been found in North America (114). This is the first time that the adult worm has been recovered from a bobcat. The isolate was identified from San Fernando, Tamaulipas State, in northeast Mexico; this location is approximately 100 km south of Brownsville, Tex. Apparently, infection risk exists in a larger geographic area than was previously suspected.

The paca is widely hunted and used for food in northern South America, and local people tend to feed the viscera of these animals to their dogs. Based on this common practice, it is assumed that the dog is probably the primary source of infection for humans in this and other areas of endemic infection.

Taenia (Multiceps) spp. (Taenia multiceps, Taenia serialis) (Coenurosis)

Although the adult tapeworms resemble *Taenia* spp., the larval form is a coenurus, a unilocular cyst with the same configuration as a cysticercus but containing multiple scolices. Human cases have been reported worldwide; however, identification to the species level is often very difficult if not impossible (Table 14.1).

Life Cycle and Morphology

The dog, wolf, and fox are the definitive hosts for *Taenia (Multiceps) spp.* (Figure 14.11). Infection of the intermediate host (herbivores) occurs on ingestion of infective eggs from the adult tapeworm in the carnivore intestine. The oncosphere hatches in the intestine, penetrates the intestinal wall, and is carried via the bloodstream to various parts of the body, primarily the central nervous system. In sheep, one of the more common herbivore intermediate hosts, the presence of the coenurus in the central nervous system causes a disease known as gid (unstable gait or giddiness). When these infected herbivore tissues are ingested by a carnivore, each scolex within the coenurus has the potential to become an adult worm in the carnivore's intestine.

The coenurus structure is intermediate between that of a cysticercus with a single scolex and that of a hydatid cyst with both multiple scolices and daughter cysts. The coenurus contains multiple scolices but no daughter cysts (Figures 14.12 to 14.14).

Clinical Disease

In humans, most coenuri have been located in the brain or spinal cord, but they can also be found in the subcutaneous tissues (51). Symptoms have been those associated

with any space-occupying lesion, including headache, vomiting, paraplegia, hemiplegia, aphasia, seizures, and eye symptoms (if the coenurus is present in the eye).

Diagnosis

Diagnosis is based on gross and histologic examinations of the coenurus after surgical removal.

Treatment

Surgical removal, if possible, is recommended. Although praziquantel has been effective in killing these parasites, there is some concern about the marked inflammation which occurs as a result of treatment (51).

Epidemiology and Prevention

An understanding of the manner of transmission among carnivores and herbivores suggests the importance of proper disposal of carcasses of potentially infected herbivores. Also, good personal hygiene for those in close contact with dogs in areas of the world where herbivores (cattle, goats, and sheep) are raised is recommended.

Spirometra mansonioides and Diphyllbothrium spp. (Sparganosis)

The larval forms (spargana) of *Spirometra mansonioides* and *Diphyllbothrium* spp. were first recognized in humans from tissues removed at autopsy. In areas where infections are endemic, similar forms can be found in the subcutaneous connective tissue and between the muscles in frogs, lizards, snakes, birds, and certain mammals. When these spargana are fed to the definitive hosts (dogs and cats), adult tapeworms of several related species of *Spirometra* develop. The general name for these spargana

Figure 14.11 Life cycle of *Taenia (Multiceps) spp.*

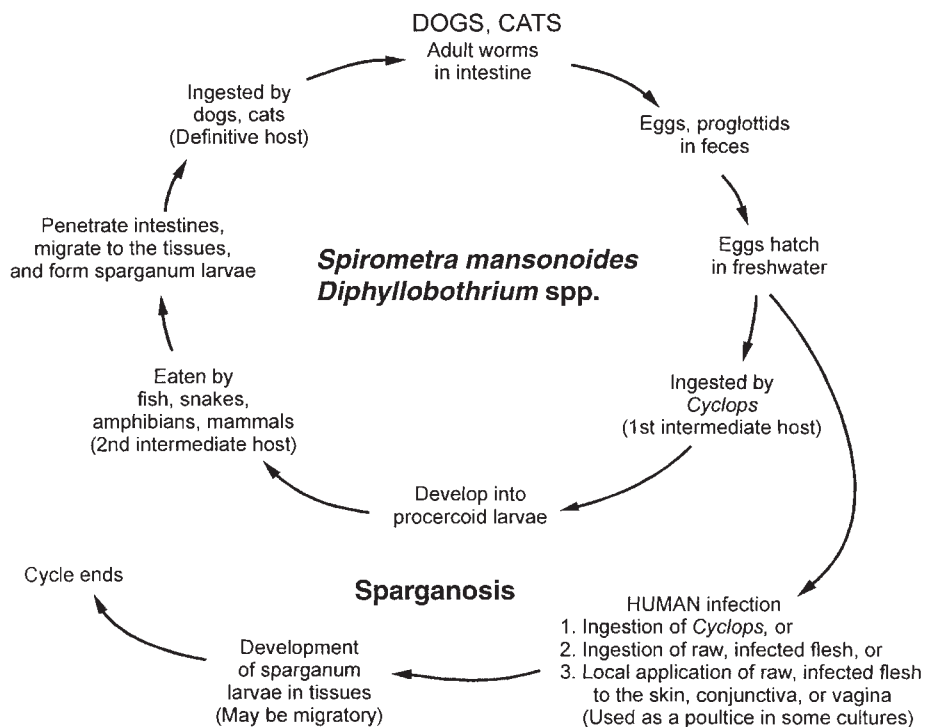

Figure 14.14 Coenurosis: cross section of cyst. (Armed Forces Institute of Pathology photograph.)

is *Spirometra mansonioides*. Although cases have been reported worldwide, sparganosis is most common in China, Japan, and Southeast Asia (Table 14.1).

Life Cycle and Morphology

Spargana. Eggs passed from adult tapeworms in the dog or cat intestine hatch in freshwater and are ingested by *Cyclops* spp., in which they develop into the proceroid larva. When the *Cyclops* spp. are eaten by a second intermediate host (fish, snakes, amphibians, or mammals), the proceroid larva penetrates the intestinal wall,

Figure 14.15 Life cycle of *Spirometra mansonioides* and *Diphyllobothrium* spp. (sparganosis).

migrates to the tissues, and develops into the larva (the sparganum). On ingestion by a dog or cat, the sparganum develops into the adult tapeworm, thus completing the life cycle (Figure 14.15).

Human infection can occur from (i) ingestion of infected *Cyclops* spp. (the proceroid stage penetrates the intestinal wall, migrates into tissues, and develops into the sparganum), (ii) ingestion of raw infected flesh of one of the second intermediate hosts (fish, snakes, amphibians, and mammals), or (iii) local application of raw, infected flesh of one of the second intermediate hosts to the skin, conjunctiva, or vagina (the spargana migrate from vertebrate host tissues into human tissue). The spargana are white, ribbonlike worms measuring from a few millimeters to several centimeters long.

Aberrant Spargana. *Sparganum proliferum* is a rare tapeworm larva that grows by continuous branching and budding. The normal tissue organization and symmetry are no longer visible. The lesion gradually expands and may ulcerate to form subcutaneous or cutaneous lesions. The adult form of this organism is unknown.

Clinical Disease

Spargana. Most patients have slowly growing, tender, subcutaneous nodules. These nodules may also be migratory (147). Ocular sparganosis is accompanied by pruritus, pain, lachrimation, and edematous swelling of the eyelid (which may look much like Romaña’s sign

in Chagas' disease). Depending on the location of the sparganum, there may be elephantiasis (lymph channels), peritonitis (intestinal perforation), or brain abscess. Most patients have leukocytosis and eosinophilia. The sparganum has been reported to live for more than 9 years. In a recent study in Thailand, 17 cases were ocular, 10 were subcutaneous, 5 involved the central nervous system, 1 was auricular, 1 was pulmonary, 1 was intraosseous, and 1 was intraperitoneal. Risk factors included a history of drinking impure water, eating frog or snake meat, or using frog or snake meat as a poultice; some patients had multiple risk factors. Most of these patients presented with superficial ocular mass lesions (141).

Aberrant Spargana. In the few documented cases of *S. proliferum* infections, thousands of spargana have been recovered in subcutaneous tissues, intermuscular fasciae, intestinal wall, mesentery, kidneys, lungs, heart, brain, and bone.

Diagnosis

Spargana. Usually, diagnosis is not made until drainage of the lesion, surgical removal of the worms, and gross and/or microscopic examination of the tissue have been performed. The more elongate, wormlike structure of the sparganum can usually be distinguished from the bladder structure of a cysticercus or coenurus, since the last two have suckers and hooklets, both of which are lacking in a sparganum. The parasites are usually recovered alive and are approximately several centimeters in length (26). They are glistening white and opaque; they resemble narrow tapeworm proglottids; and they are motile, similar to the motility seen with a *Taenia saginata* proglottid.

Aberrant Spargana. This rare form of sparganosis can be diagnosed by histologic examination. The tissue may appear to have many separate worms; however, each cross section probably represents a continuous branching worm.

KEY POINTS—LABORATORY DIAGNOSIS

Spirometra mansonioides and *Diphyllobothrium* spp. (Sparganosis)

1. The diagnosis is usually based on the identification of the worm after surgical removal.
2. The absence of suckers and hooklets will usually differentiate spargana from a cysticercus or coenurus.

Treatment

Surgical removal is the recommended approach. Drug therapy is usually not effective; however, treatment with

praziquantel is recommended. In the proliferating type of infection, surgical removal is very difficult if not impossible.

Epidemiology and Prevention

Considering the possible routes of human infection, all drinking water in areas of endemicity should be boiled or filtered to prevent accidental ingestion of *Cyclops* spp. The ingestion of raw tadpole, frog, snake, fowl, or mammalian flesh should be avoided in these areas. Educational information on the dangers of local application of raw, infected animal flesh (poulticing) to humans, particularly those with ulcerated lesions, should be disseminated.

Intestinal Trematodes

Fasciolopsis buski

Echinostoma ilocanum

Heterophyes heterophyes

Metagonimus yokogawai

Gastrodiscoides hominis

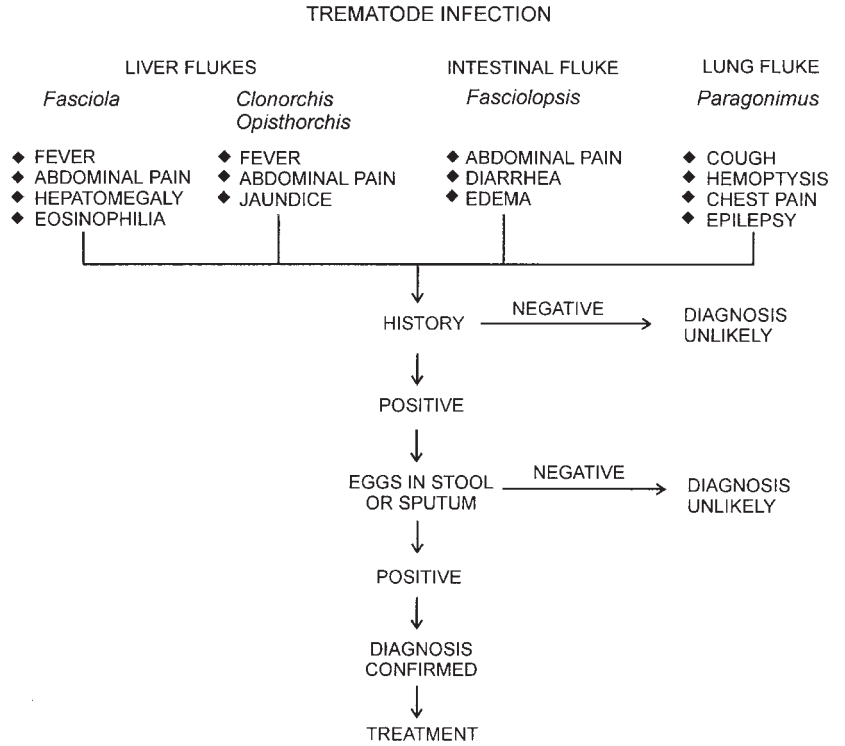

The intestinal trematodes, or flukes, are parasites of vertebrates; they are dorsoventrally flattened and hermaphroditic and require one or more intermediate hosts. The adult worms vary in size from the barely visible (*Heterophyes heterophyes*) to the very large (*Fasciolopsis buski*). To complete the life cycle, specific species of intermediate hosts must be available for trematode development. All of the intestinal trematodes require a freshwater snail to serve as an intermediate host. These infections are food borne and are emerging as a major public health problem, with more than 50 million people being infected (Algorithm 15.1) (17). The true economic impact of these infections is difficult to assess. Intestinal trematode infections can be found in Southeast Asia, the Far East, the Middle East, and North Africa.

Eggs deposited by the adult worms are passed to the outside in the feces (Figure 15.1). All intestinal trematode eggs have an operculum, or “lid,” from which the miracidium larva can escape. Eggs hatch in freshwater, and these larvae must find their way into the snail (intermediate host) through penetration of the snail tissues; in some cases, the snail ingests the eggs before they hatch. A series of developmental stages occur within the snail, eventually producing cercariae, which are released from the snail. These cercariae then encyst on aquatic plant material or encyst in the tissues of freshwater mollusks or fish and become metacercariae. When the plants or mollusks are ingested raw, the metacercariae then infect the human host, where they excyst in the small intestine and develop into mature adult trematodes within the intestinal tract.

Adult worms vary in shape and size and can be distinguished from one another (Table 15.1; Figure 15.2). The adult worms are hermaphroditic, containing both male and female reproductive systems.

Fasciolopsis buski

Fasciolopsiasis was first noted by Busk in 1843, when worms were detected in the duodenum of a deceased East Indian sailor (2). *F. buski* has also been known as the giant intestinal fluke and is one of the largest parasites to infect humans, measuring 20 to 75 mm in length, 8 to 20 mm in width, and 0.5 to 3 mm in thickness.

Algorithm 15.1 Trematode infection.

Life Cycle and Morphology

The adult worms live in the small intestine of pigs and humans, where the worms lay unembryonated eggs that are then passed from the intestinal lumen with the feces. The eggs are ellipsoidal, operculate, and yellow-brown. They measure 130 to 140 μm by 80 to 85 μm, with the operculum found at the more pointed end of the transparent eggshell (Figures 15.3 and 15.4; Table 15.1). Depending on the temperature, the eggs embryonate within 3 to 7 weeks. Once in the water, the mature miracidium hatches from the egg and tries to locate the appropriate snail

species to infect (*Segmentina* and *Hipppeutis* spp.). Once the miracidium has penetrated the soft tissues of the snail (first intermediate host), it begins to develop into a first-generation sporocyst. The sporocyst is an elongated sac, without distinct internal structures, in which germ balls proliferate. These germ balls develop into rediae that contain a mouth, pharynx, blind cecum, and birth pore. Within the rediae, the germ balls again proliferate, developing into cercariae. Unlike some of the other intestinal trematodes, *Fasciolopsis* rediae develop a second generation of rediae before forming cercariae. On reaching

Figure 15.1 Life cycle of intestinal trematodes.

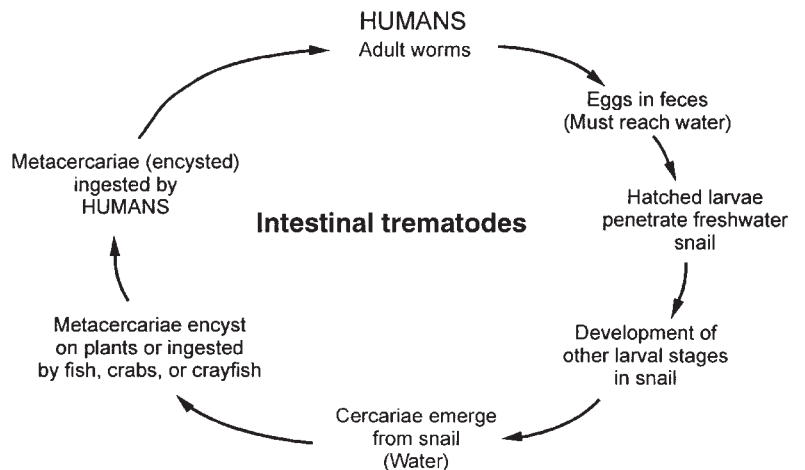

Table 15.1 Characteristics of intestinal trematodes

Species	Distribution	Agent of infection	Reservoir host	Egg		
				Size (μm)	Morphology	Comments
<i>Fasciolopsis buski</i>	Far East	Water chestnut, bamboo shoots, water caltrop	Dogs, pigs, rabbits	130–140 by 80–85	Unembryonated operculated	The less mature the egg, the more difficult it may be to see the actual operculum—it blends into the shell outline, and the “breaks” in the shell may be difficult to identify. This egg has no opercular shoulders, and so it is difficult to see where the operculum “breaks” in the shell actually occur.
<i>Echinostoma ilocanum</i>	Far East	Mollusks	Rats, dogs	86–116 by 59–69	Unembryonated operculated	Although <i>E. ilocanum</i> eggs are considerably smaller than <i>F. buski</i> eggs, some strains produce eggs that overlap in size; the operculum may be difficult to see (as indicated above for <i>F. buski</i>)
<i>Heterophyes heterophyes</i>	Far East, Middle East	Freshwater fish	Fish-eating mammals	27–30 by 15–17	Embryonated operculated with very subtle opercular shoulders; no “seated” operculum	These eggs have very inconspicuous opercular shoulders and, unlike <i>C. sinensis</i> , lack the “seated” operculum and knob at the abopercular end. <i>H. heterophyes</i> eggs are some of the smallest trematode eggs seen and may be missed using the low power of the microscope, and high dry power may be required for identification.
<i>Metagonimus yokogawai</i>	Far East, former USSR, Israel, Spain	Freshwater fish	Fish-eating mammals	26–28 by 15–17	Embryonated operculated with minimal opercular shoulders; no “seated” operculum	These eggs have inconspicuous opercular shoulders but a more obvious operculum than <i>H. heterophyes</i> eggs and are some of the smallest trematode eggs seen. They do not really have the “seated” operculum and knob at the abopercular end like those seen in <i>C. sinensis</i> eggs. They may be missed using the low power of the microscope, and high dry power may be required for identification.
<i>Gastrodiscoides hominis</i>	Far East, Middle East, former USSR	Freshwater fish	Pigs, deer mice, rats	60–70 by 150	Unembryonated operculated	The egg of <i>G. hominis</i> tends to be more slender than that of <i>F. buski</i> , but they are very much alike; this egg has no opercular shoulders, and so it is difficult to see where the operculum “breaks” in the shell actually occur.

Figure 15.2 Diagram of a general intestinal/liver trematode. (Illustration by Sharon Belkin.)

maturity, the cercariae escape from the snail host into the water. The cercariae encyst on water plants such as water caltrops, water chestnuts, and water bamboo, where they develop into metacercariae in approximately 4 weeks. Humans become infected by ingesting the raw or undercooked plants containing the metacercariae. The metacercariae excyst, attach to the duodenal or jejunal mucosa, and develop into adult worms within 3 months (Figure 15.5). The adult life span seldom exceeds 6 months to a year (2, 11, 12).

F. buski is the largest of the intestinal trematodes and attaches to the duodenal and jejunal walls (Figure 15.6). The adult worms are fleshy, dark red, and elongate-ovoid and have no cephalic cone structures like that seen in the liver fluke, *Fasciola hepatica*. The large egg tends to be yellowish brown, has a clear, thin shell with a small operculum but no opercular shoulders, and is nearly identical to that of *F. hepatica* and *F. gigantica*. The less

Figure 15.3 *Fasciolopsis buski* egg. (Illustration by Nobuko Kitamura.)

Figure 15.4 Intestinal trematode eggs. (A) *Fasciolopsis buski*; (B) *Echinostoma ilocanum*; (C) *Heterophyes heterophyes*; (D) *Metagonimus yokogawai*. Note that the eggs in panels C and D are shown at a higher magnification to demonstrate very minor differences; the operculum of *H. heterophyes* is less pronounced than that of *Clonorchis sinensis* (see chapter 16), and the operculum outline of *M. yokogawai* is the least obvious of the three small trematode eggs that are often confused (*C. sinensis*, *H. heterophyes*, and *M. yokogawai*).

mature the egg, the more difficult it is to see the operculum “breaks” in the shell outline.

Clinical Disease

In light infections, the adults inhabit the duodenum and jejunum; in heavy infections, they may be found in the stomach and most of the intestinal tract. The attachment of worms to the mucosal wall produces local inflammation with hypersecretion of mucus, hemorrhage, ulceration, and possible abscess formation. In heavy infections, the worms may cause bowel obstruction, acute ileus, and absorption of toxic or allergic worm metabolites, producing general edema and ascites. Edema of

Figure 15.5 Outline of the sizes of adult intestinal trematodes. (A) *Fasciolopsis buski*; (B) *Echinostoma ilocanum*; (C) *Heterophyes heterophyes*; (D) *Metagonimus yokogawai*; (E) *Gastrodiscoides hominis*.

the face may occur as a result of hypoalbuminemia secondary to malabsorption or protein-losing enteropathy. Occasionally, vitamin B₁₂ absorption is impaired, with resulting low vitamin B₁₂ levels. A marked eosinophilia and leukocytosis are commonly seen. Few symptoms are associated with light infections, but in heavier infections, the patient may experience abdominal pain and

Figure 15.6 *Fasciolopsis buski* adult worms. (Left) Unpreserved adult worm (fleshy, dark red, elongate-ovoid with no cephalic cone as seen in *F. hepatica*; the adult *F. buski* worms measure 20 to 75 mm in length by 8 to 20 mm in width, and 0.5 to 3 mm in thickness); (right) stained and flattened adult worm (from anterior to posterior characterized by a large ventral sucker, coiled uterus, branched ovary, and two branched testes filling most of the posterior section of the worm; the lateral fields are filled with vitellaria).

diarrhea. In heavy infections, the stools are profuse and yellow-green and contain increased amounts of undigested food, suggesting a malabsorption process. The symptoms may be confused with those of giardiasis or peptic ulcer or with other causes of bowel obstruction. Depending on the worm burden, the infection can be associated with severe cachexia and prostration and can lead to death (13).

Diagnosis

The diagnosis is suggested by the clinical features in areas where infections are endemic and is confirmed by detecting the eggs in the stool. The zinc sulfate flotation concentration is not recommended for concentrating trematode eggs because of the operculum and the fragility of the eggshell. The high specific gravity of the zinc sulfate causes the operculum to “pop” open, the eggshell fills with fluid, and the egg sinks to the bottom of the tube, where it may appear to be very distorted. Therefore, when this concentration procedure is used, both the upper flotation layer and the sediment must be examined. The formalin-ethyl acetate sedimentation concentration is recommended for routine fecal concentration. The sedimented material can be examined with or without iodine. The eggs of *Echinostoma ilocanum*, *Fasciola hepatica*, *F. buski*, and *Gastrodiscoides hominis* are similar in size and shape; therefore, an exact identification cannot be made from examining the eggs. It is possible to detect adult worms in the stool in heavy infections when they lose their ability to remain attached to the intestinal mucosa.

KEY POINTS—LABORATORY DIAGNOSIS

Fasciolopsis buski

1. The eggs are found in the stool; rarely, adult worms are found during heavy infections.
2. The eggs of *F. buski*, *E. ilocanum*, *G. hominis*, *F. hepatica*, and *F. gigantica* appear almost identical and are very difficult to differentiate from one another. When passed, the eggs do not contain mature larvae but instead contain undifferentiated embryos.
3. The formalin-ethyl acetate sedimentation concentration is recommended for egg recovery; operculated eggs do not float in the zinc sulfate flotation concentration method.
4. The less mature the egg, the more difficult it may be to see the actual operculum—it blends into the shell outline, and the “breaks” in the shell may be difficult to identify. This egg has no opercular shoulders; therefore, it is difficult to see where the operculum “breaks” in the shell actually occur.

Treatment

Although different drugs have been used for therapy, the drug of choice is praziquantel, an isoquinoline derivative that is administered orally (1). The drug is well tolerated; however, there may be some side effects, including abdominal pain, headache, dizziness, nausea, drowsiness, pruritus, and myalgia. These side effects usually disappear within 48 h but may be more pronounced in heavily infected individuals. The drug is administered as a single 15-mg/kg dose after the evening meal or before going to bed. A second regimen consists of 75 mg/kg/day in three doses for 1 day. Apparently, children tend to tolerate the drug better than adults. Contraindications for use include ocular cysticercosis, cerebral paragonimiasis, pregnancy, and physically demanding tasks where dizziness or drowsiness might put the patient at risk.

An alternative drug is niclosamide (Nicolcide), a salicylamide derivative; alcohol should be avoided during treatment. The drug may be given for 1 or 2 days at 40 mg/kg/day (up to a maximum of 4 g) (3). This drug is minimally absorbed from the gastrointestinal tract, and side effects include nausea, vomiting, diarrhea, and abdominal pain (see chapter 25).

Epidemiology and Prevention

F. buski reservoir hosts include dogs, pigs, and rabbits. The infection is commonly found in Bangladesh, Cambodia, central and southern China, India, Indonesia, Laos, Malaysia, Pakistan, Taiwan, Thailand, and Vietnam; it has also been reported from Japan. Drainage of farm waste, use of manure for cultivation, and defecation in or near ponds or lakes that contain snails from the family Planorbidae (*Gyraulus*, *Polypylis*, *Segmentina*, or *Hippeutis* spp.), with water plants acting as vectors, allow the life cycle of the worm to continue. Metacercariae encyst on freshwater vegetation, such as water chestnuts, bamboo shoots, or water caltrops, and the infection is acquired when these infested plants are consumed raw or the outer coat is peeled off the nut with the teeth, resulting in accidental ingestion.

To prevent the infection, plants should be cooked or immersed in boiling water for a few seconds before they are eaten or peeled. In areas of endemicity, the use of unsterilized night soil for fertilizer should be prohibited. If these safeguards were used, the risk of infection would be considerably decreased.

Fasciolopsiasis remains a public health problem despite changes in eating habits, agricultural practices, health education, industrialization, and environmental approaches. The disease occurs focally and is most prevalent in school-age children. In areas of endemicity, the prevalence of infection in children ranges from 57% in mainland China to 25% in Taiwan and from 50% in Bangladesh and 60% in India to 10% in Thailand.

Control programs are not fully successful because of long-standing traditions of eating raw aquatic plants and using untreated water. Control measures are also impacted by social and economic factors, an expanding free-food market, a lack of sufficient food inspection and sanitation, and declining economic conditions (6).

Echinostoma ilocanum

A number of species of echinostomes have been reported to infect humans. Most of the species are found in oriental countries; *E. ilocanum* is the most important species. The infection was first noted by Garrison in 1907 (2).

Life Cycle and Morphology

Adult worms are attached to the mucosal wall of the small intestine and lay eggs, which are passed from the intestinal lumen in the feces (Figure 15.7). The eggs are immature, ellipsoidal, yellow-brown, and operculated. They measure 86 to 116 μm by 58 to 69 μm (Table 15.1; Figure 15.4). The miracidia take 1 to 2 weeks to mature in the environment before they hatch from the eggs and infect the snail intermediate host. Two or more generations

Figure 15.7 *Echinostoma ilocanum* adult worms. (Upper) Stained adult worm characterized by having a circumoral disk with a crown of spines surrounding the small oral sucker. (Lower) Enlarged image of the crown of spines (surrounding the oral sucker) and the large ventral sucker. The living worm is reddish gray and measures 2.5 to 6.5 mm in length by 1 to 1.35 mm in width.

of rediae are produced before cercariae develop. These cercariae encyst in freshwater mollusks, and humans are infected by eating these mollusks raw rather than cooked. The metacercariae hatch in the intestine, attach to the mucosal wall, and develop into mature adult worms.

The adults are less than 1 cm long and 0.2 cm wide and are reddish gray (Figure 15.5). The anterior end of the adult worm has a circumoral disk with a crown of spines surrounding the oral sucker (Figure 15.7).

Clinical Disease

With light infections, the patient may be asymptomatic and the adult worms cause only minor problems other than localized inflammation. In heavy infections, the worms can produce catarrhal inflammation and mild ulceration and the patient may experience diarrhea and abdominal pain.

Diagnosis

Eggs of *E. ilocanum* can be detected in the stool. They are the same size (some strains) and shape as the eggs of *F. hepatica* and *F. buski*. Because of the overlap in size range, exact identification cannot be made from the eggs; therefore, the diagnosis may have to be made on the basis of patient history or clinical findings.

KEY POINTS—LABORATORY DIAGNOSIS

Echinostoma ilocanum

1. The eggs are found in the stool; rarely, adult worms are found during heavy infections.
2. The eggs of *E. ilocanum*, *G. hominis*, *F. buski*, *F. hepatica*, and *F. gigantica* appear almost identical and are very difficult to differentiate from one another. When passed, the eggs do not contain mature larvae but instead contain undifferentiated embryos.
3. The formalin-ethyl acetate sedimentation concentration is recommended for egg recovery; operculated eggs do not float in the zinc sulfate flotation concentration method.
4. The less mature the egg, the more difficult it may be to see the actual operculum—it blends into the shell outline, and the “breaks” in the shell may be difficult to identify. This egg has no opercular shoulders; therefore, it is difficult to see where the operculum “breaks” in the shell actually occur.

Treatment

Praziquantel is the drug of choice and can be given in a single dose of 40 mg/kg at bedtime. Another option would be albendazole at 400 mg twice a day for 3 days (see chapter 25).

Epidemiology and Prevention

Information concerning *E. ilocanum* infections and epidemiology is limited. Both rats and dogs have been found to be infected in areas where infections are endemic. The infection has been reported from China, Indonesia, Thailand, Taiwan, the Philippines, and the Celebes. In some areas in northeastern Thailand, the infection rate may be as high as 50%. In areas of the Philippines with high levels of endemic infection (Luzon, Mindanao, and Leyte), local infection rates from 1 to 44% have been reported (3). In China, the infection appears to be limited to dogs, with an infection rate of 14% being reported. The miracidia must infect a susceptible species of snail from the family Planorbidae (*Gyraulus* or *Hippentis* spp.). The cercariae can encyst in a number of freshwater mollusks, particularly snails, which, if eaten raw, will allow the metacercariae to excyst in the intestinal tract and develop to adult worms. The infection can be prevented in areas of endemicity by restricting the use of night soil for fertilizer and eating cooked rather than raw mollusks.

Human infections with other echinostome species have been reported; however, actual infection rates are unknown or estimated. Some of these species have been identified and are listed in Table 15.2. For a number of these species, the food source is often fish rather than mollusks.

Heterophyes heterophyes

H. heterophyes is one of the smallest trematodes to infect humans and is acquired through the ingestion of pickled or uncooked fish. The heterophyids are capable of parasitizing birds and mammals, and infection was first reported by Bilharz in 1851 (14).

Life Cycle and Morphology

The adult worms measure 1.0 to 1.7 mm in length by 0.3 to 0.4 mm in width, are gray, and have a broadly rounded posterior end (Figures 15.5 and 15.8). They lay embryonated eggs in the intestinal lumen, and the eggs are discharged into the environment via the feces. The eggs are small, brownish yellow, and operculate, and they possess very subtle opercular shoulders. They measure 27 to 30 μm by 15 to 17 μm (Table 15.1; Figure 15.4). The eggs are ingested by the snail intermediate host before the miracidium hatches. A sporocyst and one or two redia generations develop in the snail before the production and release of cercariae. The cercariae encyst under the scales or in the flesh of freshwater fish. Humans become infected by eating raw, pickled, or poorly cooked fish containing the metacercariae (9). The metacercariae excyst in the intestinal tract, attach to the walls of the small intestine, and grow to maturity. The adult worm, in addition to an oral and ventral sucker, contains a third sucker, the genital sucker, surrounding the genital pore.

Table 15.2 Other echinostome infections reported from humans^a

Trematode	Location	Host	No. and location of spines	Infection acquired
<i>Echinostoma malayanum</i>	Northeastern and northern Thailand	Rats, dogs	43 crown	Freshwater snails, usually cooked
<i>Echinostoma revolutum</i>	Taiwan (3–7% infection rate)	Ducks, geese, rats	37 circumoral	Raw mollusks
<i>Echinostoma lindoense</i>	Indonesia (infection may no longer be present in this area [Lindu Valley]); found in Brazil	Rats, mice	37 collar	Raw mollusks
<i>Hypoderaeum conoideum</i>	Northeastern Thailand	Ducks, other fowl, rats, humans	Two rows of 45–53	Salted or raw snails or clams
<i>Echinostoma cinetorchis</i> , <i>Psilorchis hominis</i> ^b	Japan, Taiwan			Tadpoles, frogs
<i>Euparyphium melis</i> , <i>E. beaveri</i>	Romania, China; may also be in Douglas Lake, Mich. (not studied)		27 crown	Tadpoles
<i>Hypoderaeum cibiuduyn</i>	Northeast Thailand (55% infection rate)	Ducks, geese, fowl		Raw snails
<i>Artyfechinostomum mebrai</i>	India (2 cases)	Pig	39–42 collar	Raw snails
<i>Echinostoma recurvatum</i>	Taiwan, Indonesia, Egypt	Rats	45 crown	Tadpoles, frogs
<i>Echinoparyphium paraulum</i> ^c	Former USSR	Ducks, geese, swans, doves		
<i>Himasthla muehlensi</i>	New York City		32 circumoral	Raw clams
<i>Echinochasmus perfoliatus</i>	Hungary, Italy, Romania, former USSR, Far East	Dogs, cats, pigs, foxes	24 circumoral	Raw freshwater fish

^a Data from reference 2.

^b May or may not be an echinostome; specimens may have lost crown spines.

^c May be the same as *Echinostoma revolutum*.

Clinical Disease

Following ingestion of metacercariae, the prepatent period is approximately 9 days. The adult worms cause little damage to the intestinal tract mucosa except for a mild inflammatory reaction. In heavy infections, the worms cause abdominal pain, mucous diarrhea, and ulceration of the intestinal wall. Because of the small size of the eggs and the fact that the adult may attach itself deeply into the intestinal wall, some of the eggs may end up in the general circulation of the host. The eggs may provoke pathologic lesions, particularly in the heart and brain (5, 7). In the Philippines, 15% of fatal heart disease may be a result of heterophyid myocarditis. Neurologic manifestations due to adult worms or eggs in the brain have been reported (13).

Diagnosis

The diagnosis is suggested by detecting the eggs in the stool. Because the eggs of *H. heterophyes* are similar in shape and size to those of *Metagonimus yokogawai* and

Clonorchis sinensis, differentiation must be made on the basis of patient history, clinical findings, or recovery of adult worms in the stool.

In Kobe, Japan, *H. katuradai*, a closely related species that is broader and more rounded, with a very large ventral sucker and smaller eggs (25 to 26 μm by 14 to 15 μm), has been recovered after therapy in patients with diarrhea. Apparently, infection is acquired from the ingestion of raw mullet.

KEY POINTS—LABORATORY DIAGNOSIS

Heterophyes heterophyes

1. The eggs are found in the stool; rarely, adult worms are found in patients with heavy infections after therapy or at autopsy.
2. The eggs of *H. heterophyes*, *M. yokogawai*, and *C. sinensis* appear almost identical and are very difficult to differentiate from one another. When passed, each egg contains a miracidium larva, but the eggs are ingested by the snail before they hatch.

Figure 15.8 *Heterophyes heterophyes* adult worm. These worms tend to have a broadly rounded posterior end, measure approximately 1 to 1.7 mm in length by 0.3 to 0.4 mm in width, and tend to be gray.

Figure 15.9 *Metagonimus yokogawai* adult worm. These worms are quite small like *Heterophyes* and measure 1 to 2.5 mm by 0.4 to 0.75 mm. The ventral sucker is deflected to the right of the midline and is visible in this image.

3. The formalin-ethyl acetate sedimentation concentration is recommended for egg recovery; operculated eggs do not float in the zinc sulfate flotation concentration method.
4. The eggs have very inconspicuous opercular shoulders and, unlike *C. sinensis*, lack the “seated” operculum and knob at the abopercular end. *H. heterophyes* eggs are some of the smallest trematode eggs seen and may be missed using the low power of the microscope (10× oculars and 10× objective); high dry power may be required for identification (10× oculars and 40× objective).

Treatment

Praziquantel is the drug of choice and can be given in a single dose of 15 to 25 mg/kg at bedtime (see chapter 25).

Epidemiology and Prevention

Numerous fish-eating mammals, including dogs, cats, and birds, act as reservoirs (15). The infection is found in China, Egypt, India, Iran, Israel, Japan, Korea, Sudan, Taiwan, the Philippines, Tunisia, and Turkey. Snails serving as the first intermediate host include *Pironella* and *Cerithidea* spp., and a variety of freshwater fish can serve as the second intermediate hosts (4, 9).

Humans become infected by ingestion of parasitized fish that is raw, inadequately cooked, or improperly pickled or salted. Metacercariae can survive for up to 7 days in salted fish. Off the coast of Israel a brackish-water fish, *Mugil capito*, can be heavily infected with *H. heterophyes*, with metacercariae numbering 2,300 to 6,000 per g of fish. The life cycle could be disrupted by improved sanitary conditions and educational information about proper sewage disposal away from ponds or lakes where the intermediate hosts reside.

Metagonimus yokogawai

M. yokogawai was first discovered by Katsurada in 1911 in an infected human (16). The infection is found most often in the Far East and clinically resembles that of *H. heterophyes*.

Life Cycle and Morphology

The adult worm measures 1.0 to 2.5 mm by 0.4 to 0.8 mm, attaches to the mucosal wall of the small intestine, and lays embryonated eggs that are passed out with the feces into the environment (Figure 15.9). The egg is small, brownish yellow, and operculate, with minimal opercular shoulders; it measures 26 to 28 μm by 15 to 17 μm (Table 15.1). The eggs are ingested by the snail intermediate host before the miracidium is liberated. On infection of the snail, a sporocyst generation and two redia generations develop before cercariae are liberated. Cercariae encyst under the scales or in the flesh of freshwater fish, which are eaten uncooked or pickled by humans. The metacercariae excyst in the intestinal tract, attach to the mucosal wall, and develop to mature worms. A *Metagonimus* adult is slightly larger than a *Heterophyes* adult and has a ventral sucker that is deflected to the right of the midline axis. The genital pore is attached to the outer rim of the ventral sucker.

Clinical Disease

Symptoms and pathologic changes are similar to those produced by *H. heterophyes* and depend largely on the worm burden of the host. Eggs may infiltrate into the intestinal capillaries and lymphatics and be carried to the myocardium, brain, spinal cord, and other tissues, where emboli or granulomatous reactions may occur.

Diagnosis

The diagnosis is based on recovery of the eggs in the feces. Because the eggs of *M. yokogawai* are similar in shape and size to those of *H. heterophyes* and *C. sinensis*, the

definitive diagnosis must be made on the basis of clinical findings, patient history, or recovery of adult worms after therapy or at autopsy.

KEY POINTS—LABORATORY DIAGNOSIS

Metagonimus yokogawai

1. The eggs are found in the stool; rarely, adult worms are found in patients with heavy infections after therapy or at autopsy.
2. The eggs of *M. yokogawai*, *H. heterophyes*, and *C. sinensis* appear almost identical and are very difficult to differentiate from one another. When passed, each egg contains a miracidium larva, but the eggs are ingested by the snail before they hatch.
3. The formalin-ethyl acetate sedimentation concentration is recommended for egg recovery; operculated eggs do not float in the zinc sulfate flotation concentration method.
4. The eggs have inconspicuous opercular shoulders but a more obvious operculum than *H. heterophyes* eggs and are some of the smallest trematode eggs seen. *M. yokogawai* eggs do not really have the “seated” operculum and knob at the abopercular end like those seen in *C. sinensis* eggs. They may be missed using the low power of the microscope (10× oculars and 10× objective), and high dry power may be required for identification (10× oculars and 40× objective).

Treatment

Praziquantel is the drug of choice and can be given in a single dose of 15 to 25 mg/kg at bedtime (see chapter 25).

Epidemiology and Prevention

Reservoir hosts are similar to those of *H. heterophyes*. The infection is found in China, Indonesia, Israel, Korea, Japan, Russia, Spain, the Balkans, and Taiwan. *M. yokogawai* is considered the most common intestinal fluke infection in the Far East; the prevalence tends to be high in Japan, Korea, and Taiwan, with rates of 2 to 50% being reported from Japan. Freshwater snails (*Semisulcospira* spp.) act as the first intermediate hosts, and a variety of freshwater fish act as the second intermediate hosts.

Preventive measures are similar to those proposed for *H. heterophyes*. Improved education and sanitary standards would greatly reduce the risk of infections.

Other heterophyid species have been found in areas of Asia where people eat raw or poorly cooked freshwater fish. A list of these trematodes can be found in Table 15.3.

Aquaculture of fish has increased dramatically from 5.3% in 1970 to 32.2% in 2000 (8). Freshwater production has increased greatly and now accounts for 45.1% of the

Table 15.3 Other heterophyid infections reported in humans^a

Organism	Comments
<i>Centrocestus formosanus</i>	Reservoir hosts are fish-eating birds and mammals; reported from Taiwan and mainland China
<i>Haplorchis pumilio</i> , <i>H. yokogawai</i>	Reservoir hosts are fish-eating birds and mammals; reported from Taiwan, the Philippines, Indonesia, and Thailand
<i>Metagonimus minutus</i> , <i>Diorchitrema formosanum</i> , <i>D. amplicaeale</i>	Reservoir hosts are fish-eating birds and mammals; reported from Taiwan
<i>Stellantchasmus falcatus</i>	Reservoir hosts are fish-eating birds and mammals; reported from Hawaii (from eating raw mullet), Japan, the Philippines, and Thailand
<i>Pygidioopsis summa</i>	Reservoir hosts are fish-eating birds and mammals; reported from Korea (up to 4,000 worms have been recovered from patients)

^a Intestinal lesions are similar to those produced by *H. heterophyes* and *M. yokogawai*. Eggs of *Haplorchis yokogawai*, *H. pumilio*, and *H. taichui* have been found in cardiac lesions but rarely cause complications such as vascular occlusion. Treatment with praziquantel in a single dose of 15 to 25 mg/kg is effective.

total aquaculture production. The production of grass carp, an important species that serves as an intermediate host for food-borne trematodes, has increased from >10,000 tons in 1950 to >3 million tons in 2002. This growth must be monitored for potential problems related to increased disease in which infection is transmitted through the ingestion of raw or poorly cooked fish.

Gastrodiscoides hominis

Gastrodiscoides hominis was first recovered in the late 1800s by Lewis and McConnell from an Indian patient suffering from diarrhea (2). The infection is commonly found in Assam, India. Although gastrodiscoidiasis was initially supposed to be restricted to Asian countries, this infection is now being reported in African countries (10).

Life Cycle and Morphology

The complete life cycle is unknown but is probably similar to that of other amphistome trematodes; aquatic plants, crustaceans, and amphibians are thought to be involved. The adult worm is bright pink, can be found attached to the cecum and ascending colon in humans, and may produce a mucous diarrhea. In India, the planorbid snail *Helicorbis coenosus* serves as an intermediate host for this infection.

Figure 15.10 *Gastrodiscoides hominis* adult worms. Note the pyriform shape and the deep concavity on the ventral surface, which contains a large sucker. The adult worms measure 8 to 14 mm in length by 4 to 5 mm in width and are usually bright pink. (Illustration by Sharon Belkin. Adapted from references 2 and 3.)

The living worm measures approximately 4 to 5 mm by 8 to 14 mm, is usually bright pink, and is pyriform in outline with a conical anterior (Figures 15.5 and 15.10). The anterior portion measures about 2 mm. The ventral surface has a prominent acetabulum that bears a characteristic notch. The eggs are greenish brown, operculated, and immature when laid; they measure 60 to 70 μm by 150 μm .

Clinical Disease

The adult worms live in the cecum and ascending colon; symptoms are related to the overall worm burden. In light infections the patient may be asymptomatic, while in heavier infections there may be a mucous diarrhea; lymphocytes, plasma cells, and eosinophils infiltrate the mucosa and submucosa (3). At the attachment site, papular lesions with surface desquamation may lead to necrosis.

Diagnosis

The diagnosis is based on recovery of eggs in the feces. They resemble the eggs of *F. buski* but tend to be more slender. A definitive diagnosis could be made on the basis of clinical findings, patient history, geographic area, or recovery of adult worms after therapy or at autopsy.

KEY POINTS—LABORATORY DIAGNOSIS

Gastrodiscoides hominis

1. The eggs are found in the stool; rarely, adult worms are found after therapy or at autopsy in patients with heavy infections.
2. The eggs of *G. hominis*, *F. buski*, *E. ilocanum*, *F. hepatica*, and *F. gigantica* appear very much

alike and can be difficult to differentiate from one another. When passed, these eggs do not contain mature larvae but instead contain undifferentiated embryos. The egg of *G. hominis* tends to be a bit smaller and more slender than that of *F. buski*, but they are very much alike.

3. The formalin-ethyl acetate sedimentation concentration is recommended for egg recovery; operculated eggs do not float in the zinc sulfate flotation concentration method.
4. The less mature the egg, the more difficult it may be to see the actual operculum—it blends into the shell outline, and the “breaks” in the shell may be difficult to identify. This egg has no opercular shoulders, and so it is difficult to see where the operculum “breaks” in the shell actually occur.

Treatment

Praziquantel is the drug of choice and is administered as a single 15-mg/kg dose after the evening meal or at bedtime. A second regimen consists of 75 mg/kg/day in three doses for 1 day. Apparently, children tend to tolerate the drug better than adults (see chapter 25).

Epidemiology and Prevention

G. hominis is commonly found in Asia and has been reported from Assam, Bihar, and Orissa in India, as well as from Vietnam, Burma, China, the Philippines, Thailand, Kazakhstan, and Guyana. One study in India found a 41% prevalence rate in which pigs were the reservoir host. Other reservoir hosts include deer mice in Malaysia and rats in Indonesia, Japan, and Thailand.

Liver and Lung Trematodes

Liver Flukes

Clonorchis sinensis

Opisthorchis viverrini

Opisthorchis felineus

Fasciola hepatica

Fasciola gigantica

Less Common Liver Flukes

Dicrocoelium dendriticum,
Dicrocoelium hospes, and
Eurytrema pancreaticum

Lung Flukes

Paragonimus spp.

Clonorchis, *Opisthorchis*, and *Fasciola* spp. are trematodes that parasitize the biliary ducts of humans. *Clonorchis* and *Opisthorchis* spp. are narrow, elongate worms that localize in the more distal, smaller ducts of the biliary tree. *Fasciola hepatica*, because of its much larger size, resides in the larger bile ducts and gallbladder.

Paragonimus spp., also known as lung flukes, cause paragonimiasis in humans. The adults encapsulate in the lungs and are occasionally found in other body sites.

The infections caused by the liver and lung trematodes are food borne and have considerable economic and public health impact. It is estimated that more than 50 million people have acquired foodborne trematode infections. It is estimated that 601 million, 293 million, 91 million, and 80 million people are at risk of infection with *Clonorchis sinensis*, *Paragonimus* spp., *Fasciola* spp., and *Opisthorchis* spp., respectively (23). Of great public health concern is cholangiocarcinoma associated with *Clonorchis* and *Opisthorchis* infections, severe liver disease associated with *Fasciola* infections, and the misdiagnosis of tuberculosis in those infected with *Paragonimus* spp.

Liver Flukes

Clonorchis sinensis

McConnell was the first to describe the adult worms and pathologic changes caused by *C. sinensis*, in a Chinese patient who died in Calcutta, India. The complete life cycle was developed in a number of publications by Iijima in 1887, Saito in 1898, Kobayashi in 1914, and Muto in 1918 (9). *C. sinensis* is also known as the Chinese or oriental liver fluke (Table 16.1).

Life Cycle and Morphology

Adult worms deposit eggs in the bile ducts, and the eggs are discharged with the bile fluid into the feces and passed out into the environment (Figure 16.1). The eggs are fully embryonated when laid and measure 28 to 35 μm by 12 to 19 μm (Figure 16.2). The eggs are ovoid, with a thick, pale brownish yellow shell and an operculum. There are distinct opercular shoulders surrounding the operculum. Frequently, the eggs contain a comma-shaped appendage at

Table 16.1 Characteristics of liver and lung trematodes

Species	Distribution	Agent of infection	Reservoir host	Egg		
				Size(μm)	Morphology	Comments
<i>Clonorchis sinensis</i>	Far East	Uncooked fish	Dogs, cats, other fish-eating mammals	28–35 by 12–19	Embryonated, operculated	Very prominent opercular shoulders; has a “seated” operculum and knob at the abopercular end.
<i>Opisthorchis viverrini</i>	Northern Thailand, Laos	Uncooked fish	Dogs, cats, other fish-eating mammals	19–29 by 12–17	Embryonated, operculated	Prominent opercular shoulders; has a “seated” operculum and may or may not have a knob at the abopercular end; eggs tend to be broader with less prominent shoulders than <i>C. sinensis</i> eggs.
<i>Opisthorchis felineus</i>	Poland, Germany, Russian Federation, Kazakhstan, western Siberia	Uncooked fish	Dogs, cats, other fish-eating mammals	28–30 by 11–16	Embryonated, operculated	Prominent opercular shoulders; has a “seated” operculum and may or may not have a knob at the abopercular end; eggs tend to be broader with less prominent shoulders than <i>C. sinensis</i> eggs.
<i>Fasciola hepatica</i>	Worldwide; mixed <i>F. hepatica</i> and <i>F. gigantica</i> infections have been reported from Pakistan	Uncooked water plants	Herbivores	130–150 by 63–90	Unembryonated, operculated	The less mature the egg, the more difficult it may be to see the actual operculum—it blends into the shell outline, and the “breaks” in the shell may be difficult to identify. This egg has no opercular shoulders, and so it is difficult to see where the operculum “breaks” in the shell actually occur. Eggs resemble those of <i>F. buski</i> , <i>E. ilocanum</i> , <i>F. gigantica</i> , and <i>G. hominis</i> ; eggs may have thickening at the abopercular end of the shell (unlike eggs of <i>F. buski</i>).
<i>Fasciola gigantica</i>	Africa, southern Europe, southern United States, Hawaii, former Soviet Union, Middle East, Southeast Asia	Uncooked water plants	Herbivores	160–190 by 70–90; egg is larger than <i>F. hepatica</i>	Unembryonated, operculated	The egg is larger than that of <i>F. hepatica</i> ; both <i>F. hepatica</i> and <i>F. gigantica</i> worms have been found in ectopic sites.
<i>Dicrocoelium dendriticum</i> , <i>D. hospes</i> , <i>Eurytrema pancreaticum</i>	Europe, Turkey, northern Africa, Far East, China, Japan, North and South America	Ants, grasshoppers, crickets	Cattle, sheep, deer, water buffalo	38–45 by 22–30; dark brown	Embryonated, operculated, thick shell	Eggs have a thick, dark brown shell and essentially no opercular shoulders; they cannot be differentiated from each other.
<i>Paragonimus westermani</i>	Far East, Africa	Crabs, crayfish	Dogs, cats, tigers, lions	80–120 by 45–65	Unembryonated, operculated	Eggs have a moderately thick, dark golden-brown shell, a prominent operculum, opercular shoulders, and a thickened abopercular end; may be confused with <i>D. latum</i> eggs (smaller, abopercular knob).
<i>P. mexicanus</i>	Central and South America	Crabs	Opossum, cats, dogs	60–70 by 42–56	Unembryonated, operculated	Thin, irregular undulations on outer shell; eggs have a prominent operculum, opercular shoulders, and a thickened abopercular end; may be confused with <i>D. latum</i> eggs (smaller, abopercular knob); eggs smaller than <i>P. westermani</i> ; also golden-brown shell.

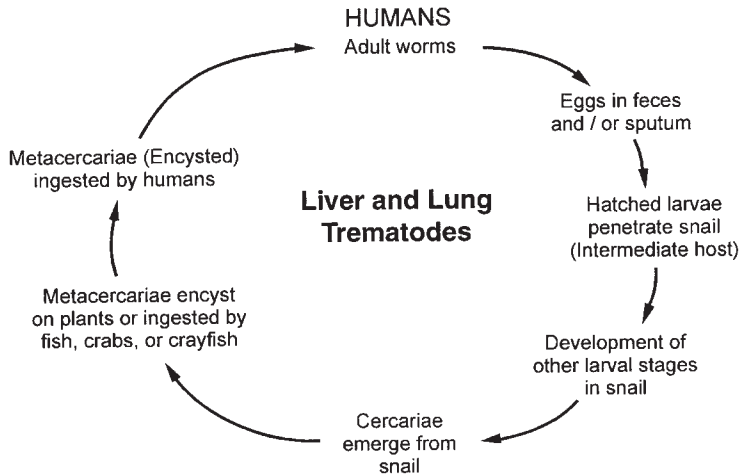

Figure 16.1 Life cycle of the liver and lung trematodes.

the abopercular end. Eggs are ingested by the snail host, at which time the miracidium hatches to infect the snail. More than 100 species of snails can serve as an intermediate host for *C. sinensis*. The snails generally live in ponds used for commercial fish raising, lakes, and slow-moving water, and the overall infection rate is relatively low (12). Sporocyst and redia generations are produced before cercariae are released to encyst in the skin or flesh of freshwater fish. Humans become infected by ingesting the metacercariae in uncooked fish.

Metacercariae excyst in the duodenum, enter the common bile duct, and travel to the distal bile capillaries, where the worms mature (Figures 16.3 and 16.4). The life cycle takes approximately 3 months to complete in humans. Reservoir hosts include dogs, cats, pigs, mink, rats, and other fish-eating mammals.

Clinical Disease

In general, the complications of clonorchiasis are the result of biliary obstruction. As the worms mature in the

distal bile ducts, an inflammatory response is seen in the biliary epithelium. The extent of pathologic changes is related to the intensity and duration of infection (Algorithm 16.1). The lesions are confined mainly to the biliary system and are the result of mechanical irritation and toxins produced by the worms. In light infections, there appears to be little or no change in liver parenchyma, whereas heavy infections cause thickening and localized dilations of the bile ducts with hyperplasia of the mucinous glands. As a result, the biliary tract may become obstructed, causing bile retention, infiltration of lymphocytes and eosinophils, and fibrosis (Figure 16.5). The adenomatous changes may persist for many years in patients with light infections. The infections have been associated with obstructive jaundice, which may be aggravated by biliary stones and liver abscesses. Many patients infected with *C. sinensis* have recurrent pyogenic cholangitis. There is no direct evidence that infection with *C. sinensis* causes chronic bacterial infection. Acute pancreatitis, cholecystitis, and cholelithiasis may be the result of worm

Figure 16.2 Eggs of *Clonorchis sinensis*. Note the range of sizes and shapes.

Figure 16.3 *Clonorchis sinensis* adult (10 to 25 mm long by 3 to 5 mm wide). (Armed Forces Institute of Pathology photograph.)

invasion. Cirrhosis is probably related to malnutrition rather than parasitic infections. Computed tomographic (CT) evaluation has shown that in the presence of diffuse mild intrahepatic bile duct dilation, enlargement of the body or tail (or both) of the pancreas, with a cluster of small cystic changes within the pancreatic parenchyma, provides strong evidence of *C. sinensis* pancreatitis (25). This infection may continue in the human host for more than 20 years.

C. sinensis has been linked to neoplasms of the bile duct and to cholangiocarcinoma (1, 15), which is most frequently observed in areas where clonorchiasis is endemic. Cholangiocarcinoma is a malignant tumor that arises from the bile duct epithelium and is the second most prevalent liver cancer after hepatocellular carcinoma. The tumor usually occurs in patients 60 to 80 years of age and rarely in patients younger than 40 years. There appears to be no direct link between infection and carcinoma, although one of the first steps in malignant transformation may be induced by the biliary tract hyperplasia caused by the worms. Patients with primary sclerosing cholangitis (PSC) have a substantial predisposition for bile duct carcinoma. Although the exact mechanisms are not well defined, long-standing inflammation can lead to cholangiocarcinoma in patients with chronic *C. sinensis* infection. PSC is an uncommon disease, characterized by stricturing, fibrosis, and

inflammation of the biliary tree, which is closely associated with chronic inflammatory bowel disease, particularly ulcerative colitis. The only effective treatment for PSC is orthotopic liver transplantation, which in the absence of cholangiocarcinoma has a 5-year survival rate of 89%. However, patients with cholangiocarcinoma who undergo liver transplantation have a high risk of recurrence and poor survival statistics. Between 10 and 20% of patients with PSC will go on to develop a cholangiocarcinoma (14). Therefore, identification of patients with deteriorating liver function prior to the development of cholangiocarcinoma remains an important goal in the management of PSC, particularly in areas where *C. sinensis* infection is endemic (18). It is also probable that cofactors play a role; liver flukes are promoters and not initiators of cholangiocarcinoma (1). It has been suggested that regular biliary cytologic sampling to detect dysplasia can predict the development of cholangiocarcinoma; however, this approach is unlikely to be widely used. In the Far East, forms of chronic inflammation associated with cholangiocarcinoma include infestation with either of the liver flukes, *C. sinensis* or *Opisthorchis viverrini*.

Immunoglobulin E (IgE) and *C. sinensis*-specific IgE levels in serum are elevated in infected individuals. In patients with acute infections, there is an increase in IgM levels in serum followed by increases in IgA and IgG levels. In patients with chronic infections, the IgA level returns to normal while the IgG and IgM levels remain elevated.

In light infections, the patient generally experiences no symptoms. In heavier infections acquired over time, the patient may experience dull pain and abdominal discomfort that may last for 1 to 2 h, often in the afternoon. As the disease progresses, the duration of pain lengthens and the pain may become so severe that the patient is unable to work. Patients who have had the disease for a long time show liver enlargement with some degree of functional impairment that is secondary to biliary obstruction. Acute infections caused by ingestion of large numbers of metacercariae cause fever, chills, diarrhea, epigastric pain, enlarged tender liver, and possibly jaundice within a month of ingestion. The acute symptoms last for about 1 month and subside at about the time when eggs are detected in the stool. In chronic infections, cholangitis, cholelithiasis, pancreatitis, and cholangiocarcinoma are common complications and can lead to death (15, 41).

Figure 16.4 Adult liver and lung trematodes. (A) *Fasciola hepatica*; (B) *Paragonimus westermani*; (C) *Clonorchis sinensis*; (D) *Opisthorchis viverrini* and *O. felinus*.

Diagnosis

Individuals who have lived in areas where infections are endemic, have a history of eating raw fish, and have symptoms of upper abdominal pain, indigestion, diarrhea, and hepatomegaly may be suspected of having liver trematode infection. Eggs can be detected in the feces by direct microscopy or by examination of fecal concentrates.

Algorithm 16.1 Trematode infection.

Sedimentation concentration is recommended since these eggs have opercula and do not float in the zinc sulfate flotation concentration method. Sedimented material can be examined using saline or D'Antoni's iodine or both. It is important not to add too much iodine; if the eggs stain too darkly, they may resemble debris. In light infections, egg counts may be low and so multiple specimens may be required to confirm their presence. The eggs of *C. sinensis* (Figure 16.2) and *O. viverrini* are similar in size and shape to those of *Heterophyes heterophyes* and *Metagonimus yokogawai* and cannot be readily differentiated from them. If a patient has not resided in or recently visited areas where infections are endemic, the infection is probably due to *C. sinensis* or *O. viverrini*. The infection may be confirmed by detecting eggs in the bile fluid (duodenal aspirate), by recovering adult worms, or from the clinical history. Some strains of *C. sinensis* produce eggs that have a comma-shaped appendage at the abopercular end. Multiple egg measurements are usually required to determine size differences; however, absolute identification among the small trematode eggs can be very difficult. Eggs can also be seen in duodenal drainage material or, if the Entero-Test capsule is used, in the mucus removed from the string. Definitive identification usually requires examination of adult worms recovered after therapy or during surgery or autopsy.

Eggs are not found in stool specimens from patients with biliary obstruction; needle aspiration, surgery, or autopsy specimens may be required to confirm their

presence. In these patients, biliary obstruction must be differentiated from enlarged gallbladder, cholangitis with jaundice, liver carcinoma, and cholangiocarcinoma. Cholangiography, ultrasonography, and liver scans may reveal lesions consistent with liver fluke infection.

Clonorchiasis is often diagnosed incidentally during abdominal ultrasonography, since symptoms tend to be nonspecific. However, none of these methods are any more sensitive than fecal examination because of their limited sensitivity and specificity (27).

In general, immunologic procedures are not readily available; however, they have been developed and are used in the research setting. A multiplex PCR approach has proven to be species specific, sensitive, and rapid in the accurate diagnosis of clonorchiasis and/or opisthorchiasis. This test can be used for the detection of metacercariae in infected fish or adult worms or eggs from patients in areas of endemic infection (26).

KEY POINTS—LABORATORY DIAGNOSIS

Clonorchis sinensis

1. Multiple stool specimens may be required to find the eggs.
2. The sedimentation concentration method should be used; because the eggs are operculated, they do not float in the zinc sulfate flotation concentration method.

3. It is important not to add too much iodine to the wet preparation, or the small eggs will stain very darkly and resemble debris.
4. Although the wet preparation can be examined using the 10× (low-power) objective, these eggs measure approximately 30 μm and can be easily missed. It is recommended that the 40× (high dry) objective be used for the wet preparation examination.
5. Eggs of *C. sinensis* can resemble those of many other intestinal and liver trematodes.
6. The wet preparation should not be so thick that the small eggs are obscured by normal stool debris.
7. Some strains of *C. sinensis* and *O. viverrini* produce eggs that have a comma-shaped appendage at the abopercular end; this finding generally differentiates the liver fluke eggs from those of the intestinal flukes, *Heterophyes heterophyes* and *Metagonimus yokogawai*.
8. If duodenal sampling is performed (drainage or the Entero-Test), eggs may be found in this material.
9. If available, antigen or antibody detection may be helpful in confirming the infection.

Treatment

Praziquantel is the drug of choice for treatment of *C. sinensis* infections. It has very few or limited side effects but is not recommended for use during pregnancy. The recommended dose is 75 mg/kg after meals three times a day for 1 or 2 days (2). These regimens yielded 85 and 100% cure rates, respectively. The majority of patients do well, with the exception of those who have pyogenic cholangitis, obstructive jaundice, or cholangiocarcinoma. Albendazole may be used as an alternative drug. Once cholangiocarcinoma is diagnosed, complete resection with negative histologic margins provides the greatest chance for long-term survival. Unfortunately, cholangiocarcinoma responds poorly to chemotherapy.

Epidemiology and Prevention

Humans, dogs, cats, and other fish-eating mammals are reservoir hosts and, in some areas, the sole cause of continual transmission. The infection is found in China, Japan, Korea, Malaysia, Singapore, Taiwan, and Vietnam, and it is estimated that 7 million individuals are infected, with 4.7 million in China and approximately 1 million in Korea (12). Natives of Hawaii also harbor the infection, which is contracted through the ingestion of frozen, pickled, or dried fish imported from areas of endemicity. Human infections result from the widely prevalent practice of consumption of metacercaria-infested freshwater fish eaten uncooked, pickled, smoked, salted, or dried. The traditional eating habits which are a part of a cultural

Figure 16.5 *Clonorchis sinensis* adult in a biliary duct (cross section). (Panel A, Armed Forces Institute of Pathology photograph; panel B, from A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

heritage are very difficult to change. In the past few years, clonorchiasis has often been found in refugee immigrants from areas of endemic infection who are resident in the United States, Canada, France, or Australia. Participants in laboratory proficiency testing programs have improved their ability to identify these eggs in challenge stool samples, thus increasing the probability that patients who are infected with *C. sinensis* will be diagnosed.

The life cycle is perpetuated by humans or reservoir hosts defecating in or near freshwater sources containing suitable species of snails. In areas where fish cultivation is of economic importance, toilets have been built over ponds to provide a source of fish food. Operculate snails noted to be infected are *Parafossarulus*, *Bulinus*, *Semisulcospira*, *Alocinma*, and *Melanoides* spp. Metacercariae can encyst in numerous species of freshwater fish.

Aquaculture of fish has increased dramatically from 5.3% in 1970 to 32.2% in 2000 (23). Freshwater fish production has increased dramatically and now accounts for 45.1% of the total aquaculture production. The production of grass carp, an important species that serves as an intermediate host for food-borne trematodes, has increased from >10,000 tons in 1950 to >3 million tons in 2002. Growth of this industry must be monitored for potential problems related to an increased incidence of disease in which infection is transmitted through the ingestion of raw or poorly cooked fish.

The life cycle can be broken and infection can be prevented in humans by thorough cooking of all freshwater fish. Although cultural habits are difficult to change, public health education can be used to modify them. Night soil used without disinfection for fertilizer should not be applied in lakes or ponds containing susceptible snails. It has been suggested that night soil should be stored prior to use; eggs of *C. sinensis* die within 2 days when stored at 26°C.

Opisthorchis viverrini

O. viverrini has been reported to infect a significant portion of the population in northern Thailand and Laos. In some areas, the prevalence was 100% for age groups older than 10 years, and it is estimated that 10 million people are infected (19) (Table 16.1). Although the overall prevalence rate has been reported to be 35%, there are some areas where it is greater than 90%. There is an association between infection with *O. viverrini* and carcinoma of the bile duct epithelium (cholangiocarcinoma) (39).

Life Cycle and Morphology

Adult worms in distal bile ducts produce eggs that are carried by the bile to the intestinal lumen and to the outside environment in the feces (Figures 16.1, 16.4, and 16.6). The eggs are brownish yellow, oval, and operculated; they have opercular shoulders and may have a comma-shaped appendage at the abopercular end. The egg size averages 27 by 15 µm. The life cycle is similar to that of *C. sinensis*, requiring developmental periods in susceptible snails and finally in freshwater fish, in which the metacercariae encyst. Metacercariae excyst in the duodenum of the mammalian host and migrate to the intrahepatic bile ducts, where they develop to mature adults. The adult worms are transparent and leaf-shaped and measure approximately 8 to 12 mm long (Figure 16.4). The length-to-width ratio is similar to that of *C. sinensis*; therefore, the two can be confused. The life span of *O. viverrini* can exceed 20 years.

Clinical Disease

As with *C. sinensis*, the pathologic changes are confined mainly to the biliary tract system and morbidity is

significantly associated with the worm burden of the host. Intensity of infection is correlated with clinical signs of abdominal pain, flatulence, weakness, hepatomegaly, cholangitis, chronic cholecystitis, cholelithiasis, and obstructive jaundice. Patients with heavy worm burdens may have severe cirrhosis, ascites, pedal edema, and acute abdominal pain. There may be severe jaundice, secondary infection of the biliary system (as seen with *C. sinensis*), cholangitis, and hepatomegaly. The bilirubin transaminase level tends to be elevated, while the serum albumin is low.

A large number of individuals with *O. viverrini* infection have cholangiocarcinomas, which were also seen at autopsy. The biliary epithelium may be highly susceptible to malignant transformation because of chronic proliferation due to *O. viverrini* infection. There is a significant relationship between the intensity of infection and cholangiocarcinoma, and there is a high prevalence of the disease among males (1, 39). There is a definite relationship between a high risk of liver cancer and infestation with *O. viverrini* in northeastern Thailand. However, in other areas of the country where the prevalence of liver cancer is high, there is little to no exposure to *O. viverrini* infection. Case-control studies suggest that exposure to exogenous and possibly endogenous nitrosamines in food or tobacco in betel nut cigarettes may play a role in the development of hepatocellular carcinoma, while infestation with *O. viverrini* and chemical interaction of nitrosamines may also be etiologic factors in the development of cholangiocarcinoma (30). Carcinomas of the biliary tract are rare cancers developing from the epithelial or blast-like cells lining the bile ducts. A variety of known predisposing factors, including infection with *O. viverrini*, have been identified. Chronic inflammatory processes, generation of active oxygen radicals, altered cellular detoxification mechanisms, activation of oncogenes, functional loss of tumor suppressor genes, and dysregulation of cell proliferation and apoptotic mechanisms have been identified as important contributors to the development of cholangiocarcinomas (21). Approximately 20,000 worms have been recovered from a single individual at autopsy.

Elevated IgE levels in serum of up to three or four times normal can be detected in infected patients (42). There is an early rise in the serum levels of IgM followed by elevations of IgA and IgG. In chronic infections, the

Figure 16.6 *Opisthorchis viverrini* adult trematode.

IgG and IgM levels remain elevated whereas the IgA levels return to normal (43).

Diagnosis

Individuals who have lived in areas where infections are endemic, have a history of eating raw fish, and have symptoms of right upper abdominal pain, indigestion, diarrhea, and hepatomegaly may be suspected of having liver trematode infection. Pain usually appears in the late afternoon and lasts several hours. Eggs can be detected in the feces by direct microscopy or by examination of fecal concentrates. Sedimentation concentration is recommended since these eggs have opercula and do not float in the zinc sulfate flotation concentration method. Sedimented material can be examined using saline or D'Antoni's iodine or both. It is important not to add too much iodine; if the eggs stain too darkly, they may resemble debris. In light infections, egg counts may be low and so multiple specimens may be required to confirm their presence. The eggs of *O. viverrini* and *C. sinensis* are similar in size and shape to those of *H. heterophyes* and *M. yokogawai* and cannot be readily differentiated from them. If a patient has not resided in or recently visited areas where infections are endemic, the infection is probably due to *O. viverrini* or *C. sinensis*. The diagnosis can be confirmed by detecting eggs in the bile fluid (duodenal aspirate), by recovering adult worms, or from the clinical history. Like *C. sinensis*, some strains of *O. viverrini* produce eggs that have a comma-shaped appendage at the abopercular end. Differentiation is difficult without a patient history. Multiple egg measurements are usually required to determine size differences; however, absolute identification among the small trematode eggs can be very difficult. Eggs can also be seen in duodenal drainage material or if the Entero-Test capsule is used. Definitive identification usually requires examination of adult worms recovered after therapy or during surgery or autopsy.

Eggs are not found in stool specimens from patients with biliary obstruction, so needle aspiration, surgery, or autopsy specimens may be required to confirm their presence. In these patients, biliary obstruction must be differentiated from enlarged gallbladder, cholangitis with jaundice, liver carcinoma, and cholangiocarcinoma. Cholangiography, ultrasonography, and liver scans may reveal lesions consistent with liver fluke infection. However, over 75% of patients with this infection tend to have normal ultrasonograms.

DNA hybridization and detection of antigen have been used to detect infections in stool (36). DNA hybridization and antigen detection methods have not been extensively tested in areas where infections are endemic but may be slightly better than classical methods of detection

(37). Although serologic diagnostic tests for detection of antibodies have been developed, they are not widely available, are not standardized, and give false-positive results due to cross-reactivity with other parasitic diseases (5).

KEY POINTS—LABORATORY DIAGNOSIS

Opisthorchis viverrini

1. Multiple stool specimens may be required to find the eggs.
2. The sedimentation concentration method should be used; because the eggs are operculated, they do not float in the zinc sulfate flotation concentration method.
3. It is important not to add too much iodine to the wet preparation, or the small eggs will stain very darkly and resemble debris.
4. Although the wet preparation can be examined using the 10× (low-power) objective, these eggs measure approximately 30 μm and can be easily missed. It is recommended that the 40× (high dry) objective be used for the wet preparation examination.
5. Eggs of *O. viverrini* can resemble those of many other intestinal and liver trematodes.
6. The wet preparation should not be so thick that the small eggs are obscured by normal stool debris.
7. Some strains of *O. viverrini* and *C. sinensis* produce eggs that have a comma-shaped appendage at the abopercular end; this finding differentiates the liver fluke eggs from those of the intestinal flukes, *Heterophyes heterophyes* and *Metagonimus yokogawai*.
8. If duodenal sampling is performed (drainage or the Entero-Test), eggs may be found in this material.
9. If available, antigen or antibody detection may be helpful in confirming the infection.

Treatment

In patients with asymptomatic and mild to moderate cases, 75 mg of praziquantel per kg given three times after meals in a single day or a single dose of 40 mg/kg is 100 and 90% effective, respectively (2). In those with heavy infections, a single dose of 50 mg/kg produces a cure rate of 97% (12). No eggs are recovered in the stool after about a week; however, clinical symptoms and gallbladder dysfunction may take several months to resolve. Any side effects can be minimized by administration of the single-dose regimen at bedtime.

Mebendazole has also been given at 30 mg/kg/day for 3 or 4 weeks, with cure rates of 89 and 94%, respectively. No adult worms were recovered after therapy (12).

It is important to remember that only 5 to 10% of cases are relieved with praziquantel alone and that relapsing cholangitis and obstructive jaundice may require the use of antimicrobials. For complicated cases, surgery may also be required. Unfortunately, cholangiocarcinoma associated with *O. viverrini* infection carries a poor prognosis.

Epidemiology and Prevention

Dogs, cats, and other fish-eating mammals including humans are reservoir hosts. The infection has been reported to occur in Cambodia, Laos, and Thailand. In Southeast Asia, close to 70% of the population may be infected in some villages. Human infections result from the widely prevalent practice of consumption of metacercaria-infested freshwater fish eaten uncooked, pickled, smoked, salted, or dried. *Bithynia* snails are the first intermediate hosts, and freshwater fish are the second intermediate hosts. The metacercarial cysts are somewhat less resistant to pickling than those of *C. sinensis*; however, thorough cooking of fish is the only guaranteed method of prevention.

Public health education should be used to advise the at-risk population in areas of endemicity about the hazards of eating uncooked fish. This approach has not met with much success because of the difficulty in disrupting established cultural and dietary traditions. Also, defecation in or near ponds or lakes should be prevented, as should the application of night soil where the intermediate hosts are abundant. Community-based therapy of opisthorchiasis will significantly decrease the prevalence of infection; however, therapy alone will not solve the problem because of the high rates of reinfection due to cultural habits. Mass treatment can be undertaken with praziquantel as a single dose of 40 to 50 mg/kg at bedtime.

Opisthorchis felineus

Opisthorchis felineus infections in humans have been reported from Poland, Germany, the Russian Federation, and Kazakhstan, with the largest area of endemicity being found in western Siberia. Over 1.5 million people are infected, with some prevalence rates reaching 95%. The first report of a human infection was in 1892.

Life Cycle and Morphology

The life cycle can be seen in Figure 16.1. The eggs are elongate and ovoid, with an operculum that resembles that seen in *O. viverrini*. They are generally light yellowish brown and measure approximately 30 by 11 μm . Like the eggs of some strains of *C. sinensis* and *O. viverrini*, some eggs have a small tubercular thickening (“comma”) at the abopercular end. Although the miracidium larva is

Figure 16.7 *Opisthorchis felineus* adult trematode.

fully developed when the egg is laid, hatching occurs only after ingestion by the snail intermediate host. Apparently, the only known molluscan host is the snail *Cordiella (Bithynia)*, in which the first- and second-generation sporocysts and rediae develop. The cercariae leave the snail host and then encyst within the tissues of freshwater fish in the carp family. More than 20 species from 17 genera of freshwater fish serve as second intermediate hosts. Humans, cats, and other reservoir hosts become infected after ingestion of raw or poorly cooked fish. The metacercariae excyst in the duodenum, migrate to the distal bile passages, attach, and begin egg production within 3 to 4 weeks. The adult worm lives attached in the biliary and pancreatic ducts of the host. The adult worm is lancet-shaped and measures 7 to 12 mm in length, which is larger than the adult worms of *O. viverrini* (Figures 16.4 and 16.7).

Clinical Disease

Although this infection tends to have an incubation period of several weeks, symptoms may appear at the end of the first week. Like infections with other liver flukes, the degree of clinical involvement depends on the extent and duration of the infection. With a low worm burden (up to 50 or 60 worms), there may be localized damage in the distal bile ducts but the liver function remains normal. With a worm count up to 1,000, there may be hepatomegaly and jaundice; the pancreas may also be involved, which can result in digestive problems. Like some of the other liver trematode infections, it is quite likely that chronic infection will lead to cholangiocarcinoma. Overall, the symptoms and clinical sequelae are similar to those seen with *O. viverrini* infection. Acute symptoms can include abdominal pain, urticaria, dizziness, and fever.

Diagnosis

The infection is diagnosed by finding the eggs in the stool; however, they resemble eggs of the other liver trematodes such as *C. sinensis* and *O. viverrini*. The eggs have been described as being slightly more narrow (30 by 12 μm) than *C. sinensis* eggs and are more regularly ovoid without a clear shoulder at the operculum. Eggs can also be seen in duodenal drainage material or if the Entero-Test capsule is used.

KEY POINTS—LABORATORY DIAGNOSIS*Opisthorchis felineus*

1. Multiple stool specimens may be required to find the eggs.
2. The sedimentation concentration method should be used; because the eggs are operculated, they do not float in the zinc sulfate flotation concentration method.
3. It is important not to add too much iodine to the wet preparation, or the small eggs will stain very darkly and resemble debris.
4. Although the wet preparation can be examined using the 10× (low-power) objective, these eggs measure approximately 30 μm and can be easily missed. It is recommended that the 40× (high dry) objective be used for the wet preparation examination.
5. Eggs of *O. felineus* can resemble those of many other intestinal and liver trematodes; however, they tend to be somewhat more narrow than the other eggs.
6. The wet preparation should not be so thick that the small eggs are obscured by normal stool debris.
7. Like some strains of *C. sinensis* and *O. viverrini*, *O. felineus* usually produces eggs that have a comma-shaped appendage at the abopercular end; this finding generally differentiates the liver fluke eggs from those of the intestinal flukes, *Heterophyes heterophyes* and *Metagonimus yokogawai*.
8. If duodenal sampling is performed (drainage or the Entero-Test), eggs may be found in this material.
9. If available, antigen or antibody detection may be helpful in confirming the infection.

Treatment

A single praziquantel dose of 40 mg/kg after a meal has been recommended. Although side effects are usually mild, they tend to occur in a number of patients and include abdominal pain, vomiting, diarrhea, lassitude, myalgia, headache, and rashes. Any side effects can be minimized by administration of the single-dose regimen at bedtime.

Epidemiology and Prevention

In central, eastern, and southeastern Europe, the Russian Federation, and Kazakhstan, the dog and cat, the red, silver, and polar foxes, domestic and wild swine, Norway rat, water rat, wolverine, marten, beaver, rabbit, polecat, Caspian seal, bearded seal, and lion (in captivity) are infected (5). In some areas of the Ukraine, there is an 82% infection rate, primarily from eating fish on the first day of salting. There is a 15 to 68% infection rate in the middle Urals, with an 84% infection rate in cats. There

has been as high as 90% infection with metacercariae in carp in the Tyumen Region of western Siberia (32). Cats are an important reservoir host, with a 43% infection rate being reported from the Ukraine.

Fasciola hepatica

Fascioliasis (sheep liver fluke disease) is primarily a zoonotic disease that causes liver infections with adult flukes. Over 2.4 million people are infected with this parasite worldwide, including Europe, the Americas, northern Asia, Oceania, Africa, New Zealand, Tasmania, Great Britain, Iceland, Cyprus, Corsica, Sardinia, Sicily, Japan, Papua New Guinea, the Philippines, and the Caribbean. This infection has been recognized by the World Health Organization as an important health problem, particularly in the Andean countries of Peru, Bolivia, and Chile (17). *F. hepatica* was the first trematode to be described and the first for which the entire life cycle was defined; it is interesting that approximately 500 years passed between the description of the parasite and the clarification of its life cycle. The first recorded information on *F. hepatica* infections was provided by de Brie in 1379, when he described the effects of certain types of water plants on sheep that had eaten them. The complete life cycle was established by the investigations of Leuckart and Thomas in 1883, independently of one another (9). The most common definitive hosts are sheep; however, other herbivores such as goats, cattle, horses, camels, hogs, vicuna, rabbits, and deer are often infected as well. In sheep, the migratory phase produces such extensive liver parenchyma damage that the disease is known as liver rot.

Although the disease has a cosmopolitan distribution, only a single case of autochthonous infection in a human in the United States has been reported (33) (Table 16.1).

Life Cycle and Morphology

Adult worms, which may live for many years in the bile ducts, produce eggs that are carried by the bile fluid into the intestinal lumen and passed into the environment with the feces (Figures 16.1, 16.4, and 16.8). The eggs are unembryonated, operculated, large, ovoid, and brownish yellow and measure 130 to 150 μm by 63 to 90 μm (Figure 16.8). The miracidium develops within 1 to 2 weeks in water from 22 to 26°C and escapes from the egg to infect the snail intermediate host, *Lymnaea* sp. These snails are amphibious. Within 4 to 7 weeks, cercariae are liberated from the snail after the production of a sporocyst generation and two or three redia generations. Cercariae encyst on water vegetation, e.g., watercress. Humans are infected by ingestion of uncooked aquatic vegetation on which metacercariae are encysted. Metacercariae excyst in the duodenum and migrate through the intestinal wall

into the peritoneal cavity. The larvae enter the liver by penetrating the capsule (Glisson's capsule) and wander through the liver parenchyma for up to 9 weeks. The larvae finally enter the bile ducts, where they mature and produce eggs, which are passed out in the feces. The adult worms can attain a length of 30 mm and a width of about 13 mm and can live for more than 10 years (Figures 16.4 and 16.8).

Clinical Disease

The incubation period for fascioliasis can range from a few days to a few months. The patient's symptoms reflect the phase of the infection, as well as the number of parasites present in the host. In the acute phase, symptoms may be present over a period of weeks to months. Metacercarial larvae do not cause significant pathologic damage until they begin to migrate through the liver parenchyma. The amount of damage depends on the worm burden of the host. Linear lesions of 1 cm or greater can be found. Hyperplasia of the bile ducts occurs, possibly as a result of toxins produced by

Figure 16.8 *Fasciola hepatica* adult worm (upper left), egg (upper right), and living worm (lower). The operculum can be difficult to see; this egg resembles that of *F. buski* (intestinal trematodes) and *F. gigantica* (liver trematodes), although the egg of *F. gigantica* is larger. The *F. hepatica* adult worm is 20 to 30 mm long by 8 to 13 mm wide.

Figure 16.9 *Fasciola hepatica* adult worm in a bile duct; note the U-shaped worm within the bile duct with surrounding tissues.

the larvae. Symptoms associated with this migratory phase have included fever, epigastric and right upper quadrant pain, intestinal complaints, and urticaria, although other patients remain asymptomatic. Asymptomatic infections appear to be more common in Peru (12). Other symptoms include loss of appetite, flatulence, nausea, diarrhea, and a nonproductive cough. Patients may also have hepatomegaly, splenomegaly, ascites, chest signs, and jaundice. Leukocytosis, eosinophilia, and mild to moderate anemia are found in many patients. Levels of IgG, IgM, and IgE in serum are usually elevated.

In the more chronic phases of the disease, the patient generally has few to no symptoms once the flukes have lodged in the biliary passages (Figure 16.9). However, there may be some epigastric and right upper quadrant pain, diarrhea, nausea, vomiting, hepatomegaly, and jaundice. If the flukes are found in the extrahepatic biliary ducts, symptoms may mimic those seen in cholelithiasis. In the chronic phase, there tend to be some liver function abnormalities, as well as eosinophilia (Figure 16.10). Larvae may be found in ectopic foci after penetrating the peritoneal cavity. Worms in human infections have been discovered in many areas of the body other than the liver. Other body sites include the intestinal wall, lungs, heart, brain, and skin. Symptoms mimic those seen with visceral larva migrans and include vague abdominal pain. Unfortunately, surgery may be required to determine the exact cause of the symptoms.

Once the worms have established themselves in the bile ducts and matured, they cause considerable damage from mechanical irritation and metabolic by-products as well as obstruction. The degree of pathologic change depends on the number of flukes penetrating the liver. The infection produces hyperplasia of the biliary epithelium and fibrosis of the ducts with portal or total biliary obstruction. The gallbladder undergoes

Figure 16.10 *Fasciola hepatica* adult worm in the liver; note the U-shaped worm with surrounding hepatic tissue, with a cellular response seen around the worm.

similar pathologic changes and may even harbor adult worms. Adult worms may reinvade the liver parenchyma, producing abscesses.

Symptoms and signs of infection during the late stages after egg production has begun are those associated with biliary obstruction and cholangitis. Acute epigastric pain, fever, pruritus, jaundice, hepatomegaly, and eosinophilia are common.

In areas of endemicity where uncooked goat and sheep livers may be eaten, such as Lebanon, adult worms may attach to the pharyngeal mucosa, causing suffocation (halzoun syndrome). This condition is temporary, although it may cause considerable discomfort. The adult worms may lodge on the pharyngeal mucosa, causing edema and congestion of the soft palate, pharynx, larynx, nasal fossae, and eustachian tube. The symptoms include dyspnea, dysphagia, deafness, and occasionally suffocation. It has also been suggested that a number of these cases may be caused by infection with larval linguatulids rather than adult worms of *F. hepatica*.

Diagnosis

Stool examinations and enzyme-linked immunosorbent assay (ELISA) are recommended for presumptive diagnosis, while radiographic techniques and magnetic resonance imaging are used for confirmation and follow-up. Although they may be helpful, invasive techniques such as percutaneous cholangiography, endoscopic retrograde cholangiography, and liver biopsy are not always essential (6). However, liver biopsy may be very important in diagnosing fascioliasis, particularly for asymptomatic disease (3).

The eggs of *F. hepatica*, *Fasciolopsis buski*, *Echinostoma ilocanum*, and *Gastrodiscoides hominis* are similar in size and shape. Differentiation may be difficult without a patient history. Patients may be symptomatic during the first weeks of infection, but no eggs are found in the stool until the worms mature, which takes 8 weeks (20). Multiple stool examinations may be needed to detect light infections.

Eggs may be detected in the stools of individuals who have eaten *F. hepatica*-infected liver, thereby yielding an erroneous laboratory result (not a true human infection, but what is called a “spurious” infection). True infection and spurious infection can be differentiated by maintaining the patient on a liver-free diet for at least 3 days. If the patient continues to pass eggs in the stool, the infection is probably genuine.

Serologic diagnosis with *F. hepatica* excretion-secretion antigens has been successfully used in areas of endemicity to detect patient antibodies (20). This approach includes ELISA, counterelectrophoresis, and enzyme-linked immunoelectrotransfer blots. Serologic tests can be used to monitor treated patients to ensure successful therapy (8). Serologic cross-reactions have been noted in patients infected with schistosomiasis. Serologic assays are the tests of choice for the diagnosis of acute and chronic fascioliasis when few eggs can be found in the stool or when large populations are to be screened (35).

KEY POINTS—LABORATORY DIAGNOSIS

Fasciola hepatica

1. Multiple stool specimens may be required to find the trematode eggs. In a very light infection, eggs may not be recovered; however, the patient might be asymptomatic.
2. The sedimentation concentration method should be used; because the eggs are operculated, they do not float in the zinc sulfate flotation concentration method.
3. It is important not to add too much iodine to the wet preparation, or the eggs will stain very darkly and resemble debris.
4. The wet preparation can be examined using the 10× (low-power) objective; these eggs are large enough that they can usually be seen using this magnification.
5. Eggs of *F. hepatica* can resemble those *Fasciola gigantica* (liver fluke) and *Fasciolopsis buski* (intestinal fluke).
6. The wet preparation should not be so thick that the eggs are obscured by normal stool debris.
7. If available, antigen or antibody detection may be helpful in confirming the infection.

Treatment

Although praziquantel is sometimes effective at a dose of 25 mg/kg taken after each meal for 2 days, it does not appear to be effective in treating patients in Egypt. Treatment with biothionol at 30 to 50 mg/kg on alternate days for 10 to 15 doses is recommended. Triclabendazole at 10 mg/kg as a single dose is also recommended, but this dose may not be as easily obtained. If a single dose has failed, the use of triclabendazole at 20 mg/kg is recommended (16); the drug is given orally in single or multiple doses and has few side effects (8). It acts by inhibiting protein synthesis in *F. hepatica* and will probably become the drug of choice; however, it is not currently available in the United States unless possibly through a compounding pharmacy (2).

Epidemiology and Prevention

Fascioliasis is a cosmopolitan disease that is found where there is close association of livestock, humans, and snails. The largest numbers of infections have been reported from Bolivia, Ecuador, Egypt, France, Iran, Peru, and Portugal. Although animal fascioliasis is endemic throughout the Americas, human infections are rare in most countries (29). Reservoir hosts include herbivores such as cattle, goats, and sheep. Animal fascioliasis is a major veterinary problem in Europe. The infection is contracted by the ingestion of metacercariae encysted on uncooked water plants, such as watercress. Watercress is the main source of infection; however, in many countries, wild watercress is touted as a healthy natural food. In many areas of the world, animal manure is used as the primary fertilizer for cultivation of watercress.

In surveying potential risk factors in the Northern Peruvian Altiplano, the principal exposure factor for *F. hepatica* infection was drinking alfalfa juice. Human fascioliasis should be suspected when a patient from an area in Peru where livestock is raised presents with recurrent episodes of jaundice and has a history of alfalfa juice or aquatic-plant ingestion or has eosinophilia (28).

Prevention may be accomplished by public health education in areas where infections are endemic, stressing the dangers of eating watercress grown in the wild where animals and snails are abundant. Other measures have included killing snails, treating infected animals, and draining pasture lands.

Fasciola gigantica

Fasciola gigantica is closely related to *F. hepatica*. It is also a common parasite of cattle, camels, and other herbivores in Africa and of herbivores in some Pacific islands. Human infections have been reported in a number of areas of endemicity. Generally, *F. hepatica* is found in temperate zones and is the predominant species in Europe,

the Americas, and Oceania, while *F. gigantica* is better adapted to tropical and aquatic environments and is the predominant species in Africa.

Life Cycle and Morphology

The life cycle is similar to that of *F. hepatica*; however, the snail hosts of *F. gigantica* are aquatic rather than amphibious like the first intermediate host for *F. hepatica*. Humans become infected through ingestion of water plants which carry the infective metacercariae. Apparently, developmental stages of *F. gigantica* grow more slowly, survive longer at high temperatures, and are more susceptible to drying than those of *F. hepatica*. The adult worm resembles *F. hepatica* but is somewhat more lanceolate, with a less distinct cephalic cone (Figure 16.11). The eggs are very difficult to differentiate from those of *F. hepatica* or *Fasciolopsis buski*; however, they tend to be larger (160 to 190 μm by 70 to 90 μm) (Figure 16.11).

Clinical Disease

The clinical symptoms of *F. gigantica* infection are very similar to those of *F. hepatica* infection and depend on the worm burden. The prepatent period between infection and the presence of adult worms in the bile ducts is 9 to 12 weeks. Patients may experience fever, nausea, vomiting, abdominal pain, hepatomegaly, hepatic tenderness, and eosinophilia. As in many light trematode infections,

Figure 16.11 *Fasciola gigantica* adult worm (left) and egg (right). The operculum can be difficult to see; this egg resembles that of *F. buski* (intestinal trematodes) and *F. hepatica* (liver trematodes), although the egg of *F. gigantica* is larger (160 to 190 μm by 70 to 90 μm). The *F. gigantica* adult worm is 25 to 75 mm long by 12 mm wide. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

there may be vague symptoms or the patient may remain asymptomatic. Abscess or tumorlike reactions have also been reported to occur in subcutaneous tissues or in the liver (12).

Diagnosis

The eggs can be found in the stool; however, they may be absent more often than in infections with *F. hepatica*, so that multiple stool examinations may be required to demonstrate the eggs. Although these eggs are larger than those of *F. hepatica* or *F. buski*, they are very similar in shape. Recovery of adult flukes at surgery would confirm the diagnosis. Other diagnostic options discussed for *F. hepatica* are also recommended for this infection.

KEY POINTS—LABORATORY DIAGNOSIS

Fasciola gigantica

1. Multiple stool specimens may be required to find the trematode eggs. In a very light infection, eggs may not be recovered; however, the patient might be asymptomatic.
2. The sedimentation concentration method should be used; because the eggs are operculated, they do not float in the zinc sulfate flotation concentration method.
3. It is important not to add too much iodine to the wet preparation, or the eggs will stain very darkly and resemble debris.
4. The wet preparation can be examined using the 10× (low-power) objective; these eggs are large enough that they can usually be seen under this magnification.
5. Eggs of *F. gigantica* can resemble those *F. hepatica* (liver fluke) and *F. buski* (intestinal fluke); however, they are somewhat larger and could probably be differentiated by careful measurement. Unfortunately, many people might not consider this particular species and thus might not even measure the eggs.
6. The wet preparation should not be so thick that the eggs are obscured by normal stool debris.
7. If available, antigen or antibody detection may be helpful in confirming the infection.

Treatment

Although praziquantel is sometimes effective at a dose of 25 mg/kg taken after each meal for 2 days, it is not always effective. Treatment with biothionol at 30 to 50 mg/kg on alternate days for 10 to 15 doses is recommended. Triclabendazole at 10 mg/kg as a single dose is also recommended, but this drug may not be as easily obtained.

If a single dose has failed, the use of triclabendazole at 20 mg/kg is recommended (16). It is not currently available in the United States unless possibly through a compounding pharmacy (2).

Epidemiology and Prevention

Like *F. hepatica*, infection can occur in a wide range of herbivorous mammals when they ingest infected water plants or drink water contaminated with metacercariae. In some areas, the rate of infection in these animal hosts is quite high: in China, the rates are 50% for cattle, 45% for goats, and 33% for water buffalo; in Iraq, the rates are 71% for water buffalo and 27% for cattle; in northeastern Thailand, the rate is 60% for cattle (12). In various surveys, the occurrence of infections in cattle in Zambia was approximately 61%; in Tanzania, the incidence in cattle in traditional, large-scale dairy, and small-scale dairy herds was 63, 46.2, and 28.4% (24, 34). Studies in Australia testing a commercially available ELISA for antibody detection have been reported; the results indicate this test will be very valuable in screening cattle and sheep for infections with *F. hepatica* and probably also *F. gigantica* (31).

Human infections have also been reported in specific areas where animal infection is relatively uncommon; these include Zimbabwe, Uganda, Tashkent, Iraq, Vietnam, Hawaii, and some areas within Thailand.

Less Common Liver Flukes

Dicrocoelium dendriticum, *Dicrocoelium hospes*, and *Eurytrema pancreaticum*

Dicrocoelium dendriticum (lancet fluke, lanceolate fluke) is commonly found in the biliary passages of sheep, deer, and other herbivores and omnivores in Europe, Poland, Turkey, northern Africa, northern Asia, Turkistan, parts of the Far East, and North and South America; as an example, in southern Poland, 80% of the sheep are reported to be infected. Although many human infections have been reported, most are probably spurious infections acquired from eating infected raw sheep liver. However, true human infections have been reported from Europe, Egypt, Iran, Nigeria, Ivory Coast, and China. Approximately 30 cases of human infection with *D. hospes* have been reported from Ghana, Sierra Leone, Nigeria, and Democratic Republic of Congo. Although *D. hospes* has been thought to be a polymorph of *D. dendriticum*, ultrastructural studies can now distinguish *D. hospes* from other species in the family Dicrocoeliidae (4).

Eurytrema pancreaticum is usually found in the pancreatic ducts of hogs in southern China and of herbivores such as cattle, sheep, goats, monkeys, and camels in the

Orient and Brazil. True infection in humans has been reported in China and Japan.

Life Cycle and Morphology

The life cycle is similar to that of the other liver trematodes. However, in this case, the snail intermediate host is a land snail. The cercariae are released from the snail after rains follow a long period of dry weather. They are released from the snail's respiratory chamber as slime balls that are left behind on grass as the snail crawls along the ground or on plants. The ant (*Formica fusca*) is the required second intermediate host for *D. dendriticum* within the United States, while other ants serve this function in other areas. The second intermediate hosts for *E. pancreaticum* are either tree crickets or grasshoppers. Human infection is acquired through accidental ingestion of ants, primarily on fresh herbs or plants used for human consumption. Accidental ingestion of infected crickets or grasshoppers can also result in human infection. The metacercariae excyst and migrate to the biliary passage (for *D. dendriticum*) or the pancreatic ducts (for *E. pancreaticum*), where they then become adult flukes.

The adult worms of *D. dendriticum* are lancet-shaped, flat, and transparent and measure 5 to 15 mm long by 1.5 to 2.5 mm wide (Figure 16.12). The eggs are thick-shelled, operculate, and deep golden brown and measure 38 to 45 μm by 22 to 30 μm ; the eggs of the two flukes cannot be differentiated (Figure 16.12). The eggs are embryonated when passed and are resistant to drying. The adult worm of *E. pancreaticum* is 8 to 16 mm long by 5 to 9 mm wide and tends to be more ovate and broader than that of *D. dendriticum* (Figure 16.13).

Clinical Disease

Although the life cycle is similar to that of *F. hepatica*, the pathogenic effects are less severe and patients may report mild symptoms. Symptoms include chronic constipation and flatulent dyspepsia. In patients with heavy infections, there may be jaundice with an enlarged liver. There may also be vomiting and diarrhea, as well as systemic toxemia. Eosinophilia tends to be absent in this infection.

Diagnosis

Diagnosis is based on recovery of the eggs in the stool, bile, or duodenal drainage specimens. It is important to remember that any presumptive true infection must be differentiated from spurious infections acquired from the ingestion of infected raw animal liver. True infection can be distinguished from spurious infection by maintaining the patient on a liver-free diet for at least 3 days. If the patient continues to pass eggs in the stool, the infection is

Figure 16.12 *Dicrocoelium dendriticum* adult worm (left) and egg (right). Adapted from reference 9.

probably genuine. Definitive diagnosis would require the recovery of adult worms at surgery or autopsy.

KEY POINTS—LABORATORY DIAGNOSIS

Dicrocoelium dendriticum, *Dicrocoelium hospes*, and *Eurytrema pancreaticum*

1. Multiple stool specimens may be required to find the eggs; bile and duodenal specimens can also be examined for the eggs.
2. The sedimentation concentration method should be used; because the eggs are operculated, they do not float in the zinc sulfate flotation concentration method.

Figure 16.13 *Eurytrema pancreaticum* adult worm (left) and egg (right). Adapted from reference 9.

3. It is important not to add too much iodine to the wet preparation, or the small eggs will stain very darkly and resemble debris.
4. Although the wet preparation can be examined using the 10× (low-power) objective, these eggs measure approximately 40 μm and can be easily missed. It is recommended that the 40× (high dry) objective be used for the wet preparation examination.
5. Eggs of *D. dendriticum*, *D. hospes*, and *E. pancreaticum* can resemble those of many other small intestinal and liver trematodes such as *C. sinensis*, *O. viverrini*, *H. heterophyes*, and *M. yokogawai*.
6. The wet preparation should not be so thick that the small eggs are obscured by normal stool debris.
7. If duodenal sampling is performed (drainage or the Entero-Test), eggs may be found in this material.
8. If available, antigen or antibody detection may be helpful in confirming the infection.

Treatment

Praziquantel is the drug of choice, and the same dosage is recommended as that used for infection with *Opisthorchis* infection. Triclabendazole, an imidazole derivative, may also be effective.

Epidemiology and Prevention

Because infection in humans is usually accidental, few preventive measures are effective. Use of wild herbs and grasses as food should be avoided unless they are carefully washed. Crickets or grasshoppers could also be accidentally ingested if they were within plant material that had not been carefully washed.

Lung Flukes

Paragonimus spp.

Paragonimiasis is a disease of humans and carnivores in which adult flukes of the genus *Paragonimus* are found in the lungs. Naterer first detected the lung fluke in 1828; however, Kerbert detected flukes in the lungs of a Bengal tiger in 1878 and named the worms *Distoma westermani*, after the director of the Amsterdam Zoo, Westerman. Both Manson and von Baelz in 1880 reported finding eggs in the sputum of humans, and Yokogawa in 1915 and Nakagawai in 1916 completely described the life cycle. Since 1899, the name *Paragonimus westermani* has been used (Table 16.1). *P. mexicanus* is an important human pathogen in Central and South America, while *P. kellicotti* infections are found in North and South America. Most paragonimiasis infections are caused by *P. westermani*, which is the focus of this section (Table 16.2).

Life Cycle and Morphology

The life cycle is shown in Figure 16.1. The adult worm is a plump, ovoid, reddish brown fluke found encapsulated in the lung. Eggs deposited by the worms are ovoid, brownish yellow, unembryonated, and thick-shelled, with an operculum at one end and opercular shoulders. The eggs measure 80 to 120 μm by 45 to 65 μm (Figure 16.14). *P. westermani* eggs are often confused with *Diphyllobothrium* eggs because they are operculated, unembryonated, and somewhat similar in size. However, unlike *Diphyllobothrium* eggs, *P. westermani* eggs have opercular shoulders and a thickened shell at the abopercular end (Figure 16.15). Eggs escape from the encapsulated tissue through the bronchioles, are coughed up and voided in the sputum, or are swallowed and passed out in the feces. The eggs hatch in the water in 2 to 3 weeks, releasing a miracidium to infect a susceptible snail host. Cercariae are released after sporocyst and redia generations. Crabs and crayfish are infected by cercariae via the gill chamber or on ingestion of an infected snail. Cercariae encyst in the gill vessels and muscles. Humans are infected by ingesting uncooked crabs or crayfish containing metacercariae (Fig. 16.16). The metacercariae excyst in the duodenum and migrate through the intestinal wall into the abdominal cavity. The larvae migrate around or through the diaphragm into the pleural cavity and the lungs; they mature to adults in the vicinity of the bronchioles, where they discharge their eggs into the bronchial secretions. Although these worms are hermaphroditic, two worms are usually required for fertilization to occur. The worms can live as long as 20 years, but most die after about 6 years.

Although we generally think of infected raw crabs or crayfish as the most common sources of infection, a number of other foods and cultural practices can be implicated as well, including the ingestion of metacercariae in the flesh of paratenic hosts (Figure 16.16). Some of these are listed in Table 16.3.

Clinical Disease

Migration of the larval forms through the intestinal wall into the abdominal cavity is generally not associated with any significant pathologic changes or symptoms. If the larvae remain in the abdomen, some patients may have abdominal pain, intra-abdominal masses, tenderness, fever, diarrhea, nausea, vomiting, and eosinophilia. Once the larvae have reached the peritoneal cavity, they begin to migrate through organs and tissues, producing localized hemorrhage and leukocytic infiltrates.

Pulmonary Disease. When the worms finally reach the lungs and mature, a pronounced tissue reaction occurs, with infiltration of eosinophils and neutrophils. A fibrotic

Table 16.2 Human paragonimiasis

Species	Geographic distribution	Disease (mode of transmission)	Mean egg size (μm) and characteristics
<i>P. westermani</i> ^a	Asia	Pulmonary (crabs, crayfish, freshwater shrimp)	85–100 by 47; abopercular thickening; oval with barrel-shaped center, operculum with opercular shoulders
<i>P. heterotremus</i> ^a (<i>P. truanshanensis</i>)	China, Laos, Thailand	Pulmonary (crabs, raw shrimp salad in Thailand)	86 by 48, uniform thickness
<i>P. mexicanus</i> ^a (<i>P. peruvianus</i> , <i>P. ecuadoriensis</i> , <i>P. caliensis</i>)	Mexico, Central and South America	Pulmonary (crabs)	79 by 48; eggshell thin, irregularly undulated
<i>P. africanus</i>	Cameroon, Congo, Nigeria, Liberia, Guinea, The Gambia, and Côte d'Ivoire	Pulmonary (crabs)	90 by 50; tend to be more narrow, abopercular thickening
<i>P. kellycotti</i>	North and South America	Pulmonary (crabs, crayfish)	75–118 by 48–68; shell 2–3 μm thick; abopercular thickening; tapers more sharply than <i>P. westermani</i>
<i>P. miyazakii</i> ^b	Japan	Pleural; high frequency of pleural effusion, pleural exudate, marked eosinophilia (crabs, raw juice of crabs, crayfish)	75 by 43; shell very thin; thinner at abopercular end
<i>P. westermani filipinus</i> (<i>P. philippinensis</i>)	Philippines	Pulmonary (crabs)	79 by 50; abopercular thickening
<i>P. skrjabini</i> (<i>P. szechuanensis</i>) ^b	China	Pleural, subcutaneous nodules (crabs)	75 by 46; egg slightly asymmetrical, small knob at abopercular end
<i>P. hueitungensis</i>	China	Migratory, subcutaneous nodules (crabs); high leukocytosis, elevated eosinophilia	75 by 46; widest part of egg slightly anterior to middle; thin shell, visible opercular shoulders; small knob at abopercular end
<i>P. uterobilateralis</i>	Cameroon, Guinea, Liberia, Nigeria, The Gambia, Gabon, Sudan, Côte d'Ivoire, and southern Africa	Pulmonary (crabs)	70 by 45; abopercular thickening of shell

^a Pathogenic organisms most frequently isolated from humans; synonyms are given in parentheses.

^b It has been suggested that in some areas in China and Japan, *P. skrjabini* and *P. miyazakii* should be referred to as *P. skrjabini miyazakii*. Some workers regard the following as synonyms of *P. skrjabini*: *P. miyazakii*, *P. szechuanensis*, and *P. hueitungensis*. Examination of specimens and reclassification studies are under way (10).

capsule forms around the worm. The cysts contain purulent fluid with flecks or “iron filings” composed of brownish yellow eggs. Many of the cysts perforate into the bronchioles, releasing their contents of eggs, necrotic debris, metabolic by-products, and blood into the respiratory tract. The eggs may also enter the pulmonary tissue, or they may be carried by the circulatory system to other body sites, where they cause a granulomatous reaction (Figure 16.17).

Symptoms of paragonimiasis depend largely on the worm burden of the host and are usually insidious in onset and mild in patients with chronic infections. Light infections may be asymptomatic, although peripheral

blood eosinophilia and lung lesions may be noted on X-ray examination. As the cysts rupture, a cough develops, with increased production of viscous blood-tinged sputum (rusty sputum, which may have a foul fish odor) and increasing chest pain. The patient may experience increasing dyspnea with chronic bronchitis and be misdiagnosed as having tuberculosis or bronchial asthma (40). The individual generally has a moderately high peripheral blood eosinophilia and leukocytosis, with elevated levels of IgG and IgE in serum. Although some patients exhibit symptoms continuously, others may remain asymptomatic for weeks to months between periods of hemoptysis.

Figure 16.14 *Paragonimus westermani* adult worm (left) and egg (right). The opercular shoulders are clearly visible at the top of the egg, as is the thickened abopercular end.

Cerebral Disease. Larval forms may end up in many ectopic sites other than the lungs; ectopic infections are generally associated with *P. heterotremus*, *P. mexicanus*, and occasionally *P. westermani*. Cysts have been detected in the liver, intestinal wall, muscles, peritoneum, and brain (Figure 16.18). The most serious consequences of paragonimiasis are the cerebral complications, which are commonly found in younger age groups. Unlike adult flukes in other extrapulmonary sites, worms found in the brain usually contain eggs. The worms probably migrate from ruptured lung cysts and travel through the soft tissues surrounding veins

Figure 16.15 Photographs (top) and drawings (bottom) of *Diphyllobothrium latum* egg (A) and *Paragonimus westermani* egg (B). (Illustration by Nobuko Kitamura.)

Figure 16.16 Crab second intermediate host for *Paragonimus* spp.

into the brain area. The worms eventually encapsulate, but before being walled off they cause necrosis within the brain tissue, as well as possible cerebral hemorrhage, edema, and meningitis.

Most patients with cerebral or other extrapulmonary lesions have an associated lung lesion or a history of lung

Table 16.3 Possible means of acquiring infection with *Paragonimus* spp.^a

Geographic area	Food or cultural practice
Asia	Ingestion of raw or inadequately cooked crabs, crayfish, and shrimp
China	“Drunken crab” (immersion of live crabs in wine for 12 h); raw crab sauce or jam; crayfish curd
Thailand	Kung Ten (raw shrimp salad); Nam Prik Poo (crab sauce)
Philippines	Sinugba (roasted crab); Kinilao (raw crab)
Korea	Ke Jang (crab immersed in soy sauce)
Korea and Japan	Raw juice of crabs or crayfish used in traditional medicine (treatment of measles, diarrhea, and urticaria)
Japan	Ingestion of raw infected wild boar meat (paratenic host)
Africa	Ingestion of raw crustaceans to increase fertility
Any of the above	Contaminated utensils, chopping blocks, and cloths used in food preparation

Figure 16.17 *Paragonimus westermani* egg in the lung (cross section). (Armed Forces Institute of Pathology photograph.)

disease. Symptoms include fever, headache, nausea, vomiting, visual disturbances, motor weakness, localized or generalized paralysis, and possibly death. More than half of these patients also exhibit personality changes, possible disorientation, and a general decline in cognitive function. Depending on the central nervous system location, symptoms may also include paraplegia, sensory loss, or vision problems. Specific sites can include the cerebral cortex, cerebellum, basal ganglia, medulla oblongata, and spinal cord (11, 32). When a worm dies, the lesion cavity becomes filled with necrotic material. Cerebral paragonimiasis can be difficult to differentiate from brain disease caused by other parasites such as *Schistosoma japonicum*, *Gnathostoma spinigerum*, or *Angiostrongylus cantonensis*, as well as other infectious agents such as bacteria or viruses.

Paragonimiasis in Other Body Sites. Abdominal or subcutaneous masses are frequently seen in patients with infections caused by *P. skrjabini*, *P. heterotremus*, *P. hueitungensis*, or *P. mexicanus*. Migratory subcutaneous nodules occur in 20 to 60% of patients with *P. skrjabini* infection and approximately 10% of patients with *P. westermani* infection. The nodules are firm, tender, a few millimeters to 10 cm, and somewhat irritating. They are often located in the lower abdomen, inguinal region, and thigh and are somewhat mobile. Ulcers or abscesses can

also occur in the skin or subcutaneous tissue. Involvement of the mastoid area has been seen in *P. africanus* infections. Other body sites that have been infected include the breast, lymph nodes, heart, pericardium, mediastinum, kidneys, adrenal gland, omentum, bone marrow, stomach wall, bladder, spleen, pancreas, and reproductive organs. While ectopic lesions are usually thought to be caused by worm migration, dissemination of eggs to other body sites can also be responsible for the pathology.

In China, *P. skrjabini* does not develop to the adult worm stage, but the disease is characterized by the presence of trematode larva migrans (12). These migratory subcutaneous nodules are associated with a high eosinophilia, as well as necrotic liver lesions. Brain involvement is common and is associated with subarachnoid hemorrhage.

Diagnosis

Laboratory Tests. Individuals with symptoms of chronic cough, vague chest pains, and hemoptysis who have resided in an area where infections are endemic and have a history of eating raw crayfish or crabs should be suspected of having paragonimiasis. *Paragonimus* eggs can be detected in the sputum and the stool, and concomitant examinations should be performed to improve the overall detection rate. In many individuals in whom the infection is eventually confirmed, small numbers of eggs are present intermittently in the sputum and feces. For patients with light infections, up to seven sputum examinations have been recommended. Frequently, pulmonary paragonimiasis is misdiagnosed as pulmonary tuberculosis. The Ziehl-Neelsen method for detecting mycobacteria destroys *Paragonimus* eggs (40). It is important to remember that the typical findings of cough, hemoptysis, and eggs in the feces or sputum may be absent in patients with ectopic or pleural *Paragonimus* infection.

Radiography and Scans. Skull radiographs generally reveal round or oval cystic calcifications; they have been described as looking like bubbles. CT scans reveal multilocular cysts with edema, migration tracks, peripheral density, bronchial wall thickening, and centrilobular nodules; ring enhancement may be visible after the use of contrast. Magnetic resonance imaging (MRI) demonstrates areas of granulomatous inflammation surrounding the lesions; MRI of the brain may reveal multiple conglomerated iso- or low-signal-intensity round nodules with peripheral rim enhancement. In the liver, CT and MR images may reveal a cluster of small cysts with rim enhancement in the subcapsular area. This finding seems to be characteristic for hepatic paragonimiasis. Solitary nodular lesions can often mimic lung cancer, tuberculosis, or fungal diseases. When a pulmonary mass lesion or empyema is detected in patients who live in areas where paragonimiasis is endemic, paragonimiasis should always be included in the differential diagnosis of lung diseases.

Immunodiagnostic Tests. In addition to the methods described in the Diagnosis section, immunodiagnostic tests have been used to diagnose pulmonary and extrapulmonary infections. Complement fixation has been used to diagnose active infections; however, the test becomes negative soon after the death of the worms. An immunoblot assay for the detection of antibodies to *P. westermani* by using adult worm homogenates is highly sensitive and specific (38). Only one false-positive result has been detected by this method, in a patient with a *Schistosoma haematobium* infection. ELISA with adult excretory-secretory antigens is very sensitive for detecting parasite-specific IgG and IgE (22). Pleural effusion fluid

is more suitable than serum for detection of infections. Dot ELISA has also been used to detect parasite-specific antigen in human sera (45). Monoclonal antibodies used to detect species-specific and stage-specific antigens are highly sensitive and specific for the detection of active infections (44). The serologic assays are available in areas of endemicity or in specialized diagnostic centers. Most of these assays involve nonstandardized reagents and have not been used in clinical trials. An intradermal test is also available for epidemiologic surveys in areas of endemicity; however, positive reactions persist for years after parasitologic cures.

KEY POINTS—LABORATORY DIAGNOSIS

Paragonimus spp.

1. *Paragonimus* eggs may be confused with *Diphyllobothrium latum* eggs because of similarities in their size and shape. However, most *Paragonimus* eggs have opercular shoulders and a marked thickening at the abopercular end, unlike *D. latum* eggs.
2. The sedimentation concentration method should be used; because the eggs are operculated, they do not float in the zinc sulfate flotation concentration method.
3. It is important not to add too much iodine to the wet preparation, or the eggs will stain very darkly and resemble debris.
4. The wet preparation can be examined using the 10× (low-power) objective; these eggs are large enough that they can usually be seen under this magnification.
5. The wet preparation should not be so thick that the eggs are obscured by normal stool debris.
6. When looking at sputum specimens for eggs, it is necessary to carefully examine any blood-tinged flecks for eggs; the egg clusters have been described as looking like iron filings.
7. In light infections, multiple stool and sputum specimens may be needed before the eggs are detected.
8. If available, antigen or antibody detection may be helpful in confirming the infection.

Treatment

The drug of choice is praziquantel at 25 mg/kg three times at 4-h intervals after meals for 2 or 3 days. Very few patients require retreatment; 100% cure is usually obtained except for certain patients with a heavy worm burden. There is dramatic improvement in symptoms, and they are usually gone within a few months. The dose required in cerebral paragonimiasis is generally higher

and may have to be adjusted relative to the clinical outcome; convulsions and coma have been seen. These patients should be hospitalized for therapy and should be monitored closely; corticosteroids may also have to be given when treating patients with praziquantel. Bithionol is an alternative drug, which is available under an Investigational New Drug protocol from the Centers for Disease Control and Prevention Drug Service (2).

Triclabendazole at 10 mg/kg as a single dose or two doses is also recommended, but this dose may not be as easy to obtain. Patients should be examined at 3 months to determine the need for retreatment. If a single dose has failed, the use of triclabendazole at 20 mg/kg is recommended (13). Triclabendazole is not currently available in the United States unless possibly available through a compounding pharmacy (2).

Pulmonary paragonimiasis is rarely fatal; however, cerebral disease is characterized by chronic morbidity and symptoms including epilepsy, dementia, and other neurologic sequelae. About 5% of patients with cerebral disease die due to hemorrhage in the first 2 years of the disease (12).

Epidemiology and Prevention

There are approximately 200 million people at risk and 22 million people with paragonimiasis worldwide; 10 species are recognized as causing human disease (40) (Table 16.2). *P. westermani* is the most common human pathogen.

Reservoir hosts include dogs and cats in areas of endemic infection (the Far East and Africa). Eggs expectorated or passed in the feces in the vicinity of lakes or streams where the intermediate hosts live serve as the source of infection. Snail intermediate hosts include *Semisulcospira* and *Brotia* spp. In Ecuador, the intermediate host for *P. mexicanus* is *Aroapyrgus* sp., a freshwater snail belonging to the family Hydrobiidae (7). Humans contract the infection through ingestion of raw, undercooked, pickled, or wine-soaked crabs or crayfish; they may also become infected by the ingestion of uncooked meat from wild animals, such as wild boar. The migrating larvae in this meat may pass through the intestinal wall and continue their developmental cycle when eaten. Raw juice from crushed crayfish used as a home remedy for the treatment of measles has been a significant source of infection and may be a cause of cerebral paragonimiasis in children (43).

In most areas, the disease is primarily one of crab- or crayfish-eating mammals, with humans being incidental hosts. Measures devoted to public health education, warning people of the dangers of eating uncooked crabs or crayfish from areas of endemic infection, and sanitary care of utensils and fingers used to prepare food would

reduce the risk of infection. Because the cycle depends on animals, the elimination of human paragonimiasis would have little effect on the overall prevalence of the disease.

Blood Trematodes: Schistosomes

Schistosoma mansoni

Schistosoma japonicum

Schistosoma mekongi

Schistosoma haematobium

Schistosoma intercalatum

Schistosomes belong to the phylum Platyhelminthes, family Schistosomatidae, and are a group of digenetic, dioecious trematodes requiring definitive and intermediate hosts to complete their life cycles. Four species are important agents of human disease: *Schistosoma mansoni*, *S. japonicum*, *S. mekongi*, and *S. haematobium*. *S. intercalatum* is of less epidemiologic importance. Schistosomiasis affects between 200 million and 300 million people in 77 countries throughout the world and is a significant cause of disease in areas of endemic infections. In Egypt, approximately 20% of the population is infected; prevalence rates in some villages have been estimated to be 85%. The number of infected individuals in China is estimated to be 1.52 million. Although only about 10% of infected people have serious disease, this represents 20 million to 30 million individuals worldwide. Approximately half of the remaining 180 million to 270 million infected individuals have symptoms.

The earliest known instance of schistosomiasis was found in Egyptian mummies of the predynastic period (3100 BC), using enzyme-linked immunosorbent assay (ELISA) to detect circulating anodic antigen (43). Previously, eggs were detected in the kidneys of mummies from the Twentieth Dynasty (1250 BC to 1000 BC). Fujii in 1947 described schistosomiasis caused by *S. japonicum*, and Bilharz in 1951 noted *S. haematobium* infections in Cairo. Sambon proposed the name for *S. mansoni*. Schistosome infections in the New World probably began with the African slave trade in the Americas during the 16th and 17th centuries.

Schistosomes are somewhat different from other human trematodes since they (i) have two sexes, (ii) live in the blood vessels, (iii) have nonoperculated eggs, and (iv) have no encysted metacercarial stage in the life cycle. The human is the definitive host for *S. mansoni*, *S. japonicum*, and *S. haematobium*; for *S. mekongi* and *S. malayi* (both similar to *S. japonicum*); and for *S. intercalatum*. *S. matthei*, which causes infections in sheep, cattle, and horses, also infects humans and can cause disease. Other schistosomes have been found in humans but do not tend to cause any pathology. Also, cercariae from birds and mammals can penetrate human skin but cannot complete the life cycle and tend to die without migrating or maturing; however, they do cause cercarial dermatitis.

Figure 17.1 Life cycle of schistosomes.

Schistosoma mansoni

In one of the earliest reports on African schistosomiasis, Theodor Bilharz first noted the disease but mistakenly described two types of eggs, one with a lateral spine and one with a terminal spine, as occurring in the same adult worm. Manson was the first to note schistosomiasis in the New World, but it was Sambon who adequately described the differences between intestinal and urinary tract schistosomiasis and proposed the name *S. mansoni*. *S. mansoni* was probably established in the Western Hemisphere as a result of the African slave trade.

In Egypt, hepatitis C virus (HCV) infection, along with *S. mansoni*, is the main cause of chronic liver disease and liver cirrhosis. HCV genotype 4a is highly prevalent in Egypt. Schistosomiasis, HCV, HBV, and HGV are all associated with liver disease. However, coinfection with two or more of these infectious agents may potentiate the pathogenesis of the liver disease (21).

Life Cycle and Morphology

Humans become infected by penetration of cercariae through intact skin rather than by ingestion of metacercariae (Figure 17.1); penetration can occur within as little as 5 min after initial skin contact. Cercariae consist of a body with glands containing a proteolytic enzyme (elastase), which is used to penetrate skin, and a bifurcated tail that is lost when the cercariae penetrate the skin (Figure 17.2). Once the cercariae have successfully entered the host, the organism is termed a schistosomulum. After about 48 h, the schistosomulum migrates through the tissues and finally invades a blood vessel. On entry into the blood vessels, the schistosomulum is carried to the lungs and then the liver. Once within the liver sinusoids, the worms begin to mature into adults. The adults of *S. mansoni* are found in the inferior mesenteric veins. The worms form pairs (male and female), with the female lying in the

gynecophoral canal of the male (Figures 17.3 and 17.4). Sexual maturity of female schistosomes depends on the presence of mature male worms. The female worm has selective gene expression in the reproductive tract in the presence of male worms, whereas females separated from

Figure 17.2 Schistosome cercariae. (Top, illustration by Sharon Belkin.)

Figure 17.3 Scanning electron micrograph of male and female schistosome in copula.

male worms lose this capability. Exploitation of these genetic differences may be of value in drug research and in attempts to reduce host morbidity. Prior to egg production, migration and maturation generally require about 4 to 6 weeks.

Humans are the only important definitive hosts of *S. mansoni* (Table 17.1). Fully embryonated eggs without an operculum (114 to 180 μm by 45 to 73 μm) are passed

Figure 17.4 *Schistosoma mansoni* male and female in copula; note the female within the male worm.

in the stool (Figures 17.5 and 17.6). The eggs are light yellowish brown and elongate, and they possess a large lateral spine projecting from the side near one end of the egg. The eggshell is acid fast when stained by a modified Ziehl-Neelsen technique. On reaching water, the eggs hatch, liberating miracidia (Figure 17.7), which must penetrate a suitable snail host (*Biomphalaria* spp.). Cercariae liberated from the infected snail infect humans when the latter come in contact with cercaria-infested water. A period of 4 weeks or more from the time of first infection with a miracidium is required before the snail sheds cercariae. On infection, the cercariae lose their tails, and the body (now called a schistosomulum) migrates through the lungs to the liver, where it develops to a mature adult in the mesenteric veins of the large bowel. Some worms are also found in the superior mesenteric veins, vesical plexus, and intrahepatic portion of the portal veins.

The adult male and female can reach lengths of 1.2 and 1.6 cm, respectively. They have oral and ventral (acetabulum) suckers at the anterior end. The worm surface is a tegument containing a syncytium of cells. The male worm's body, which is flattened behind the ventral sucker, appears cylindrical as it curves to form the gynecophoral canal to clasp the female worm. The female worm is long, slender, and cylindrical in cross section (Figure 17.4). While held in the gynecophoral canal of the male, the female ingests 10 times more red blood cells than does the male. The tegument of the male contains many prominent tuberculations, while the tegument of the female is devoid of the tuberculations (Figure 17.3). The uterus of the female is short and usually contains only one egg at a time. After mating, the female leaves the male and migrates against the flow of blood to the small venules of the intestine. Initial egg production begins 4 to 7 weeks after infection. *S. mansoni* mature females produce 100 to 300 eggs per day.

The eggs are immature when first laid and take approximately 8 to 10 days to develop a mature miracidium. They are nonoperculate and contain a lateral spine. Egg deposition takes place intravascularly. Many of the eggs laid are swept away and become lodged in the microvasculature of the liver and other organs. About half of the eggs swept away by the bloodstream become embedded in the mesenteric venule wall. The presence of eggs in the tissues stimulates granuloma formation; the eggs die, calcify, and are eventually absorbed by the host (Figures 17.8 and 17.9).

The eggs that are not trapped in the tissues will continue the normal life cycle. The process of maturation and tissue penetration takes about 8 to 10 days; the eggs work their way through the tissues into the lumen of the intestine to be released from the body in the feces. Egg migration through the tissues is facilitated by the release of enzymes

Table 17.1 Characteristics of blood trematodes

Species	Distribution	Reservoir hosts	Intermediate snail host genus	Diagnostic specimen or test	Egg		
					Size (μm)	Morphology	Comments
<i>S. mansoni</i>	Africa, Madagascar, West Indies, Suriname, Brazil, Venezuela	Humans, nonhuman primates	<i>Biomphalaria</i>	Stool, rectal biopsy, serology	114–180 by 45–73	Elongate, prominent lateral spine; acid-fast positive	In a wet preparation, egg may be turned so lateral spine is not visible; evidence of flame cell activity is proof of viability; can use hatching test (unpreserved specimens) to confirm; occasionally found in urine
<i>S. japonicum</i>	China, Indonesia, Japan, Philippines	Dogs, cats, cattle, water buffalo, pigs	<i>Oncomelania</i>	Stool, rectal biopsy, serology	70–100 by 50–65	Oval, minute lateral spine; acid-fast positive	Eggs can mimic debris in the wet preparation; small spine may be very hard to see; debris often clings to the surface of the egg; less likely to be found in urine, but possible
<i>S. mekongi</i>	Mekong River basin	Humans, dogs, rodents	<i>Lithoglyphopsis</i>	Stool, rectal biopsy, serology	50–65 by 30–55	Subspherical, minute lateral spine	Looks very much like <i>S. japonicum</i> egg; lateral spine may be difficult to see
<i>S. haematobium</i>	Africa, Middle East, India, Portugal	Humans	<i>Bulinus</i>	Urine, stool (some cases), bladder biopsy, serology	112–170 by 40–70	Elongate, terminal spine; acid-fast negative	If present, usually easy to identify; however, urine sedimentation can be time-consuming; can use membrane filter approach as well; eggs occasionally found in stool; hatching test on urine (unpreserved) sediment is relevant
<i>S. intercalatum</i>	Central and western Africa	Humans	<i>Bulinus</i>	Stool, rectal biopsy, serology	140–240 by 50–85	Elongate, terminal spine; acid-fast positive	Egg resembles <i>S. haematobium</i> egg but is found in stool rather than urine

Figure 17.5 *Schistosoma mansoni* egg with a mature miracidium. (Illustration by Nobuko Kitamura; adapted from Figure 27.15A in P. C. Beaver, R. C. Jung, and E. W. Cupp, *Clinical Parasitology*, 9th ed., Lea & Febiger, Philadelphia, Pa., 1984.)

by the miracidium through the eggshell. These enzymes help digest the tissue. Eggs making their way through the tissues into the lumen contain a mature miracidium that is released when the eggs are in contact with water (Figure 17.7). The actively swimming miracidium seeks a suitable snail host, which it penetrates. Within the snail, the miracidium develops into a mother sporocyst, which in turn produces daughter sporocysts. The daughter sporocysts develop in the hepatopancreas of the snail and produce cercariae (Figure 17.2). The miracidium, which may be either female or male, gives rise to cercariae of the same sex. This portion of the cycle in the intermediate snail host takes approximately 3 to 5 weeks. The cercariae are released from the snail into freshwater, where they may infect humans by penetrating the skin. Stimuli for cercarial shedding of *S. mansoni* cercariae include bright, direct sunlight and water temperatures of 24 to 30°C, leading to higher transmission rates during the summer. *S. mansoni* cercariae move vertically, alternating between migrations toward the surface and sinking. The cercariae attach to the skin of the definitive host via their ventral or oral suckers. Approximately 40% of the cercariae that penetrate the skin will go on to become adult worms; if the cercariae do not find a suitable host, they usually die within 48 to 72 h.

Clinical Disease

Disease syndromes associated with schistosomiasis are related to the stage of infection, previous host exposure,

Figure 17.6 *Schistosoma mansoni* eggs. Note the large lateral spine.

worm burden, and host response. Syndromes include cercarial dermatitis, acute schistosomiasis (Katayama fever), and related tissue changes resulting from egg deposition. It has been noted that schistosomiasis exerts disruptive influences on the nutritional reserves and growth of humans from middle childhood through adolescence.

Schistosome Cercarial Dermatitis. Cercarial dermatitis follows skin penetration by cercariae, and the reaction may be due partly to previous host sensitization. Few clinical manifestations are associated with primary exposure, but both humoral and cellular immune responses are elicited on subsequent exposure. After cercarial skin penetration, petechial hemorrhages with edema and pruritus occur. The subsequent maculopapular rash, which may become vesicular, may last 36 h or more. Cercarial dermatitis is common with *S. mansoni* infections. Dermatitis is a constant feature of human infection with avian

Figure 17.7 *Schistosoma miracidium*. (Armed Forces Institute of Pathology photograph.)

schistosomes, with cercarial death occurring in the subcutaneous tissues and immediate hypersensitivity reactions occurring at the invasion sites. This condition is known as swimmer's itch. Avian schistosomiasis can be found in the Great Lakes and Delaware Bay regions in the United States and in Lake Geneva. Any body of water, typical of bay regions with freshwater or saltwater, where infected snails are found can be linked to nonhuman cercarial dermatitis. Previous contact with cercariae will lead to a more immediate intense immune response.

Acute Disease: Katayama Fever. Acute schistosomiasis (Katayama fever) is associated with heavy primary infections and the initiation of egg production throughout areas of high transmission risk. The signs and symptoms resemble those of serum sickness. Characteristic symptoms include high fever, hepatosplenomegaly, lymphadenopathy, eosinophilia, and dysentery. This clinical syndrome occurs a few weeks after the primary infection, particularly with *S. mansoni*; however, it is infrequent in inhabitants of areas where infections are endemic. Although widely described, this syndrome does not appear to be as common as it once was, nor are its immunology and pathology well understood.

Immune Response. After infection and the transformation of cercariae to schistosomula, the schistosomulum expresses antigens on its surface that evoke a host immune response that provides some degree of resistance to reinfection. As the worms mature, they become less antigenic and more resistant to the immune system-mediated killing mechanisms of the host. The worms are able to incorporate host antigen onto their surface, thus preventing the host from recognizing these parasites as foreign.

Figure 17.8 Hepatic fibrosis with multiple schistosome egg granulomas. (Armed Forces Institute of Pathology photograph.)

Because schistosomes are incapable of synthesizing fatty acids or cholesterol, they must bind low-density lipoproteins onto their surface. These bound low-density lipoproteins may be essential in allowing the parasite to evade the host immune response. The adult worms do not appear to cause any damage to the host, nor do they evoke much of an immune response. Immunoglobulin E (IgE) antibodies and eosinophilia appear to play a major role in the host immune response and resistance to reinfection (14). In infected individuals, there is a marked increase in the levels of IgE and IgG4 against various parasitic antigens (36). Individuals develop an age-acquired resistance as they are exposed to infection (16). These antibodies have also been associated with resistance to reinfection. In acute schistosomiasis, the levels of IgA and IgM correlate with the intensity of infection (54). The detection of IgA might be useful for the differentiation of acute and chronic schistosomiasis. High IgM levels can be detected in both acute and chronic disease.

Chronic Schistosomiasis. After production of eggs by the adult worms (Figure 17.6), the eggs become trapped in the fine venules and are able to pass through the tissues, escaping into the intestine or, less commonly, the bladder.

Figure 17.9 Schistosome eggs in tissue. (Left) *S. haematobium*, (right) *S. mansoni*.

The eggs liberate a number of soluble antigens, evoking minute abscesses, which facilitate their passage into the lumen. The passage of eggs through the wall of the intestine or bladder leads to symptoms that correlate with the worm burden of the host, including fever, abdominal pain, liver tenderness, urticaria, and general malaise. In *S. mansoni* infection, blood and mucus are detected in the stools and the patient may have diarrhea or dysentery.

Intestinal disease. As eggs are deposited in the tissues, the antigenic substances released by the eggs invoke a host immune response that includes the formation of granulomas around the eggs trapped in the tissues. Many eggs are retained in the intestinal tissue. Cellular infiltrates include lymphocytes, eosinophils, macrophages, and fibroblasts. Granuloma aggregation in the intestinal tract wall is the major cause of pathologic change. The intestinal wall becomes inflamed, thickened, and fibrotic, leading to mechanical obstruction. Apparently, adhesion molecules are important elements in schistosomal intestinal granuloma formation (28). Intestinal schistosomiasis is common in *S. mansoni* infections but can also occur in *S. haematobium* infections.

Hepatosplenic disease. Although many eggs remain where they are deposited, others are swept into the circulation and filtered out in the liver, leading to hepatosplenic schistosomiasis. Hepatosplenomegaly is common in patients with *S. mansoni* chronic infections. In some areas, *S. mansoni*, *S. japonicum*, and viral hepatitis are the most common causes of chronic liver disease. Patients with concomitant viral hepatitis may develop a more severe form of hepatosplenic schistosomiasis. Eggs deposited in the portal triads of the liver stimulate a granulomatous response, leading to continuous fibrosis of the periportal tissue (Figure 17.8). The fibrotic tissue is white and hard and has been referred to as Symmer's pipe-stem fibrosis (Figure 17.10). However, Symmer's pipe-stem fibrosis is now known as fibro-obstructive hepatic schistosomiasis

Figure 17.10 Pipe-stem fibrosis in the liver as a result of *Schistosoma mansoni*. (Original photograph by L. Millman; from A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

(56). The liver increases in size as a result of the lesions induced by the eggs. The major effect of the liver changes is the blockage of portal blood flow, resulting in increased portal hypertension and the development of collateral circulation, such as esophageal varices (Figure 17.11). Ascites may be evident, depending on the degree of liver obstruction. The spleen becomes congested and increases greatly in size (Figure 17.12). The presence of large quantities of antigenic material in the spleen could suggest an important role for this organ in antigen clearance and might provide an additional explanation for the hepatosplenomegaly seen in *S. mansoni*-infected children.

Other body sites and sequelae. Collateral circulation allows the eggs to be carried to the lungs, leading to fibrosis of the pulmonary bed. In addition to being deposited in the liver and lungs, eggs may be trapped in other tissues, such as the brain, spinal cord, spleen, pancreas, and myocardium. Eggs trapped in the brain have caused focal and generalized seizures. Spinal cord schistosomiasis has been found in patients with *S. mansoni* infections; the myelopathy is probably the result of hypersensitization to the eggs. Myelopathies occur infrequently, and eggs are commonly found in the spinal cord of patients without eliciting symptoms.

Pulmonary involvement is seen with all forms of schistosomiasis in patients with heavy worm burdens. Schistosomal lung disease is usually seen only after the development of collateral circulation in infections with

Figure 17.11 Schistosomiasis. Note the engorgement of collateral circulation of the abdomen. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

S. mansoni and *S. japonicum*. The subsequent development of pulmonary hypertension leads to cor pulmonale (right-sided heart failure). Signs of the disease include fatigue, cough with possible hemoptysis, palpitations, dyspnea on exertion, right ventricular hypertrophy, and pulmonary artery dilation.

Figure 17.12 *Schistosoma mansoni* infection showing liver and splenic enlargement; 800 worms were removed from this patient. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.* Photograph courtesy of R. Goldsmith and B. H. Kean.)

Chronic bacteremic infections with *Salmonella* spp. have been associated with *S. mansoni* infections. Common features of this association between *Salmonella* and *Schistosoma* infections include a long history of recurrent febrile illness, frequent isolation of *Salmonella* spp. from the blood, and chronic active schistosomiasis. The *Salmonella-Schistosoma* infection association is seen most frequently in males between the ages of 15 and 30 years. If the underlying schistosome infection is not treated, the *Salmonella* infection will continue to recur.

The level of circulating immune complexes appears to be correlated with the worm burden of the host. These immune complexes may be deposited on the basement membrane and glomerular capillaries, causing nephrosclerosis and kidney failure. The severity of kidney disease is associated with the worm burden and the degree and duration of hepatic fibrosis. The relationship between renal and hepatic disease may be the result of development of a collateral circulation, which would interfere with the normal clearance of circulating antigens and immune complexes by Kupffer cells.

Diagnosis

Schistosomiasis should be suspected in individuals who have had significant contact with water in areas of endemic infection. Symptoms of acute schistosomiasis include fever, diarrhea, abdominal pain, weight loss, and eosinophilia. Symptoms of chronic disease include chronic diarrhea, abdominal pain, and hepatomegaly or hepatosplenomegaly.

Diagnostic Procedures. Specific diagnosis of schistosomiasis by detection of eggs in stool or urine specimens is possible only after egg production has begun. Eggs may be found in feces as early as 5 weeks after infection. The ease of egg detection depends on the worm burden and the duration of the infection. Patients with a low worm burden or old (chronic) infections may have very few eggs in the feces or urine, and the infections may not be confirmed due to insensitive diagnostic methods. Multiple stool or urine examinations should be performed for any individual suspected of having schistosomiasis. Occasionally, *S. mansoni* eggs are detected in the urine; adult worms may be found in vessels that are not their normal habitat, and this finding is known as “crossover.”

S. mansoni eggs are yellowish brown and measure 114 to 180 μm long by 45 to 73 μm wide (Figure 17.6; Table 17.1). The eggs are elongate and ovoid and have a large lateral spine projecting near one end. Direct detection or concentration techniques can be used to detect eggs in the stool or urine. Direct microscopic examination of stool smears is not very sensitive but may be useful for screening purposes. The Kato thick smear is a simple

and sensitive quantitation technique that has been used successfully in the field. In one study, more than 50% of the eggs were missed by the sedimentation technique; the geometric mean egg count was 94 eggs/g when two Kato-Katz smears were used and 43 eggs/g when the sedimentation technique was used (15). However, no details of the centrifugation speed and time were given. Another study indicated that examination of fewer samples collected on different days was more effective than examination of more slides from one stool specimen for accurate estimation of the real infection status.

The zinc sulfate concentration technique is not recommended for schistosome eggs. The eggs rupture and do not float but instead are found in the sediment. The formalin-ethyl acetate technique is recommended for concentrating eggs; however, because it involves fixation, it cannot be used to detect egg viability.

In chronic infections in which the worm burden is light, hatching tests can be performed. The stool specimens are diluted with nonchlorinated water in a sedimentation flask or a beaker. The sides of the flask or beaker are covered with aluminum foil to prevent light from passing through. A light source is used to project a perpendicular light beam through the water at the top. Miracidia that hatch from the live eggs will concentrate in the light and can be detected swimming around. This motility can easily be observed with a hand lens. Aliquots of the surface water can be transferred to a small petri dish and observed under a dissecting microscope for miracidia. Observation periods should be frequent because of the limited life span of the miracidia. Ideally, observations should be made every 30 min over a period of 4 h. The hatching test is designed to mimic the conditions in nature with spring water and sunlight (see chapter 28).

Biopsy Specimens. Rectal biopsy specimens have been particularly useful in detecting eggs in patients with light, chronic, or inactive infections (Figure 17.13). The biopsy tissue can be crushed between two glass slides. This technique is more effective than histologic examination and allows assessment of the species and viability of the eggs. The viability of the eggs can be determined by closely observing the miracidium for flame cell activity. Each miracidium contains two pairs of flame cells, and these are actively beating in live miracidia (Figure 17.7). Eggs can also be recovered from tissue by digestion in 4% KOH at 37°C for 6 to 18 h and examination of the sediment. *S. mansoni* eggshells can be stained acid fast with a modified Ziehl-Neelsen stain. This technique has been used in tissue sections to differentiate *S. mansoni* eggs from *S. haematobium* eggs, which are not acid-fast positive.

Antibody Detection. A large number of serologic tests have been used in the diagnosis of schistosomiasis (69);

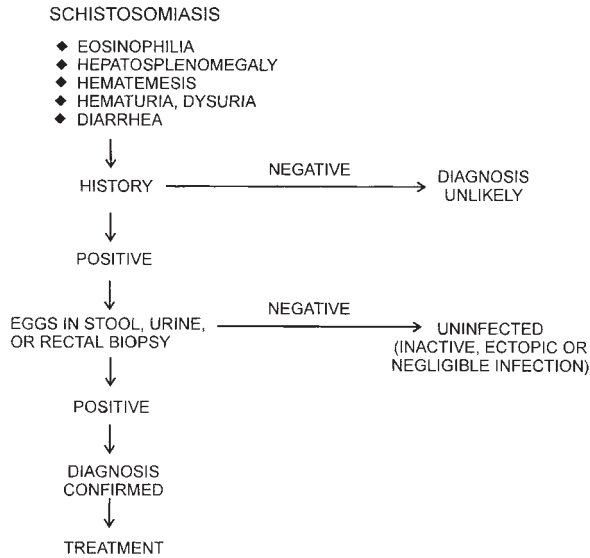

Figure 17.13 *Schistosoma mansoni* eggs in crushed rectal biopsy tissue. (Armed Forces Institute of Pathology photograph.)

however, many have not been particularly useful because of cross-reactions with other helminth infections, continuation of elevated titers long after successful treatment, and slow immunologic response of the host. Because of the complex life cycle, a large number of antigens have been used in serologic tests. Only a few have been useful. The most frequently used tests are the circumoval precipitin test, the cercaria-Hullen reaction, the indirect fluorescent-antibody test, the indirect hemagglutination test, and ELISA (57, 69). See Algorithm 17.1.

ELISA methods using soluble adult worm or egg antigens for the detection of antibodies have been used as screening tests, and infection has then been confirmed by the enzyme-linked immunoelectrotransfer blot (EITB) test (69). Individuals infected with schistosomes have elevated IgE and IgG4 responses, as do patients with other helminthic infections. Few studies have investigated the persistence of antibodies over time after therapy (69). It is possible that high titers posttherapy reflect treatment failure and reinfection.

Antigen Detection. ELISA has also been used to detect circulating schistosome antigens in the serum and urine of

Algorithm 17.1 Schistosomiasis.

infected patients and may be one of the preferred methods of diagnosis (5, 51, 76). In addition to diagnosis of infection, antigen levels have been used to assess disease severity in terms of intensity of infection and to monitor the efficacy of therapy (51, 76) (Table 17.2). Individuals treated with praziquantel experienced a rapid clearance of circulating anodic (CAA) and cathodic (CCA) antigens; however, in individuals treated with other therapeutic drugs, clearance may take much longer. A dipstick assay based on the anti-CCA sandwich ELISA, on a nitrocellulose format, can detect CCA in the urine of *S. mansoni*-infected patients with a sensitivity of 92%. The results were at least as good as those obtained by ELISA or the Kato-Katz fecal smear examination. This rapid, simple approach may lend itself to more extensive use in future screening programs (64, 65, 73). The combination of urine CCA and serum CAA for the detection of circulating antigens and the combination of the *S. haematobium* adult worm microsomal antigens (HAMA) FAST-ELISA and the HAMA EITB test for detecting antibodies has significantly improved the sensitivity of antibody and antigen detection (3).

When a soluble egg antigen (SEA) monoclonal antibody (MAb) was used, circulating schistosome antigen was undetectable in serum from patients with other parasitic infections and in 94% of serum samples and 84% of urine samples from *S. mansoni*-infected patients; however, it was present in serum (90.5%) and urine (94%) samples from patients with *S. haematobium* infection. A significant reduction in circulating schistosome antigen levels was detected in serum and urine samples approximately 12 weeks after praziquantel therapy (58). No cross-reactivity with *S. mansoni* was seen.

KEY POINTS—LABORATORY DIAGNOSIS

Schistosoma mansoni

1. Eggs cannot be detected in stool until the worms mature (may take 4 to 7 weeks after initial infection).
2. In very light or chronic infections, eggs may be very difficult to detect in stool; therefore, multiple stool examinations may be required. Biopsy and/or immunologic tests for antigen or antibody may be helpful in diagnosing infection in these patients.
3. The zinc sulfate flotation concentration method should not be used; the eggs do not float. The sedimentation method is recommended.
4. It may be necessary to tap the coverslip to move the eggs; the lateral spine may not be visible if the egg is turned on its side.
5. Occasionally, eggs of *S. mansoni* are detected in the urine (crossover phenomenon).
6. Patients who have been treated should have follow-up ova and parasite examinations for up to 1 year to evaluate treatment.
7. In active infections, the eggs should contain live or mature miracidia. Examination for the confirmation of flame cell activity must be performed with fresh specimens, using the microscopic wet mount test or the hatching test; no preservatives can be used prior to these two tests.
8. During the hatching test, the light must not come too close to the surface of the water, since excess heat can kill the liberated larvae. Also, the water should be examined about every 30 min for up to 4 h.

Treatment

Praziquantel. Praziquantel, a pyrazinoquinolone, is the drug of choice for treating schistosome infections (2). The current recommendation is 40 mg/kg/day in two doses for 1 day. Praziquantel can also be taken orally in a single dose and is well tolerated by the host. Side effects, which are usually mild and transient, include abdominal discomfort, dizziness, drowsiness, headache, fever, and loose stools. These effects usually disappear within 48 h. In heavily infected individuals, the side effects, although transient, may be very severe (62). Split doses have been recommended for treating heavy infections, but this may be a concern for population-based therapy, where individuals may not present themselves for follow-up therapy. Data suggest that a single dose of praziquantel (40 mg/kg of body weight) may have a longer-lasting effect than previously thought, possibly more than 2.5 years (18). Praziquantel has little effect on immature stages of the parasite, and this affects the cure rates as the immature

Table 17.2 Improved immunologic testing for the diagnosis of *S. mansoni* infection

Test	Comments	Reference
ELISA, IgG, IgM, IgA	Crude adult worm extract as an ELISA antigen provides a serologic method with high sensitivity and specificity for the diagnosis of acute and chronic schistosomiasis and for serologic distinction between the two forms of the disease.	72
Immunomagnetic beads with 1 ml of urine	Assay method uses larger sample volumes than ELISA; enhanced detection can be achieved. Valuable in areas with low prevalence or assessment of cure after therapy.	47
ELISA for cercarial elastase	Cercarial elastase is one of the first proteins released in the host by invading cercariae. Detection of antibodies to this protein indicates exposure but not necessarily active infection.	55
ELISA using egg antigen (CEF6)	In areas of endemicity there was a positive correlation between egg intensity and ELISA value. In other areas, specificity was 90%; false-positive results may have been due to inapparent or cured infection.	19
APIA	Solid-phase alkaline phosphatase immunocapture assay for detection of human IgG antibodies to the alkaline phosphatase of <i>S. mansoni</i> adults was evaluated. The method appears to be specific for <i>S. mansoni</i> and is useful in areas of endemicity where mixed infections occur.	10
Immunoblot	Sm31/32 protein fraction is highly immunogenic; may be a useful serologic marker for diagnosing and differentiating between acute and chronic infection.	71
Fast dot-ELISA	C5C4 MAb is used for rapid and simple diagnosis; the 63-kDa circulating antigen was detected in 92% of 330 urine samples; the false-positive rate in 130 noninfected individuals was 16%.	4
Indirect hemagglutination combined with ELISA	Erythrocytes coated with <i>S. mansoni</i> adult worm antigens and ELISA using <i>S. mansoni</i> egg antigens; combined use of these two tests led to high degrees of sensitivity and specificity for <i>S. mansoni</i> , <i>S. haematobium</i> , and combined infections.	75
Antigen detection in urine or serum	Test provides a quantitatively more stable diagnosis of <i>S. mansoni</i> than fecal egg counts based on a single stool exam.	50
Antigen detection in fecal specimens	Compared with the Kato-Katz parasitologic exam, PCR has a sensitivity of 96.7% and a specificity of 88%.	52
Antigen detection in urine using dipstick or reagent strip test	Lateral flow on nitrocellulose strip; detection of CCA; sensitivity equal to CCA ELISA; specificity of 96%.	73
Antigen detection in urine using dipstick	Commercially available antigen capture dipstick; detection of CCA; sensitivity of 83% and specificity of 81%; may be too expensive for wide use (US \$2.60).	64

parasites develop to maturity and egg production. The mechanism of action may involve glutathione *S*-transferase, a detoxifying enzyme found in many helminths. Cure rates have been reported to be from 70 to 95%. Praziquantel damages the tegument of the worm, thereby exposing the antigens to parasite-specific antibodies. The use of immunoglobulins along with praziquantel has been proposed to increase the efficacy of treatment.

Although the exact mechanism by which praziquantel kills the parasite is not well understood, it is known that the immune response of the host plays an important role

in drug efficacy. It is possible that disease states of humans that lead to immunodeficiencies, such as infection with human immunodeficiency virus type 1 (HIV-1), may render praziquantel less effective in treating schistosomiasis. However, studies indicate that persons with HIV-1 infection can be treated effectively for schistosomiasis with praziquantel (30).

Repeated praziquantel therapy can lead to improvement of liver morbidity and prevention of hepatic fibrosis, even in a well-established focus of hyperendemic infection. These results were based on a parasitologic, clinical, and

ultrasonographic longitudinal study in a focus of hyperendemic *S. mansoni* infection. Support is also emphasized for programs that encourage people to seek examination and treatment on their own. This type of chemotherapy-based control strategy is called passive chemotherapy.

Reduced efficacy of praziquantel in treating human *S. mansoni* infections and infected animal models has been reported (27). Drug resistance to praziquantel has been demonstrated in the murine model, and there have been unsubstantiated field study reports of resistance. However, resistance to praziquantel in schistosomes is now considered a fact in strains selected in the laboratory. In at least two human populations in Senegal and Egypt with endemic infections, resistance or tolerance to praziquantel has been confirmed. Although the extent of the problem is unclear, it is important to determine the prevalence and significance of the problem and to develop alternate control strategies.

Oxamniquine. Oxamniquine, a nitroquinolone, is active only against *S. mansoni* infections and is very effective against the strains in the Americas and West Africa when given at 15 to 20 mg/kg of body weight. North and East African strains of *S. mansoni* are less sensitive to this drug, and doses of up to 60 mg/kg given over 2 to 3 days may be required to achieve the same results. The drug is more active against male than female worms and has little effect against immature worms. Side effects include abnormal electroencephalograms and dizziness. Oral treatment has reduced egg counts by 95%, with 70 to 100% cure rates. Despite being tolerant to praziquantel, a Senegal isolate of *S. mansoni* was fully susceptible to oxamniquine (17). Unfortunately, this drug is relatively expensive, making it more difficult to use in control programs, particularly if a higher dosage is required. Although mass therapy with this drug can lead to reduction of schistosomiasis morbidity, approximately 68% of patients do not show improvement in their condition (11). It is also important to remember that oxamniquine is contraindicated in pregnancy.

Summary. Patients who have been treated for schistosomiasis should be monitored posttherapy to determine the effectiveness of the treatment. Depending on the drug, follow-up stool or urine examinations may be needed for as long as 1 year posttherapy. It is not safe to assume that one course of therapy or disappearance of symptoms is indicative of cure. Optimal posttreatment reevaluation times have not been established. Patients, particularly those who were heavily parasitized, should be monitored for a reduction in the number of excreted and viable eggs within a few months of therapy.

For patients with secondary bacterial infections, appropriate antibiotics may also be needed to treat systemic infections. Patients suffering from severe Katayama fever and transverse myelitis may require steroid treatment.

A complete review of the management and therapy of schistosomiasis can be found in Table 17.3.

Epidemiology and Prevention

S. mansoni infections occur in western and central Africa, Egypt, Madagascar, and the Arabian peninsula. As a consequence of the African slave trade, the infection was established in the Western Hemisphere in Brazil, Suriname, Venezuela, and the West Indies. Human infections are nearly all derived from human sources, even though non-human primates, insectivores, marsupials, and rodents can carry the infection. The infection is transmitted by *Biomphalaria* sp., an aquatic snail.

The geographic distribution of the disease depends on the distribution of the intermediate snail hosts and the opportunity to infect humans and snails. Schistosomiasis is transmitted from infected people defecating or urinating in or near water where the appropriate snail host resides. Infections can persist indefinitely in humans. Most infected individuals have low worm burdens, but a few have very heavy infections. It is this latter group that probably makes the greatest contribution to the dissemination of schistosomiasis. The highest rates of infection have been found in children; the greatest cercarial exposure usually occurs in boys aged 5 to 10 years. Older children may have less recreational exposure but are more likely to be exposed while performing chores such as agricultural activities, washing dishes and clothes, and bathing younger siblings. Although adults also have less recreational exposure to water, they also have partial acquired immunity.

Information on the presence of cercariae in water is important when only one of many snails is infected yet capable of shedding enough cercariae to maintain high endemicity. The use of sentinel mice for this purpose is inaccurate, time-consuming, and costly. Filtration is also limited and is associated with many problems. A PCR assay for the detection of *S. mansoni* cercariae in water has been developed. The high sensitivity of this test permits the detection of a single cercaria; a single cercaria could be detected in repeated tests of water filtrates (22).

Studies indicate that there was little transmission of *S. mansoni* in Puerto Rico during the first half of the 1990s and confirm physician anecdotal data that no new infections have been seen during the past few years (24). Recent trends indicate that human schistosomiasis is disappearing from Puerto Rico (23a). The Puerto Rico Public Health Department reports that from 1990 through 26 September 2005, only 21 cases were reported. The last single case was in 2005 in a 69-year-old male from the east coast, this case probably being an "old" case. Although low transmission is still possible in Puerto Rico, data suggest that human schistosomiasis has been eliminated from this area. However, in other areas the news is not as good. The emergence of *S. mansoni* in Upper Egypt

Table 17.3 Management and therapy of schistosomiasis^a

Condition or disease manifestation	Approach	Comments
Schistosome cercarial dermatitis	Self-limited and may go undiagnosed; in severe cases, topical corticosteroids and parenteral antihistamines reduce symptoms	Other names include swimmer's itch, schistosome dermatitis, clam digger's itch, sawah itch, and koganbyo; symptoms will vary due to host susceptibility, schistosome type, and patient's previous exposure history
Katayama fever	Corticosteroids for life-threatening disease; therapy according to schistosome species	Tourists who returned home within a month of exposure; history of water contact, possible swimmer's itch, serum sickness-like disease are clues for possible schistosomiasis
Gastrointestinal disease	<i>S. mansoni</i> : Praziquantel (40 mg/kg) single dose or oxamniquine (15 mg/kg) single dose for adults (20 mg/kg for children); North and East Africa (60 mg/kg) over 2–3 days in 3 or 4 equally divided doses <i>S. japonicum</i> : Praziquantel (60 mg/kg) 2 or 3 doses in a single day Colonic polyps : Colonoscopy to confirm extent of disease; chemotherapy; surgery may be required for fibrotic obstructive bowel lesion; intussusception (barium enema should be used with care to avoid perforation); rectal prolapse/chemotherapy; anorectal fistulas/abscess, surgical drainage and antibiotic therapy	Many complications of intestinal granulomas and/or polyp disease are the same as for inflammatory bowel disease (Crohn's and ulcerative colitis); misdiagnosis could have serious sequelae due to potential use of steroid therapy Seen in 10–15% of some Middle Eastern populations; symptoms are those of focal granulomatous large bowel disease; may mimic chronic severe muco-hemorrhagic diarrhea; residual fibrotic scarring may lead to permanent partial bowel obstruction or wall deformation
Hepatosplenic disease	<i>S. mansoni</i> : Praziquantel or oxamniquine; ultrasonography to define extent of disease <i>S. japonicum</i> : Praziquantel; ultrasonography Hypersplenism : Therapy Ascites : Low-salt diet and diuretics Bleeding esophageal varices : Esophagoscopy to confirm diagnosis (transfusion and esophageal sclerotherapy; surgical shunt for portal hypertension in severe cases)	May be genetic predisposition to hepatosplenic syndrome; jaundice characteristically absent; liver cell function generally normal until terminal stages Moderate and generally tolerable to patient End-stage disease can involve massive ascites; usually irreversible Liver sonography can estimate degree of portal hypertension (measure distention of portal vein)
Urinary disease	Uncomplicated : Praziquantel (40 mg/kg) single dose; ultrasonography or intravenous pyelogram to detect silent obstructive disease Obstructive uropathy : Chemotherapy; may require surgery Urinary tract infection : Antibiotics plus anti-schistosomal therapy; pyelonephritis may require parenteral antibiotics Renal failure : Hemodialysis or renal transplantation Bladder cancer : Radical surgery, chemotherapy usually only palliative	Most infections are mild and asymptomatic Most lesions occur in lower third of ureters or bladder; pyelonephritis/gram-negative sepsis common Primarily gram-negative infections Bilateral ureteral obstruction common; may be accompanied by <i>Salmonella</i> bacteriuria and/or bacteremia Usually lags 10–20 yr behind the peak <i>S. haematobium</i> infection; bladder calcifications may resolve over years if the patient remains schistosome free
Cardiopulmonary disease	Larval pneumonitis : Self-limited course; may require short-course therapy with steroids if respiratory distress present Reactionary pneumonitis : Discontinue therapy until resolution; may require short-course therapy with steroids if respiratory distress is present Cor pulmonale : Antischistosome therapy; symptomatic therapy	Occurs days to weeks after heavy cercarial exposure; symptoms last 2–4 wk (marked eosinophilia) Löfller-like syndrome seen during therapy of heavy infections Heart affected after exposure to chronic abnormal pressure gradients; antischistosomal therapy prevents disease progression but does not lead to improvement

(continued)

Table 17.3 Management and therapy of schistosomiasis^a (continued)

Condition or disease manifestation	Approach	Comments
Central nervous system disease	Praziquantel therapy: steroids recommended to reduce inflammation and size of space-occupying lesions	
	Cerebral: Focal, generalized seizures	Most occur with <i>S. japonicum</i> (2–4% of cases); parietal lobe is the most common site
	Spinal: Transverse myelitis of various degrees	Most occur with <i>S. mansoni</i> , also <i>S. haematobium</i> ; lesions may be reversible
Miscellaneous	Salmonella-schistosome syndrome: Simultaneous anti-schistosomal and antibacterial therapy	Occurs most commonly in males 15–30 yr old; anti-biotic response is dramatic; disease remains if schistosome disease is not also treated
	Hepatitis B or C schistosome disease: Antischistosomal therapy; transmission precautions for hepatitis B or C	Prognosis more guarded with dual infections

^a Adapted from reference 65.

has not followed any particular pattern; however, the high prevalence detected in certain areas could be associated with the increasing abundance of the snail vector seen in the canals. Underreporting may also be associated with changing surveillance data. Water resource development projects involving the construction of artificial bodies of water and canals for irrigation have contributed to the extension of the disease. The migration of infected persons into virgin areas where suitable snail hosts reside also contributes to the spread of schistosomiasis. These two important factors make control programs difficult.

Schistosoma japonicum

Fujii in 1847 published the first clinical description of *S. japonicum* infections in his Katayama memoir. Katsurada in 1904 described the ova and adult worms that he detected in dogs, cats, and humans and named the parasite *S. japonicum*. Also known as the Oriental blood fluke, the parasite is confined to the Far East and has been separated from *S. mekongi*, a more recently described species also found in the Far East. There is enough genetic variation in *S. japonicum* strains isolated from different areas of endemic infection that there may be separate species.

Life Cycle and Morphology

In addition to infections in humans, *S. japonicum* infections can be found in many mammals exposed to infected water; thus, there are many reservoir hosts, in contrast to other major human schistosomes (Table 17.1). Fully embryonated eggs without an operculum (70 to 100 µm by 50 to 65 µm) are passed in the feces. The eggs are smaller and somewhat more spherical than those of *S. haematobium* and *S. mansoni*. Near one end of the egg is a minute lateral spine; this may be absent in some strains (Figures 17.14 and 17.15).

The adult worms resemble those of *S. haematobium* and *S. mansoni*; however, they lack integumentary tuberculations. *S. japonicum* adults are found in the radicles of the superior mesenteric vein draining the small intestine (Figure 17.16). The female worm may contain as many as 50 eggs at one time in the uterus. Because of the higher egg production (3,000 eggs per worm pair per day) and the smaller egg size, an infection with just a few worm pairs can be very serious because the eggs, free in the general circulation, can be filtered out in the liver, the lungs, and even the central nervous system. The miracidium, released from the egg on contact with water, must find a suitable snail host (*Oncomelania* spp.) to continue the life cycle. Cercariae of *S. japonicum* tend to attach themselves to the water surface film, where they remain unless disturbed.

Clinical Disease

The pathology caused by *S. japonicum* is similar to that caused by *S. mansoni* infections and may include cercarial dermatitis as the first sequence in the disease process (Table 17.4). Although the severity is dependent on the worm burden, the disease has a poor prognosis because of the higher egg production capacity of *S. japonicum* females and the smaller eggs. *S. japonicum* infections have been associated with hepatocellular carcinoma and colorectal cancer. The mechanism of this schistosome-associated carcinogenic enhancement is unknown. The adult worms also have a greater tendency to be found in ectopic sites. Although adult worms have never been detected in the brain, cerebral schistosomiasis is a distinct syndrome that occurs with *S. japonicum* infections. The entire intestinal tract may be involved, but the large intestine is often the primary site and the disease is more severe there.

Acute Disease: Katayama Fever. Acute schistosomiasis (Katayama fever) is associated with heavy primary

Figure 17.14 *Schistosoma mansoni* (top), *S. haematobium* (middle), and *S. japonicum* (bottom) eggs. Note how much smaller the *S. japonicum* egg normally is than those of the other two species, and note the small size of the lateral spine. (Illustration by Nobuko Kitamura.)

Figure 17.15 *Schistosoma japonicum* eggs. Note the small lateral spine.

fibrosis and stenosis may occur with thickening of the mesentery.

Hepatosplenic Disease. Eggs that do not reach the intestinal lumen may be trapped or swept up by the portal blood flow. The eggs tend to accumulate in the venules within the portal triads, especially the left lobe; this is followed by granulomatous inflammation, fibrosis, venous obstruction, portal hypertension, and splenomegaly. Hepatosplenomegaly results from the granulomatous response surrounding the eggs. Although splenomegaly generally occurs during the early stages of chronic disease, the enlargement is due to tissue hyperplasia rather than granulomatous inflammation; thus schistosome eggs are rarely found in the spleen. In China, splenectomy is frequently used for severe hypersplenism (56).

After extended chronic disease, gross periportal fibrosis occurs with portal hypertension and secondary

infections and the initiation of egg production. The signs and symptoms include high fever, nocturnal fever peaks, coughing, generalized muscle pain, headache, hepatomegaly, lymphadenopathy, eosinophilia, and dysentery. Splenomegaly also occurs in approximately one-third of the patients, while all patients have eosinophilia. Diffuse pulmonary infiltrates are found; some patients have signs of meningoencephalitis. Generally, disease onset occurs about 40 or more days after exposure to a first infection or a large infection (56).

Intestinal Disease. As egg clusters accumulate, mucosal inflammation, hyperplasia, ulceration, microabscess formation, blood loss, and pseudopolyposis may occur. Lower abdominal pain is common and may be colicky and in the left lower quadrant. Diarrhea alternating with constipation is also common, with either visible blood, occult blood, or both. In severe chronic disease, bowel

Figure 17.16 *Schistosoma japonicum* paired adult male and female in a mesenteric vein. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Table 17.4 Pathogenesis, pathology, and symptoms seen with *S. japonicum* infection

Stage of infection	Comments
Incubation (migration, maturation)	
Dermatitis	Associated with penetration of cercaria; urticarial rash; diarrhea at the end of this period
Lungs	Traumatic infiltrative changes, at times with hemorrhages, local accumulation of eosinophils, epithelioid cells, giant cells around pulmonary blood vessels (in wake of migrating larvae)
Liver	Acute hepatitis during larval growth in intrahepatic portal blood vessels
Small intestine	Hyperemia in wall of small intestine following arrival and during maturation of worms in superior mesenteric venules
Blood	Marked increase in number of circulating eosinophils
Egg deposition and extrusion	
Small intestine	Trauma with hemorrhage as eggs laid by female worms escape from venules through intestinal submucosa and mucosa into intestinal lumen; may be profuse dysentery; acute attack subsides in 3–10 wk; pseudotubercles form around eggs; repair occurs with scar tissue formation; giant cells develop within pseudotubercles, which become transformed to fibrous nodules
Blood	Blood picture changes from leukocytosis and hypereosinophilia to that of secondary anemia
Liver, spleen, lymph nodes	Liver increases in size as result of lesions around eggs; spleen becomes congested, fibrous reticulum increases, becomes greatly enlarged; mesenteric lymph nodes lose active lymphoid tissue
Tissue proliferation and repair	
Liver, spleen	Liver gradually decreases in size as parenchyma becomes replaced by scar tissue; spleen continues to enlarge; thoracic viscera are pushed upward; patient is weak with marked dyspnea on slight exertion; dilatation of superficial veins of abdomen and thorax is common
Intestine	Intestinal wall becomes thickened and fibrosed; papillomata develop on mucosa
Other problems	Ascites may be present; physical and mental retardation may occur in children; anemia is more pronounced
Blood vessels	Mesenteric and portal vessels become thrombosed; portal fibrosis due to egg deposition around the portal triads; severe fibrosis with white and hard tissue, frequently referred to as Symmer's fibrosis or pipe-stem fibrosis (fibro-obstructive hepatic schistosomiasis)
Cerebral disease	Patients classified as acute, chronic with granulomas or diffuse lesions, psychotic, or as having portal system encephalopathies; 2–4% (in some areas, this figure is higher) of all patients with <i>S. japonicum</i> schistosomiasis have acute or chronic cerebral involvement, including epileptic seizures

esophageal varices. Histology reveals wide bands of fibrous tissue extending along the portal tracts, hence the term “pipe-stem fibrosis,” also seen with *S. mansoni* infections. These sequelae are more serious with *S. japonicum* infections, due primarily to the high daily egg production by the female worms. The parenchymal form of hepatic fibrosis occurs most commonly with *S. japonicum* infection and may be a subclinical find in groups who have been treated repeatedly and undergone overt liver disease resolution.

Central Nervous System Disease. Although not every patient with eggs in the central nervous system is symptomatic, symptoms can include Jacksonian convulsions and grand mal seizures. The use of praziquantel has led to improvement in over 75% of the cases in which it has been used. It is also unclear why Chinese schistosomiasis is associated with ectopic cerebral lesions while

African disease tends to be associated with ectopic spinal lesions.

Cancer and *S. japonicum* Infection. The incidence of colorectal cancer and *S. japonicum* infection correlates with the prevalence, intensity, and length of inflammatory bowel symptoms. This correlation has been reported from both China and Japan. In a study published in 2005 from rural China, schistosomiasis was thought to be responsible for 24% of colon cancers and 27% of liver cancer within that study group (53).

In a study investigating the relationship between schistosomiasis due to *S. japonicum* and liver cancer and cirrhosis in an area where no cases of schistosomiasis have been reported since 1978, schistosome eggs were found in the livers of newly deceased liver cancer and cirrhosis patients. The chronic effect of *S. japonicum* could contribute to the high mortality rate due to liver cancer in this area.

However, there are certainly other issues that need to be considered, such as HBV, HCV, and alcohol intake (67).

Viral, Bacterial, and Alcohol Associations. Although hepatitis B has been reported to be more frequent in patients with schistosomiasis, the evidence is not that strong. Chronic bacteremic infections with *Salmonella* spp. have been associated with *S. haematobium*, *S. japonicum*, and *S. mansoni* infections (65). Common features of this association between *Salmonella* and *Schistosoma* infections include a long history of recurrent febrile illness, frequent isolation of *Salmonella* spp. from the blood, and chronic active schistosomiasis. The *Salmonella-Schistosoma* infection association is seen most frequently in males between the ages of 15 and 30 years. If the underlying schistosome infection is not treated, the *Salmonella* infection will continue to recur. However, this association appears to be rare for *S. japonicum* compared with the other schistosome species. There is evidence that there may be some association between alcoholic cirrhosis and hepatic fibrosis; however, details of specific mechanisms for this association are minimal.

Diagnosis

Schistosomiasis should be suspected in individuals who have had significant contact with water in areas of endemic infection. Symptoms of acute schistosomiasis include fever, diarrhea, abdominal pain, weight loss, and eosinophilia. Symptoms of chronic disease include chronic diarrhea, abdominal pain, and hepatomegaly or hepatosplenomegaly.

Diagnostic Procedures. Specific diagnosis of schistosomiasis by detection of eggs in stool specimens is possible only after egg production has begun. Eggs may be found in feces as early as 5 weeks after infection. The ease of egg detection depends on the worm burden and the duration of the infection. Patients with low worm burden or old (chronic) infections may have very few eggs in the feces or urine, and the infections are often not diagnosed because of the limits of sensitivity of examination techniques. Multiple stool examinations should be performed for any individual suspected of having schistosomiasis. Occasionally eggs of *S. japonicum* or *S. mansoni* are detected in the urine. The eggs of *S. japonicum* are more spherical than those of *S. mansoni* or *S. haematobium*; they measure 70 to 100 μm by 50 to 65 μm (Figures 17.14 and 17.15). A minute lateral spine may be found at one end of the egg; however, it is absent in some strains of *S. japonicum*.

Data from China suggest that a single Kato-Katz smear may be quite adequate for detecting moderately to heavily infected individuals (>100 eggs/g of stool); however,

for estimating the true prevalence of infection within a community or for obtaining an accurate estimate of egg excretion, multiple Kato-Katz smears are recommended. It should be noted that large variations in egg counts and the lack of sensitivity of the Kato-Katz method, particularly in light and moderate infections, have been reported (81). Eggs also appear to be nonrandomly distributed in stool specimens between the center and surface of the stool; stirring the specimen prior to sampling decreased the count variability. Direct detection or concentration techniques can be used to detect eggs in stool. Direct microscopic examination of stool smears is not very sensitive but may be useful for screening purposes. The Kato thick smear is a simple and sensitive quantitation technique that has been used successfully in the field.

The zinc sulfate concentration technique is not recommended for schistosome eggs. The eggs will rupture and do not float but instead are found in the sediment. The formalin-ethyl acetate technique is recommended for concentrating eggs; however, because it involves fixation, it cannot be used to detect egg viability.

In chronic infections in which the worm burden is light, hatching tests can be performed. The miracidium hatching test has been widely used in China for many years; however, only 50 to 70% of the eggs will hatch, thus presenting problems for detection of light infections. The stool specimens are diluted with nonchlorinated water in a sedimentation flask or a beaker. The sides of the flask or beaker are covered with aluminum foil to prevent light from passing through. A light source is used to project a perpendicular light beam through the water at the top. Miracidia that hatch from the live eggs become concentrated in the light and can be detected swimming around. This motility can easily be observed with a hand lens. Aliquots of the surface water can be transferred to a small petri dish and observed under a dissecting microscope for miracidia. Observation periods should be frequent because of the limited life span of the miracidia. Ideally, observations should be made every 30 min over a period of 4 h. The hatching test is designed to mimic the conditions in nature with spring water and sunlight.

Biopsy Specimens. Although rectal biopsy specimens can be examined, this approach is neither practical nor convenient for population surveys. Also, it is difficult to differentiate dead from living eggs; these findings can lead to excessive therapy.

Sonography. Infection with *S. japonicum* currently affects about 1 million people, mainly in the Philippines and China. Individuals with chronic infection may develop liver fibrosis with portal hypertension, potentially resulting in life-threatening upper gastrointestinal hemorrhage.

Apparently, there is no clear evidence about which sonographic features of infection with *S. japonicum* are related to portal hypertension and thus to a more likely fatal outcome. Using Doppler sonography, a recent study demonstrated that measurements of portal perfusion are a prognostic indicator of the risk of gastrointestinal hemorrhage and overall survival of these patients (31). This study also confirmed the suitability of Doppler sonography for research under tropical field conditions.

Antibody Tests. A large number of serologic tests have been used in the diagnosis of schistosomiasis (69); however, most have not been particularly useful because of cross-reactions with other helminth infections, continuation of elevated titers long after successful treatment, and slow immunologic response of the host. Because of the complex life cycle, a large number of antigens have been used in serologic tests. Only a few have been useful. The most frequently used tests are the circumoval precipitin test, the cercaria-Hullen reaction, the indirect fluorescent-antibody test, the indirect hemagglutination test, and ELISA (57, 69). See Algorithm 17.1.

ELISA methods using soluble adult worm or egg antigens for the detection of antibodies have been used as screening tests, and infection has then been confirmed by the EITB test (69). Individuals infected with schistosomes have elevated IgE and IgG4 responses, as in those with other helminthic infections. Few studies have investigated the persistence of antibodies over time after therapy (69). It is possible that high titers posttherapy reflect treatment failure and reinfection. In a more recent study, the overall diagnostic effectiveness of the keyhole limpet hemocyanin dot-ELISA and the soluble egg antigen dot-ELISA for the detection of *S. japonicum* infection in regions of China with endemic infection was 97 and 92%, respectively (38).

ELISA has also been used to detect circulating schistosome antigens in the serum and urine of infected patients and may be the preferred method of diagnosis (51, 76). In addition to diagnosis of infection, antigen levels have been used to assess disease severity in terms of intensity of infection and to monitor the efficacy of therapy (51, 76). Individuals treated with praziquantel experience a rapid clearance of CAA and CCA; however, with other therapeutic drugs, clearance may take much longer.

Antigen Tests. The sensitivity of antigen tests is usually higher than that of routine fecal examinations for eggs; however, the specificity is lower. A rapid one-step enzyme immunoassay has been reported to have a sensitivity of 95% and a specificity of 100% (56). Unfortunately, antigen detection methods are not widely used in China. Limitations include the cost per case detected, complicated

protocols, expensive reagents with a short shelf life, and a lack of complete understanding of the mechanics of circulating schistosome antigens. However, the potential advantages of the simple dipstick test(s) may lead to improved antigen testing, and the tests may become more widely available.

KEY POINTS—LABORATORY DIAGNOSIS

Schistosoma japonicum

1. Eggs cannot be detected in stool until the worms mature (may take 5 to 6 weeks after initial infection).
2. In very light or chronic infections, eggs may be very difficult to detect in stool; therefore, multiple stool examinations may be required. Biopsy and/or immunologic tests may be helpful in diagnosing infection in these patients.
3. The zinc sulfate flotation concentration method should not be used, since the eggs do not float; the sedimentation method is recommended.
4. It may be necessary to tap the coverslip to move the eggs; the small lateral spine may be difficult to see if debris is deposited on the egg (this is common).
5. Occasionally, eggs of *S. japonicum* are detected in the urine.
6. Patients who have been treated should have follow-up ova and parasite examinations for up to 1 year to evaluate treatment.
7. In active infections, the eggs should contain live or mature miracidia. Examination for the confirmation of flame cell activity must be performed on fresh specimens; no preservatives can be used prior to this test or the hatching test.
8. During the hatching test, the light must not come too close to the surface of the water, since excess heat can kill the liberated larvae. Also, the water should be examined about every 30 min for up to 4 h.

Treatment

Praziquantel is the drug of choice for treating infection with *S. japonicum*; the adult and pediatric doses are the same (60 mg/kg/day in three doses within 1 day). Side effects, which are usually mild and transient, include abdominal discomfort, dizziness, drowsiness, headache, fever, and loose stools. These effects usually disappear within 48 h. In heavily infected individuals, the side effects, although transient, may be very severe (62). Split doses have been recommended for treating heavy infections, but this may be a concern for population-based therapy, where individuals may not present themselves for follow-up therapy. Praziquantel has little effect on

immature stages of the parasite, and this affects the cure rates as the immature parasites develop to maturity and egg production. The mechanism of action may involve glutathione *S*-transferase, a detoxifying enzyme found in many helminths. Cure rates have been reported to be from 70 to 95%. Praziquantel damages the tegument of the worm, thereby exposing the antigens to parasite-specific antibodies. The use of immunoglobulins along with praziquantel has been proposed to increase the efficacy of treatment.

Epidemiology and Prevention

S. japonicum infections occur in the Far East, including China, Indonesia, Japan, and the Philippines. There is a focus of enzootic infection in Taiwan; however, there is no evidence of locally acquired human infections. In addition to humans, numerous animals (cats, cattle, dogs, goats, horses, sheep, pigs, mice, rats, and water buffaloes) are naturally infected in many areas of endemic infection. The infection is transmitted by *Oncomelania* snails, which are operculated, amphibious, and able to survive prolonged periods of desiccation. On contact with water, the snails become active again and shed infective cercariae. The widespread use of night soil as fertilizer significantly increases the occupational hazards of the disease for rice farmers. There is evidence that congenital *S. japonicum* infection of pigs can occur if sows are infected during mid to late pregnancy; this may have implications not only for pigs but also for other mammalian hosts of schistosomes, including humans (77). Praziquantel tends to be highly effective against *S. japonicum* in pigs without causing pathologic side effects in the liver.

The geographic distribution of the disease depends on the distribution of the intermediate snail hosts and the opportunity to infect humans and snails. Schistosomiasis is transmitted from infected people defecating or urinating in or near water where the appropriate snail host resides. Infections can persist indefinitely in humans. Most infected individuals have low worm burdens, but a few have very heavy infections. It is the latter group that probably makes the greatest contribution to the dissemination of schistosomiasis. The highest rates of infection have been found in children; the greatest cercarial exposure usually occurs in boys aged 5 to 10 years. Older children may have less recreational exposure but are more likely to be exposed while performing chores such as agricultural activities, washing dishes and clothes, and bathing younger siblings. Although adults also have less recreational exposure to water, they also have partial acquired immunity.

Dongting Lake is located in Hunan Province in southern China. Asian schistosomiasis has been endemic in this region for centuries, with a significant impact on the public health of the local population. Even with dedicated

control programs, the snail habitats are huge (1,768 km²) and are increasing at a rate of 34.7 km² annually. It is anticipated that the construction of the Three Gorges Super Dam, the largest engineering project ever undertaken and due for completion in 2009, will substantially increase the range of the snail habitats and hence increase the number of new cases of schistosomiasis. In many areas, human reinfections after praziquantel therapy remain very high (up to 20%), primarily due to occupational water contact. Efforts aimed at control or eradication of the infection in the future will be very complex (39).

Domestic cattle and buffalo are the most important reservoir hosts in China, with humans and animals frequently coming in contact at water sources, which lead to increased transmission. Although praziquantel is used for periodic treatment of bovines, the animals are prone to reinfection.

Vaccine Development. The development of an effective vaccine against *S. japonicum* has been under way for some time. Selection and manufacture of the final product will be difficult, particularly regarding funding issues related to Good Manufacturing Practice scale-up for extensive veterinary coverage and to support any future human trials. The final product will probably be a mixture of several molecules and will be used in an integrated program of control that would also include health education and targeted chemotherapy (42). A number of immunogens have been identified which could be used for vaccines, and vaccine development is ongoing (23, 41, 79). A number of other initiatives are also under way and include newer drugs, improved diagnostics, disease risk prediction, and transmission control using satellite-based remote sensing (70).

Schistosoma mekongi

Schistosomiasis resembling the disease caused by *S. japonicum* has been known to exist in the lower Mekong River basin since 1957. Further investigation has shown the etiologic agent to be a new species, *S. mekongi*; this species is responsible for most of the cases reported from mainland Indochina and has a prevalence of up to 25% in some areas.

Life Cycle and Morphology

Dogs as well as humans may serve as definitive hosts (Table 17.1). The adult worms are found in the mesenteric veins and resemble those of *S. japonicum*, although they lack tuberculations. Egg production occurs within 4 to 6 weeks after infection, and adult females may have many eggs in the uterus. The eggs of *S. mekongi* are similar in shape to those of *S. japonicum* but are smaller. They

are subspherical, with a size range of 30 to 55 μm by 50 to 65 μm , and they have a small lateral spine near one end (Figure 17.17). Fully embryonated eggs without an operculum are passed in the feces. When the egg comes in contact with freshwater, the miracidium is released. The miracidium must infect the aquatic snail *Lithoglyphopsis aperta* to continue the life cycle.

Clinical Disease

Few clinical studies have been conducted in areas of endemic infection; however, the pathologic effects of *S. mekongi* infections appear similar to those of other human intestinal schistosomes. *S. mekongi* appears to be no more or less pathogenic than *S. japonicum*, with hepatosplenomegaly and portal venous hypertension being the most important serious sequelae (Table 17.5). Brain involvement of the infection has also been confirmed (26).

Diagnosis

Schistosomiasis should be suspected in individuals who have had significant contact with water in areas of endemic infection, particularly along the Mekong River in Laos and Cambodia. Symptoms of acute schistosomiasis include fever, diarrhea, abdominal pain, weight loss, and eosinophilia. Symptoms of chronic disease include chronic diarrhea, abdominal pain, and hepatomegaly or hepatosplenomegaly.

Diagnostic Procedures. Specific diagnosis of schistosomiasis by detection of eggs in stool specimens is possible only after egg production has begun. Eggs may be found in feces as early as 5 weeks after infection. The ease of egg detection depends on the worm burden and the duration of the infection. Patients with low worm burden or old (chronic) infections may have very few eggs in the feces or urine, and the infections are often not diagnosed because of the limits of sensitivity of examination techniques. Multiple stool examinations should be performed for any individual suspected of having schistosomiasis. The eggs

Figure 17.17 *Schistosoma mekongi* eggs. Note the subspherical shape and smaller size than *S. japonicum* eggs.

of *S. mekongi* are more round and tend to be smaller than those of *S. japonicum*; they measure 50 to 65 μm by 30 to 55 μm (Figure 17.17). A minute lateral spine is found at one end of the egg; however, it may be very difficult to see.

Direct detection or concentration techniques can be used to detect eggs in stool. Direct microscopic examination of stool smears is not very sensitive but may be useful for screening purposes. The Kato or Kato-Katz thick smears are simple and sensitive quantitation techniques that have been used successfully; however, sensitivity is lacking in light infections.

The zinc sulfate concentration technique is not recommended for schistosome eggs. The eggs rupture and do not float but instead are found in the sediment. The formalin-ethyl acetate technique is recommended for concentrating eggs; however, because it involves fixation, it cannot be used to detect egg viability.

For diagnosis of chronic infections in which the worm burden is light, hatching tests can be performed. See chapter 28 and the discussion under *Schistosoma mansoni*.

Antibody Tests. A large number of serologic tests have been used in the diagnosis of schistosomiasis (69); however, most have not been particularly useful because of cross-reactions with other helminth infections, continuation of elevated titers long after successful treatment, and slow immunologic response of the host. Because of the complex life cycle, a large number of antigens have been used in serologic tests. Only a few have been useful. The most frequently used tests are the circumoval precipitin test, the cercaria-Hullen reaction, the indirect fluorescent-antibody test, the indirect hemagglutination test, and ELISA (57, 69). See Algorithm 17.1.

ELISA methods using soluble adult worm or egg antigens for the detection of antibodies have been used as screening tests, and infection has been confirmed by the EITB test (69). Individuals infected with schistosomes have elevated IgE and IgG4 responses, as in those with other helminthic infections. Few studies have investigated the persistence of antibodies over time after therapy (69). It is possible that high titers posttherapy reflect treatment failure and reinfection.

The dipstick dye immunoassay was developed in China for the detection of antibodies against *S. japonicum*. This assay has also been tested in the diagnosis of *S. mekongi* infections in Cambodia and Laos. When testing Cambodians, the sensitivity was 97.1%; when testing patients from Laos, the sensitivity was 98.6%. Cross-reactivity was found in patients infected with *Opisthorchis viverrini*; interpretation may therefore be more difficult in areas where both *S. mekongi* and *O. viverrini* are endemic (82).

Table 17.5 Distribution of infection and morbidity due to *Schistosoma mekongi* in northern Cambodia

Information	Comments
Study population 1	Household surveys in villages on east and west banks of Mekong River (1,396 participants)
Diagnostic method	Single stool examination (Kato-Katz smear)
Overall infection prevalence	49.3%
Infection intensity	118.2 eggs/g of stool
Prevalence and intensity distribution	No differences between east and west shores of Mekong (see below)
Morbidity	Severe morbidity common; hepatomegaly (48.7%), splenomegaly (26.8%), visible diverted circulation (7.2%), ascites (0.1%); significantly more hepatomegaly, splenomegaly, diverted circulation seen on west bank
Prevalence details	West bank, 71.8%; east bank, 71.9%; age group most affected was 10–14 yr; west bank, 172.4 eggs/g; east bank, 194.2 eggs/g
Peak age group (10–14 yr)	West bank, hepatomegaly (88.1%); east bank, hepatomegaly (82.8%)
Study population 2	20 primary schools on east and west banks (2,391 participants, age 6–16 yr)
Diagnostic method	Single stool examination (Kato-Katz smear)
Overall infection prevalence	40.0% (range 7.7–72.9% per school)
Infection intensity	110.1 eggs/g of stool (range 26.7–187.5 eggs/g per school)
Prevalence and intensity distribution	Significantly higher in schools on the east bank
Morbidity	Severe morbidity common; hepatomegaly (55.2%), splenomegaly (23.6%), visible diverted circulation (4.1%), ascites (0.5%), reported blood (26.7%) and mucus (24.3%) in stool; significantly more hepatomegaly, splenomegaly, diverted circulation, and blood in stool in schools on the east bank
Prevalence details	No differences in sex for prevalence and intensity of infection or prevalence of hepatomegaly; boys more likely to have splenomegaly, ascites, and bloody stools; overall prevalence and intensity of infection highly associated in this study population

Antigen Tests. ELISA has also been used to detect circulating schistosome antigens in the serum and urine of infected patients and may be the preferred method of diagnosis (5, 51, 76). In addition to diagnosis of infection, antigen levels have been used to assess disease severity in terms of intensity of infection and to monitor the efficacy of therapy (51, 76). Individuals treated with praziquantel experienced a rapid clearance of CAA and CCA; however, with other therapeutic drugs, clearance may take much longer.

KEY POINTS—LABORATORY DIAGNOSIS

Schistosoma mekongi

1. Eggs cannot be detected in stool until the worms mature (may take 4 to 6 weeks after initial infection).
2. In very light or chronic infections, eggs may be very difficult to detect in stool; therefore, multiple stool examinations may be required. Biopsy and/or immunologic tests may be helpful in diagnosing infection in these patients.
3. The zinc sulfate flotation concentration method should not be used; the sedimentation method is recommended.

4. It may be necessary to tap the coverslip to move the eggs; the small lateral spine may be difficult to see if debris is deposited on the egg (this is common).
5. These eggs tend to be more round and are smaller than those of *S. japonicum*.
6. Patients who have been treated should have follow-up ova and parasite examinations for up to 1 year to evaluate treatment.
7. In active infections, the eggs should contain live or mature miracidia. Examination for the confirmation of flame cell activity must be performed on fresh specimens by using the wet mount or hatching test; no preservatives can be used prior to the wet mount examination or the hatching test.
8. During the hatching test, the light must not come too close to the surface of the water, since excess heat can kill the liberated larvae. Also, the water should be examined about every 30 min for up to 4 h.

Treatment

Praziquantel is the drug of choice for treating infection with *S. mekongi*; the adult and pediatric dose is the same

(60 mg/kg/day in three doses within 1 day). Side effects may include abdominal discomfort, dizziness, drowsiness, headache, fever, and loose stools; however, these effects usually disappear within 48 h. In heavily infected individuals, the side effects may be more severe. Split doses have been recommended for treating heavy infections, but this may be a concern for population-based therapy, where individuals may not present themselves for follow-up therapy. Praziquantel has little effect on immature stages of the parasite. Cure rates have been reported to be from 70 to 95%. Praziquantel damages the tegument of the worm, exposing the antigens to parasite-specific antibodies. In treating the patient with brain involvement mentioned above, the response to praziquantel was excellent but repeated courses of corticosteroid therapy were required to suppress recurring neurologic symptoms (26).

Epidemiology and Prevention

S. mekongi infections occur in the Mekong River basin in Cambodia, Laos, and Thailand. Dogs and rodents also harbor the infection, which presents a problem for prevention of the spread of infection. The snail *Lithoglyphopsis aperta*, a member of the family Hydrobiidae, is aquatic, lives on solid debris in water, has a limited distribution, and is responsible for transmission of the disease. Although the snail host is sensitive to common molluscicides, control measures have not been undertaken on a concerted basis.

A baseline epidemiologic survey of *S. mekongi* was conducted along the Mekong River in northern Cambodia; this comprehensive study documents for the first time the public health importance of schistosomiasis mekongi in this area and the high level of morbidity associated with the infection (Table 17.5) (63). Schistosomiasis control in both Laos and Cambodia was based on universal treatment campaigns and resulted in a dramatic decrease of the prevalence of the infection and in morbidity control. However, even if the disease and the infection have been satisfactorily controlled, transmission still occurs, and in very limited areas the prevalence reaches rates of more than 15%. Today, 60,000 people are estimated to still be at risk of infection in Laos and about 80,000 are at risk in Cambodia.

Schistosoma haematobium

Urinary schistosomiasis was common in the Nile River valley and has been found during examination of the kidneys of Twentieth Dynasty Egyptian mummies. Bilharz in 1851 documented the disease when he recovered adult worms from the veins of autopsy cadavers. Leiper in 1915 definitively proved the existence of two separate species,

S. haematobium and *S. mansoni*, which until that time had been confused with one another.

Life Cycle and Morphology

Humans are the only significant reservoir hosts of *S. haematobium* (Table 17.1). Fully embryonated eggs without an operculum (112 to 170 μm by 40 to 70 μm) escape from the body in the urine. The eggs are light yellowish brown and contain a conspicuous terminal spine (Figures 17.14 and 17.18).

The adult male worm contains minute integumentary tuberculations, smaller than those found on adult *S. mansoni* males. *S. haematobium* adults reside in the vesical and pelvic plexuses of the venous circulation. The adult female can contain 20 to 100 eggs in the uterus at one time. In addition to the vesical and pelvic plexuses, oviposition may occur in the rectal venules (Figure 17.19). To maintain the life cycle, the miracidium must find a suitable snail host (*Bulinus* sp.) when it is released from the egg in freshwater. The immature larval worms, after reaching the liver, may migrate via the inferior mesenteric veins to the rectal vein in order to mature. However, they most commonly migrate through the hemorrhoidal and pudendal veins to the vesical and pelvic plexuses. Within 3 months of exposure to cercariae, egg production begins.

Clinical Disease

Urogenital Disease. Light infections with urinary schistosomiasis usually produce no symptoms; however, in early disease there may be dysuria and hematuria due to cystitis from deposited eggs. Depending on the worm burden, symptoms may include dysuria, frequency, and terminal or total hematuria. Hematuria is so common that in some areas of endemic infection this phenomenon was considered to be analogous to menarche in girls (6). Symptoms are usually not seen for 3 to 6 months and

Figure 17.18 *Schistosoma haematobium* eggs. Note the terminal spine and slight size variations.

Figure 17.19 *Schistosoma haematobium*. (Upper) Egg in the appendix. Note the terminal spine. (Lower) Eggs in a rectal biopsy specimen. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*.)

may take a year or more to develop. Physical examination is usually normal, but urinalysis may reveal many red blood cells and a few white blood cells on microscopic examination; reagent strip results may indicate hematuria and proteinuria. Chronic disease may lead to major diseases, including obstructive uropathy, chronic bacteriuria, bladder carcinoma, and bladder calcification (Table 17.6).

Eggs are most highly concentrated in the tissues of the bladder and lower ureter (Figures 17.20 and 17.21). As the eggs become trapped in the tissues, granulomas and pseudoabscesses form, leading to fibrosis and ulceration. With extensive fibrosis, the bladder loses its contractility. The urethra frequently is occluded because of hyperplasia, polyp formation, and discharge of purulent debris plugs from the bladder. The ureters are also frequently involved, and obstruction can cause urine reflux, hydronephrosis, retrograde infections, and renal failure. Heavy infections in males may involve the penis, resulting in elephantiasis due to blockage of the scrotal lymphatics by egg deposition. Detection of *S. haematobium* eggs in 43% of semen samples with increased levels of eosinophil

cationic protein suggests that the male genital organs are frequently affected (37).

Up to 75% of women with urinary schistosomiasis have *S. haematobium* eggs in the genitalia; urinary schistosomiasis is associated with sandy patches in the lower genital tract. Eggs have also been detected in biopsy specimens from vaginal mucosa. Female genital schistosomiasis (FGS) is often associated with eggs in the cervix, vagina, and/or vulva, as seen during examination of a wet cervical biopsy specimen crushed between two glass slides. There is significant correlation between the size of the genital lesions and the number of eggs per square millimeter of crushed tissue. Women with FGS also tend to have more tumors in the vulva than do women with schistosomiasis limited to the urinary tract (35). In one study, only 43% of the patients with FGS had hematuria. Also, since FGS frequently exists in women with scanty or no egg excretion in the urine and since this disease represents both an individual and public health hazard in areas of endemic infection, mass treatment targeted to women of childbearing age should be a consideration (49). *S. haematobium* eggs have been associated with homogeneous yellow sandy patches, mucosal bleeding, and abnormal blood vessels. However, the finding of eggs was not a predictor for ulcers, papillomata, leukoplakia, polyps, or cell atypia (34). Genital pathology due to sequestered *S. haematobium* ova is partially reversible 2 to 9 weeks after the adult worms have been killed by praziquantel. A reduction in inflammatory responses can be detected in histologic sections and vaginal lavage fluid. However, these sandy patch lesions associated with contact bleeding and vessel abnormalities may be refractive to treatment for up to 12 months and may be an important risk factor for potential acquisition and transmission of HIV (33).

Obstructive Uropathy. Egg deposits in the ureter walls are the general causes of obstructed urinary flow; conditions leading to obstruction include polypoid patches, fibrosis, ureteritis cystica, calculi, and the total number of eggs present. Often these patients remain asymptomatic other than having symptoms related to cystitis or pain from the ureters.

Bladder Calcification. Calcified eggs produce the typical image, which consists of confluent sandy patches as seen in Figure 17.21 (left). The tissues of the bladder are not calcified and may continue to function normally; however, the visual radiologic picture suggests a heavy infection. Calcified eggs can also be seen in the ureters and seminal vesicles and less often in the colon.

Bladder Carcinoma. Carcinoma of the bladder has been frequently noted in patients infected with *S. haematobium*.

Table 17.6 Disease manifestations seen with *Schistosoma haematobium* infection

Disease manifestation	Comments
Obstructive uropathy	Hydronephrosis, hydroureter, pyelonephritis, renal failure often silent clinically but can be demonstrated by intravenous pyelogram, ultrasonography, or renogram function testing; most lesions occur in lower third of ureters or bladder
Pyelonephritis	Secondary to obstruction; gram-negative sepsis; may be the leading cause of mortality in urinary disease
Renal failure	Bilateral ureteral obstruction common; may be the direct result of obstruction, pyelonephritis, or ureterovesicular urinary reflux
Chronic bacteriuria	Infection rates up to 5% in schoolboys with <i>S. haematobium</i> infection; coliforms are responsible, with <i>Salmonella</i> being the most common in some studies; treatment usually unsuccessful unless schistosome infection is also treated and schistosomal mucosal lesions are eliminated
Bladder carcinoma	Bladder irritation, gross hematuria, weight loss, metastasis (inguinal, femoral, and retroperitoneal lymph nodes) tend to lag 10–20 yr behind age at which <i>S. haematobium</i> infection peaks; most cases diagnosed in patients aged 40–49 yr; biopsy is the usual method of confirmation; urinary cytology may be helpful
Bladder calcification	The “fetal head” sign is seen in abdominal X rays and is caused by calcium deposits around schistosome eggs in the bladder and uterine walls (Figure 17.20); sonography can also be used to see calcification in the bladder walls; although bladder loses contractility due to fibrotic walls, it does not become rigid; calcification resolves over years if patient remains free of schistosomiasis
Cutaneous disease	Has been previously reported but is an unusual presentation; skin lesions, appearing 3 yr after exposure, have been seen as the only manifestation of schistosomiasis; routine biopsy confirmed infection; awareness of this infection when evaluating patients with unusual skin lesions who have traveled in areas of endemicity is recommended (12)
Other body sites	Cerebral schistosomiasis has also been reported (49)

Many factors have been suggested as agents promoting schistosome-associated bladder cancer (Table 17.7). *N*-Nitroso compounds in association with secondary bacterial infections of the urinary tract may contribute to the high prevalence of bladder cancer (44). Bladder cancer is the most prevalent cancer in Egyptians (Figure 17.21). Many of the tumors involve the posterior wall of the bladder and are noted to occur more frequently in males than in females. The extent of *S. haematobium*

Figure 17.20 Calcified *Schistosoma haematobium* eggs in a crushed sliver of fixed tissue from the bladder of an Egyptian patient. Unstained, $\times 239$. (Armed Forces Institute of Pathology photograph.)

infection plays a significant role in the induction of different types of carcinoma, since squamous cell carcinoma is usually associated with moderate and/or high worm burdens while transitional cell carcinoma occurs more frequently in areas associated with lighter parasite loads. The predominance of squamous cell carcinoma in urinary bladder tissues in patients with schistosomiasis is probably due to continuous exposure to the larger quantities of carcinogens (*N*-nitroso compounds) in urine in patients with the disease (45).

Other Body Sites. Periportal fibrosis with hepatomegaly and splenomegaly has been noted in patients in areas where infections are endemic (1). Splenic enlargement has been correlated with the intensity of *S. haematobium* infection. Cardiopulmonary disease can develop in patients with hepatosplenic schistosomiasis; eggs are carried via the mesenteric veins to the lungs through systemic collateral veins. Schistosomal cor pulmonale tends to be rare in infections with *S. haematobium*; and eggs can be found in lung tissue at autopsy but are generally not clinically relevant. Although any *Schistosoma* species may involve the central nervous system, *S. mansoni* and *S. haematobium* more commonly involve the spinal cord than the brain. Severe disease presents as transverse myelitis.

As with *S. mansoni*, chronic bacteremic infections with *Salmonella* are seen, particularly in cases of chronic

Figure 17.21 *Schistosoma haematobium*: (Left) X ray of the pelvis in a 24-year-old Egyptian with schistosomal obstructive uropathy. Linear calcification is seen in the base of the bladder and along the lower ureters, which are dilated (arrows). (Armed Forces Institute of Pathology photograph. Courtesy of Marcia Young.) (Right) Urinary bladder. An exophytic squamous cell carcinoma is present in the central portion of the photograph, and infiltrating squamous cell cancer extends to the left. Magnification, $\times 4$. (Armed Forces Institute of Pathology photograph.)

active schistosomiasis. Also, schistosomal appendicitis appears to be specific to infection with *S. haematobium* and is an uncommon cause of appendicitis in areas where schistosomiasis is not endemic. Therapy requires anti-schistosomal medication in addition to surgery (13, 61).

Diagnosis

Diagnostic Procedures. *S. haematobium* eggs are usually detected in the urine, although in heavy infections they may also be found in the stools. The terminal hematuria portion of the urine specimen may contain numerous eggs trapped in the mucus and pus. Peak egg excretion occurs between noon and 3 p.m. Samples collected during this time, or during a 24-h urine collection without preservatives, may be used for examination. Urine can be examined under a microscope after sedimentation or centrifugation. It is important to use saline and not water for the concentration procedures; this will avoid hatching of the eggs. Nuclepore filtration is an excellent method for the concentration of eggs in urine. Some data indicate that egg output in urine is an accurate method of confirming the diagnosis and shows less day-to-day variation than in ELISA detection of schistosome circulating antigens in urine (74).

Use of reagent strips to detect hematuria and proteinuria in areas of endemic infection has proven to be an effective screening technique for *S. haematobium* infections (7). The assay correctly identified 87% of egg-negative controls and 98% of parasitologically confirmed cases, including those in six individuals who had been treated but

not cured. Also, antigen was detected in the urine of three individuals from whom two specimens had to be examined microscopically to confirm the infection. This suggests that the test is more sensitive than microscopy. To increase the sensitivity of the reagent strip tests, the tests should be performed during the period of peak egg excretion in the urine (noon to 3 p.m.). Although the use of reagent strips allows one to rapidly screen a population at risk, other conditions can yield a positive result. The strips should be used in conjunction with microscopic examination or serologic testing for confirmation of infection. Reagent strips coated with MAbs to CCA were developed for testing urine specimens for *S. haematobium*. The levels of CCA are much higher in the urine than are the levels of CAA. Although not as sensitive as ELISA methods, this technique is suitable for screening large populations in areas of endemic infection. Eosinophilia has also been used to diagnose infections, with a positive predictive value of $>80\%$.

Antibody Detection. A large number of serologic tests have been used in the diagnosis of schistosomiasis (69); however, many have not been particularly useful because of cross-reactions with other helminth infections, continuation of elevated titers long after successful treatment, and slow immunologic response of the host. Because of the complex life cycle, a large number of antigens have been used in serologic tests. Only a few have been useful. The most frequently used tests are the circumoval precipitin test, the cercaria-Hullen reaction, the indirect fluorescent-antibody test, the indirect hemagglutination test, and ELISA (69, 75). See Algorithm 17.1.

Table 17.7 Mechanisms of bladder carcinogenesis due to *Schistosoma haematobium*

Mechanism	Comments
Inflammatory cells (IC)	Macrophages and neutrophils are important sources of endogenous oxygen radicals that are implicated in the formation of carcinogenic <i>N</i> -nitrosamines; IC induce mutations, sister chromatid exchanges, and DNA strand breaks; increased numbers of IC may enhance carcinogenic potential of aromatic amines by increasing their rate of activation
Microorganisms	Hospitalized patients (39–66%) had bacteriuria; interaction between schistosomiasis and bacterial infection appears to depend on gender (more common in males than females); there may be a symbiotic relationship between worms and bacteria; bacterial infection of the urinary tract increases the risk of bladder cancer in patients with problems other than schistosomiasis; individuals with bacterial cystitis and schistosomiasis are potentially more exposed to nitrate and/or nitrite, increasing the risk of in situ formation of <i>N</i> -nitrosamines
Genetic changes	<p>Specific genes associated with neoplastic progression in schistosomal bladder cancer include the activation of <i>H-ras</i> (the <i>ras</i> gene family consists of frequently activated oncogenes), inactivation of <i>p53</i>, and inactivation of the retinoblastoma gene; alterations in genes and/or proteins can change function, leading to uncontrolled cell growth and tumor formation</p> <p>Mutation of the coding sequence of the <i>p53</i> tumor suppressor gene is the most frequent genetic alteration in a number of human malignancies; 6 of 7 Egyptian bladder cancer patients had <i>p53</i> mutations; the frequency of <i>p53</i> mutations varies with different grades of schistosomiasis-associated bladder cancer; alterations in the <i>p53</i> gene may modulate gene expression for regulation of relevant DNA repair processes, as well as cell division and death by apoptosis</p> <p><i>Bcl-2</i> is overexpressed in some schistosomiasis-associated bladder cancers (expressed at high levels in squamous cell carcinoma but not transitional cell carcinoma); may be upregulated in later stages of tumor progression; <i>Bcl-2</i> may also be related to tumor cell lineage</p> <p>A 9p gene, possibly <i>CDKN2</i>, may contribute to the development of the majority of schistosomiasis-associated bladder tumors, but the genes on 9q play a much less important role (59)</p> <p>Detection of early genetic changes may be valuable in identifying high-risk individuals</p>
Diet	Dietary fat is consistently high on a list of associated factors (attenuated when other diet components are included); small amounts of <i>N</i> -nitroso compounds are found in Egyptian food (cheese, fava beans, raw salted fish), all of which are consumed almost daily
Carcinogen metabolism	Increased levels of enzymes responsible for activation of carcinogenic <i>N</i> -nitroso compounds, aromatic amines, and polycyclic aromatic hydrocarbons have been found in schistosomiasis; may increase and prolong bladder exposure to DNA-damaging agents; nitrite levels are about 20 times higher in <i>S. haematobium</i> -infected patients with bladder cancer than in those without bladder cancer; these compounds may play a role not only in initiation of the carcinogenic process, but also in its progression
Carcinogens, consequences of DNA damage	Damage to bladder tissue DNA may be responsible for initiation of bladder cancer

ELISA methods using soluble adult worm or egg antigens for the detection of antibodies have been used as screening tests, and infection has then been confirmed by the EITB test (69). Individuals infected with schistosomes have elevated IgE and IgG4 responses, as in those with other helminthic infections. Few studies have investigated the persistence of antibodies over time after therapy (69). It is possible that high titers posttherapy reflect treatment failure and reinfection.

Antigen Tests. Based on 92% specificity and 90% sensitivity, an ELISA using MAb 290-2E6-A is one of the most promising assays for immunodiagnosis of *S. haematobium*

infections (46). Another study of children from Kenya indicates that the SEA ELISA compared well with microhematuria within egg count classes and with egg counts within hematuria classes (29). Levels of SEA and egg output have shown similar correlations with sonographically detectable pathology; these correlations were better than the correlation between hematuria and pathology (29). Another antigen capture ELISA using MAb 128C3/3/21 has shown a correlation between the level of circulating antigen and the intensity of infection as measured by egg counts. There appears to be a direct relationship between antigen level and disease severity, as monitored by sonography. Also, a purified recombinant serine protease

inhibitor that is species specific for *S. haematobium* has been used in serologic assays.

Using the SEA MAb, circulating schistosome antigen was undetectable in serum from patients with other parasitic infections and was detected in 90.5% of serum samples and 94% of urine samples from *S. haematobium*-infected patients. A significant reduction in circulating schistosome antigen levels was detected in serum and urine samples 12 weeks after praziquantel therapy (58). No cross-reactivity with *S. mansoni* was seen.

A MAb-based dipstick assay has been used with a sensitivity of 98.8% and specificity of 53.6%. Although the detection of microhematuria and proteinuria had a higher specificity, the sensitivity was much lower than that of the dipstick assay (8).

KEY POINTS—LABORATORY DIAGNOSIS

Schistosoma haematobium

1. Eggs cannot be detected in urine until the worms mature (may take up to 3 months after initial infection).
2. In very light or chronic infections, eggs may be very difficult to detect in urine; therefore, multiple urine examinations may be required. Biopsy and/or immunologic tests may be helpful in diagnosing infection in these patients.
3. Both 24-h and spot urine samples should be examined as wet mounts (after concentration using no preservatives [use saline so hatching will not occur]); the urine specimens should be collected with no preservatives. These eggs are also occasionally recovered in stool, and so both urine and stool specimens should be examined.
4. The membrane filtration technique using Nuclepore filters can be very helpful in diagnosing infection with *S. haematobium*.
5. Patients who have been treated should have follow-up ova and parasite examinations for up to 1 year to evaluate treatment.
6. In active infections, the eggs should contain live or mature miracidia. Examination for the confirmation of flame cell activity must be performed on fresh specimens using the wet mount or hatching test; no preservatives can be used prior to the wet mount or the hatching test.
7. During the hatching test, the light must not come too close to the surface of the water, since excess heat can kill the liberated larvae. Also, the water should be examined about every 30 min for up to 4 h.
8. It is important to remember that the small and less commonly seen miracidium larva of *S. haematobium* may be present in the urine; motility

in unpreserved specimens or stained morphology could confirm this diagnosis.

9. It is also possible to see *S. haematobium* eggs in semen specimens, even when repeated urinary and fecal examinations and serologic tests are negative.

Treatment

Praziquantel is the drug of choice for treating infections with *S. haematobium*. It can be taken orally in a single dose and is well tolerated by the host. Side effects, which are usually mild and transient, include abdominal discomfort, dizziness, drowsiness, headache, fever, and loose stools. These effects usually disappear within 48 h. In heavily infected individuals, the side effects, although transient, may be very severe (62). Split doses have been recommended for treating heavy infections, but this may be a concern for population-based therapy, where individuals may not present themselves for follow-up therapy. Data suggest that a single dose of praziquantel (40 mg/kg of body weight) may have a longer-lasting effect than was previously thought: possibly more than 2.5 years (18). In certain population-based treatment programs, it appears that a 20-mg/kg dose of praziquantel may be sufficient to provide control of morbidity due to urinary schistosomiasis (32). Praziquantel has little effect on immature stages of the parasite, and this will affect the cure rates as the immature parasites develop to maturity and egg production. The mechanism of action may involve glutathione *S*-transferase, a detoxifying enzyme found in many helminths. Cure rates have been reported to be 70 to 95%. Praziquantel damages the tegument of the worm, thereby exposing the antigens to parasite-specific antibodies. Adults are more resistant to schistosome infection than are children, and the switch to an “adult” response suggests that praziquantel treatment may have an immunizing effect, with benefits beyond a transient reduction in infection levels (40). Treatment can significantly reduce urinary tract morbidity despite reinfection; important risk factors in adulthood are cumulative intensity and duration of infection during early adolescence (66). Data also indicate that therapy given in childhood or adolescence decreases the risk for some but not all manifestations of *S. haematobium* infection in later adult life (48).

Although the exact mechanism by which praziquantel kills the parasite is not well understood, it is known that the immune response of the host plays an important role in drug efficacy. It is possible that disease states of humans that lead to immunodeficiencies, such as infection with HIV-1, may render praziquantel less effective in treating schistosomiasis. However, recent studies indicate that persons with HIV-1 infection can be treated effectively for schistosomiasis with praziquantel (30, 33).

Therapeutic failure of praziquantel in the treatment of *S. haematobium* infection in Brazilians returning from Africa has been reported. Patients were treated with a single dose of praziquantel (40 mg/kg, single dose). Two additional treatments were given, and cystoscopy between 6 and 24 months after each treatment confirmed the presence of viable eggs. These findings confirm the possible need for repeated therapy, as well as using the urinary bladder biopsy as the criterion of cure (60).

The efficacy of praziquantel during the incubation period of schistosomiasis has recently been studied for the first time (19a). In a group of 18 tourists infected with *S. haematobium* in Mali, the authors observed the efficacy of praziquantel given at different phases of the infection. Early praziquantel treatment from days 10 to 15 after exposure was less effective than later treatment (days 28 to 40) in preventing acute schistosomiasis, while neither treatment effectively prevented chronic schistosomiasis.

Patients with *S. haematobium* infection are suitable recipients for kidney transplantation, although they are at risk for urologic complications. Long-term urologic follow-up is recommended, including urethroscopy, due to the increased risk for bladder cancer.

Metrifonate, an organophosphorus cholinesterase inhibitor, is an alternative to praziquantel for the treatment of *S. haematobium* infections. The drug is given orally over a number of weeks. Side effects, which are mild and transient, include abdominal discomfort, diarrhea, dizziness, headache, vomiting, and weakness. Metrifonate should not be given to patients who have been recently exposed to insecticides or who are using therapeutic agents that can potentiate cholinesterase inhibition. It has been noted that the dorsal tegumental surface of adult male schistosomes contains acetylcholinesterase and nicotinic acetylcholinesterase receptors, which may be the target of metrifonate. Because the acetylcholine receptor expression is increased when the worms pair and become sexually mature, it appears that acetylcholine plays a vital function in nutrient transport.

Epidemiology and Prevention

S. haematobium infections occur in Africa, Asia Minor, Cyprus, the islands off the African east coast, and southern Portugal; there is a focus of endemic infection in India. Humans appear to be the only important reservoir hosts, although naturally infected monkeys, baboons, and chimpanzees have been found. The intermediate snail host, *Bulinus* sp., can survive in the mud when the water dries up. The snails retain their infectivity and resume shedding cercariae when the rainy season begins. In some areas, cercariae are found in areas where infected snails are absent, and sometimes cercariae are absent in the presence of infected snails.

Data suggest that fewer than 1 in 100 contacts result in infection and fewer than 1 in 1,000 result in egg output.

This suggests that there may be substantial attrition of invading cercariae even in naïve individuals (78).

In many areas of endemic infection, awareness of urinary schistosomiasis and its symptom of blood in the urine is high, but specific knowledge about the parasite, its vector, and the interaction between them in the life cycle is lacking. Activities that require behavior and attitude modification can be identified and encouraged as components in the control of schistosomiasis.

An *S. haematobium*-derived recombinant glutathione S-transferase (Sh28GST) vaccine is capable of significantly reducing worm fecundity in experimentally infected primates. Although Freund's complete adjuvant induced higher levels of protection, the efficacy of *Mycobacterium bovis* as an adjuvant appeared sufficient to justify consideration of its use in a vaccine against human urogenital schistosomiasis (9).

A summary of the control methods that can be used for all types of schistosomiasis is given in Table 17.8. All of these initiatives are coupled with public health communication and training for populations in areas of endemic infection.

Schistosoma intercalatum

S. intercalatum infections were first noted by Fisher in the early 1930s, and the species has been extensively described. The infection has been found in central and western Africa. In areas where both *S. haematobium* and *S. intercalatum* are endemic, hybridization with the two trematodes appears to be occurring; natural hybrids have been found in Loum, Cameroon (68). Also, it appears that the competitive exclusion between *S. mansoni* and *S. intercalatum* may be an important factor restricting the distribution of *S. intercalatum* in Africa. *S. intercalatum* causes an intestinal form of schistosomiasis similar to that caused by *S. mansoni* but characterized by lesions, mainly situated at the rectum and sigmoid level. Urinary schistosomiasis caused by *S. haematobium* has a tendency to supplant recto-sigmoidal schistosomiasis caused by *S. intercalatum*, especially in endemic areas where hybridization between the two species of schistosomes is occurring.

Life Cycle and Morphology

The life cycle is similar to that of the other schistosomes. Adult worms are found in the mesenteric veins, and eggs are shed in the feces. Eggs are fully embryonated without an operculum and resemble *S. haematobium* eggs in shape, having a terminal spine (Table 17.1; Figure 17.22). The eggs are 140 to 240 μm by 50 to 85 μm in size and can be differentiated from *S. haematobium* eggs since they are Ziehl-Neelsen acid-fast positive. This technique cannot be totally relied on, because if hybridization occurred between *S. intercalatum* and *S. haematobium*, the eggs identified from the urine by

Table 17.8 Schistosomiasis control measures

Approach	Comments
Chemotherapy	
Mass	Most appropriate in population with prevalence rates of >30%; all members of population treated (no attempt at individual diagnosis) (25)
Targeted population	Relies on identification of individual moderate to heavy egg excretors; follow-up for evaluation of cure
Snail control	
Molluscicide use	Niclosamide commonly used; well suited for arid areas (seasonal infections) and small habitats; unfortunately, snail populations can reestablish themselves within 3 mo of molluscicide application
Biologic control	Use of natural predators of snail hosts (ducks, fish, turtles, fungi, other snails); not realistic on a mass level
Environmental modification	Prevention and/or reduction of breeding; site modification to produce detrimental conditions; cementing or closing over irrigation ditches; increasing canal water flow
Reduction of water contact and contamination	
Domestic water supplies	Clean water availability; however, population may continue to use contaminated water sources
Sanitary excreta disposal	Mandatory; combined with health education on biological transmission and importance of control measures; improvement in living standards is important
Vaccination	Continued problem of reinfection is a problem due to slow maturation of natural resistance; several antigens have reached an advanced stage of development and are undergoing testing; vaccination will be used in conjunction with all other control methods; vaccines can be used to attenuate infection and/or to prevent pathology and/or to reduce worm burdens (80)

DNA analysis would be Ziehl-Neelsen stain positive. The snail intermediate hosts are *Bulinus forskalis* and *B. africanus*.

Figure 17.22 *Schistosoma intercalatum* egg. The miracidium tends to be somewhat narrower in the middle, giving it an hourglass shape. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Clinical Disease

Clinical manifestations are similar to those of *S. mansoni* infections. Pathology is confined to the mesenteric-portal system; rectal bleeding appears to be the most common finding. Other symptoms can include pain in the left iliac fossa with tenesmus, anorexia, nausea, abdominal pain, and diarrhea. There may also be changes in liver function tests. The prevalence and intensity of infection were noted to increase during the first two decades of life and gradually decrease thereafter. As with other species of *Schistosoma*, there is an association between *Salmonella* bacteremia and infection with *S. intercalatum*. Without treatment for schistosomiasis, the *Salmonella* infection cannot be cured. Complications of *S. intercalatum* infection include severe rectal or genital lesions.

Diagnosis

The infection can be diagnosed by finding the characteristic eggs in feces or in squash preparations of tissues from the rectum; occasionally, eggs are also found in the urine. The miracidium often appears to be more narrow in the middle, giving it an “hourglass” shape.

KEY POINTS—LABORATORY DIAGNOSIS***Schistosoma intercalatum***

1. Eggs cannot be detected in stool until the worms mature (may take from 4 to 6 weeks after initial infection).
2. In very light or chronic infections, eggs may be very difficult to detect in stool; therefore, multiple stool examinations may be required. Biopsy and/or immunology may be helpful in these patients.
3. The zinc sulfate flotation concentration method should not be used; the sedimentation method is recommended.
4. It may be necessary to tap the coverslip to move the eggs; the terminal spine may be difficult to see if debris is covering the egg (this may occur).
5. Occasionally eggs of *S. intercalatum* are detected in the urine.
6. Patients who have been treated should have follow-up ova and parasite examinations for up to 1 year to evaluate treatment.
7. In active infections, the eggs should contain live or mature miracidia. Examination for the confirmation of flame cell activity must be performed on fresh specimens, using a wet mount or the hatching test; no preservatives can be used prior to the wet mount examination or the hatching test.
8. During the hatching test, the light must not come too close to the surface of the water, since excess heat can kill the liberated larvae. Also, the water should be examined about every 30 min for up to 4 h.

Treatment

Praziquantel is the drug of choice for treating infections with *S. intercalatum*. It can be taken orally in a single dose and is well tolerated by the host. Side effects, which are usually mild and transient, include abdominal discomfort, dizziness, drowsiness, headache, fever, and loose stools. These effects usually disappear within 48 h. A single dose of praziquantel (40 mg/kg of body weight) has been recommended.

Epidemiology and Prevention

S. intercalatum infections occur in the same geographic areas as *S. mansoni* infections, i.e., western and central Africa (Cameroon, Equatorial Guinea, Gabon, Nigeria, Democratic Republic of Congo, and Sao Tome), Egypt, Madagascar, and the Arabian peninsula. Human infections are nearly all derived from human sources, even though nonhuman primates, insectivores, marsupials, and rodents can carry the infection. Disease spread is linked to seasonal migration of nomad populations, as well as migrant African laborers. In regions of endemic infection, prevalences of 5 to 25% have been found. The infection is transmitted by *Bulinus* sp., an aquatic snail.

Review of 333 reports related to imported cases of schistosomiasis in Europe showed that male patients accounted for 64% of all cases. The average age of all patients was 29.5 years. The majority of patients were of European origin (53%). Europeans traveled predominantly for tourism (52%). Travel for people from areas of endemic infection was related to immigration and refuge (51%) and visits to relatives and friends (28%). The majority of infections were acquired in Africa; 92 infections were clearly attributable to *S. haematobium*, 130 to *S. mansoni*, and 4 to *S. intercalatum*. Praziquantel was the only treatment used, and no deaths were recorded (20).

Raillietina celebensis

Mesocestoides spp.

Taenia crassiceps

Trematodes

Alaria americana

Plagiorchis spp.

Neodiplostomum seoulense

Spelotrema brevicaca

Brachylaima sp.

Troglorema salmincola

Stellantchasmus falcatus

Phaneropsolus bonnei and

Prosthodendrium molenkempi

Phaneropsolus spmicirrus

Haplorchis taichui

Gymnophalloides seoi

Metorchis conjunctus (North American liver fluke)

Schistosoma mattheei

Philophthalmus lacrimosus

Achillurbaenia spp.

Pentastomids

Armillifer spp., *Linguatula serrata*, and *Sebekia* spp.

Acanthocephalans

Macracanthorhynchus hirudinaceus and *Moniliformis moniliformis*

Most parasites infecting humans are recognized as being able to survive easily within the human host and to possibly cause disease, but there are some organisms that only rarely infect humans. Perhaps humans are only accidental hosts. In any case, because these infections, being so rare, are not reported frequently, such parasites may not be considered possible etiologic agents. It is important to at least be aware of such parasites and of the possible disease process created by these relatively benign organisms, because they can become a problem in immunocompromised patients. Examples of these unusual infections are described in Table 18.1.

Aquatic Protist

Rhinosporidium seeberi

Rhinosporidiosis is a granulomatous disease of humans and animals that is characterized by slow-growing tumorlike polyps, affecting primarily the nasal mucosa and ocular conjunctiva. The causative agent is *Rhinosporidium seeberi*, an organism that has undergone several reclassifications. Although it was thought to be a fungus or protozoan, it is now placed in a novel clade of aquatic protistan parasites, the Mezomycetozoea; this occurs at the divergence between animals and fungi (32, 71). Since this organism cannot be grown in synthetic media or human or animal cell lines, diagnosis is established by seeing the organism in tissue biopsy specimens. Two stages are seen in tissue: the larger endosporulating spherical form, or sporangia, and the smaller trophocyte (Figure 18.1). The genus *Rhinosporidium* may include multiple host-specific strains (83).

The sporangium is the mature form and measures 100 to 350 μm ; contained within the sporangium are numerous endospores (sporangiospores). The zonal arrangement of sporangiospores is characteristic, with the immature ones forming a crescent-shaped mass at the periphery, the maturing ones arranged sequentially toward the center, and the mature ones in the center. This arrangement of the sporangiospores separates *R. seeberi* from other spherical endosporulating organisms seen in tissue.

Rhinosporidiosis has been found in young men between 20 and 40 years old; the lesions tend to be slow-growing polyps or tumorlike masses, usually of the nasal mucosa or conjunctiva. Lesions have been found in the paranasal

Table 18.1 Unusual parasitic infections

Organism	Body site	Diagnosis	Comments
Aquatic protist <i>Rhinosporidium seeberi</i>	Nasopharynx, ocular conjunctiva, genitalia	Identification of sporangium and/or trophocytes in tissue biopsy specimens	Cannot be grown in synthetic media or animal/human tissue cell lines; classification has been difficult over a number of years
Protozoa Myxozoa	Intestine	Recovery of spores in stool	The morphology can mimic normal human spermatozoa, causing confusion with possible sexual abuse situations; true human infection is still somewhat unclear
Nematodes <i>Oesophagostomum</i> spp.	Intestine or abdominal cavity (nodular mass lesions)	Examination of nodule (dissection or aspirate); definitive diagnosis depends on identification of worm (may be difficult)	Carcinoma, tuberculosis, or Crohn's disease often suspected; mass often attached to bowel wall or ileum or colon; infection via ingestion of larvae
<i>Eustrongylides</i> spp.	Abdominal cavity	Identification of larvae (bright red)	Rare but may increase with consumption of raw fish; infective larval form also found in amphibians and reptiles
<i>Mermis nigrescens</i>	Mouth	Identification of larvae or adults	Soil nematodes with eggs deposited on plants and larvae in grasshoppers; adult worm accidentally transmitted to infant, probably by dog or cat
<i>Micronema deletrix</i>	Brain (single case)	Routine histologic test with consultation	Free-living worms living in soil, manure, humus
<i>Dioctophyma renale</i>	Primarily right kidney (may be in left kidney or body cavities)	Identification of worm in autopsy specimens or living worms passed from the urethra	Route of infection probably ingestion of raw freshwater fish and frogs; widely reported in dogs
<i>Ternidens deminutus</i>	Large intestine	Identification of eggs in stool; ulcers and/or cystic nodules may be seen in the large intestine	Third-stage larvae will develop in soil; probably infective for humans; life cycle not known
<i>Mammomonogamus laryngeus</i>	Trachea	Identification of Y-shaped male and female worms (in copulo) from coughed-up sputum or from eggs in sputum or stool	Third-stage larvae thought to be infective for the vertebrate host; normal host cattle, felines; life cycle not known
<i>Ascaris suum</i>	Intestine or liver, lungs; intestine but worms do not mature (can be serious disease)	Identification based on size and shape of denticles and patient history of exposure to pigs raised on farms; dose required for symptoms of pneumonitis very minimal; large doses can lead to severe disease	Ingestion of infective eggs probably more common than thought, particularly in people who live and/or work on farms where pigs are raised
<i>Gongylonema pulchrum</i>	Mucosa or submucosa of buccal cavity; esophageal mucosa	Identification based on worm recovery and egg morphology	Accidental ingestion of insect intermediate hosts, possibly cockroaches or other infected insects
<i>Haycocknema perplexum</i>	Skeletal muscle fibers	Identification of adults or larvae in muscles	Symptoms of progressive muscle weakness, eosinophilia, active polymyositis

(continued)

Table 18.1 Unusual parasitic infections (*continued*)

Organism	Body site	Diagnosis	Comments
Cestodes			
<i>Diplogonoporus</i> spp.	Intestine	Identification of proglottids or eggs (similar to those of <i>Diphyllobothrium latum</i>)	Ingestion of infected fish; usual parasites of whales
<i>Bertiella</i> spp.	Intestine	Identification of chains of proglottids or very characteristic eggs	Accidental ingestion of mites containing the infective form; most infections seen in children
<i>Inermicapsifer madagascariensis</i>	Intestine	Identification of proglottids, eggs, or egg packets in stool	Very difficult to differentiate from <i>Raillietina</i> spp.; patient is asymptomatic to mild symptoms; usually seen in children; infection probably from ingestion of arthropod vector (unknown)
<i>Raillietina celebensis</i>	Intestine	Identification of proglottids, eggs, or egg packets in stool	Intermediate hosts are ants (accidental ingestion)
<i>Mesocestoides</i> spp.	Intestine	Identification of proglottids in stool	Infection probably due to ingestion of raw meat of some animal (unknown) carrying the intermediate larval form in the tissue; usually found in children; symptoms minimal
<i>Taenia crassiceps</i>	Eye, subcutaneous paravertebral infiltrate (AIDS)	Identification of small, white, spherical masses (2–3 mm) of larval worms	Common parasite of the red fox; in animals, larval forms found under skin and in body cavities; human cases very rare but very serious
Trematodes			
<i>Alaria americana</i>	Disseminated throughout many tissues including eye, organs, central nervous system; can be very serious disease	Recovery of mesocercariae at surgery or autopsy	Ingestion of inadequately cooked frogs or frog legs
<i>Plagiorchis</i> spp.	Intestine	Recovery of adult worms and/or eggs in stool	Ingestion of insect grubs containing the infective stage; raw fish also implicated in transmission
<i>Neodiplostomum seoulense</i>	Intestine	Recovery of adult worms and/or eggs in stool	Associated with ingestion of raw or poorly cooked snake meat, frogs, or house rats
<i>Spelotrema brevicaca</i>	Intestine or disseminated to other tissues	Recovery of adult worms in stool and/or eggs in stool or tissues	Ingestion of raw crabs containing infective metacercariae; reported to cause severe illness in compromised patients
<i>Brachylaima</i> sp.	Intestine	Recovery of adult worms and/or eggs in stool	Ingestion of raw snails containing infective metacercariae; may be mild abdominal pain and diarrhea
<i>Troglootrema salmincola</i>	Intestine	Recovery of adult worms and/or eggs in stool	Ingestion of raw fish viscera and/or giant salamander; rickettsia associated with infection causes severe illness in dogs, may also be human pathogen

(continued)

Table 18.1 (continued)

Organism	Body site	Diagnosis	Comments
<i>Stellantchasmus falcatus</i>	Intestine	Recovery of adult worms and/or eggs in stool	Ingestion of raw brackish-water fish; reported from Hawaii after ingestion of raw mullet
<i>Phaneropsolus bonnei</i> , <i>Prosthodendrium molenkempii</i>	Intestine	Recovery of adult worms and/or eggs in stool; eggs resemble those of <i>Opisthorchis viverrini</i> or each other	Ingestion of raw small fish infected with naiads (water nymphs of dragonflies)
<i>Phaneropsolus spinicirrus</i>	Intestine	Recovery of adult worms and/or eggs in stool	Second species of genus found in humans; adults small (651 μ m long by 502 μ m wide); eggs 29 μ m long by 14 μ m wide, smooth, operculate (some with shoulders)
<i>Haplorchis taichui</i>	Small intestine	Identification of eggs or adult worms	Mucosal ulceration, mucosal and submucosal hemorrhages, fusion and shortening of the villi, chronic inflammation, and fibrosis of the submucosa
<i>Gymnophalloides seoi</i>	Intestine	Recovery of adult worms and/or eggs in stool	New human intestinal trematode; southwestern island of Korea; bivalves serve as first or second intermediate hosts; eggs smaller than <i>Clonorchis</i> eggs
<i>Metorchis conjunctus</i> (North American liver fluke)	Biliary tree	Recovery of adult flukes and/or eggs in stool	Ingestion of raw white sucker fish (sashimi) containing infective metacercariae
<i>Schistosoma mattheei</i>	Venules of the bladder and/or intestine	Recovery of eggs in urine and/or stool; eggs resemble those of <i>S. intercalatum</i>	Skin penetration of infective cercaria from freshwater snail
<i>Philophthalmus lacrimosus</i>	Conjunctiva	Identification of adult worm from eye	Main symptom is the feeling of having a foreign-body sensation in the eye
<i>Achillurbainia</i> spp.	Granulomata, retroauricular cysts or abscesses	Identification of eggs or adult worms from biopsy specimens	Symptoms may or may not be present
Pentastomids (tongue worms) <i>Armillifer</i> spp., <i>Linguatula serrata</i>	Infective larvae die in situ (tissues, including the eye); ingestion of mature larvae may lead to development of adults in nasopharyngeal tissues (halzoun syndrome)	Identification of the worm/larvae in biopsy or autopsy specimen	Most infections acquired from ingestion of raw, infected snakes; liver, lung, spleen involved; often not discovered until autopsy; lung involvement may cause congestion
<i>Sebekia</i> spp.	Dermatitis, serpiginous burrow, erythema	Larvae in burrow	Adult parasites of respiratory tract of reptiles, immature forms found in viscera, muscles, along spinal cord of freshwater fish
Acanthocephalans <i>Macracanthorhynchus hirudinaeaus</i>	Intestine	Identification of adult worms; immature worms very difficult to identify	Infections acquired by ingestion of raw beetles; clinical manifestations are intestinal obstruction and perforation; eggs often not seen in feces
<i>Moniliformis moniliformis</i>	Intestine	Identification of adult worms; immature worms very difficult to identify; eggs can be used to identify the helminth	Infections acquired by ingestion of raw cockroaches; symptoms can be diarrhea, pallor, anorexia, weight loss, weakness

Figure 18.1 Histology of rhinosporidiosis; human nasal polyp. (Upper) Immature *Rhinosporidium seeberi* trophocytes; note the thick walls and the surrounding inflammatory cells. (Lower) Sporangium containing endospores. (Images from the Centers for Disease Control and Prevention.)

sinuses, larynx, and external genitalia. Dissemination appears to be rare. Symptoms include nasal obstruction and epistaxis. Surgical excision of the lesions is generally recommended as the treatment of choice; if total excision is not possible, recurrences are typical.

Over 90% of rhinosporidiosis cases occur primarily in India and Sri Lanka; however, cases have been reported from the Americas, Europe, Africa, and Asia. Three cases have been reported from the southeastern United States. Various studies have linked infection to swimming or bathing in freshwater ponds, lakes, or rivers (32, 71).

Protozoa

Myxozoan Parasites

Myxozoans are commonly found as parasites in aquatic vertebrates (especially fish) and invertebrates. They are recognized as a separate phylum with two classes: the

Myxosporea, which infect fish, amphibians, and reptiles, and the Actinosporea, which infect aquatic invertebrates (primarily oligochaetes and sipunculids) (59, 60). Classification has been difficult, and it has been recommended that a number of factors be used in making taxonomic decisions, including determination of 18S rRNA gene sequences combined with information on tissue tropism, host species infected, and developmental cycles in the fish and alternate host (when known). There are over 1,000 species, and new ones are being described each year; however, many of the life cycles have not yet been defined. Alternation between actinosporean stages in oligochaetes and myxosporean stages in fish may occur (59, 95). These organisms parasitize a variety of fish tissues, where they produce pseudocysts that contain hundreds of thousands of small spores. As marine netpan farming of salmonid fish continues to expand in many countries, more unusual host-parasite relationships may be seen in the future (49).

Many of these myxozoan spores contain chitin in their spore coat, and the spores can be passed intact through the vertebrate gastrointestinal tract (68). There is no evidence that these organisms cause human disease; however, spores have been recovered in stool samples from patients with gastrointestinal tract symptoms, including abdominal pain and/or diarrhea (9). There is also speculation that these parasites could be potentially infectious and pathogenic in immunocompromised patients. Coinfections with other parasites such as *Cryptosporidium* spp., *Isospora belli*, *Giardia lamblia*, *Hymenolepis nana*, *Strongyloides stercoralis*, and *Ascaris lumbricoides* have been found, thus complicating the determination of the pathogenic role of *Myxobolus* spp.

Spores of a myxosporean parasite (*Henneguya salminicola*) have been detected in fecal samples from two human patients (66), in one case being mistaken for human spermatozoa and leading to suspicion of sexual abuse (Figure 18.2). The spores were passed undigested in feces after the consumption of infected salmon and were not thought to have any causal relationship to the patient's symptoms. True infections with myxosporean parasites in humans have not previously been recorded, other than this case. Organisms resembling human spermatozoa have been seen in fecal concentrates at high dry magnification ($\times 400$). They measured about 40 μm in total length with a teardrop-shaped spore body of approximately 10 μm , which tapered gradually to one or two caudal filaments. Most of the spores had two pyriform polar capsules situated in the anterior region of the spore body. Although routine iron hematoxylin and trichrome staining failed to stain the spores, the modified trichrome stain was effective.

A second report discussed the detection of a second myxosporean species in stool samples from three

Figure 18.2 (A) Normal human spermatozoa. (B) Myxosporean spore from salmon. Note the similarities between panels A and B. (C and D) Two spores demonstrating the polar filaments. (Reprinted from reference 66 with permission.)

additional patients (9). It is very likely that additional cases will be recorded; it is important that clinicians and microbiologists understand the possible presence of myxozoan spores in stool samples, particularly in patients with a high dietary intake of fish.

In an iodine preparation, the spores appear as dark pyriform bodies, while in modified acid-fast stains, the spore wall and enclosed sporoplasmic and capsulogenic cells stain acid fast. When the fecal specimen is stained with trichrome stain, the spores appear as darkly stained pear-shaped bodies measuring 11 to 12 μm by 7 to 8 μm with two polar capsules each measuring 5 by 2 μm . It is important to use the modified acid-fast stains, since these methods allow the visualization of the convolutions of the polar filament.

Nematodes

Oesophagostomum spp.

The roundworms of *Oesophagostomum* spp. infect the intestine or abdominal cavity of humans or animals, normally ruminants, primates, or swine. The disease is most common in the tropics or subtropics, with approximately 60 human cases being reported, primarily from Africa. Several species of *Oesophagostomum* have been implicated in human disease; however, accurate species identification is very difficult if one cannot examine an intact whole worm. The life cycle is seen in Figure 18.3. Usually, the worms are unable to complete their life cycle in humans; however, there have been instances in which stunted

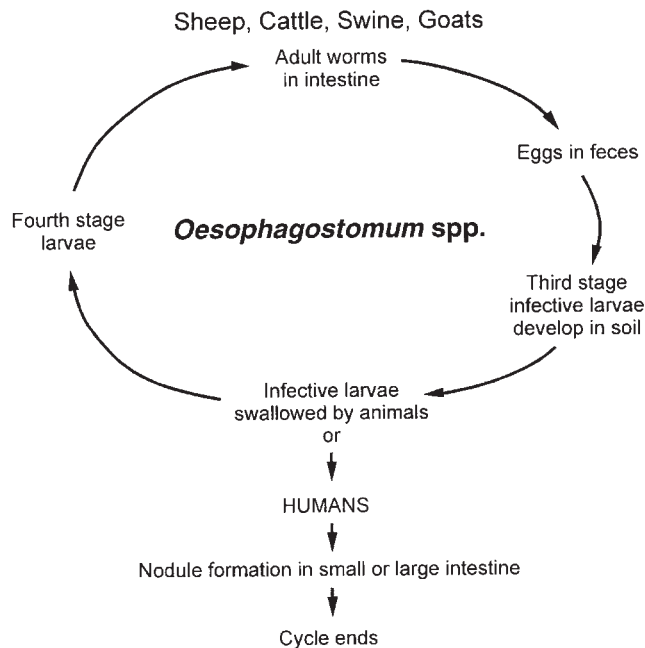

Figure 18.3 Life cycle of *Oesophagostomum* spp.

adult worms have been recovered. In northern Togo and Ghana, this infection is found in humans, with the recovery of both adult males and females passed in the stool after therapy (Figures 18.4 and 18.5) (97). The parasite is *Oesophagostomum bifurcum*, which apparently does not require an animal reservoir. The eggs passed in the stool closely resemble those of hookworm (75), and both infections are found in this population (Figure 18.6).

The infection can develop in humans at any age. Most of the worms recovered from humans are immature. Symptoms include abdominal pain, with localized tenderness (usually right lower quadrant). There may be gradual onset of pain, with a low-grade fever and no diarrhea, vomiting, or anorexia (37). Careful examination of the patient may reveal a mass in the abdominal cavity, adhering to the abdominal wall (Figure 18.7) (1). Although these nodular mass lesions usually do not cause intestinal obstruction, other complications, such as hernia, intussusception, or worm penetration of the bowel wall, may occur (36). The mass is often attached to the bowel wall of the ileum or colon (91). Nodules usually measure 4 to 6 cm. Often carcinoma, tuberculosis, or Crohn's disease may be suspected. In one patient, the worm produced a cutaneous lesion, the first report of a lesion outside of the gastrointestinal tract and without evidence of bowel infection (78).

If oesophagostomiasis is suspected, confirmation can be made by immediate examination of the nodule, either by nodule dissection (Figure 18.8) or by examination of aspirate material. Definitive diagnosis depends on identifying the whole worm or serial sections of it. At present,

Figure 18.4 Anterior end of an adult *Oesophagostomum bifurcum* worm recovered from human feces. Note the cephalic groove, characteristic of the genus ($\times 115$). (Reprinted from reference 75 with permission.)

surgical resection of the involved tissue or removal of the worm from the nodules is the only means of treatment. However, both pyrantel pamoate and albendazole have been effective in removing adult worms from the intestine (76). It is very likely that a single dose of albendazole will cure an *O. bifurcum* infection (96).

Oesophagostomum spp., as well as hookworm infections, are hyperendemic among the population in northern Togo and Ghana. In northern Togo, all the villages examined contained residents who were infected with hookworm, with a patchy distribution of *Oesophagostomum* spp. Women were infected with *O. bifurcum* more often than men were, while infections with hookworm were the opposite. The prevalence and intensity of infection with both parasites were clearly age dependent. It is estimated that more than 100,000 people

Figure 18.5 Scanning electron micrograph of the cephalic end of a female *Oesophagostomum bifurcum* worm recovered from human feces. Note the inner and outer leaf crowns with 12 and 24 (sometimes 10 and 20) lips, respectively, and the papillae ($\times 630$). (Photograph by the Department of Electron Microscopy, Medical Faculty, Leiden University; reprinted from reference 75 with permission.)

in Togo are infected with *O. bifurcum* and more than 230,000 are infected with hookworm (73).

Using a panel of 155 well-defined fecal and DNA samples, a new PCR assay achieved a sensitivity of 94.6% and a specificity of 100% in the identification of *O. bifurcum*. This PCR assay will be useful for the diagnosis of *O. bifurcum* infection, as well as being a molecular biology tool to help clarify the epidemiology of human disease with this parasite (90). When using routine diagnostic methods to estimate the intensity of infection, it is sufficient to make repeated coprocultures from only a single stool sample; collection of multiple samples on subsequent days does not give better estimates of the individual infection status (72). It is also important to remember that coproculture can also yield larvae of *Oesophagostomum* and *Ternidens* species, as well as the more common hookworm and *Strongyloides stercoralis* (45).

Figure 18.6 *Oesophagostomum bifurcum* egg. This egg cannot be differentiated from that of the hookworm.

Figure 18.7 Nodular lesion of oesophagostomiasis seen as a paraumbilical mass in an otherwise healthy 5-year-old girl in Nigeria. At laparotomy, the lesion was found to have arisen in the ascending colon and was adherent to the muscles and fascia of the anterior abdominal wall ($\times 11$). (Armed Forces Institute of Pathology photograph.)

Eustrongylides spp.

The larvae of *Eustrongylides* nematodes are found in raw fish and in amphibians and reptiles. Although not all fish hosts are known, it was assumed that, in one

Figure 18.8 Surgically resected nodule of oesophagostomiasis. Note the worm protruding into the cavity. Specific identification of these worms is difficult, because intact specimens are rarely obtained. (Armed Forces Institute of Pathology photograph.)

case, the patient most probably acquired the infection by eating raw fish (sashimi and sushi) approximately once a month. He usually ingested the fish in restaurants; however, the day prior to admission, he had eaten raw fish of an unknown species from a neighborhood fish market. He presented with a history of pain in the right lower quadrant. On the basis of the symptoms, the patient underwent an appendectomy, at which time the appendix and distal ileum were found to be normal. However, prior to closure of the incision, a pinkish red worm was seen crawling onto the surgical drapes from the abdominal cavity. The patient's recovery was unremarkable. On the basis of larval morphology, the worm was determined to be in the *Eustrongylides* group, which includes parasites that are commonly found in fish-eating birds (92). A second patient also presented with symptoms simulating acute appendicitis. The patient had consumed two live minnows obtained from Big Timber Creek, Belmawr, N.J. The parasite *Eustrongylides ignotus* was recovered surgically from this patient (69). Human infection with *Eustrongylides* spp. is certainly uncommon, but with the increased consumption of raw or improperly

cooked fish, additional cases may be seen. The majority of cases have been related to anisakine larvae such as those of *Anisakis*, *Phocanema*, *Contracaecum*, and *Pseudoterranova* spp., which are indigenous to marine fish found off both coasts of the United States as well as in Japan and Europe.

Mermis nigrescens

Mermis nigrescens nematodes are found in the soil and have a unique life cycle. After mating and egg maturation, the females leave the soil and deposit eggs on the aboveground portions of plants. The normal hosts are grasshoppers, which become infected by ingesting eggs while feeding on vegetation. After completing their development in the grasshoppers, the worms emerge and enter the soil, where mating occurs. One specimen that was removed from the mouth of a 1-month-old infant was identified as a gravid female *M. nigrescens* (Figure 18.9). On the basis of the parasite life cycle, it was assumed that the female was ovipositing on vegetation and was carried, perhaps on the fur of a dog or cat present in the house,

Figure 18.9 (1) Head of *Mermis nigrescens* removed from the mouth of an infant. Note the mouth opening (arrow), lip papilla (L), and cephalic papillae (C). Bar, 80 μ m. (2) Eggs of *M. nigrescens* inside the uterus of the specimen. Note the thick, double-walled shell surrounding the fully developed embryos. Arrows point to poles containing collapsed byssi. Bar, 55 μ m. (Reprinted from reference 74 with permission.)

to the vicinity of the child. The parasite was possibly attracted to the moisture of the mouth (74).

Micronema deletrix

Micronema deletrix roundworms are free-living and are normally found in soil, manure, or decaying humus. *M. deletrix* is reported to have caused a fatal meningoencephalomyelitis in a 5-year-old boy who accidentally fell into a manure spreader and passed through the mechanism. He sustained multiple severe wounds and fractures, all of which had been heavily contaminated with manure. Although his lesions appeared to heal satisfactorily, 18 days after the injury he became lethargic. Lumbar puncture revealed over 300 cells per ml and equal numbers of lymphocytes and macrophages. The child died of meningoencephalitis 24 days after the accident (42). The autopsy revealed extensive inflammatory foci in the brain, each of which contained various developmental stages of the worms (Figure 18.10) (8).

Figure 18.10 Longitudinal section through the rhabditiform esophagus in the anterior end of a mature female *Micronema deletrix* worm in the brain. The procorpus (pc), metacarpus (mc), isthmus (is), bulb (bu), and intestine (in) are indicated ($\times 1,040$). (Armed Forces Institute of Pathology photograph; published in *Can. J. Neurol. Sci.* 2:125, 1975.)

A second fatal case of human meningoencephalitis caused by *M. deletrix* has been reported. The patient had severe granulomatous meningoencephalitis with many foci of hemorrhage and encephalomalacia. Many adult female and larval worms were found in the brain. The organisms probably live in decaying organic material but occasionally parasitize the kidneys, nose, or central nervous system of the horse. In its parasitic form, the nematode reproduces parthenogenetically (82).

Diectophyma renale

The large (14 to 20 cm long by 46 mm wide) roundworm *Diectophyma renale* is widely reported to have been isolated from dogs. Infection in humans is acquired from the ingestion of raw freshwater fish and frogs. The adult worms usually live in the pelvis of the right kidney or in body cavities. The kidney parenchyma is gradually destroyed, leaving only the capsule. In all but 1 of the approximately 13 reported human cases, the kidney was involved (5). Infections were discovered at autopsy, by detection of worms migrating from the urethra, by detection of a worm discharged through the skin over an abscessed kidney (1), and by recovery of eggs in the urine (1) (Figure 18.11).

A 50-year-old Chinese man was found to have a retroperitoneal mass in the right upper quadrant of the abdomen by ultrasonography and computed tomography. At surgery, a hemorrhagic cyst was seen at the upper pole of the right kidney adjacent to the adrenal gland. Histologic examination revealed that the granulomatous cyst wall was filled with eggs and cross sections of parasites that were subsequently identified as *D. renale*. The eggs had a birefringent striated double wall (Figure

Figure 18.11 *Diectophyma renale* egg. This egg measures 60 to 80 μm by 39 to 46 μm and has a thick shell that appears wrinkled; the ends of the egg are usually lighter in color.

18.11). The right kidney was intact, and no eggs were seen in the urine (88).

Liesegang rings (LRs) in tissue are periodic precipitation zones from supersaturated solutions in colloidal systems. They are formed by a process involving interplay of diffusion, nucleation, flocculation or precipitation, and supersaturation. In a description of LR from the lesions of 29 patients, the LR formed in cysts or in fibrotic, inflamed, or necrotic tissue. Special stains and energy-dispersive radiographic analysis or scanning electron microscopy revealed that some LR contained calcium, iron (hemosiderin), silicon, and sulfur. Some pathologists have mistaken LR for eggs, larvae, or adults of *D. renale*. It is important to remember that these LR can be mistaken for parasites and have been found in tissues and from renal cyst fluid (48, 89).

Ternidens deminutus

The nematode *Ternidens deminutus* is found as a parasite of the large intestine of several simian hosts and is occasionally found in humans (45). The worms inhabit the wall of the large intestine and may produce ulcers or cystic nodules (4). The geographic range includes Africa, India, and Indonesia; human infections have been reported in Southeast and South Africa. Although it is apparently fairly common in natives of Zimbabwe and has been found in large numbers in certain specific communities, it is not found in Europeans (4). Morphologically, *T. deminutus* resembles a hookworm; however, the anterior buccal capsule is guarded by a double crown of 22 stout bristles. The oval eggs closely resemble those of human hookworms but are larger (84 by 51 μm) (Figure 18.12). Third-stage larvae develop in soil or Harada-Mori cultures in 8 to 10 days; however, the complete life cycle is unknown. Newly identified genetic markers provide a foundation for an improved PCR-based diagnosis of these infections (79). Both thiabendazole and pyrantel pamoate produce cure rates over 90%.

Figure 18.12 *Ternidens deminutus* egg. This egg measures 85 by 50 μm and closely resembles the egg of hookworm and *Oesophagostomum*; however, it is larger.

Mammomonogamus laryngeus (*Syngamus laryngeus*)

Mammomonogamus laryngeus is commonly found in the upper respiratory tract of some mammals, including cattle and felines. There have been approximately 100 cases of human infection, with almost all cases being reported from the Caribbean islands; more than half of the cases occurred in Martinique or in France in people who had traveled to Martinique (4, 70). Other reports have mentioned Puerto Rico, Dominica, St. Lucia, Trinidad, Guyana, Brazil, and the Philippines. Although third-stage larvae are probably infective for the vertebrate host, little is known about the life cycle.

The worm is red to reddish brown because of the ingestion of blood (70). The male and female worms are permanently joined in copula and present a Y shape. The short arm of the Y is the male worm, and the longer arm and base of the Y is the female worm (Figure 18.13.) Both worms have a thick-walled buccal capsule which is armed in the inner base with eight small teeth. Male worms measure 3.0 to 6.3 mm long and 360 to 380 μm wide. Female worms measure 8.7 to 23.5 mm long and 550 to 570 μm wide. The eggs are oval, have a thick cortical shell, and measure 78 to 95 μm long by 42 to 54 μm wide (Figure 18.14).

The worms in the trachea are often associated with a severe, nonproductive cough; the cough is often accompanied by hemoptysis and occasionally asthma, possibly because of obstruction of the bronchi or bronchioles (22, 23, 70). Eosinophilia may or may not be present. Diagnosis can be performed by examination either of

Figure 18.13 *Mammomonogamus laryngeus* (*Syngamus trachea*) worms in the trachea of a turkey; note the typical Y configuration of the adult male and female worms. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

worms or eggs coughed up in the sputum or of eggs that may be swallowed and recovered in the stool. Direct visual examination of the throat and/or endoscopy may also reveal the presence of worms; worms can be removed by using forceps or surgical techniques. There have been no controlled studies of specific therapy of human infections with *M. laryngeus*.

M. laryngeus is a common veterinary parasite, and the adult worms are normally found in the laryngotracheal region of ruminants. The eggs are coughed up and swallowed and can be found in the sputum or stool. Once the eggs are outside of the host, they undergo development until the larva becomes infective; the larva can remain in the egg or be released into the environment. Ruminants become infected through the ingestion of food or water contaminated with infective larvae. Carrier hosts such as earthworms, snails, or arthropods may also play a role in infection. Apparently, the larvae are released in the digestive tract, cross the intestinal wall to the mesenteric veins, and migrate to the tracheolaryngeal area, where the adult worms mate and begin reproduction (70).

Ascaris suum

Human infection with adult *A. suum* is occasionally documented, based primarily on very specific worm morphology and relevant history with potential exposure to pigs. Generally, *Ascaris lumbricoides* and *A. suum* are morphologically so similar that individual worms usually cannot be identified as one or the other.

Of much greater concern are the human infections with *A. suum* in which the larvae cause visceral larva migrans (VLM) and invade the liver, lungs, and the intestine but do not mature to adult worms (65). In some cases,

encephalopathy can also be associated with VLM caused by *A. suum* (44). In one case, the patient suffered from drowsiness, quadriparesis, eosinophilia, and elevated immunoglobulin E levels in serum. Magnetic resonance imaging revealed multiple cerebral cortical and white matter lesions, and serologic test results indicated recent infection with *A. suum*.
