Patients with VLM have respiratory symptoms; although eosinophilia is marked, no eggs or larvae have been found in stool specimens. Multiple small mass lesions can be seen on magnetic resonance imaging; they all disappear after anthelmintic therapy. Although liver tissue biopsy specimens showed marked infiltrations by eosinophils in the portal tracts and hepatic sinusoids, no larvae or eggs were seen (38). Hepatic nodules have been located mainly in periportal or subcapsular regions, which may represent periportal eosinophilic granuloma (47).

The number of infective eggs required to initiate an infection is apparently quite small; massive infections with *A. suum* can cause severe disease (5). However, the actual significance of human infection with this nematode is not known. Among people who visit or live on farms where pigs are raised, *A. suum* may be a significant cause of illness.

Gongylonema pulchrum

The thin nematode *Gongylonema pulchrum* is a common parasite of ruminants and has been diagnosed in pigs, bears, hedgehogs, monkeys, and occasionally humans. Human cases have been reported from Europe, Morocco, the former USSR, China, New Zealand, Sri Lanka, and the United States. Human infection is acquired by accidental ingestion of infected insects. Pathology in human cases is due to maturing and adult worms migrating through the mucosa and submucosa of the buccal cavity and the esophageal mucosa. Worms have been recovered from the lips, gums, hard and soft palate, tonsils, and angle of the jaw. In some cases, blood is present. In a case report from the United States, a 41-year-old woman living in New York City presented with a history of a sensation of a "moving organism" in her mouth for more than a year (27). On two occasions she removed worms from her mouth, once from the lip and once from the gum. The patient also reported a history of reflux-like symptoms that may have been associated with esophageal involvement. The worm extracted from the lip was identified as a mature female *Gongylonema* worm, probably *G. pulchrum*. The anterior was very thin and threadlike, with a diameter of 0.5 mm; it was covered with typical bosses (scutes) arranged in longitudinal rows (Figure 18.15). The posterior end of the worm was considerably wider. The eggs measured 50 by 28 μm .

Figure 18.15 *Gongylonema pulchrum*. (A) Anterior end of the worm. (B) Posterior end of the worm. (C) Egg. (Panel A adapted from H. B. Ward, *Gongylonema* in the role of a human parasite. *J. Parasitol.*, 1916. Panel B adapted from reference 4. Panel C adapted from reference 27.)

Haycocknema perplexum

Adult male and female nematodes and larvae were recovered from myofibers after biopsy of the right vastus lateralis muscle. This infection in a man in Tasmania, Australia, was associated with a polymyositis (85). Two other potential cases have been reported, one of which was also in a patient from Tasmania (24). A muspiceoid nematode causing polymyositis was involved in these cases. These minute adult worms are very slender ($<35\ \mu\text{m}$) and measure approximately $300\ \mu\text{m}$ (male) and $425\ \mu\text{m}$ (female) in length. The adult worms are very small and may be mistaken for larvae.

Muscle weakness, eosinophilia, and biopsy results have been consistent with an active polymyositis. While treatment with prednisone produced no improvement, subsequent treatment with albendazole led to immediate improvement (34).

Cestodes

Although *Echinococcus oligarthrus* and *Echinococcus vogeli* were covered in this chapter in previous editions of this book, they have been moved to chapter 14 (61).

Figure 18.16 *Diplogonoporus* tapeworm proglottids. Note the width of the proglottids and their very short length; also note the two genital organs in each proglottid.

A new species, *Echinococcus shiquicus*, has been identified from China. Although no human infections have yet been identified, the possibility of infection certainly exists (93).

Diplogonoporus spp.

Diplogonoporus grandis and *D. balaenopterae* have been identified as tapeworm parasites of humans. This tapeworm is normally found in whales but has been isolated from approximately 50 Japanese patients (5). The adult worm measures 1.4 to 5.9 m long and has gravid proglottids that are very wide (15 to 25 mm) and very short (0.54 mm). There are two sets of genital organs in each proglottid (Figure 18.16). The eggs are operculated, their morphology is very similar to that of eggs of *Diphyllobothrium latum*, and they measure 63 to $68\ \mu\text{m}$ by $50\ \mu\text{m}$ (Figure 18.17).

A more recent case has been reported from Spain, in which a 58-year-old man who consumed raw fish passed a short chain of gravid proglottids. After therapy with 50 mg of paromomycin sulfate per kg divided into three doses, all given on the same day, the worm was finally evacuated. The man had not been out of Zaragoza Province in Spain for approximately 20 years, and the infection was probably associated with the importation

Figure 18.17 *Diplogonoporus* egg. This egg measures 63 to $68\ \mu\text{m}$ by $50\ \mu\text{m}$; note the resemblance to the *Diphyllobothrium latum* egg.

of fish into Spain. Outside of the Far East, this is the first confirmed case of diplogonoporiasis. The viability of the infective larval stage is evidence of resistance to export/import conditions (20).

Bertiella studeri

The tapeworm *Bertiella studeri* was originally recovered from an orangutan in Borneo and has been isolated from approximately 30 patients from India, Sumatra, Java, Borneo, Vietnam, Singapore, East Africa, St. Kitts, British West Indies, Philippines, Malaysia, Sri Lanka, and Yemen. The worm is relatively small, measuring up to 300 mm long and 10 mm wide. The proglottids are shed about 20 at a time; each mature proglottid is approximately 6 mm broad by 0.75 mm long. The eggs have an irregular, oval shape and measure 45 to 46 μm by 49 to 50 μm . There is a delicate middle envelope and an inner shell with a bicornuate protrusion on one side (Figure 18.18).

Infection is acquired by the accidental ingestion of mites containing the cysticercoid larval stage of the worm. After therapy with niclosamide or other anthelmintics, the worms are evacuated; they may also be passed spontaneously, as seen with other tapeworms. Patients may be asymptomatic or complain of vague intestinal disturbances. Some symptoms include intermittent epigastric pain after meals, accompanied by nausea, diarrhea, and anorexia, with no fever or weight loss (7). The eggs are very characteristic, and identification can be confirmed

Figure 18.18 *Bertiella studeri*. (A) Scolex. (B) Egg. (C) Mature proglottid. Note the description of the egg in the text related to the illustration. (Adapted from an original drawing by R. Blanchard, in E. C. Faust, *Human Helminthology*, Lea & Febiger, Philadelphia, Pa., 1929, and reference 4.)

by finding the eggs or a chain of proglottids in the stool. Most of the confirmed human infections have been found in children. Although both niclosamide (Yomesan) and albendazole have been used for therapy, treatment is not always successful (94).

Human infections with *B. mucronata* have also been found; however, fewer than 10 cases have been recorded. One infection has been recorded in a child in Fargo, N.D., who may have come in contact with an imported monkey (5).

Inermicapsifer madagascariensis

The tapeworm *Inermicapsifer madagascariensis* is often seen in humans in Havana, Cuba; in fact, outside of Africa, where it causes a disease of rodents, it may be restricted to humans. Although the life cycle has not been established, an arthropod vector is thought to be involved in human infections, which are most common in children aged 1 to 3 years. Symptoms are vague, but there may be anorexia, weight loss, abdominal pain, or irritability (34). Diagnosis is performed by finding the rice grain-like proglottids; however, these proglottids, eggs, or egg capsules are extremely similar to those of *Raillietina* spp. Specific treatment with praziquantel has been reported to be effective in eliminating the tapeworm (35).

Raillietina celebensis

The tapeworm *Raillietina celebensis*, common in rats, has also been found in humans, mostly children. The intermediate hosts are various species of ants. Usually, the infection causes no symptoms. The proglottids are small (3 mm or less) and resemble those of *I. madagascariensis*.

The adult worm is approximately 40 cm long; each egg packet contains one to four large eggs measuring 90 by 46 μm . Any symptoms that might be present tend to disappear after treatment with niclosamide.

A number of other species in the genus *Raillietina* have been implicated in human disease, although the number of cases has been small. *R. demerariensis* has been found in approximately 5% of patients in the rural areas near Quito, Ecuador; cases have also been reported from Cuba. The adult worms measure up to 60 cm long by 3 mm wide and have around 5,000 proglottids (5). The individual proglottids resemble rice grains and contain about 200 to 250 egg packets, each measuring about 200 μm in diameter. The oval eggs contain very conspicuous hooklets. *R. asiatica*, *R. garrisoni*, and *R. siriraji* all cause infection in humans, and, again, children rather than adults are affected. Accidental ingestion of arthropod intermediate hosts is implicated in transmission.

Mesocestoides spp.

Approximately 27 cases of human infection have been reported, probably acquired from ingestion of the larval form (tetrathyridium) in inadequately cooked meat from some animal that serves as the intermediate host. The tapeworm in one case measured 40 cm by 2 mm. The infected child was irritable, had a poor appetite and abdominal colic, and was anemic (16). A second case was reported from Korea (28). The patient, who was a farm worker, complained of abdominal pain and passed a number of proglottids in the stool over a period of several months. The proglottids were described as looking like sesame seeds. Adult worms were recovered after therapy with niclosamide and consisted of 32 complete worms. This is probably the heaviest worm burden reported in a human case. The patient had a history of frequently eating raw viscera of chickens. The seventh case has been reported in the United States; the patient was a 19-month-old boy from Alexandria, La. The infection was probably food borne, associated with local dietary customs in the Acadian and Creole communities of Louisiana, including eating sausage containing wild-animal viscera (33).

Taenia crassiceps

Taenia crassiceps is a common tapeworm of the red fox. Larval forms are generally found under the skin and in the body cavities in animals. Human cases are quite rare. An infection was reported in a 33-year-old patient with AIDS and a history of *Pneumocystis jiroveci* pneumonia and cerebral toxoplasmosis. The patient developed a subcutaneous paravertebral infiltrate that resembled a hematoma. During a period of several weeks, the lesion spread such that almost the entire back was covered. Approximately 3 weeks after admission, the infiltrate ruptured spontaneously, releasing blood and many white spherical masses (2 to 3 mm in diameter). The masses were identified as the larval form of *T. crassiceps*. After therapy with mebendazole and praziquantel, the infiltrate regressed. Praziquantel treatment was continued for 10 weeks, at which time the patient stopped taking the medication. At the end of 4 months, the lesion recurred but was successfully treated with an additional course of mebendazole and praziquantel (50).

A second case in an AIDS patient has been reported from France; this case involved invasion of subcutaneous and muscular tissues by the larval forms of *T. crassiceps* (17). The authors emphasized the problems in differentiating this infection from cysticercosis, coenurosis, sparganosis, and hydatidosis. The proliferative growth of the larvae, recurrence of lesions after surgical removal, and possible invasion of other tissues carry a poor prognosis for this group of immunocompromised patients. The biological

Figure 18.19 *Taenia crassiceps*. Retinal photographs showing budding cysticercus in situ. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*. Photograph courtesy of Renio Freeman.)

properties of *T. crassiceps* cysticerci and the epidemiologic characteristics of pandemic AIDS could indicate the potential for new cases of this disease in humans (31).

Another case illustrates a non-AIDS-associated infection with *T. crassiceps* (2). A healthy 15-year-old girl developed an iridocyclitis in her right eye. A contractable living parasite measuring about 2 mm could be seen in the anterior chamber, while the rest of the eye was not involved (Figure 18.19). The patient reported having close contact with a young dog in the family. The larval form was removed alive but was not developed enough to have the characteristic scolex (Figure 18.20). Western blot results provided sufficient indirect evidence to confirm the identity of the organism as *T. crassiceps*. After follow-up for 2 years, no further evidence of ocular or general infestations with this parasite could be found.

The method for obtaining antigenic extracts from *T. crassiceps* cysticerci and their cross-reactivity with *T. solium* cysticerci antigens have made them an interest-

Figure 18.20 *Taenia crassiceps* cysticercus after surgical removal from the eye. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*. Photograph courtesy of Renio Freeman.)

ing antigen source for diagnostic work. The use of 18- and 14-kDa *T. crassiceps* immunoaffinity-purified proteins for detection of anti-cysticercus antibodies in cerebrospinal fluid and/or serum samples by using an enzyme-linked immunosorbent assay system showed good performance and a high specificity for serum samples, dispensing with the use of confirmatory tests, such as immunoblotting, for checking specificity (29).

Trematodes

Alaria americana

Alaria americana is a trematode that is normally found in the intestines of wild mammalian carnivores such as wolves, foxes, raccoons, bobcats, and skunks. The eggs are passed in the stool, hatch in water, and invade freshwater snails of the genus *Helisoma*. Cercariae then leave the snail and infect frog tadpoles. The first case of disseminated human infection by the mesocercarial stage of this worm was found in a 24-year-old man in Canada who died 8 days after the onset of his illness (30). The infection was probably acquired through ingestion of inadequately cooked frogs, which serve as intermediate hosts for this parasite. The infection was diagnosed by lung biopsy, and mesocercariae were found in the stomach wall, lymph nodes, liver, myocardium, pancreas and surrounding adipose tissue, spleen, kidney, lungs, brain, and spinal cord at autopsy (Figures 18.21 and 18.22). Apparently, there was no host reaction to the parasites. Granulomas were present in the stomach wall, lymph nodes, and liver, but no worms were recovered from these sites.

Two cases of eye infections with mesocercariae of *Alaria* were found in unrelated Asian men who had unilateral decreased vision (67). Both patients had pigmented tracks in the retina, areas of active and/or healed retinitis, and other signs of diffuse unilateral subacute neuroretinitis (Figure 18.23). The worms were seen in the

Figure 18.21 *Alaria americana*. Living mesocercaria removed from a human liver at autopsy. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of R. S. Freeman.)

Figure 18.22 *Alaria americana*. Mesocercaria in the patient's pons. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of R. S. Freeman.)

retinas and vitreous several years after the original infection was thought to have occurred. The probable source of infection was ingestion of undercooked frogs' legs containing the infective stage. In addition to the prolonged intraocular infection, the mesocercariae caused diffuse unilateral subacute neuroretinitis, a condition thought to be caused only by intraocular nematode larvae.

Plagiorchis spp.

Plagiorchis spp. cause human intestinal infections that have been confirmed in the Philippines, Indonesia, Korea, Thailand, and Japan. The infection is acquired from the ingestion of grubs of certain insects thought to be

Figure 18.23 *Alaria americana* in the human eye. Note the relationship to the optic disk and macula. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of R. S. Freeman.)

the second intermediate host for this fluke. Ingestion of raw or poorly cooked freshwater fish containing the metacercariae was implicated in the case in Korea (41). Metacercariae obtained by an artificial ingestion technique used on freshwater fish were administered to a Sprague-Dawley rat; on day 8 postinfection, one *Plagiorchis muris* worm was recovered from the small intestine of the rat. Infections with multiple helminths from northeast Thailand have included *P. harinasutai*, as well as other unusual trematodes (77). Confirmation of these infections may be difficult since the eggs resemble those of *Opisthorchis viverrini* and *Clonorchis sinensis*.

Neodiplostomum seoulense

Neodiplostomum seoulense is known to infect humans in Korea and has been linked to snake consumption. The parasites can normally be found in house rats, frogs and their tadpoles, and several terrestrial snakes. Symptoms have been noted in human infections and include epigastric pain, diarrhea, fever, and eosinophilia. The eggs can be differentiated from those of *Paragonimus*, *Echinostoma*, and *Fasciola*; they measure 81 to 102 μm long by 51 to 63 μm wide, are golden brown and bilaterally symmetrical, have an oblique opercular margin, and are immature when passed in the stool. In animal studies, this parasite appears to have the potential to kill most strains of mice by causing irreversible damage to their intestine (51). In follow-up studies of intestinal parasitic infections of the Army soldiers in Whachon-gun, Korea, additional cases of infection with *N. seoulense* were identified (43). Additional molluscan intermediate hosts for *N. seoulense* continue to be identified (19).

Spelotrema brevicacaeca

Spelotrema brevicacaeca has been reported to cause infections in humans in the Philippines. The eggs of these trematodes are suspected of causing lesions in the heart, brain, and spinal cord of patients dying of acute cardiac dilation. Although the complete life cycle is not known, the encysted metacercarial stage has been found in the crab *Cararius maenas*, which is the implicated food source. The adult worms are small, measuring 0.5 to 0.7 mm long by 0.3 to 0.4 mm wide, and have a spinose cuticle. The eggs are quite small (15 to 16 μm long by 9 to 10 μm wide). The infection can be confirmed by finding the eggs in stool or tissues or by finding adult worms in the stool after therapy.

Brachylaima sp.

Two 21-month-old children from the same rural area of South Australia presented 18 months apart with mild abdominal pain and diarrhea; trematode eggs of

Brachylaima sp. were found in the stool (13). Therapy with praziquantel resulted in cessation of the symptoms and elimination of eggs in the stool. The life cycle involving the common house mouse, poultry, and introduced European helcid snails is well established in South Australia. Both children had been seen eating raw snails; examination of the snails from the environment confirmed that they were infected with metacercariae of this brachylaimid trematode.

In 1998, a 78-year-old woman presented with an 18-month history of intermittent diarrhea. Eggs of a brachylaimid trematode were seen in the stool for a week. After treatment with praziquantel, a degenerated adult fluke was recovered from the stool and subsequently identified as *Brachylaima* sp. She lived in South Australia and consumed vegetables grown in her garden, which was infested with helcid snails. These snails, commonly infected with brachylaimid intermediate larval stages, are considered to be the source of human infection (12). *B. cribbi* is the first brachylaimid known to have infected humans and is probably of European origin; the intermediate host snails were all introduced into Australia from Europe. This life cycle was established in the laboratory from eggs recovered from human feces in Australia (11).

Trogloitrema salmincola

The trematode *Trogloitrema salmincola* has been associated with poisoning in dogs eating raw salmon or trout on the Pacific coast of North America and Canada. Normal hosts would include the coyote, fox, raccoon, mink, and lynx in North America and aborigines of eastern Siberia. The adult worms are quite small, measuring 0.8 to 1.1 mm long by 0.3 to 0.5 mm wide. The eggs are broadly oval, operculated, thick-shelled, and yellow and measure 60 to 80 μm long by 34 to 50 μm wide. When salmon and trout, as well as other fish and the Pacific giant salamander, are eaten raw, metacercariae in their kidneys cause infection in the intestine of the definitive host (the dog). A rickettsia is associated with the fluke infection and has caused severe and fatal symptoms in dogs, coyotes, and foxes; this rickettsia is also possibly a human pathogen. Praziquantel is the recommended therapy for human infection with this trematode.

Stellantchasmus falcatus

Stellantchasmus falcatus infections in two humans have been reported from Korea. Vague abdominal discomfort and hunger pains were reported. In both patients, adult worms were recovered in the stool after treatment with praziquantel (39, 84). Both patients reported eating several kinds of brackish-water fish. Based on these case histories,

the total number of human infections remains at <10 to date. This infection has also been documented in a patient eating raw mullet in Hawaii (10). Another infection linked to the ingestion of raw mullet is caused by a *Phagicola* sp. A patient in Brazil complained of mild intestinal pain, and examination of the stool specimen revealed trematode eggs in the stool. The patient also had an 8% eosinophilia. After treatment with praziquantel, the symptoms disappeared (18). Another infection linked to the ingestion of raw brackish-water or freshwater fish in Korea is caused by *Heterophyopsis continua*, a trematode whose consumption results in vague abdominal complaints (40).

Phaneropsolus bonnei and *Prosthodendrium molenkempi*

The two small trematodes *Phaneropsolus bonnei* and *Prosthodendrium molenkempi* have been recovered in large numbers from the intestine of humans; however, there are no well-defined intestinal pathologic or clinical findings. These infections are documented and endemic among rural populations in northeastern Thailand and Laos; in some areas the prevalence is as high as 10 to 40%. Infection occurs after ingestion of raw or poorly cooked small fish contaminated with infected naiads (water nymphs of dragonflies). Diagnosis can be confirmed by

finding adult worms or eggs in the stool; however, the eggs may be difficult to differentiate from each other and from those of *O. viverrini*. *O. viverrini* and several species of heterophyid and lecithodendriid flukes are endemic in two riverside localities in Laos, suggesting that the intensity of infection and the relative proportion of fluke species vary by locality along the Mekong River basin (15). Staining using a 1% (wt/vol) concentration of potassium permanganate for 1 min is useful in differentiating the egg surface morphology of *O. viverrini*, *Haplorchis taichui*, and *P. bonnei* eggs (86).

Phaneropsolus spincirrus

Members of the *Phaneropsolus* group of trematodes have been found in reptiles, birds, and mammals; however, only *Phaneropsolus bonnei* was reported to have been isolated from humans (58). Adult worms of *P. spincirrus* sp. nov. were recovered after treatment with praziquantel followed by a magnesium sulfate purgative 5 h after medication. All stools passed over the next 48 h were preserved in 10% formalin and strained through a 120-mesh screen (200- μ m openings), and the strained material was examined with a stereoscopic microscope. The adult worms were stained with Mayer's hemalum, dehydrated, cleared, and mounted for examination. Differences in morphologic character-

Figure 18.24 *Phaneropsolus spincirrus* isolated from a patient. (1) Ventral view of the holotype. (2) Ventral view of the structure of the terminal portion of the reproductive system. c, cirrus; cs, cirrus sac; gp, genital pore; mt, metraterm; os, oral sucker; pg, prostate gland; sv, seminal vesicle. (Reprinted from reference 46 with permission.)

Figure 18.25 Photographs of two species of *Phaneropsolus* collected from the same patient. (3) The anterior part of *Phaneropsolus spinicirrus*, showing the spinose cirrus and the tegumental spines. Bar, 0.05 mm. (4) Unstained adults of *P. spinicirrus*, showing the larger excretory bladder (exb) and the more conspicuous border. Bar, 0.5 mm. (5) Unstained adults of *P. bonnei*. Bar, 0.5 mm. (Reprinted from reference 46 with permission.)

istics that provided evidence for the identification of *P. spinicirrus* rather than *P. bonnei* included more conspicuous spines on the cirrus, a larger body and internal organs, conical spines on the tegument, an ovoid to bilobed ovary, and a large, V-shaped excretory bladder (46). The structure of the tegumental spines and the characteristic excretory bladder allow the two species to be recognized, even in unstained specimens (Figures 18.24 and 18.25).

Haplorchis taichui

Haplorchis taichui is a minute human intestinal trematode that parasitizes the small intestine of humans and other mammals (Figure 18.26). Pathologic changes seen in three

Figure 18.26 *Haplorchis taichui*. Note the pyriform adult trematode, which is covered with scale-like spines on the tegument; eggs can be seen to the right of the labels, while the ventral sucker can be seen immediately above the label. The ventral sucker has a crescentic group of 12 to 16 hollow spines (scleritis) (not visible in this image). (Armed Forces Institute of Pathology photograph.)

patients from Thailand include mucosal ulceration, mucosal and submucosal hemorrhages, fusion and shortening of the villi, chronic inflammation, and fibrosis of the submucosa (87).

An exceptionally high rate of infection (36%) has been identified in human populations on Mindanao Island, southern Philippines. The source of infection has been linked to consumption of raw or undercooked freshwater fish containing infective metacercariae. Clinical symptoms include upper abdominal discomfort or pain and loud gurgling noises produced by the movement of gas, fluid, or both in the alimentary canal, sounds which are audible at a distance. Other reported symptoms were nausea, chronic diarrhea, and weight loss. Symptoms rapidly resolved after treatment with praziquantel (6). The adult fluke is pyriform; eggs and the ventral sucker can generally be seen (6).

Gymnophalloides seoi

Gymnophalloides seoi is a new human intestinal trematode that was first found in a Korean woman who complained of epigastric discomfort. This trematode is highly prevalent among the inhabitants of a seashore village on a southwestern island of the Republic of Korea. Normally, it is a parasite of shorebirds and is thought to be the only known species in the family Gymnophallidae that can infect hu-

Figure 18.27 Eggs of *Gymnophalloides seoi* from the feces of a patient, detected by formalin-ether sedimentation (unstained) (A) and cellophane thick-smear technique (malachite green stained) (B). (Reprinted from reference 57 with permission.)

Figure 18.28 Specimen of *Gymnophalloides seoi* (ventral view, unstained) showing various structures within this fluke. (Reprinted from reference 57 with permission.)

mans. Various bivalves (clams) are known to serve as the first or second intermediate hosts for some of these trematodes. Symptoms are generally somewhat nonspecific and include abdominal pain, diarrhea, indigestion, anorexia, easy fatigability, and weakness. On the basis of fecal examinations, 70 (71.4%) of 98 were found to be infected with various intestinal parasites. *G. seoi* eggs were found in 48 (49.0%) of 98 patients. Individual worm burdens, as measured by collection of adult flukes after treatment and purgation, ranged from 106 to 26,373 specimens. The average number of worms per patient was 3,326. There were no sex- or age-related differences. This study indicates that *G. seoi* is a human intestinal trematode under natural conditions and does not represent just an accidental infection (56, 57). The eggs of *G. seoi* measure 19 to 25 μm in length (smaller than *C. sinensis*) and have a thin, transparent shell (Figure 18.27). The adult worm measures approximately 0.4 mm long and 0.25 mm wide (Figure 18.28).

***Metorchis conjunctus* (North American Liver Fluke)**

A common-source outbreak of acute clinical illness among 19 people who ate raw fish (sashimi) prepared from the white sucker has been reported from Canada.

The sashimi contained infective metacercariae of *Metorchis conjunctus*. The adult fluke lives within the biliary tree of the definitive host. Symptoms included persistent upper abdominal pain, low-grade fever, high eosinophil counts, and increased liver enzyme levels with an obstructive pattern. After 15 days, trematode eggs were recovered in the stool specimens; morphologically they were identical to those of *O. viverrini*. The symptoms lasted several weeks, but the patients responded rapidly to therapy with praziquantel. Necropsy of golden hamsters that had been fed metacercariae from the fish revealed adult flukes identified as *M. conjunctus*. Apparently, this is a newly emerging human disease and represents the first report of a common-source outbreak of an acute illness caused by these North American liver flukes (63). Although some patients remain asymptomatic, the prevalence in some isolated communities within Canada reaches 20% (62). Because fish parasites infecting humans within the United States and Canada are becoming more important and prevalent, a composite list has been provided (Table 18.2).

Table 18.2 Human parasites acquired from the ingestion of raw or poorly cooked fish^{a,b}

Parasite	Fish host(s)
Nematodes	
<i>Anisakis simplex</i>	Salmonids, tuna, herring, mackerel, squid
<i>Pseudoterranova decipiens</i>	Cod, pollack, haddock
<i>Eustrongylides</i> spp.	Killifish, estuarine species
<i>Diocotophyma renale</i>	Freshwater fish, estuarine species
Cestodes	
<i>Diphyllbothriurn latum</i>	Salmonids, pike, perch, burbot
<i>Diphyllbothrium dendriticum</i>	Salmonids
<i>Diphyllbothrium ursi</i>	Salmonids
<i>Diphyllbothrium</i> spp. ^c	Salmonids
<i>Schistocephalus solidus</i>	Sticklebacks
Trematodes	
<i>Trogloitrema (Nanophyetus) salmincola</i>	Salmonids
<i>Metorchis conjunctus</i>	White sucker
<i>Haplorchis taichui</i>	Freshwater fish
<i>Plagiorchis</i> spp.	Freshwater fish
<i>Cryptocotyle lingua</i>	Flounder
<i>Amphimerus pseudofelineus</i>	Freshwater fish

^a Adapted from reference 62.

^b Not every parasite mentioned in this table has been included in this chapter on unusual parasites; often case reports are very limited. Parasites listed in this table are geographically relevant to the United States and Canada, and the table does not include all parasites discussed in the chapter.

^c The taxonomy of the genus *Diphyllbothrium* remains unclear.

Schistosoma mattheei

Schistosoma mattheei causes infections in sheep, cattle, and horses; human infections, which caused mild disease, have also been reported from South Africa. The eggs resemble those of *Schistosoma intercalatum*, have a terminal spine, and measure 120 to 180 μm in length. Clinical specimens include urine and stool; eggs can be recovered in both. Although human infections tend to be mild, the effect of this infection on animals is more serious.

The pathology of human disease is similar to that seen in other schistosome diseases and can include egg granulomas in the large intestine and liver, mild hepatosplenomegaly, and granulomatous bowel disease. There tends to be coinfection with either *S. haematobium* or *S. mansoni*. Patients may present with mild mucoid diarrhea in which blood is present, crampy abdominal pain, and general nonspecific complaints; many patients remain asymptomatic. Praziquantel is recommended for therapy.

Enzyme electrophoresis indicates that most, if not all, *S. mattheei* eggs passed in the urine in human infections

derive from *S. mattheei* females in copulo with *S. haematobium* males. It appears that *S. mattheei* males do not reach sexual maturity in humans; however, the *S. haematobium* × *S. mattheei* males possibly do (52). Studies indicate that it is highly unlikely that *S. mattheei* and *S. haematobium* will evolve into a single species; it does not seem likely that the virulence of the parental species will be influenced (53).

Philophthalmus lacrimosus

Philophthalmus lacrimosus is an avian eye trematode, found primarily in the eyes of wild and domestic birds. A number of mammals, including humans, can serve as the intermediate as well as the definitive host; however, human cases are quite rare. In cases of conjunctivitis, one of the symptoms is the feeling of having a foreign-body sensation in the eye. In one patient from Mexico, a small live parasite was found in the connective tissue of the conjunctiva and was removed surgically (Figure 18.29) (54). A recent case has been reported from Thailand (90a).

Figure 18.29 Adult *Philophthalmus* sp. trematode. Note oral sucker (os), pharynx (ph), cirrus sac (cs), acetabulum (ventral sucker) (ac), uterus (ut), and testes (te). (Armed Forces Institute of Pathology photograph.)

***Achillurbainia* spp.**

Achillurbainia spp. are trematodes (similar to *Paragonimus* spp.) that are normally found in the maxillary sinuses of the opossum. They have been isolated from humans. In one case of surgical inguinal hernia repair, massive numbers of small granulomata on the omentum and other peritoneal surfaces were found to contain trematode eggs like those of *A. recondita* (3). *Achillurbainia* eggs and/or adult worms have been found in retroauricular cysts or abscesses in individuals in West Africa and Southeast Asia.

Pentastomids

***Armillifer* spp., *Linguatula serrata*, and *Sebekia* spp.**

The organisms are found in a separate phylum, Pentastomida, and are called tongue worms. Human infections have been reported from Africa, Europe, Asia, and the Americas (14). A representative life cycle is seen in Figure 18.30. The pentastomids are a group of parasites classified between the arthropods and annelids (26).

When humans serve as the intermediate hosts, the infective larvae die in situ. However, when mature larvae (often encysted) are ingested, they may migrate from the stomach, attach themselves to nasopharyngeal tissues, develop into adult pentastomids, and produce symptoms of the halzoun syndrome. Symptoms include throat discomfort, paroxysmal coughing, sneezing, and occasionally dysphagia and vomiting (81).

Occasionally, pentastomid larvae infect the eye. Inflammation is minimal, and infection is probably the result of direct eye contact with water containing pentastomid eggs (25). In one case report, a 34-year-old woman in Guayaquil, Ecuador, presented with a 2-month history of ocular pain on the right side, with conjunctivitis and visual difficulties due to the presence of a shadow (55). Apparently, when she lay down on her right side, her vision became clear. Examination revealed a mobile body in the anterior chamber of the eye; the body was removed, fixed, stained, and mounted for more detailed microscopic examination. The parasite was identified as a third-stage instar larval form of *Linguatula serrata*. This case represents the first report in Ecuador and South America.

A case of dermatitis in a 31-year-old Costa Rican woman was reported to be caused by a pentastomid

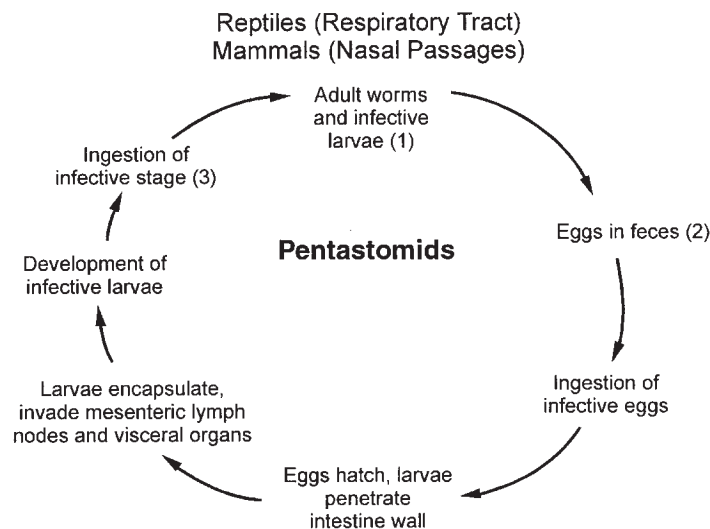

Figure 18.30 Life cycle of the tongue worms (pentastomids) *Armillifer* and *Linguatula* spp. (1) Humans ingest raw or inadequately cooked snake or lizard; (2) humans ingest eggs on vegetation or in water; (3) humans ingest the flesh of intermediate hosts containing infective larvae.

larva belonging to the genus *Sebekia*, apparently the first reported case of infection of a human by this genus. The adult worms are parasites found in the respiratory tract of reptiles, and the larval forms are found in the viscera and muscles and along the spinal cord of freshwater fish. The patient, who was pregnant, presented with a “strong itch” in the lower right quadrant of her abdomen and a “biting sensation,” particularly at night. She had a serpiginous burrow surrounded by an intense erythematous zone on her lower abdomen and a 30% eosinophilia. A white, active larva approximately 1 cm long was removed from the burrow. On the basis of morphologic features, including spines on the hooks and other details, the larva was identified as being in the genus *Sebekia*. Although there is no way to determine how the patient became infected or why the larva migrated to the skin as does larva migrans, the possibility of ingesting water containing eggs of the parasites or ingesting raw or improperly cooked fish could explain the subsequent infection (64).

Diagnosis is made by identifying the pentastomid in a biopsy specimen or at autopsy (Figures 18.31 and 18.32). Treatment is usually not necessary; however, surgical removal of the parasite is recommended if the patient is symptomatic.

Figure 18.32 Encysted *Armillifer armillatus* larva on the surface of the liver of a 55-year-old Zairian. The cyst contains a C-shaped larva ($\times 12$). (Armed Forces Institute of Pathology photograph.)

Acanthocephalans

Macracanthorhynchus hirudinaceus and *Moniliformis moniliformis*

The acanthocephalans (thorny-headed worms) were formerly included in the same phylum as the nematodes. These worms get their name from the proboscis, which is covered with spines (Figure 18.33). The life cycle is seen in Figure 18.34.

Very few cases have been reported in the literature; however, reported symptoms include abdominal pain and tenderness, anorexia, and nausea. In some cases, adult worms were passed in the stool (Figure 18.35) (76, 80).

In the last few years, a number of human infections with *Macracanthorhynchus hirudinaceus* have been reported from China. The infections have been primarily in children, probably acquired from the ingestion of raw beetles. Clinical manifestations include intestinal obstruction and perforation, with perforation occurring in over 200 cases. No eggs were found in the stool specimens of these patients. In many cases, the worms were recovered at surgery or autopsy. Signs and symptoms of infection with *Moniliformis moniliformis* include serious gastrointestinal pain, diarrhea, exhaustion, somnolence, and tinnitus; vomiting, jaundice, cough, and a protuberant abdomen have also been reported (21). In

Figure 18.33 Thorny-headed worm. Note the proboscis, which is covered with spines. (Illustration by Sharon Belkin.)

children, the infection has resulted in retarded development and irritability (5).

In some areas of China, eggs have been recovered in 16 to 60% of pigs examined (5); in pigs, this worm can be found worldwide. In Figure 18.36, the proboscis of *M. hirudinaceus* is seen attached to the pig bowel wall. The insertion of the toothed proboscis, along with the inflammation, ulceration, and hemorrhage caused, can

Figure 18.34 Life cycle of the acanthocephalans (thorny-headed worms).

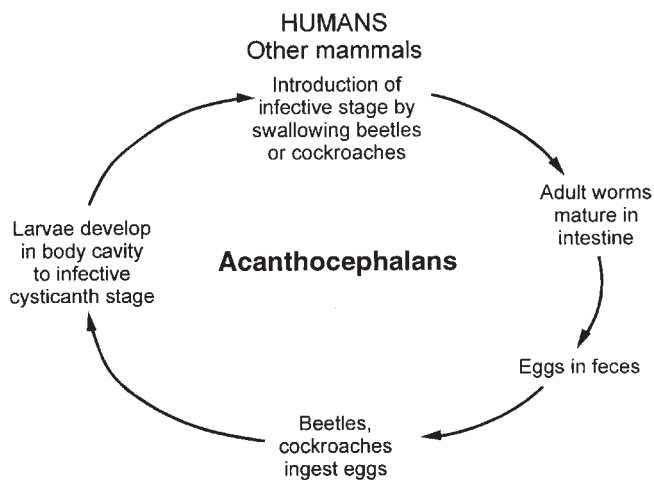

Figure 18.35 *Moniliformis moniliformis*, complete adult specimen, approximately 133 mm long ($\times 5$). (Armed Forces Institute of Pathology photograph.)

Figure 18.36 *Macracanthorhynchus hirudinaceus* proboscis attached to pig bowel wall. The insertion of the toothed proboscis, along with the inflammation, ulceration, and hemorrhage caused, are seen in this low-power view. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 18.37 *Macracanthorhynchus hirudinaceus*. A single tooth on the proboscis is visible at this higher magnification. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

be seen. In Figure 18.37, a higher-magnification photograph shows a single tooth on the proboscis that is visible. The eggs of *M. hirudinaceus* and *M. moniliformis* can be seen in Figures 18.38 and 18.39. Both eggs contain a fully developed acanthor larva, and the rostellar hooks are also visible.

Figure 18.38 *Macracanthorhynchus hirudinaceus* egg. This egg measures 80 to 100 μm by 50 μm , has a thick, dark brown, textured shell, and contains a developed acanthor larva with hooks. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

Figure 18.39 *Moniliformis moniliformis* egg. This egg measures 90 to 125 μm by 65 μm and contains a fully developed acanthor larva with visible hooks. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

Parasitic Infections in the Compromised Host

Entamoeba histolytica

Free-living amebae

Giardia lamblia

Toxoplasma gondii

Cryptosporidium spp.

Cyclospora cayetanensis

Isospora (Cystoisospora) belli

Sarcocystis spp.

Microsporidia

Leishmania spp.

Strongyloides stercoralis

Crusted (Norwegian) scabies

This chapter discusses some of the representative opportunistic organisms that can cause disease in immunocompromised patients. Any parasitic infection in the immunocompromised host may cause more severe symptoms; however, the organisms presented in this chapter have been identified as causing severe disease in this population.

The body has three types of host defense mechanisms: surface and mechanical factors, the humoral immune system, and the cellular immune system. Within these three groups, further distinction can be made between first-line (nonspecific) innate immunity and second-line (specific) adaptive immunity. By definition, a compromised host is one in whom normal defense mechanisms are impaired (e.g., AIDS), absent (e.g., congenital deficiencies), or bypassed (e.g., penetration of the skin barrier). These patients are becoming more common in most medical facilities and represent a growing problem in terms of diagnosis and subsequent therapy.

As seen in Table 19.1, first-line surface and mechanical factors include the skin, the cough reflex, ciliary motion (respiratory epithelium), and flushing action (urine); secondary defense mechanisms include immunoglobulins such as immunoglobulin A (IgA). In the humoral portion of the immune system, first-line defenses include complement, lysozyme, fibronectin, and interferon; secondary defense mechanisms include antibodies such as IgM and IgG. The cellular portion of the immune system includes first-line defenses such as phagocytes (polymorphonuclear leukocytes [neutrophils and eosinophils] and monocytes) and natural killer cells (T cells); the second line of defense is defined as cell-mediated immunity. Specific problems and potential causes that can arise include penetration of the skin barrier (needle penetrations, burns); splenectomy (impaired IgM antibody production); aspiration of stomach contents, impaired cough reflex, impaired microbicidal clearance by alveolar macrophages, defects in complement activity, etc. (alcoholism); neutropenia (use of immunosuppressive drugs); problems with inhibited phagocytosis (rheumatic diseases); neutropenia, cell-mediated immunity defects, and antibody response defects (renal failure); skin and mucous membrane defects due to poor protein production as well as diminished IgA levels in the gut (malnutrition); and diminished humoral and cellular immunity defenses (AIDS, other underlying infectious diseases). To determine possible host defense defects, a number of procedures can be used (Table 19.2).

Table 19.1 Host defense mechanisms

Immunity type	Factor		
	Surface and mechanical	Humoral (antibody dependent)	Cellular (antibody independent)
Nonspecific	Skin (intact) (intravenous lines, obstruction of ureters, bronchi) Cough reflex Ciliary motion in respiratory epithelium Flushing action (urine)	Complement Lysozyme Fibronectin Interferon	Phagocytes (neutrophils) Chemotaxis Phagocytosis (monocytes, eosinophils) Natural killer cells
Specific	Immunoglobulins (IgA) (antibody found in secretions)	Antibodies B cells (IgG, IgM) (found in serum and extravascular spaces) IgE (affinity for mast cells, basophils, and eosinophils)	Cell-mediated immunity Sensitized cells (cytotoxic T cells, activated macrophages, natural killer cells)
Additional comments		IgG and IgM fix complement; initiate complement-mediated lysis of the target cell. IgG and IgE bind to macrophages, eosinophils, and mast cells via the Fc portion and to the target cell via the Fab portion	Macrophage functions include detection of organism invasion, restriction of organism spread, recruitment of immune cells, action as accessory cells in lymphocyte activation and as effector cells in cell-mediated immunity

Humans have very effective defense mechanisms to protect themselves against foreign invaders. One system consists of surface and mechanical barriers, pH, temperature, phagocytosis, and nonspecific inflammation (innate resistance). The other system is induced and includes specific products that recognize foreign invaders (adaptive immunity). The two major components of the adaptive immune response are humoral (antibody) and cellular (sensitized cells); B lymphocytes (B cells) are responsible for the humoral response, and T lymphocytes (T cells) are responsible for the cellular response. The human immune system is very complex, with different classes of antibody and various subsets of T cells that have different functions as immune effectors. Unfortunately, the immune system is not always protective and under certain circumstances can be directed toward the human body, not the foreign invader.

Within the context of this background information on the immune system, various parasitic infections are discussed, with emphasis on infections in the immunocompromised patient. With the continued increase in the number of these patients, every institution will eventually provide medical care for someone in this category and laboratories will continue to perform more procedures for the diagnosis of opportunistic infections. Diagnostic procedures for the diagnosis of parasitic infections in the compromised host are presented in Table 19.3, and clinical findings in normal and compromised hosts are described in Table 19.4.

Parasitic infections in individuals with a normal immune system are not uncommon. Not only are they unpleasant and debilitating, but they can be fatal. However, individuals with immune system defects have an abnormally high susceptibility to infections with non-virulent and minimally pathogenic organisms. Many of these individuals contract parasitic infections in addition to suffering numerous infectious episodes with bacterial, viral, and fungal organisms. Immune system deficiencies can be attributed to congenital absence, abnormal development, malignancy, therapy with cytotoxic drugs, irradiation, or infections, such as with human immunodeficiency virus (HIV). Of particular interest are patients with AIDS.

Although any parasitic infection may be more severe in the immunosuppressed host, certain organisms tend to produce greater pathologic sequelae in these patients, while other organisms occur with a higher frequency in individuals with certain immune system deficiencies. Among the implicated organisms discussed in this chapter are *Entamoeba histolytica*, free-living amebae, *Giardia lamblia*, *Toxoplasma gondii*, *Cryptosporidium* spp., *Cyclospora cayetanensis*, *Isospora belli*, *Sarcocystis* spp., microsporidia, *Leishmania* spp., *Strongyloides stercoralis*, and *Sarcoptes scabiei* (the agent of crusted scabies). It is important for the laboratorian and clinician to be aware of problems that these organisms can cause in compromised patients and to be aware of the proper diagnostic techniques and their clinical relevance.

Table 19.2 Selected procedures for determination of host defense defects^a

Defect	Procedure	
	Screening	Diagnostic
Inflammation	White blood cell count and differential C ₅₀ hemolytic complement	Complement levels Inhibitor levels Complement-fixing immune complexes
Phagocytosis	White blood cell count and morphology Immunophenotyping	Phagocytic index Bactericidal tests Nitroblue tetrazolium test Cell surface glycoproteins Lymph node biopsy
Humoral antibody	Immunoelectrophoresis Immunoglobulin levels in serum	IgE levels in serum Secretory IgA B-cell levels, subsets Isohemagglutinins Purine-metabolizing enzymes
Cellular sensitivity	Skin tests Quantitation of T cells and T-cell subsets	Sheep erythrocyte rosettes Mitogen responses Lymph node biopsy CT, MRI of thymus

Entamoeba histolytica

Entamoeba histolytica is the cause of amebiasis (Tables 19.3 and 19.4; Figure 19.1). Two types of disease, reviewed here, are particularly helpful when one is discussing serologic test results. “Intestinal disease” indicates that the organisms are confined to the gastrointestinal tract, with no gross or microscopic invasion through the mucosal lining. “Extraintestinal disease” denotes invasion of the mucosal lining of the gastrointestinal tract, the organisms having passed through the mucosal lining, entered the bloodstream, and been carried to other body tissues, particularly the liver. In patients in whom the organisms have begun to invade the mucosal lining, interpretation of serologic tests may be difficult. In this situation, the terms “intestinal” and “extraintestinal” do not strictly apply. These differences should be understood when one is discussing the clinical interpretation of serologic tests for amebiasis.

Although a large number of people throughout the world are infected with this organism, only a small percentage develop clinical symptoms. Morbidity and mortality due to *E. histolytica* vary depending on the geographic area, organism strain, and patient immune status. For many years, the issue of pathogenicity has been very controversial; some thought that what was called *E. histolytica* was really two separate species of *Entamoeba*, one being

pathogenic and causing invasive disease and the other being nonpathogenic and causing mild or asymptomatic infections. Others thought that all organisms designated *E. histolytica* were potentially pathogenic, with symptoms depending on the result of host or environmental factors, including the intestinal flora.

In 1961, with the development of successful axenic culture methods requiring no bacterial coculture, sufficient organisms could be obtained for additional studies. Approximately 15 years later, reports indicated that *E. histolytica* clinical isolates could be classified into groups by starch gel electrophoresis and review of banding patterns related to specific isoenzymes. Sargeant concluded from this work that there are pathogenic and nonpathogenic strains (zymodemes) of *E. histolytica* that can be differentiated by isoenzyme analysis. On the basis of analysis of thousands of clinical isolates, he also concluded that the zymodeme patterns were probably genetic rather than phenotypic.

Research emphasis has been on the molecular differences between pathogenic *E. histolytica* and nonpathogenic *E. dispar*. However, the molecules considered the most important for host tissue destruction (amebapore, galactose/*N*-acetylgalactosamine-inhibitable lectin, and cysteine proteases) can be found in both organisms. Pathogenicity differences may be related to the composi-

Table 19.3 Diagnosing parasitic infection in the compromised host

Organism	Size	Specimen	Procedure	Method of examination ^a	Laboratory findings ^a	Comments ^{a,b}
<i>Entamoeba histolytica</i> Intestinal disease <i>Note:</i> Pathogenic <i>E. histolytica</i> can now be differentiated from nonpathogenic <i>E. dispar</i> using immunoassays; morphologic characteristics are identical, <i>E. histolytica</i> containing RBCs in the trophozoite could be identified as pathogenic true <i>E. histolytica</i> .	Trophozoite: usual range, 15–20 μm ; range, 10–60 μm . Cyst: usual range, 12–15 μm ; range, 8.5–20 μm . <i>Note:</i> These sizes refer to organisms seen on the permanent stained smear. There may be as much as 1–1.5 μm of shrinkage of organisms as a result of reagents.	Stool	O&P examination (minimum of concentration and permanent stained smear)	Concentration (high dry, $\times 400$)	Trophozoites or cysts	A series of 3 stools (collected every other day) is recommended for the O&P examination.
		Sigmoidoscopic biopsy or scrapings	Permanent stained smear and routine histologic test	Permanent stain (oil immersion, $\times 1,000$)	Trophozoites	The permanent stained smear is mandatory for a complete O&P examination.
		Serum	Amebic serologic tests	IHA, IFA, CIE, ID, ELISA	Not recommended for intestinal disease; negative or possible low titer, indicating present or past exposure	At least 2 different serologic tests (methods) should be performed so results can be compared.
			Radiographic studies	Barium	Intestinal abnormalities (may also be normal)	
Extraintestinal disease	Trophozoite stage only	Stool	O&P examination	See above	No organisms recovered in about 50% of cases	There may be no evidence of GI disease before or during extraintestinal invasion.
		Sigmoidoscopic biopsy or scrapings	Permanent stained smear and routine histologic test	See above	No organisms recovered in about 50% of cases	
		Serum	Amebic serologic tests (antibody); IHA, EIA reagents available	See above	Positive titers may be lower in compromised patients	At least 2 serologic tests (methods) should be performed so that results can be compared.
		Scans		Evidence of space-occupying lesion		
Free-living amebae <i>Naegleria fowleri</i>	Biphasic (amebic and flagellate forms). Trophozoite: usual range, 8–15 μm , amebic form, lobate pseudopodia. Cyst: not present in tissue, small, smooth, rounded.	CSF	Centrifugation, wet or stained preparation; agar plates with bacterial overlay (culture)	Wet: low ($\times 100$) and high dry ($\times 400$); stained: oil immersion ($\times 500$, $\times 600$, or $\times 1,000$); culture: low ($\times 100$) and high dry ($\times 400$) on material from culture plate surface	Trophozoites in specimens; trophozoites and cysts in culture	Since all these organisms are normally free-living, they will survive shipment via mail to any laboratory for subsequent examination and/or culture; various culture temperatures are recommended in different situations (refer to chapter 32).

(continued)

Table 19.3 Diagnosing parasitic infection in the compromised host (*continued*)

Organism	Size	Specimen	Procedure	Method of examination ^a	Laboratory findings ^a	Comments ^{a,b}
<i>Acanthamoeba</i> spp.	Trophozoite: large, 15–25 μm , amebic form, filiform pseudopodia. Cyst: present in tissue, large with wrinkled double wall.	CSF, eye specimens, cutaneous biopsy	Centrifugation, wet or stained preparation; agar plates with bacterial overlay (culture); histology	As above, histology and routine microscopic exam	Trophozoites and/or cysts in specimens and culture	Agar plates with bacterial overlay (culture) more sensitive than wet preparations
<i>Balamuthia mandrillaris</i>	Trophozoite: large, 12–60 μm , amebic form, fingerlike pseudopodia. Cyst: large, 6–30 μm , with wrinkled double wall.	CSF, eye specimens, cutaneous biopsy	Centrifugation, wet or stained preparation; cell culture only, will not grow on routine agar culture with bacterial overlay; histology	All of the above, including cell culture if available	Trophozoites and/or cysts in specimens and cell culture	Becoming more widely recognized as causing same types of disease as <i>Acanthamoeba</i> spp.
<i>Giardia lamblia</i>	Trophozoite: usual range, 10–12 μm long by 5–10 μm wide. Cyst: usual range, 11–14 μm long by 7–10 μm wide	Stool	O&P examination	Concentration (high dry, $\times 400$), permanent stain (oil immersion, $\times 1,000$)	Trophozoites or cysts (may not always be detected)	The parasite may not be recovered from stool even after 4 or 5 examinations on different specimens. This does not mean that the diagnostic techniques are inadequate or that the organisms are missed by inexperienced personnel. Additional diagnostic techniques (including biopsy) may have to be used. Immunoassays available and now being used as orderable tests (FA, EIA, immunochromatographic formats).
			Immunoassays	Depends on format	Presence or absence of antigen or actual organisms	
		Duodenal aspirate	Wet preparations, permanent stained smears	See above	Trophozoites	
		Entero-Test capsule	Wet preparations, permanent stained smears	See above	Trophozoites	
		Biopsy	Routine histologic tests and special stains		Possible upper GI tract changes and/or trophozoites	
	Serum	Serologic tests	Experimental (not generally available)			

<i>Toxoplasma gondii</i>	Tachyzoite: 4–6 μm long by 2–3 μm wide. Bradyzoite: individual tissue cysts may contain many hundreds of organisms. Cyst: may range up to 50–75 μm .	Serum	Serologies	IHA, IFA, ELISA, Sabin-Feldman dye test	Results are often sufficient to confirm diagnosis	Patients with positive IgM serologic test results may have Epstein-Barr virus infections. There may be nonspecific stimulation of other antibody-producing cells. Although organism isolation techniques with animals and/or tissue culture may be used, these results must be evaluated within the context of the total clinical picture.	
		Biopsy	Routine histologic test		Possible recovery of bradyzoites	Organism may not be etiologic agent of disease	
		Spinal fluid	Tissue culture or animal isolation		Possible recovery of tachyzoites	Organism may not be etiologic agent of disease	
			Organism isolation (direct, tissue culture, or animal isolation) Serologic tests		Presence of tachyzoites	Considered confirmatory	
<i>Cryptosporidium</i> spp.	Developmental stages within brush border of intestine Cells: 1–2 μm ; oocysts in stool: 4–6 μm .	Stool	Acid-fast stains (may need modified KOH digestions)	Permanent stain (high dry, $\times 400$; confirm on oil immersion, $\times 1,000$)	Oocysts visible	Regardless of staining technique used on stool, the more normal the stool specimen (formed), the greater the chances that artifacts will present problems in identifying organisms and fewer organisms will be present. Specimens representing classic diarrhea will allow easier recovery and identification of organisms. Numbers of organisms will vary from day to day.	
			Immunoassays	Depends on format	Presence or absence of antigen or actual oocysts		
		Intestinal mucosal biopsy	Routine histologic test	Hematoxylin and eosin stain	Developmental stages (1 μm) along brush border		Very specific but not very sensitive approach
			EM	Routine EM	May see developmental stages or possibly oocysts		
		Serologic specimen		Experimental only (not generally available)			Used for epidemiologic studies

(continued)

Table 19.3 Diagnosing parasitic infection in the compromised host (*continued*)

Organism	Size	Specimen	Procedure	Method of examination ^a	Laboratory findings ^a	Comments ^{a,b}
<i>Cyclospora cayetanoensis</i>	Oocyst: 8–10 μm	Stool	Acid-fast stains (modified)	Permanent stain (high dry, ×400; confirm on oil immersion, ×1,000)	Oocysts visible	Owing to morphologic similarities to <i>Cryptosporidium</i> spp., it is important to measure the oocysts. There is tremendous staining variability of the oocysts with acid-fast stains (from clear to deep purple). Oocysts appear wrinkled. Oocysts in stool are unsporulated and do not contain any internal definition or structure.
			Wet preparation examinations; oocysts will autofluoresce	Green with 450–490 DM excitation filter, blue with 365 DM excitation filter. Wet preparation (high dry, ×400).	Oocysts visible as green or blue circles (interior of oocyst does not fluoresce) (1+ to 3+)	Used as a screening method
		Intestinal mucosal biopsy	Routine histologic test EM	Hematoxylin and eosin stain Routine EM	Organisms resembling coccidia found in jejunal enterocytes May see developmental stages or possibly oocysts	Developmental location will differentiate from <i>Cryptosporidium</i> spp.
<i>Isospora</i> (<i>Cystoisospora</i>) <i>belli</i>	Oocyst: 30 by 20 μm, development within the intestinal mucosal cells; oocysts in stool range from undivided mass of protoplasm to those containing fully developed sporocysts and sporozoites	Stool	O&P examination (concentration is important; PVA distorts morphology)	Concentration (low, ×100, and high dry, ×400)	Oocysts (may be in various stages of development)	Although these organisms are thought to be rare, some workers speculate that oocysts are occasionally missed during a stool examination. There is also the possibility that a biopsy specimen is positive while the stool examination is negative.
			Intestinal mucosal biopsy	Permanent stained smear Routine histologic test	Acid-fast stains Hematoxylin and eosin stain, high dry (×400)	Oocysts (as above). High dry, ×400. Developmental stages within the mucosal cells

<i>Sarcocystis suisbominis</i> , <i>S. bovisbominis</i>	Oocyst thin walled, contains 2 mature sporocysts, each with 4 sporozoites; sporocysts are 9–16 µm long by 7.5–12 µm wide	Stool	O&P examination (concentration important; PVA may distort morphology)	Concentration (low, ×100, and high dry, ×400)	Oocysts or sporocysts	Not commonly seen; size can overlap that of <i>I. belli</i>
Other <i>Sarcocystis</i> spp.	Shapes and sizes of skeletal and cardiac muscle sarcocysts vary	Tissue biopsy	Routine histology	Hematoxylin and eosin stain (high dry, ×400)	Developmental stages within tissue cells	Sarcocysts contain several hundred to thousands of trophozoites, each measuring 4–9 µm wide by 12–16 µm long; sarcocysts may be divided into compartments by septa (not seen in <i>Toxoplasma</i> cysts).
Microsporidia (<i>Brachiola</i> , <i>Vittaforma</i> , <i>Encephalitozoon</i> , <i>Enterocytozoon</i> , <i>Pleistophora</i> , <i>Trachipleistophora</i> , “ <i>Microsporidium</i> ” spp.) ^a	Spore, 1–4 µm; dividing forms within epithelial cells	Tissue biopsy	Routine histologic test	Methenamine-silver, acid-fast, PAS-positive granule, Giemsa, hematoxylin and eosin	Spores, dividing forms	It is sometimes difficult to find and identify the organisms by routine histologic techniques. Because of the difficulties in identification at the light microscopy level, EM methods have been recommended. Organisms have been identified in stool, although current procedures may be somewhat difficult to interpret.
		Stool	EM Permanent stained smear	Routine EM Modified trichrome	Spores, dividing forms Spores	Specific but insensitive Artifacts confusing
		Serologic sample	EM Direct detection methods IFA, CF, microagglutination	Routine EM IFA; not yet available commercially Experimental (not generally available)	Spores Titers	Specific but insensitive
<i>Leishmania</i> spp.	Amastigotes in tissue measure 1–3 µm; tend to appear larger when released from cells, such as a touch or squash preparation; will appear as dots within the cells in routine histology preparations	Blood specimen (looking at buffy coat cells); tissue biopsy (bone marrow most common)	Buffy coat preparations, centrifugation, smear preparation; smears, culture (Novy-MacNeal-Nicolle medium) of bone marrow aspirates	Microscopic examination (high dry, ×400 power and ×1,000 oil immersion)	Presence of amastigotes in macrophages and/or tissues; presence of promastigotes (motile, flagellated) in culture	Multiple specimens may be required; cultures must not become contaminated or results may represent a false negative; controls must accompany all patient cultures.

(continued)

Table 19.3 Diagnosing parasitic infection in the compromised host (*continued*)

Organism	Size	Specimen	Procedure	Method of examination ^a	Laboratory findings ^a	Comments ^{a,b}
<i>Strongyloides stercoralis</i>	Larval stage: 180–380 by 14–20 μm , in feces; larvae (rhabditiform) have a short buccal cavity and a prominent genital primordium; both noninfective and infective larvae, adults, and eggs may be found in duodenal specimens	Stool	O&P examination (concentration important)	Direct smears and concentration (low, $\times 100$; confirm on high dry, $\times 400$)	Rhabditiform larvae (infective filariform larvae may also be found)	Caution should be used when working with fresh specimens that may contain infective filariform larvae. <i>Strongyloides</i> infections may be difficult to diagnose from stool specimens. Examination of material from the duodenum may be necessary, and concentrations or cultures can also be used.
		Duodenal aspirate	Baermann concentrate, Harada-Mori and petri dish cultures	As above	As above	
		Enterotest	Wet preparations (direct smears)	As above	Larvae (usually rhabditiform)	
		Enterotest	Wet preparations (direct smears)	As above	Larvae (as above)	
Crusted (Norwegian) scabies (<i>Sarcoptes scabiei</i>)	Mites are microscopic; live in cutaneous burrows where female deposits eggs; mites range from 215 to 390 μm in length; eggs are 170 μm long by 92 μm wide; fecal pellets are yellow-brown	Skin scrapings	Use skin-scraping technique (see chapter 24)	Prepare slides of skin-scraping material and examine microscopically using low power ($\times 100$) and high power ($\times 400$)	Mites, eggs, or scybala (fecal pellets) may be present	Highly infectious; most common skin sites are interdigital spaces, backs of the hands, elbows, axillae, groin, breasts, umbilicus, penis, shoulder blades, small of the back, buttocks; may see kerotic excrescences on the body; itching may be absent.

^a BAL, bronchoalveolar lavage; CF, complement fixation; CIE, counterimmunoelectrophoresis, EIA, enzyme immunoassay; EM, electron microscopy; GI, gastrointestinal; O&P, ova and parasite; PVA, polyvinyl alcohol; RBC, red blood cells.

^b The use of immunoassays for the direct and indirect detection of some of these parasites has become much more common. Reagents are available for *Entamoeba histolytica/E. dispar*, *Entamoeba histolytica*, *Giardia lamblia*, *Cryptosporidium* spp., and the microsporidia (if not yet available, should be approved in the near future).

^c These genera have been reported in humans; organisms that have not yet been classified to genus have been placed in the catchall genus called *Microsporidium*.

Table 19.4 Parasitic infections: clinical findings in normal and compromised hosts

Organism	Normal host	Compromised host
<i>Entamoeba histolytica</i>	Asymptomatic to chronic or acute colitis; extraintestinal disease may also occur (primary site: right upper lobe of liver)	Diminished immune system capacity may lead to extraintestinal disease
Free-living amoebae	Patients tend to have eye infections with <i>Acanthamoeba</i> spp.; linked to poor lens care	Primary amebic meningoencephalitis (PAM); granulomatous amebic encephalitis (GAE)
<i>Giardia lamblia</i>	Asymptomatic to malabsorption syndrome	Certain immunodeficiencies tend to predispose an individual to infection
<i>Toxoplasma gondii</i>	Approximately 50% of individuals have antibody and organisms in tissue but are asymptomatic	Disease in compromised host tends to involve the central nervous system with various neurological symptoms; <i>Toxoplasma</i> encephalitis (TE)
<i>Cryptosporidium</i> spp.	Self-limiting infection with diarrhea and abdominal pain	Owing to autoinfective nature of life cycle, is not self-limiting, may produce fluid loss of over 10 liters/day, and there may be multisystem involvement; no known totally effective therapy
<i>Cyclospora cayentanensis</i>	Self-limiting infection with diarrhea (3–4 days), with relapses common	Diarrhea may persist for 12 wk or more; biliary disease has also been reported in this group, particularly in those with AIDS
<i>Isospora (Cystoisospora) belli</i>	Self-limiting infection with mild diarrhea or no symptoms	May lead to severe diarrhea, abdominal pain, and possible death (rare case reports); diagnosis is occasionally missed because of nonrecognition of the oocyst stage; is not seen when concentrated from polyvinyl alcohol fixative
<i>Sarcocystis</i> spp.	Self-limiting infection with diarrhea, or mild symptoms	Symptoms may be more severe and last longer
Microsporidia (<i>Brachiola</i> , <i>Vittaforma</i> , <i>Encephalitozoon</i> , <i>Enterocytozoon</i> , <i>Pleistophora</i> , <i>Trachipleistophora</i> , “ <i>Microsporidium</i> ” spp.)	Little known about these infections in the normal host; serologic evidence suggests infections may be more common than recognized	Can infect various parts of the body; diagnosis often depends on histologic examination of tissues; routine examination of clinical specimens (stool, urine, etc.) becoming more common; can probably cause death
<i>Leishmania</i> spp.	Asymptomatic to mild disease	More serious manifestations of visceral leishmaniasis; some cutaneous species will manifest visceral disease; difficult to treat and manage; definite coinfection with AIDS
<i>Strongyloides stercoralis</i>	Asymptomatic to mild abdominal complaints; can remain latent for many years owing to low-level infection maintained by internal autoinfective life cycle	Can result in disseminated disease (hyperinfection syndrome due to autoinfective nature of life cycle); abdominal pain, pneumonitis, sepsis-meningitis with gram-negative bacilli, eosinophilia; distinct link to some leukemias and lymphomas; can be fatal
Crusted (Norwegian) scabies (<i>Sarcoptes scabiei</i>)	Infections can range from asymptomatic to moderate itching	Severe infection with reduced itching response; hundreds or thousands of mites on body; infection very easily transferred to others; secondary infection very common

Figure 19.1 (Upper left) *Entamoeba histolytica* trophozoite; (upper right) *Entamoeba histolytica*/*E. dispar* cyst; (lower) gross specimen, amebic liver abscess.

tion and properties of the surface coat components (or pathogen-associated molecular patterns) and the ability of the innate immune response to recognize these components, thus eliminating the organisms. Targets of the host immune system modulation appear to be both neutrophils and macrophages, which are unable to abort the infection even when present at the site of the lesion. The total body of evidence supports the classification of the pathogenic *E. histolytica* and the nonpathogenic *E. dispar* as two distinct species. See chapter 2 for additional information.

Intestinal Disease

In patients with intestinal disease, symptoms range from none to acute or chronic amebic colitis, both of which can mimic inflammatory bowel disease. A number of factors influence the outcome of an amebic infection, including the host immune system response. At one time, it was thought that invasive strains were found only in tropical areas of the world; however, it is now apparent that there are strains within the United States that cause hepatic abscess in patients who have no history of travel outside the United States.

In examining data from AIDS patients with diarrhea in India, the authors conclude that the presence of

different parasites in 62 (56.4%) of 110 stool specimens from patients with AIDS indicates that their specific diagnosis is essential. This will help initiate therapy to reduce the morbidity and mortality due to these pathogens in such patients (51).

The diagnosis of amebiasis begins with an ova and parasite examination. This procedure includes the following: the direct saline mount, which is designed to allow the mobility of the organisms to be seen; the concentration procedure, which provides a method to recover helminth eggs and larvae and protozoan cysts; and the permanent stained smear, which is the most important technique for diagnosis of the intestinal protozoa. Although motility can be seen on direct wet preparations, the material must be fresh, and a diagnosis of amebic infection should *never* be made solely from this type of examination. At the very least, the concentration procedure and permanent stained smear should be performed on every stool sample that is submitted to the laboratory for an ova and parasite examination (48).

Stools should normally be submitted to the laboratory on an every-other-day basis for a period of no more than 10 days. Although for many years the recommended minimum number of stools to be examined has been three, some laboratories are accepting two specimens. When intestinal amebiasis is suspected, six specimens may be submitted over a 15-day period. Multiple specimens are recommended because populations of intestinal protozoa tend to be cyclic. That is, the specimen may be negative on collection day 1 but positive by collection day 3. It is also possible for only a nonpathogen to be found on collection day 1 but pathogenic organisms to be recovered from the second or third specimen. If nonpathogenic protozoa are found, there is always the possibility of finding pathogenic organisms on subsequent examinations.

Presumptive identification of the organism as *Entamoeba histolytica*/*E. dispar* is based on the typical nuclear morphology (evenly arranged chromatin on the membrane and the presence of a small, central karyosome). The presence of red blood cells within the trophozoite cytoplasm would provide definitive identification as true *E. histolytica* (rather than nonpathogenic *E. dispar*); however, red blood cells must also be present in the background of the smear if they are reported to be inside the cytoplasm of the organism. In general, if the patient is symptomatic, one assumes that the causative agent is pathogenic *E. histolytica* (assuming that the cause is related to the presence of intestinal protozoa).

The cyst of *E. histolytica*/*E. dispar* may contain chromatoidal bars with smooth, rounded edges. Even though the mature cyst contains four nuclei, these are not always

visible, and the cyst can often be identified from the chromatoidal bars alone.

In a wet preparation, such as the direct smear or concentration sediment, the trophozoites and cysts of *E. histolytica* measure >12 and >10 μm , respectively. Because of artificial shrinkage during the preparation of permanent stained smears, the sizes are diminished somewhat, with the trophozoites measuring at least 10.5 to 11 μm and the cysts measuring at least 8.5 to 9 μm . Organisms measuring less than these limits and containing morphologic characteristics similar to those of *E. histolytica* would be identified as *E. hartmanni*, a nonpathogenic ameba.

One of the most important things to remember is that some human cells found in the stool can mimic *E. histolytica*. Macrophages or monocytes can look like the trophozoite form of *E. histolytica*, and polymorphonuclear leukocytes, when they have been in the stool for a while, can mimic the four-nucleus *E. histolytica* mature cyst.

Other tests include sigmoidoscopy, in which both scrapings and smears can be submitted for permanent stains. Biopsy specimens should also be submitted for histopathologic studies. Radiographic examination with barium is helpful; however, the presence of barium in the stool makes the ova and parasite examination very difficult to perform. Ova and parasite examinations should be done before barium studies or at least 1 week to 10 days afterward. The sensitivity of serologic tests for antibody in patients with intestinal amebiasis varies, and a negative serologic test does not necessarily rule out the presence of amebic infection. Serologic tests for antibody are not recommended for the diagnosis of intestinal amebiasis.

Tests for antigen detection in the stool are much more relevant for intestinal disease. Reagents are currently available for antigen detection of the *E. histolytica*/*E. dispar* group and specifically for *E. histolytica* (107). Fresh or frozen stool is required for the procedure; PCR, isoenzyme analysis, and antigen detection are available for confirmation of *E. histolytica* infection. However, the antigen detection method is both rapid and technically simple.

If *E. histolytica* organisms are not seen in the stool and the final diagnosis is inflammatory bowel disease, the patient may receive corticosteroid therapy. Immunosuppression may predispose the patient to more severe disease if the true pathogen, *E. histolytica*, is present and not detected.

Extraintestinal Disease

When organisms invade the mucosal lining and are carried via the bloodstream to the liver (extraintestinal or hepatic disease), a somewhat different approach to diagnosis is necessary. Both fecal and sigmoidoscopic examinations for organisms are negative in approximately half of the patients with extraintestinal amebiasis. Both radioactive

and computed tomographic (CT) scans are available to assist the clinician in defining the presence of an abscess.

Lesions in the liver may range from less than a few centimeters to several inches in diameter. In either case, if the patient has a normal humoral immune system, serologic tests for antibody are generally positive.

Serologic tests for extraintestinal amebiasis are generally very specific and quite sensitive. However, in some parts of the country, sensitivity may present a problem in patients previously exposed to *E. histolytica*. In these individuals, a low to moderate titer may represent past infection rather than current disease. Also, patients with diminished immunoglobulin levels may present with low or negative serologic titers (Table 19.3). Various serologic techniques include complement fixation, indirect hemagglutination assay (IHA), counterimmunoelectrophoresis, latex agglutination, indirect fluorescent-antibody (IFA) assay, and enzyme-linked immunosorbent assay (ELISA), as well as tests for the detection of antigen in the stool. It is generally recommended that two different procedures be used so that the results can be compared. One approach is to use both qualitative screen and quantitative titer procedures. Commercial suppliers of kits are limited, and few laboratories routinely provide this type of testing. Serum for serologic tests should be sent to the state and local public health laboratories if the test is not routinely available.

AIDS Patients. Invasive amebiasis appears to be an emerging parasitic disease in patients infected with HIV in areas where amebic infection is endemic. Medical, microbiological, and histopathologic records of 296 HIV-infected patients and serologic data from IHAs of samples from 126 HIV-infected patients were reviewed to identify cases of invasive amebiasis. An IHA titer of 1:128 was considered positive. Of these 296 HIV-infected patients, 18 (6.1%) were diagnosed with invasive amebiasis. Clinical manifestations included amebic colitis (13 patients), amebic liver abscess (9 patients), both colitis and abscess (4 patients), and pleural effusion (2 patients). Invasive amebiasis was the initial presentation of HIV infection in nine patients. Of the 18 patients diagnosed with invasive amebiasis, 13 had an IHA titer of $\geq 1:128$. The sensitivity of the IHA in the diagnosis of invasive amebiasis was 72.2%, and the specificity was 99.1%. The positive predictive value of IHA for invasive amebiasis in this patient population was 92.9% and the negative predictive value was 95.5% (45). It appears that invasive amebiasis is becoming more important as one of the opportunistic parasitic infections in patients with HIV infection in areas of endemicity for amebiasis. In this type of area of endemicity, the IHA should be considered a relevant diagnostic approach.

In a study from Mexico, the prevalence estimated with PCR data showed that *E. histolytica* infection was more common in the HIV-positive/AIDS group (25.32%), than in HIV-negative contacts (18.46%). *E. histolytica* and *E. dispar* infection was more frequent in HIV-positive/AIDS patients (13.3%) than in HIV-negative contacts (0.7%). However, *E. histolytica* and/or *E. dispar* infection was highly prevalent in HIV-positive/AIDS patients (34.1%) without evidence of recent or current invasive disease. Contacts of HIV-positive/AIDS patients who were infected with *E. histolytica* were asymptomatic cyst passers. These data indicate that *E. histolytica* strains prevalent in the studied community appear to be of low pathogenic potential within the compromised patient (71).

However, in another study, 49 (5.2%) of 951 HIV-infected persons had 51 episodes of invasive amebiasis. A high IHA titer was detected in 39 (6.2%) of 634 HIV-infected persons compared with 10 (2.3%) of 429 uninfected controls with gastrointestinal symptoms and 0 of 178 uninfected healthy controls. Stool specimens from 40 (12.1%) of 332 HIV-infected persons and 2 (1.4%) of 144 uninfected healthy controls were positive for *E. histolytica* or *E. dispar* antigen. Of the 40 antigen-positive stool specimens from HIV-infected persons, 10 (25.0%) contained *E. histolytica*. Therefore, persons infected with HIV in Taiwan are at increased risk for invasive amebiasis and exhibit a relatively high frequency of elevated antibody titers and intestinal colonization with *E. histolytica* (45).

High-risk areas for acquiring amebiasis include Mexico, the western portion of South America, western Africa, South Africa, parts of the Middle East, and South and Southeast Asia. Invasive disease is much more common in these areas of the world.

Free-Living Amebae

Infections caused by small, free-living amebae are becoming recognized clinically as important parasitic pathogens, particularly in immunocompromised patients. Primary amebic meningoencephalitis (PAM) caused by *Naegleria fowleri* and granulomatous amebic encephalitis (GAE) caused by *Acanthamoeba* spp. and *Balamuthia mandrillaris* (including cases in patients with AIDS) are now well recognized (Figures 19.2 and 19.3). The most recently identified group of infections caused by these organisms is *Acanthamoeba* keratitis, which is related primarily to poor lens care in those who wear contact lenses. When free-living, these organisms feed on bacteria and nutrients in moist soil and in fresh and marine waters.

Although it is well known that both free-living and pathogenic protozoa harbor a variety of endosymbiotic bacteria, it is unclear what role these organisms play

Figure 19.2 (Top) *Naegleria fowleri* trophozoite (note the large karyosome within the nucleus); (middle) *Naegleria fowleri* trophozoites within brain tissue; (bottom) *Balamuthia mandrillaris* in brain tissue. (Bottom, Armed Forces Institute of Pathology photograph.)

in terms of host survival, infectivity, and invasiveness. *Legionella pneumophila* can infect, multiply within, and kill both *Naegleria* and *Acanthamoeba* amebae. These amebae may be natural hosts for *Legionella*, as well as for other bacteria such as *Listeria monocytogenes*, *Vibrio cholerae*, *Mycobacterium leprae*, and *Pseudomonas aeruginosa*. Because of their well-known resistance to chlorine, the amebic cysts are considered to be vectors for these intracellular bacteria. This can have tremendous significance for any hospital where the water source is contaminated with free-living amebae. There

Figure 19.3 (Left) *Acanthamoeba* trophozoites (note the sharp, spiky pseudopodia); (right) *Acanthamoeba* cysts (note the hexagonal double wall).

is also evidence to suggest that the presence of amoebae in domestic water supplies may provide growth conditions that enhance the pathogenicity of the organism for the human host. These amoebae are also acceptable hosts for echoviruses and polioviruses. The epidemiology, immunology, protozoology, pathology, and clinical features of the infections produced by these free-living protozoa differ considerably.

Naegleria fowleri

Central nervous system (CNS) infections caused by free-living amoebae have been recognized only since the mid-1960s. *N. fowleri* causes PAM, a fulminant and rapidly fatal disease that affects mainly children and young adults (Figure 19.2). The disease closely resembles bacterial meningitis but is caused by this free-living amoeba, an organism found in moist soil and freshwater habitats. Although PAM is usually associated with healthy, young individuals with a history of recent water-related sport activities, it is an important infection to consider in both immunocompetent and immunocompromised individuals. However, almost all infections have been seen in otherwise healthy individuals. Close to 200 cases of PAM have occurred worldwide, and approximately 90 of those cases have been reported from the United States.

Life Cycle. There are both trophozoite and cyst stages in the life cycle, and the stage depends primarily on environmental conditions. Trophozoites can be found in water or moist soil and can be maintained in tissue culture or

other artificial media. The trophozoites can occur in two forms, amoeboid and flagellate. Motility can be observed in hanging-drop preparations from cultures of cerebrospinal fluid (CSF); the amoeboid form (the only form recognized in humans) is elongate with a broad anterior end and a tapered posterior end. The size ranges from 7 to 20 μm . The diameter of the rounded forms is usually 15 μm . There is a large central karyosome and no peripheral nuclear chromatin. The cytoplasm is somewhat granular and contains vacuoles. The amoeboid-form organisms change to the flagellate form when they are transferred from culture or teased from tissue into water and maintained at a temperature of 27 to 37°C. The flagellate form is pear shaped, with two flagella at the broad end. Motility is typical, with either spinning or jerky movements. These flagellate forms do not divide, but when the flagella are lost, the amoeboid forms resume reproduction. Cysts from nature and from agar cultures look the same and have a single nucleus almost identical to that seen in the trophozoite. The cysts are generally round, measuring 7 to 10 μm in diameter, with a thick double wall.

Amebic Meningoencephalitis. Amebic meningoencephalitis caused by *N. fowleri* is an acute, suppurative infection of the brain and meninges. In humans, with extremely rare exceptions, the disease is rapidly fatal. The period between contact with the organism and onset of clinical symptoms such as fever, headache, and rhinitis may vary from 2–3 days to as long as 7–15 days.

The amoebae may enter the nasal cavity by inhalation or aspiration of water, dust, or aerosols containing the trophozoites or cysts. The organisms then penetrate the nasal mucosa, probably through phagocytosis of the olfactory epithelial cells, and migrate via the olfactory nerves to the brain. Early symptoms include vague upper respiratory distress, headache, lethargy, and occasionally olfactory problems. Cysts of *N. fowleri* are generally not seen in brain tissue. The acute phase includes sore throat; stuffy, blocked, or discharging nose; and severe headache. Progressive symptoms include pyrexia, vomiting, and stiffness of the neck. Mental confusion and coma usually occur approximately 3 to 5 days prior to death. The cause of death is usually cardiorespiratory arrest and pulmonary edema.

Organ Transplantation. The first case of organ transplantation from a donor who had died of undiagnosed *N. fowleri* infection was reported in 1997 (96, 97). While no subsequent amoebic infections occurred in the three organ recipients, this report emphasizes the need for adequate evaluation of the benefits and risks of transplanting tissues from persons whose illness might have been caused by an infectious agent. Apparently, the Centers for

Disease Control and Prevention are also aware of another instance in which kidneys were transplanted prior to determination that the donor was infected with *N. fowleri* (96, 97). At present, the risk of transmission of *N. fowleri* by donor organs has not been clarified, and no practical test is available to ensure that donor organs are organism free. Also, no prophylactic drug regimen to treat transplant recipients has been established.

Diagnosis. PAM can resemble acute purulent bacterial meningitis and may be difficult to differentiate, particularly in the early stages. The CSF may have the predominantly polymorphonuclear leukocytosis, increased protein concentration, and decreased glucose concentration that are seen with bacterial meningitis. Unfortunately, if the CSF Gram stain is interpreted incorrectly (identification of bacteria as a false-positive result), the antibacterial therapy will have no effect on the amoebae and the patient will usually die within several days. Extensive tissue damage occurs along the path of amoebic invasion; the nasopharyngeal mucosa shows ulceration, and the olfactory nerves are inflamed and necrotic. Hemorrhagic necrosis is concentrated in the region of the olfactory bulbs and the base of the brain. Organisms can be found in the meninges, perivascular spaces, and sanguinopurulent exudates.

Clinical and laboratory data usually cannot be used to differentiate pyogenic meningitis from PAM, and so the diagnosis may have to be reached by a process of elimination. A high index of suspicion is often mandatory for early diagnosis. Although most cases are associated with exposure to contaminated water through swimming or bathing, this is not always the case. The rapidly fatal course of 4 to 6 days after the beginning of symptoms (with an incubation period of 1 day to 2 weeks) requires early diagnosis and immediate chemotherapy if the patient is to survive.

Analysis of the CSF shows decreased glucose and increased protein concentrations. Leukocyte counts may range from several hundred to $>20,000$ cells/mm³. Gram stains and bacterial cultures of CSF are negative. A definite diagnosis could be made by demonstration of the amoebae in the CSF or in biopsy specimens. Either CSF or sedimented CSF should be placed on a slide under a coverslip and observed for motile trophozoites; smears can also be stained with Wright's or Giemsa stain. CSF, exudate, or tissue fragments can be examined by light microscopy or phase-contrast microscopy. Care must be taken not to mistake leukocytes for actual organisms or vice versa. It is very easy to confuse leukocytes and amoebae, particularly when one is examining CSF by using a counting chamber, hence the recommendation to use just a regular slide and coverslip. Motility may vary, so that the main differential characteristic is the spherical nucleus with a large karyosome.

Unfortunately, most cases are diagnosed at autopsy; confirmation of these tissue findings must include culture and/or special staining using monoclonal reagents in IFA procedures. Organisms can also be cultured on nonnutrient agar plated with *Escherichia coli*. In cases of presumptive pyogenic meningitis in which no bacteria are identified in the CSF, the CT appearance of basal arachnoiditis (obliteration of basal cisterns in the precontrast scan with marked enhancement after the administration of intravenous contrast medium) should indicate the possibility of acute PAM.

The amoebae can be identified in histology preparations by using indirect immunofluorescence and immunoperoxidase techniques. The organism in tissue sections looks very much like an *Iodamoeba bütschlii* trophozoite, with a very large karyosome and no peripheral nuclear chromatin; the organisms can also be seen with use of routine histologic stains. In general, serologic tests have not been helpful in the diagnosis of this infection. The disease progresses so rapidly that the patient is unable to mount an immune response.

***Acanthamoeba* spp.**

Granulomatous Amoebic Encephalitis. Another type of meningoencephalitis, GAE, caused by freshwater amoebae may occur as a subacute or chronic disease with focal granulomatous lesions in the brain (Figure 19.3) (13, 60). The route of CNS invasion is thought to be hematogenous, with the primary site being the skin or lungs. In this infection, both trophozoites and cysts can be found in the CNS lesions. A case involving acute onset of fever, headache, and pain in the neck preceded by 2 days of lethargy has been described. Conditions associated with GAE include skin ulcers, liver disease, pneumonitis, diabetes mellitus, renal failure, rhinitis, pharyngitis, and tuberculosis (76). Predisposing factors include alcoholism, pregnancy, systemic lupus erythematosus, hematologic disorders, AIDS, chemotherapy, radiation therapy, and steroid treatment. This infection has become more widely recognized in AIDS patients, particularly those with a low CD4⁺ cell count. Although *Acanthamoeba* infections stimulate a granulomatous response, the response in AIDS patients is minimal or absent, consistent with the poor immune response in these patients. Examples of specific infections seen in immunocompromised patients are listed in Table 19.5.

The *Acanthamoeba* group also causes keratitis and corneal ulceration. There are a number of published cases, which emphasizes the need for clinicians to consider acanthamoebic infection in the differential diagnosis of eye infections that fail to respond to bacterial, fungal, or viral therapy. These infections are often due to direct eye exposure to contaminated materials or solutions.

Table 19.5 *Acanthamoeba* infections in immunocompromised patients

Underlying condition ^a	Disease manifestation	Comments	Reference(s)
AIDS	Cutaneous nonhealing lesion	Cutaneous disease in the absence of CNS involvement is increasingly recognized	109
AIDS	Granulomatous uveitis	<i>Acanthamoeba</i> infection should be considered in the differential diagnosis of uveitis in patients with AIDS	41
AIDS	Osteomyelitis	Disseminated disease has been described (the usual sites are skin, sinus, and brain); the patient had a 6-mo history of cutaneous infection	98
AIDS	Disseminated disease	Patients had cutaneous manifestations but no CNS involvement; lesions included pustules, subcutaneous and deep dermal nodules, and ulcers, primarily on extremities and face; high index of suspicion necessary for both dermatologist and dermatopathologist	94, 109
AIDS	GAE	Primary foci in lungs, skin; inflammatory response is chronic, with granulomatous response characterized by presence of multinucleated giant cells; though nonspecific, imaging can support the diagnosis and direct biopsy results; physician should be aware of potential diagnosis in AIDS patients with an insidious encephalitis and cerebral cognitive abnormalities, with or without focal motor signs	60
SLE therapy	GAE	Lung probably primary focus; infectious encephalitis difficult to differentiate from a flare-up of CNS lupus	57
Immunosuppressive drugs for BMT	GAE	Autologous stem cell transplantation; leg weakness, fever, and urinary retention developed 69 days after transplantation; patient then developed fever, seizures, and rapid deterioration of mental functions	60
Renal transplant	Osteomyelitis, widespread cutaneous lesions	Both trophozoites and cysts found at autopsy in skin and bone specimens; no causative agent identified prior to death	105

^a SLE, systemic lupus erythematosus; BMT, bone marrow transplantation.

Unlike *N. fowleri*, *Acanthamoeba* spp. do not have a flagellate stage in the life cycle, only the trophozoite and cyst (Figure 19.3). Motile organisms have spinelike pseudopods; however, progressive movement is usually not very evident. There is a wide range in size, with the average diameter of the trophozoites being 30 μm . The nucleus has the typical large karyosome, like that seen in *N. fowleri*. This morphology can be seen on a wet preparation. The cysts are usually round with a single nucleus, also having the large karyosome seen in the trophozoite nucleus. The double wall is usually visible, with the slightly wrinkled outer cyst wall and what has been described as a polyhedral inner cyst wall. This cyst morphology can be seen in organisms cultured on agar plates.

Laboratory examinations similar to those for *N. fowleri* can be used to recover and identify these organisms; the one exception is recovery by culture, which has not proven to be as effective with GAE cases. The most effective approach uses nonnutrient agar plates

with Page's saline and an overlay growth of *E. coli* on which the amebae feed. There is also evidence to indicate that phosphate-buffered saline can be used. Specimens transported in ameba saline (5.0 ml) and filtered through 13-mm-diameter, 0.22- μm -pore-size cellulose acetate and nitrate filters (Millipore Corp., Bedford, Mass.) have also been acceptable for organism recovery. The filter is then placed in the center of the nonnutrient agar plate seeded with *E. coli*. Tissue stains are also effective, and cysts can be stained with Gomori's methenamine-silver, periodic acid-Schiff (PAS), and calcofluor white.

Although detection of antibodies to *Acanthamoeba* spp. has been confirmed, the usefulness of serologic tests for the diagnosis of these infections has not been proven. Also, these procedures are not generally available. Further work related to the issue of false-positive and false-negative results and interpretive guidelines regarding past exposure or present infection need to be pursued before these diagnostic procedures can be routinely used.

Balamuthia mandrillaris

The leptomyxid ameba *Balamuthia mandrillaris* is relatively uncommon and was originally thought to be another harmless soil organism, unlikely or unable to infect mammals. However, in studies from the Centers for Disease Control and Prevention, antisera to the leptomyxid amebae have been shown to react in indirect-immunofluorescence assays with tissues from both animals and humans with GAE. There have been over 70 cases worldwide, some of which have occurred in AIDS patients (96, 97, 112). The disease is very similar to GAE caused by *Acanthamoeba* spp. and has an unknown incubation period. The clinical course tends to be subacute or chronic and is usually not associated with swimming in freshwater. No characteristic clinical symptoms, laboratory findings, or radiologic indicators have been found to be diagnostic for GAE. The neuroimaging findings show heterogeneous, hyperdense, nonenhancing, space-occupying lesions (Figure 19.2). Whether single or multiple, they involve mainly the cerebral cortex and subcortical white matter. These findings suggest a CNS neoplasm, tuberculoma, or septic infarcts. Patients complain of headaches, nausea, vomiting, fever, visual disturbances, dysphagias, seizures, and hemiparesis. There may also be a wide range in terms of the clinical course, from a few days to several months. Death can occur from a week to several months after the onset of stroke-like symptoms that can mimic other conditions. Both trophozoites and cysts of *B. mandrillaris* are found in many of the same CNS tissues as are *Acanthamoeba* organisms. Although differentiation of these two organisms in tissue by light microscopy is difficult, in some tissue sections *B. mandrillaris* appears to have more than one nucleolus in the nucleus. Generally, electron microscopy and histochemical methods are required for definitive identification of *B. mandrillaris*.

Attempts to isolate the organisms from some humans with GAE have not been successful, and leptomyxid amebae do not grow well on *E. coli*-seeded nonnutrient agar plates. In the diagnostic laboratory, these organisms can be cultured using mammalian cell cultures; some success has been obtained with monkey kidney cells and with MRC, HEP-2, and diploid macrophage cell lines. The trophozoites have extensive branching and a single nucleus (occasionally binucleate forms are seen) with a central karyosome, and they measure 15 to 60 μm . Occasionally a few elongated forms with several contractile vacuoles are seen. The cysts have a single nucleus (occasionally binucleate forms are seen), have the typical double wall with the outer wall being thick and irregular, and measure 15 to 30 μm . Using primary cultures of human brain microvascular endothelial cells, amebae have been isolated from the brain and CSF (50). Serum antibodies to *B. mandrillaris* have been found in both adults and children;

however, testing is generally limited to the Centers for Disease Control and Prevention, where PCR has also been used for the detection of mitochondrial 16S rRNA gene DNA from the amebae in clinical specimens (117).

From the information presented above, it is clear that *B. mandrillaris*, formerly regarded as having no pathogenic potential, will continue to be identified as the etiologic agent of fatal meningoencephalitis in humans as well as animals. This opportunistic infection may also continue to cause disease in individuals with AIDS.

Giardia lamblia

Giardia lamblia is a flagellate commonly found in many parts of the world (Tables 19.3 and 19.4; Figure 19.4). An infection with this organism can be transmitted via the cyst form in both water and food contaminated with fecal material, as can *E. histolytica* infections. Various conditions that have been associated with giardiasis in the compromised patient include hypogammaglobulinemia, protein or caloric malnutrition, previous gastrectomy, histocompatibility antigen HLA YB-12, gastric achlorhydria, blood group A, differences in mucolytic proteins in Ig deficiencies, and reduced secretory IgA levels in the gut (Table 19.2). Generally, adults and children are mentioned in relation to giardiasis; however, it is important to remember that the elderly, in both tropical and temperate zones, are also susceptible. These patients tend to be somewhat immunodepressed due to age and may be overlooked as having giardiasis.

Although patients with HIV infection have also been found to have giardiasis, the infection does not appear to be more severe among this group, regardless of the CD4⁺ cell count (52). In some groups, the prevalence of *G. lamblia* is greater for HIV-infected subjects (30, 113). Both humoral and cellular immune responses play a role in acquired immunity, and the mechanisms involved remain somewhat unclear. However, the immune response to intestinal parasites, including *G. lamblia*, might be a risk factor for HIV/AIDS and tuberculosis (2). It is well known that diagnosing intestinal parasites in HIV/AIDS patients is necessary, especially in those who are chronic alcoholics or are not receiving antiretroviral treatment (17, 39, 70, 102).

Symptoms of giardiasis may range from none to the malabsorption syndrome, characterized by gas, bloating, frothy green foul-smelling stools, and abdominal pain. The organism is reasonably easy to identify. The trophozoite form is teardrop shaped, and the flagella and sucking disk are easily visible. On side view, the trophozoite often looks somewhat like the curved end of a spoon. Trophozoites tend to stain pale, while the cysts usually stain darker and are easier to identify. Cysts are round

Figure 19.4 (Upper left) *Giardia lamblia* trophozoite (note two nuclei, curved median bodies, and linear axonemes); (upper right) *Giardia lamblia* cyst; (lower) *Giardia lamblia* cyst (large) and *Cryptosporidium* oocysts (small) demonstrating fluorescence in the fecal FA immunoassay (note that the background demonstrates use of the counterstain).

to oval, with long axonemes and curved median bodies being visible. Normally, cysts can be seen and identified on wet mount preparations from concentrated material and confirmed by using the permanent stained smear.

In contrast to *E. histolytica*, *G. lamblia* inhabits the duodenal area of the intestine, tends to adhere very tightly to the mucosa, and can be very difficult to recover, even after a series of five or six stool examinations. For this reason, other techniques, such as the Entero-Test string capsule, duodenal aspirate, or biopsy, may have to be used. Fecal immunoassays are also recommended for the diagnosis of giardiasis.

Toxoplasma gondii

Toxoplasma gondii is worldwide in distribution, and serologic data indicate that human infections are common, although most infections are benign or cause no symptoms (Tables 19.3 and 19.4). Serologic evidence from throughout the United States indicates that anywhere from 20 to 70% of the population are serologically positive for *T. gondii*. The percentage of serologically positive patients tends to be higher in the tropical areas of the world.

Toxoplasmosis can vary from an asymptomatic, self-limiting infection to a fatal disease, as seen in patients

with congenital infections or in debilitated patients in whom underlying conditions may influence the final outcome of the infection (Table 19.2). In immunocompromised patients, the infection most often involves the nervous system, with diffuse encephalopathy, meningoencephalitis, or cerebral mass lesions (Figure 19.5). In one study, multiplex nested PCR analysis was used to determine the genotypes of parasites in CSF; 8 of 10 human HIV-positive patients had infections with type I strains, even though this lineage is normally uncommon in humans and animals (54). Although gastric toxoplasmosis is rare, in some patients with AIDS it is the primary manifestation (33, 67).

Underlying conditions associated with toxoplasmosis in the compromised host include various types of malignancies, such as Hodgkin's disease; non-Hodgkin's lymphomas, leukemias, or solid tumors; collagen vascular disease; and organ transplantation. We must also add to this category patients with AIDS. Over 50% of such patients with toxoplasmosis have alterations of mental status, motor impairments, seizures, abnormal reflexes, and other neurologic symptoms. Studies have shown that even among compromised patients, 80% of those receiving chemotherapy for toxoplasmosis experienced significant clinical improvement or complete remission; however, in those with AIDS, therapy must be continued for long periods to maintain a clinical response.

Toxoplasma encephalitis has been reported as a life-threatening opportunistic infection among patients with AIDS. The overall prognosis can be poor, with the median survival following initiation of therapy being 4 months. A clinical relapse of *Toxoplasma* encephalitis has been reported to occur in 50% of patients discharged from hospital. In AIDS patients who may not receive prophylaxis for *Pneumocystis jiroveci* pneumonia, almost half of the *Toxoplasma*-seropositive patients can develop CNS toxoplasmosis. This figure is considerably higher than previously thought for the development of CNS involvement.

Figure 19.5 *Toxoplasma gondii* in bone marrow.

Statistics indicate that, overall, approximately 2.5% of AIDS patients have been diagnosed with cerebral toxoplasmosis. Information on toxoplasmosis and the immunocompromised host can be seen in Table 19.6.

Humans usually become infected with *T. gondii* by ingesting raw or poorly cooked meats. Another means of transmission is ingestion of infected oocysts found in cat feces. It has been recommended that litter boxes be cleaned daily, with feces disposed of in the toilet and the pans disinfected with boiling water. Since we know that transplacental transmission can occur during an acute but perhaps undiagnosed maternal infection, pregnant women, unless they have serologic evidence of previous infection, should avoid contact with cats whose source of food is not controlled and should not empty litter boxes. Uterine or neonatal infections can give rise to a number of serious sequelae, including microcephaly and hydrocephalus.

In humans, *T. gondii* is found in two different stages. The actively proliferating intracellular forms are called trophozoites or tachyzoites and are crescent shaped. Many different tissues may be parasitized by these organisms, particularly lung, heart, lymphoid organ, and CNS tissues. The resting forms or cyst stages are found in the tissues and contain the more slowly developing bradyzoites.

Toxoplasmosis can be diagnosed by using various serologic procedures, histologic findings from the examination of biopsy specimens, and isolation of the organism, either in a tissue culture system or by animal inoculation. Individuals with positive serologic tests have been exposed to *Toxoplasma* organisms and may have the resting stages within their tissues. This is why histologic identification of the organism and its recovery either in a tissue culture system or by animal inoculation may be misleading, since the organisms could be isolated yet might not be the etiologic agent of disease. Thus, serologic tests have been recommended as the diagnostic tests of choice. One of the first serologic tests was the Sabin-Feldman dye test, a reaction based on the fact that serum antibodies to *T. gondii* will affect the organisms so that they become refractory to staining with methylene blue. However, since this test requires the use of living *Toxoplasma* trophozoites, most laboratories do not provide it for clinical use.

In an immunodeficient or immunosuppressed patient, a presumptive diagnosis of toxoplasmosis can be made by observing an elevated serologic titer and the presence of the clinical syndrome, which would include neurologic symptoms. However, in certain patients with monoclonal gammopathies, titers to *T. gondii* may be extremely high but may not reflect the cause of the clinical condition. One of the most common diagnostic tests used for toxoplasmosis is the IFA procedure. Definitive diagnosis is usually made when there is a rising titer, an IgM-IFA titer

of at least 1:64, or an IgM-ELISA titer of 1:256. A finding that the Sabin-Feldman dye reaction is higher in CSF than in serum is also significant but not that common. An elevated serologic titer in conjunction with demonstration of the actual trophozoites or isolation of the organisms from cerebrospinal fluid is very significant.

Cryptosporidium spp.

Although it has been recognized as an animal parasite for many years, one of the newer parasitic organisms infecting humans, particularly compromised patients, is *Cryptosporidium*, a cause of diarrhea (Tables 19.3 and 19.4; Figure 19.6). *Cryptosporidium* differs from other coccidia that infect warm-blooded vertebrates in that the developmental stages do not occur deep within host cells but are confined to an intracellular, extracytoplasmic location. Each stage is within a parasitophorous vacuole of host cell origin. What was previously called *C. parvum* and was thought to be the primary *Cryptosporidium* species infecting humans is now classified as two separate species, *C. parvum* (mammals, including humans) and *C. hominis* (primarily humans). Differentiation of these two species based on oocyst morphology is not possible.

Studies have shown that calves and perhaps other animals may serve as potential sources of human infections. Kittens, rodents, and puppies are possible reservoir hosts, since they are easily infected with human *Cryptosporidium*. Person-to-person transmission is also likely and may occur through direct or indirect contact with stool material in the environment and the hospital setting.

This organism is worldwide in distribution, and although the first cases in the literature indicated that the patients were immunosuppressed or immunodeficient, current literature reports numerous infections and outbreaks in patients with a normal immune system capability. In patients with a normal immune system capability, cryptosporidiosis is self-limiting. However, in certain compromised patients, the diarrhea is very severe and prolonged, with death being the eventual outcome (Tables 19.4 and 19.7). Clinical symptoms include nausea, low-grade fever, abdominal cramps, anorexia, and 5 to 10 watery stools per day. Fluid loss in these patients is significant and has been reported to be as great as 17 liters/day.

Although many therapeutic regimens have been tried, there is no completely satisfactory therapy for cryptosporidiosis in humans. Paromomycin, clarithromycin, nitazoxanide, and hyperimmune bovine colostrum are among the drugs being tried in different regimens; the current recommendation is nitazoxanide (1). Specific recommendations for immunocompromised patients in

Table 19.6 *Toxoplasma gondii* infections in immunocompromised patients

Underlying condition	Disease manifestation and complication ^a	Comments ^a	Reference
AIDS and lymphoma	Cerebral toxoplasmosis	Regional CBV (rCBV) determined by perfusion MRI; rCBV reduced throughout toxoplasmosis lesions; all active lymphomas had increased rCBV results; differences were significant; perfusion MRI is a rapid, non-invasive tool that may allow differentiation between cerebral lymphoma and toxoplasmosis	28
AIDS and lymphoma	Cerebral toxoplasmosis	Knowledge of patient's serostatus does not aid discrimination between lymphoma and toxoplasmosis; single lesions on MRI with focal accumulation of thallium-201 strongly suggest lymphoma; multiple lesions on MRI with uptake ratios of ≥ 2.9 also suggest lymphoma; uptake ratios of < 2.1 do not aid in discrimination	69
AIDS	CNS disease	Diagnosis of CNS toxoplasmosis often incorrect; another diagnosis is most likely in patients who are anti- <i>Toxoplasma</i> seronegative or who are receiving prophylactic TMP-SMX	63
AIDS	CNS disease and intracranial mass lesions	Neurologic disease is first indication of AIDS in 10–20% of HIV-seropositive individuals; over half will present with intracranial mass lesion; toxoplasmosis is the most common cause in developed countries; data indicate that it is also the most common cause in underdeveloped countries	9
AIDS	CNS disease and gastrointestinal mastocytosis	Simultaneous occurrence of both conditions and regression after treatment for toxoplasmosis; may suggest a possible relationship between mast cell proliferation and parasitic infection	56
AIDS	Chorea	Chorea not unusual in AIDS; however, its causes are variable; AIDS-related disease should be considered in young patients presenting with chorea with no family history of movement disorders	84
AIDS	Risk factors	While risk factors are still somewhat unclear, specific prophylaxis for patients with low CD4 cell counts and high <i>Toxoplasma</i> Ab titers is recommended	7
AIDS	Emerging disease in India (TE)	Management protocol in AIDS patients critical to the diagnosis of TE in patients with CNS symptoms; increasing numbers of AIDS patients require constant consideration of opportunistic infections	65
AIDS	Immunoblot profiles (TE)	In patients with <i>Toxoplasma</i> Ab (ELISA), IgG 27 band or IgG 31 band on Western blot is highly indicative of TE, independent of each other; Western blot positivity provides useful data for improving diagnosis of presumptive TE in HIV-infected patients with suspected TE and positive <i>Toxoplasma</i> serology	89
AIDS	Long-term outcome (TE)	Cerebral infections like TE may negatively influence HIV-1 activity so far latent in the brain	6
AIDS	Sulfadiazine and obstructive nephropathy	Patients receiving sulfadiazine for cerebral toxoplasmosis can develop obstructive nephropathy; will resolve with alkalic hydration and discontinuation of sulfadiazine	18
AIDS	High or low doses of TMP-SMX	High doses of TMP-SMX appear to be more effective than low doses for decreased risk for toxoplasmosis in HIV-infected patients; rifampin may reduce the efficacy of TMP-SMX	92
Immunosuppressive drugs for BMT	Cerebral toxoplasmosis	Clinical diagnosis confirmed by PCR on CSF and blood leukocytes; retrospective testing indicated PCR was positive 52 days prior to onset of clinical symptoms; results highlight value of PCR in early detection of cerebral toxoplasmosis	55

(continued)

Table 19.6 *Toxoplasma gondii* infections in immunocompromised patients (continued)

Underlying condition ^a	Disease manifestation and complication ^a	Comments ^a	Reference
Immunosuppressive drugs for BMT	TE	In group of 27 BMT patients (allogeneic only) who developed CNS infections, the most common (74%) was TE; one group showed edema but no enhancement, while one group showed the typical MRI pattern with the exception of frequent hemorrhagic transformation	64
Immunosuppressive drugs for BMT	Cerebral toxoplasmosis reactivation	<i>T. gondii</i> infection reactivation occurs predominantly in patients after allogeneic BMT; tends to occur within 3 mo after transplantation; late cerebral toxoplasmosis reactivation may be triggered by a course of corticosteroids (administered for graft-versus-host disease); risk factors should signal reinstitution of prophylactic treatment with TMP-SMX	121
Immunosuppressive drugs for BMT	MRI problems	In patients with low leukocyte count (poor immunologic response) and/or high doses of immunosuppressive therapy, typical contrast enhancement may be absent (poor visualization of cerebral lesions)	26
SLE therapy	Cerebral toxoplasmosis	Symptoms of fever, confused state, convulsions consistent with lupus cerebritis; patient died of cerebral toxoplasmosis, which was confused with lupus cerebritis	120
Non-Hodgkin's lymphoma	TE	Involvement of mediastinum, para-aortic lymph nodes, pleura, peritoneum, bone marrow; patient deteriorated; CSF smear revealed tachyzoites; TE should be considered a potential cause of consciousness disturbance in patients with malignant lymphoma	119

^a Ab, antibody; BMT, bone marrow transplantation; CBV, cerebral blood volume; MRI, magnetic resonance imaging; SLE, systemic lupus erythematosus; TE, *Toxoplasma* encephalitis; TMP-SMX, trimethoprim-sulfamethoxazole.

avoiding potential risk situations for acquiring infection with *Cryptosporidium* spp. can be found in chapter 4 and Table 19.8.

Since the organisms live in the microvillous surface of the mucosal epithelial cells of the intestine, diagnostic techniques have included histologic examination of intestinal biopsy material, scanning and transmission electron microscopic examination of duodenal aspirates and biopsy specimens, and the examination of stool specimens for oocysts.

Figure 19.6 *Cryptosporidium* oocysts stained using the modified acid-fast stain (note the spherical shape; oocysts measure 4 to 6 μ m).

Although biopsy techniques have been used to recover and identify the organisms in tissue, one problem with a tissue specimen is that the specific area where the organisms reside may not be subjected to biopsy. The examination of stool material for oocysts by using an acid-fast technique or immunoassays allows one to screen a sample from the entire intestinal tract. It is considerably cheaper to examine a stool specimen than to perform endoscopy or histologic testing. *Cryptosporidium* oocysts in the stool range from 4 to 6 μ m in diameter and can be very difficult to identify. One must also remember that even in patients with typical watery diarrhea, the numbers of organisms passed can be quite variable.

Respiratory cryptosporidiosis has also been detected in AIDS patients. Sputum specimens should be submitted in 10% formalin or as a fresh specimen and can be examined by the same techniques as used for stool samples.

Some techniques have included sugar flotation, formalin sedimentation, Giemsa stain, trichrome, PAS, silver methenamine, acridine orange, auramine-rhodamine, iodine, modified acid-fast, Kinyoun and Ziehl-Neelsen acid-fast, and immunoassay techniques. The most widely used techniques are modified acid-fast stains, Kinyoun's methods, and fecal immunoassays. Specimens preserved in polyvinyl alcohol do not stain well in the acid-fast techniques.

Table 19.7 *Cryptosporidium* infections in immunocompromised patients

Underlying condition	Disease manifestation	Comments	Reference
AIDS	Diarrhea and possible dissemination	Parasites associated with 14% of acute diarrheal episodes (≤ 28 days) and 35% of chronic episodes (> 28 days); parasite associated with diarrhea in 14% of patients when CD4 ⁺ counts are ≥ 200 cells/ μ l and in 27% when counts are < 200 cells/ μ l; <i>Cryptosporidium</i> associated with 5% of acute episodes and 13% of chronic episodes of diarrhea; <i>Cryptosporidium</i> likely to be associated with diarrhea as immunosuppression worsens and with chronic rather than acute diarrhea	77
AIDS	Diarrhea	Attack rate 14% among HIV-negative individuals and 31% among HIV-positive individuals (varies due to CD4 cell count); chronic symptoms in 15% (< 150 CD4 cells/ μ l at onset); 14% had antibody before outbreak, 51% developed specific antibodies during outbreak; clinical manifestations of cryptosporidiosis strongly influenced by level of HIV-induced immunosuppression	88
AIDS	Pancreatitis	Acute or chronic pancreatitis associated with <i>Cryptosporidium</i> , infection; abdominal pain resistant to analgesics, increased amylase level in serum; abnormalities on both sonography and CT; papillary stenosis in all patients; oocysts found in both bile and stool; viral cultures negative; several antibiotic protocols ineffective	15
AIDS	Gastric involvement	Of 24 individuals, 34% positive for <i>Cryptosporidium</i> , 16 (89%) of these had parasites in gastric epithelium; most patients did not show specific symptoms indicating presence in stomach; gastric involvement probably more frequent than expected; no clear correlation between gastric location and related clinical or pathologic features	93
AIDS	Diarrhea	22 <i>Cryptosporidium</i> isolates (Kenya, Switzerland, United States); 4 distinct genotypes identified (<i>C. parvum</i> , human genotype; <i>C. parvum</i> , cattle genotype; <i>C. felis</i> ; and <i>C. meleagridis</i> , turkey); immunocompromised individuals susceptible to wide range of <i>Cryptosporidium</i> spp. and genotypes; full public health ramifications not known	73
AIDS	Diarrhea	<i>C. parvum</i> genotype subgroupings correlate to some extent with infectivity and suggest that additional heterogeneity is present within the subgroups	114
AIDS	Diarrhea	Treatment of HIV-1-associated microsporidiosis and cryptosporidiosis with combination antiretroviral therapy; combination therapy that includes protease inhibitors can restore immunity to both organisms and result in clinical, microbiological, and histologic responses; persistent CD8 cell and macrophage infiltrate and short time to relapse with declining CD4 lymphocyte counts suggest that neither infection was eradicated	16
AIDS	Diarrhea due to contaminated tap water	Risk assessment model applied to New York City population; calculated number of tap water-related cases per year was 6 (non-AIDS subgroups) or 34 (AIDS subgroups)	83
AIDS, pediatrics	Diarrhea	Some 81% of HIV-infected children with persistent diarrhea excreted <i>Cryptosporidium</i> , microsporidia, or both organisms, compared with only 10% of children with persistent diarrhea testing negative for HIV; 74% of isolates were <i>C. hominis</i> , 17% were <i>C. parvum</i> , and 8% were a mixture of the 2 or others	111
All causes	Diarrhea due to zoonotic transmission	Presence of <i>Cryptosporidium</i> in cats (5%) (in addition to other organisms such as <i>Giardia</i> spp., <i>Toxocara cati</i> , <i>Salmonella</i> , <i>Campylobacter</i>); enteric zoonotic organisms detected in total of 13% of cats studied; cats in homes of immunocompromised humans should be evaluated for zoonotic organisms	42
Hodgkin's lymphoma	Diarrhea	Immunocompromised prevalence of 14.3%; control group had 5.6%	91
Immunosuppressive therapy for pediatric oncology	Diarrhea	In contrast to studies of adult oncology patients, pediatric oncology patients in some areas appear to be at low risk for cryptosporidiosis	12

(continued)

Table 19.7 *Cryptosporidium* infections in immunocompromised patients (continued)

Underlying condition	Disease manifestation	Comments	Reference
Immunosuppressive drugs for kidney transplantation, chronic renal insufficiency	Diarrhea	<i>Cryptosporidium</i> found in 35% (renal transplant group), 25% (patients on hemodialysis), and 17% (control group with systemic arterial hypertension) of patients; when number of positive fecal samples are taken into account, there is a significantly higher frequency in renal transplant patients	110
Immunosuppressive drugs for kidney transplantation	Diarrhea	<i>Cryptosporidium</i> present in 19% of patients, <i>Blastocystis hominis</i> in 39%; symptomatic infections with <i>Cryptosporidium</i> significantly higher in transplant patients than controls	78
Immunosuppressive drugs for liver transplantation	Diarrhea	Primary hypogammaglobulinemia, chronic hepatitis C, hepatic failure; 14 mo posttransplantation, <i>Cryptosporidium</i> diarrhea; no response to therapy; patient died	10
Immunosuppressive drugs for solid-organ transplantation ^a	Diarrhea	Included 3 liver transplants and 1 small bowel transplant; all 4 patients resolved cryptosporidiosis; while cryptosporidiosis is a non-lethal complication, it allows physician to monitor degree of immunosuppression and relationship to infection	34

^a Excludes kidney transplantation.

Because other organisms may also fluoresce when auramine or the auramine-rhodamine combination is used, presumptive positive specimens should be confirmed by using one of the acid-fast methods. Both *Cryptosporidium* and *Isospora* spp. fluoresce with auramine-rhodamine and are acid-fast positive. Oocysts are fully mature and infective at the time they are passed in the stool. One can occasionally see the four sporozoites with the dark-staining residual body in the fully developed oocyst.

Immunoassay procedures for the direct detection of *Cryptosporidium* antigen or oocysts in fecal specimens have proven to be much more sensitive than the routine acid-fast stains. Since acid-fast stains do not always consistently stain all oocysts, the increased sensitivity and specificity of these immunoassays provide excellent testing methods. Enzyme immunoassay, solid-phase immunochromatographic assay in cartridge format, and FA methods are currently available. The choice of method depends on a number of variables and differs among diagnostic laboratories.

Since *Cryptosporidium* has been recovered from patients with AIDS, it has been recommended that stool specimens be submitted in 5 or 10% formalin, sodium acetate-acetic acid-formalin, or the newer single-vial collection systems for processing. However, each laboratory must confirm that the fixatives selected are compatible with diagnostic procedures performed, including the ova and parasite examination and immunoassays; not all single-vial systems are compatible with diagnostic immunoassay reagents. Laboratories should use standard precautions when working with these stool specimens. When specimens are centrifuged, capped centrifuge tubes should be used to prevent the formation of aerosols. Also,

if possible, specimen processing should be performed in a biological safety cabinet.

Cyclospora cayetanensis

Cyclospora cayetanensis organisms are acid-fast-variable coccidia and have been found in the feces of immunocompetent travelers to developing countries, immunocompetent subjects with no travel history, and patients with AIDS (Figure 19.7). The life cycle has been confirmed, but information on potential reservoir hosts has yet to be defined; however, it appears that in some areas the human is the only host (Table 19.9). Outbreaks linked to contaminated water and various types of fresh produce (raspberries, basil, baby lettuce leaves, and snow peas) have been reported.

Oocyst maturation takes approximately 5 days or more, so the mature stage may not have been seen in human specimens. The oocyst contains two sporocysts, each containing two sporozoites, a pattern which places these organisms in the coccidian genus *Cyclospora*. Unsporulated oocysts are passed in the stool, and sporulation occurs within approximately 1 to 2 weeks. In patients who have *Cyclospora* oocysts in their stool specimens, two types of meronts and sexual stages have been found within the jejunal enterocytes.

There is generally 1 day of malaise and low-grade fever, with rapid onset of diarrhea of up to seven stools per day. There may also be fatigue, anorexia, vomiting, myalgia, and weight loss with remission of self-limiting diarrhea in 3 to 4 days followed by relapses lasting from 4 to 7 weeks. In patients with AIDS, symptoms may persist for as long as 12 weeks; biliary disease has also been

Table 19.8 Prevention of cryptosporidiosis in immunocompromised patients^a

Preventive measure	Comments
Hand washing	Prior to eating and food preparation; after touching children in diapers; after touching clothing, bedding, toilets, or bed pans from anyone with diarrhea; after gardening; after touching pets or other animals; after touching or coming in contact with anything contaminated with human or animal stools (includes dirt); after removing gloves to perform any of the above activities
Safe sex	Always wash hands after touching partner's anal or rectal area
Avoidance of farm animals	Particularly important for contact with young animals (especially lambs and calves); wash hands thoroughly; avoid touching stools of any animal; after potential exposure, clean shoes (avoid having someone who is HIV infected perform this task)
Avoidance of pet stools	If HIV infected, avoid cleaning litter boxes or cages and disposing of stools; very important to avoid if animals are less than 6 months old; have puppies or kittens (if less than 6 months old) tested for <i>Cryptosporidium</i> before bringing them home; adult cats have also been found to be positive; have any pet tested that develops diarrhea
Precautions while swimming	Avoid swallowing water when in lakes, rivers, pools, or hot tubs; organisms not killed by routine chlorination; oocysts can also survive several days in salt water, so avoid swimming in polluted ocean water
Washing and cooking food	Wash well all fruits and vegetables if eating uncooked; use safe water for washing food; peel fruit; avoid unpasteurized milk or dairy products; cooking kills <i>Cryptosporidium</i> ; cooked or packaged food is safe unless handled by someone infected with the organism
Water for drinking	Do not drink directly from lakes, rivers, streams, or springs; may want to avoid unboiled tap water (includes water and/or refrigerator ice-maker ice); boil water (rolling boil for 1 min sufficient to kill organisms), filter with appropriate filters (look for "reverse osmosis," "absolute 1 micron," "Standard 53," and the words "cyst reduction" or "cyst removal"); home distiller can be used; store water as for boiled water
Bottled water	Bottled water labels reading "well water," "artesian well water," "spring water," or "mineral water" do not guarantee that the water does not contain <i>Cryptosporidium</i> ; however, water that comes from protected well or spring water sources is less likely to be contaminated than bottled water from rivers and lakes
Drinks	Canned or bottled soda, seltzer, fruit drinks, and steaming hot tea and coffee are safe; fountain drinks, fruit drinks mixed with tap water from concentrate, and iced tea or coffee may not be safe

^a Adapted from information prepared by the interagency Working Group on Waterborne Cryptosporidiosis.

found in this group. Diarrhea alternating with constipation has also been reported; this is not uncommon in a number of protozoal gastrointestinal infections. Clinical clues include unexplained prolonged diarrheal illness during the summer in any patient and in persons returning from tropical areas. The clinical presentation of patients infected with this organism is similar to that of patients infected with *Cryptosporidium* spp.

In clean wet mounts, the organisms are seen as nonrefractile spheres and are acid-fast variable with the modified acid-fast stain; those that are unstained appear as glassy, wrinkled spheres. Modified acid-fast stains stain the oocysts from light pink to deep red, and some contain granules or have a bubbly appearance. It is very important to be aware of these organisms when the modified acid-fast stain is used for *Cryptosporidium* spp. and other similar but larger structures (approximately twice the size of *Cryptosporidium* oocysts) are seen in the stained smear. It is important for laboratories to measure all acid-fast oocysts, particularly if they appear to be somewhat larger

than those of *Cryptosporidium* spp. The oocysts autofluoresce green (1+ to 3+) (450 to 490 DM excitation filter) or blue (1+ to 3+) (365 DM excitation filter) under UV epifluorescence. It is strongly recommended that, during concentration (formalin/ethyl acetate) of stool specimens, the centrifugation time and speed be 10 min at 500 × g.

Apparently, patients do not respond to conventional antimicrobial therapies. Some patients have been treated symptomatically with antidiarrheal preparations and have obtained some relief; however, the disease appears to be self-limiting within a few weeks. Trimethoprim-sulfamethoxazole is currently the drug of choice; relief of symptoms has been seen in 1 to 3 days posttreatment. However, symptoms recur within 1 to 3 months posttreatment in over 40% of the patients. Although prophylaxis with trimethoprim-sulfamethoxazole is not generally recommended, it might be worth considering for an HIV-positive person visiting an area of endemic infection like Nepal during the summer, when the risk of infection tends to be the highest.

Figure 19.7 *Cyclospora cayetanensis* oocysts stained using the modified acid-fast stain (note the spherical shape; oocysts measure 8 to 10 μm ; some oocysts do not stain, thus the organisms are said to be “modified acid-fast variable”).

Published reports indicate that individuals of all ages, including immunocompetent and immunosuppressed individuals, can become infected. In Peru, infections with this organism have shown some seasonal variation, with peaks during April to June. This pattern is similar to that seen for *Cryptosporidium* infections in Peru. Preliminary data and extrapolation from what we currently know about cryptosporidiosis suggest that modes of transmission may be similar, particularly considering waterborne transmission.

Isospora (Cystoisospora) belli

An organism similar to *Cryptosporidium* that causes diarrhea in the compromised host is *Isospora belli* (Tables 19.3 and 19.4; Figure 19.8). Transition to the new genus name will probably occur during the next couple of years. Although *Isospora* infections have been found in many areas of the world, certain tropical areas in South America appear to contain some well-defined locations of endemic infections. These organisms can infect both adults and children. Intestinal tract involvement and symptoms are generally transient unless the patient is immunocompromised (Tables 19.4 and 19.10). In a group of AIDS patients in Brazil, 2% were found to be positive for *I. belli* infection. In reviewing prevalence data for this and other parasites in this group, there did not appear to be any association between CD4^+ cell counts and any particular parasite. However, the data supported the value of using standard fecal examinations with this group of infected patients, even in the absence of diarrhea, since examinations can be easily performed, have a low cost, and can disclose treatable conditions (17).

Relapse tends to be common in both immunocompetent and immunosuppressed patients and is thought to be associated with extraintestinal stages (32). These unizote tissue cysts in extraintestinal sites have been confirmed to be present in the liver, spleen, and mesenteric lymphoid tissues in AIDS patients (32, 68).

Table 19.9 *Cyclospora cayetanensis*: updated information^a

Information	Comments
Disease	
Haiti	Fewer infections in winter; summer temperatures may influence seasonality of infection
Nepal	Oocysts identified in sewage water, vegetable washings
Egypt	HIV-negative patient with weight loss, cough with purulent sputum, and dyspnea; suggested tuberculosis, <i>Cyclospora</i> confirmed by nested PCR; 2 cases on record; organism must be considered a new respiratory system pathogen
India	Important to test for intestinal parasites in HIV-positive patients
Reservoir hosts	
Haiti	Pigs, cattle, horses, goats, dogs, cats, guinea pigs, chickens, ducks, turkeys, pigeons negative; humans may be the only natural host
Disease risk factors	
Guatemala	U.S. infections linked to importation of Guatemalan raspberries; risk factors for workers include drinking water source, sewage drainage, proximity to chickens/other fowl; risk factors for children include contact with soil
Egypt	Sporulated and unsporulated oocysts found in tap water and lettuce heads; patients with Hodgkin's lymphoma on chemotherapy at risk
Peru	Oocysts found in wastewater; may be link to oocysts on vegetables
North America	Linked to raspberries, mesclun, basil, snow peas; over 3,600 cases since 1995

^a Adapted from references 46, 59, 70, and 91.

Figure 19.8 *Isospora (Cystoisospora) belli*. (Upper) Immature oocyst (contains single sporocyst) stained using modified acid-fast stain; (lower) more mature oocyst (contains two sporocysts) in a saline wet mount of stool concentration sediment.

I. belli infection is frequent in patients with AIDS in tropical areas. It has also been reported to occur in patients with other immunodepressive diseases, such as lymphoblastic leukemia, adult T-cell leukemia, and Hodgkin's disease. Non-Hodgkin's lymphoma with chronic diarrhea due to *I. belli* has also been reported (90). *I. belli* can cause severe chronic diarrhea in patients with malignancies whose country of origin is in an area of endemic infection. Isosporiasis should be suspected in HIV-infected patients from tropical countries presenting with diarrhea, weight loss, eosinophilia, and low CD4⁺ cell counts.

Since *I. belli* infects both immunocompetent and immunocompromised adults and children, symptoms range from none to severe diarrhea. Persistent nonbloody diarrhea, similar to that seen with microsporidiosis or cryptosporidiosis, is the major symptom seen in immunocompromised individuals. Pathology with blunting of the villi, villous atrophy, and collagen deposition in the lamina propria is commonly seen. Extraintestinal infections have been detected in AIDS patients, revealing infections in lymph nodes, liver, spleen, and biliary system.

The life cycle of *I. belli* is generally considered to be similar to the life cycles of other coccidia; however, *I. belli* is thought to infect only humans (see chapter 4). Oocysts are passed in the stool and are usually underdeveloped

and noninfectious when passed. These oocysts are most often seen in wet preparation, such as the direct smear or the concentration sediment.

There has been much speculation over the years that many cases of *Isospora* infection go undetected and that the incidence may be higher than that reported in the literature. However, it is also possible to have a positive biopsy specimen and not recover the oocysts in the stool because of the small numbers of organisms present. The oocyst wall in *I. belli* remains intact, and development can range from little differentiation to the presence of two well-defined sporocysts within the oocyst wall.

Sarcocystis spp.

Sarcocystis spp. require two hosts for completion of the life cycle. Two well-described species are *Sarcocystis bovi-hominis* (cattle) and *S. suihominis* (pigs). When raw or poorly cooked meat from infected animals is ingested by humans, gamogony occurs within the intestinal cells, with the production of sporocysts in the stool. In this case, humans who have ingested meat containing the mature sarcocysts serve as the definitive hosts. There have been reports of fever, severe diarrhea, abdominal pain, and weight loss in compromised hosts. Eosinophilic enteritis and ulcerative obstructive enterocolitis may be seen as occasional complications. In one group of Thai laborers, a 26.6% prevalence of *Sarcocystis* infection was seen. This high prevalence rate was indicative of the local habit of eating raw beef and pork; sarcocystosis could be a significant food-borne zoonotic infection in Thailand (115).

The sporocysts that are recovered in the stool are broadly oval, measuring 9 by 16 μm and containing four mature sporozoites and the residual body. Normally two sporocysts are contained within the oocyst (similar to *I. belli*); however, in *Sarcocystis* infections, the sporocysts are released from the oocyst and normally are seen singly. They tend to be larger than *Cryptosporidium* oocysts, which contain four sporozoites, and so there should be no confusion between the two (29). Differentiation of encysted protozoan parasites in human feces is described in Table 19.11.

When humans serve as the accidental intermediate host, they accidentally ingest oocysts from other animal stool sources. The sarcocysts that develop in human muscle (schizogony) apparently do little if any harm (Figure 19.9). There is essentially no inflammatory response to these stages in the muscle and no conclusive evidence of pathogenicity of the mature sarcocyst. A number of different morphologic types of skeletal and cardiac muscle sarcocysts have been recovered in humans; sarcocysts have also been found in muscles of the larynx, pharynx,

Table 19.10 *Isospora (Cystoisospora) belli*: parasite development and disease

Characteristic	Description	Comments
Infection source	Transmitted by infective oocysts in fecal-oral transmission	Excystation induced by body temperature with bile or bile salts and trypsin
Infective stage	Mature oocysts containing sporocysts with internal sporozoites; not infectious when passed	Oocyst wall is split, thus releasing sporozoites
Developmental stages	Zoites and meronts develop within epithelial cells; eventually merozoites form macrogametes and microgametes	Small intestine; in immunocompromised, parasite development occurs in biliary epithelial cells, as well; parasite cysts also seen in extraintestinal sites such as lymph nodes, liver, and spleen
Immunocompromised host	Recurrence of infection in AIDS patients following successful chemotherapy	May be due to activation of cysts in extraintestinal sites
Cellular and molecular biology	Parasite material difficult to obtain; culture difficult, complete development difficult	Overall little known about biology of this parasite
Clinical aspects	Infects both immunocompetent and immunocompromised patients; 54% have peripheral eosinophilia; vomiting, steatorrhea, headache, fever, malaise; symptoms in children can be severe	Most information comes from disease as seen in Chile; persistent nonbloody diarrhea like that seen with microsporidiosis and cryptosporidiosis
Immunology	CD4 T cells involved	Infection more severe in AIDS patients (low CD4 counts)
Pathology	Moderate to severe villous atrophy; collagen deposition in the lamina propria	Both sexual and asexual stages seen in epithelium, enclosed by parasitophorous vacuole
Diagnosis	Routine fecal ova and parasite examination; concentration important	Modified acid-fast stains helpful; auramine-rhodamine; unstained oocysts autofluorescent; intestinal biopsy (routine stains)
Epidemiology	Transmission most common in tropical zones (subequatorial Africa, Caribbean, parts of South America)	Prevalence in populations with high HIV infection quite variable; percentages vary from 3% to over 20%; rarely seen in HIV-positive children
Treatment	Trimethoprim-sulfamethoxazole recommended	An approved drug, but considered investigational for this condition by the Food and Drug Administration

and upper esophagus. Generally, histopathologic diagnoses are myositis with vasculitis and sometimes myonecrosis. No specific therapy is known for this type of infection. Characteristics of this infection can be seen in Table 19.12. In another four cases, the patients presented with lumps, pain in the limbs, or a discharging sinus. Histologic examination of biopsy specimens in all cases revealed characteristic cysts of *Sarcocystis* spp.

For infections in which humans serve as definitive hosts, prevention involves adequate cooking of beef and pork; for infections in which humans are intermediate hosts, preventive measures involve careful disposal of animal feces possibly containing the infective sporocysts. This may be impossible in the wilderness areas, where wild animals may serve as reservoir hosts for many of the different types of organisms that have been grouped under the term

“*Sarcocystis lindemanni*.” However, evidence of multiple morphologically different cysts indicates that there are probably several species of *Sarcocystis* that cause human infections. Therefore, the name is no longer used. No specific therapy is known for the muscle stages of *Sarcocystis* spp., and there is no report of prophylaxis in humans.

Microsporidia

The microsporidia are obligate intracellular parasites that have been detected in a variety of animals, particularly invertebrates; the organisms found in humans tend to be quite small, ranging from 1.5 to 3 μm . Until recently, awareness and understanding of human infections have been marginal; only with increased understanding of AIDS within the immunosuppressed

Table 19.11 Encysted pathogenic protozoan parasites seen in human feces

Protozoan parasite	Size (μm)	Shape	Features
<i>Sarcocystis hominis</i> and <i>S. suihominis</i>			Excreted sporulated (immediately infectious)
Oocysts	15–19 by 15–20	Spherical	Contain 2 sporocysts
Sporocysts	15–19 by 8–10	Oval	Contain 4 sporozoites
<i>Isospora (Cystoisospora) belli</i>	20–33 by 10–19	Ovoid with tapered ends	Excreted unsporulated (not immediately infectious)
<i>Cyclospora cayetanensis</i>	7.7–10	Spherical	Excreted unsporulated (not immediately infectious)
<i>Cryptosporidium hominis</i> and <i>C. parvum</i>	4–6	Nearly spherical	Excreted sporulated (immediately infectious); some internal sporozoites difficult to see
<i>Giardia lamblia</i>	11–14	Spherical to ovoid to ellipsoid	4 nuclei, curved median bodies, linear axonemes (immediately infectious)
<i>Entamoeba histolytica</i> and <i>E. dispar</i> (<i>E. histolytica</i> / <i>E. dispar</i> group)	10–15	Spherical	Precyst generally contains single nucleus (karyosome with peripheral nuclear chromatin); mature cyst contains 4 nuclei and possible chromatoidal bars (with round, smooth ends) (mature cyst immediately infectious)
<i>Blastocystis hominis</i> (currently classified with the protozoa)	6–40	Spherical to somewhat oval	Central body form with nuclei around the central body area (immediately infectious as far as known)
<i>Balantidium coli</i>	50–70	Spherical to oval	Large macronucleus, thick wall (infectious)

population has attention been focused on these organisms (Tables 19.3, 19.4, and 19.13; Figure 19.10). Limited availability of electron microscopy capability has also played a role in our inability to recognize and diagnose these infections.

Phylogenetic studies have confirmed that the microsporidia evolved from the fungi, being most closely related to the zygomycetes (66). Features shared with fungi include the presence of chitin and trehalose, similarities in cell cycles, and certain gene organizations. Microsporidia are now considered to be highly derived fungi that underwent genetic and functional losses, thus resulting in one of the smallest eukaryotic genomes known. However, at this point, clinical and diagnostic issues and responsibilities may remain with the parasitologists, and these organisms are maintained as a part of this parasitology text. We may be in a transition stage, similar to that seen with *Pneumocystis jiroveci* as it was moved from the parasites to the fungi in terms of classification status.

The organisms are characterized by having spores containing a polar tubule, which is an extrusion mechanism for injecting the infective spore contents into host cells. To date, seven genera have been recognized in humans: the more common, *Encephalitozoon* and *Enterocytozoon*, and the less common, *Brachiola*, *Pleistophora*, *Trachipleistophora*, *Vittaforma*, and “*Microsporidium*,” a catch-all genus for

organisms that have not yet been classified (or may never be classified due to a lack of specimen). Classification criteria include spore size, configuration of the nuclei within the spores and developing forms, the number of polar tubule coils within the spore, and the relationship between the organism and host cell. Infection occurs with the introduction of infective sporoplasm through the polar tubule into the host cell. The microsporidia multiply extensively within the host cell cytoplasm; the life cycle includes repeated divisions by binary fission (merogony) or multiple fission (schizogony) and spore production (sporogony). Both merogony and sporogony can occur in the same cell at the same time. During sporogony, a thick spore wall is formed, providing environmental protection for this infectious stage of the parasite. An example of infection potential is illustrated by *Enterocytozoon bieneusi*, an intestinal pathogen. The spores are released into the intestinal lumen and are passed in the stool. These spores are environmentally resistant and can then be ingested by other hosts.

Encephalitozoon

Both *Encephalitozoon cuniculi* and *E. hellem* have been isolated from human infections, the first species from the CNS and the second from the eye. The first case occurred in a 9-year-old Japanese boy who presented with neurologic symptoms such as convulsions, vomiting,

Table 19.12 *Sarcocystis*: parasite development and disease^a

Characteristic	Infection in muscle	Infection in intestine
Infection source	Food or water contaminated with feces from unknown carnivore or omnivore	Raw or undercooked meat
Infective stage	Oocyst or free sporocysts	Sarcocyst containing bradyzoites
Developmental stages	Intravascular schizonts (not seen); intramuscular sarcocysts	Sexual stages in lamina propria; oocysts passed in feces
Incubation period from ingestion to symptoms	Weeks to months; can last months to years	3–6 h, lasting 36 h
Symptoms	Musculoskeletal pain, fever, fleeting pruritic rash, transient lymphadenopathy, subcutaneous nodules associated with eosinophilia, cardiomyopathy, and bronchospasm	Nausea, loss of appetite, vomiting, stomach ache, bloat, diarrhea, dyspnea, and tachycardia
Diagnosis	Biopsy specimen containing sarcocyst; antibodies to bradyzoites (routine histology)	Oocysts or sporocysts in feces, beginning 5–12 days after ingestion (routine ova and parasite examination, particularly concentration)
Therapy (none approved)	Co-trimoxazole, furazolidone, albendazole, anticoccidials, pyrimethamine, anti-inflammatories	None

^a Adapted from reference 29.

headaches, fever, and periods of unconsciousness (66). The spores were recovered in the CSF and in urine. This particular patient was treated with sulfisoxazole and recovered. Another case of *E. cuniculi* infection was in a 2-year-old child with a similar neurologic illness; the spores were recovered from the urine. A recent case of keratoconjunctivitis and chronic sinusitis due to infection with *E. cuniculi* has been found in an AIDS patient; the diagnosis was confirmed by electron microscopy (66). Several eye infections with *E. hellem* have been found in AIDS patients, including the first reported case of *E. hellem* infecting not only sinuses and conjunctivae but

Figure 19.9 *Sarcocystis* sp. in muscle tissue (note the bradyzoites contained within the sarcocyst).

also the nasal epithelium. In the first case of disseminated *E. hellem* infection in an AIDS patient, a complete autopsy revealed organisms in the eyes, urinary tract, and respiratory tract. The presence of numerous organisms within the lining epithelium of almost the entire length of the tracheobronchial tree was very suggestive of respiratory acquisition. It is also interesting that although *E. cuniculi* and *E. hellem* differ biochemically and immunologically, their fine structure and development are indistinguishable. Some of the eye infections have also suggested a topical route rather than dissemination.

Brachiola spp.

Brachiola connori (formerly referred to as *Nosema connori*) was identified in human tissues in a 4-month-old infant with combined immunodeficiency disease who had contracted a disseminated, fatal infection. Parasites were found in the myocardium, diaphragm, arterial walls, kidney tubules, adrenal cortex, liver, and lungs. Concurrently, this patient also had *P. jiroveci* pneumonia. *B. algerae* (formerly *Nosema algerae*) is apparently transmitted by a mosquito. Infections have been found in the eye and muscle, possibly from a disseminated case. Both immunocompromised (HIV-negative, but receiving immunosuppressive therapy for rheumatoid arthritis) and immunocompetent patients have become infected. *B. vesicularum* has also been associated with AIDS and myositis. Muscle tissue obtained at biopsy and examined by light and electron microscopy revealed organisms developing in direct contact with muscle cell cytoplasm and

Figure 19.10 Microsporidia. (Top) Microsporidial spores seen in fecal specimen (concentration sediment) stained with Ryan modified trichrome stain (note the horizontal line through some of the spores, representing the presence of the polar tubule); (middle) spores stained with specific FA reagents for the detection of *Encephalitozoon* spp.; (bottom) spores within a urine sediment after staining with Ryan modified trichrome stain (taken at a lower magnification).

fibers. Apparently, no other tissue types were infected. Clinical and histologic clearing of the infection was achieved after treatment with albendazole and itraconazole.

***Pleistophora* and *Trachipleistophora* spp.**

Microsporidia in the genera *Pleistophora* and *Trachipleistophora* have rarely been identified in humans. However, when *Pleistophora* was found, atrophic and degenerating muscle fibers were full of spores which

were seen in clusters of about 12 organisms, each cluster enclosed by an enveloping membrane, the pansporoblastic membrane. The disease was characterized by a 7-month history of progressive generalized muscle weakness and contractions, in addition to fever, generalized lymphadenopathy, and an 18-kg weight loss. Although the patient was diagnosed as having AIDS, the presence of HIV was never demonstrated. Specimens from early biopsies demonstrated atrophic and degenerating muscle fibers; specimens from later biopsies showed fibrosis and scarring. *Trachipleistophora hominis* causes severe myositis and sinusitis and was first found in an AIDS patient. To date, no natural hosts other than humans have been identified; however, when inoculated intraperitoneally into athymic mice, the organisms infect the skeletal muscle, as seen in human infections. *T. antropophthera* is the most recently described microsporidian in humans and has been found in brain tissue of two AIDS patients at autopsy; organisms were also found in the kidneys and heart.

Enterocytozoon bieneusi

Although currently there are seven genera, one of which is the catchall genus “*Microsporidium*,” human infections with some genera are more common than with others. A number of infections with *Enterocytozoon bieneusi* have been found in AIDS patients. Chronic intractable diarrhea, fever, malaise, and weight loss are symptoms of *E. bieneusi* infections and are similar to those seen with cryptosporidiosis or isosporiasis. These patients have already been diagnosed with AIDS and each day have four to eight watery, nonbloody stools, which can be accompanied by nausea and anorexia. There may be dehydration with mild hypokalemia and hypomagnesemia, as well as D-xylose and fat malabsorption. The patients tend to be severely immunodeficient, with a CD4 count always below 200/mm³ and often below 100/mm³. *E. bieneusi* infection has also been implicated in AIDS-related sclerosing cholangitis.

Dual infections with *E. bieneusi* and *Encephalitozoon intestinalis* have been reported. *Encephalitozoon intestinalis* infects primarily small intestinal enterocytes, but infection does not remain confined to epithelial cells. *E. intestinalis* is also found in lamina propria macrophages, fibroblasts, and endothelial cells. Dissemination to the kidneys, lower airways, and biliary tract appears to occur via infected macrophages. Fortunately, these infections tend to respond to therapy with albendazole, unlike the infections with *E. bieneusi*.

A number of techniques for recovery and identification of microsporidia in clinical specimens are available. Although the organisms can be identified in routine histologic preparations, they do not tend to stain predictably. Occasionally, the spores take on a refractile

Table 19.13 Microsporidia: updated information (AIDS patients)

Findings in AIDS patients	Comments ^a	Reference
Intestinal microsporidiosis	High proportion of patients remained symptomatic after 6 mo (54.8% with persistent diarrhea, 51.2% with weight loss); predictors include high HIV RNA viral load and no initiation of protease inhibitor therapy	23
Children in Spain	1.2% overall and 2% of those with diarrhea ($n = 83$) had microsporidiosis; different data from those previously reported for adults (13.9%) in the same area, although adult group showed more severely depressed CD4 lymphocyte counts than children did	25
Children in Uganda	Some 81% of HIV-infected children with persistent diarrhea excreted <i>Cryptosporidium</i> , <i>Enterocytozoon bieneusi</i> , or both organisms, compared with only 10% of children with persistent diarrhea testing negative for HIV; 74% of isolates were <i>C. hominis</i> (the anthroponotic species), 17% were <i>C. parvum</i> (the zoonotic species), and 8% were a mixture of the 2 or others	111
Patients with or without diarrhea in Germany	Prevalence of intestinal microsporidiosis varies from 7 to 50%; most common enteropathogen in 18/50 patients (36%) with diarrhea and 2/47 (4.3%) without diarrhea; microsporidia present in 60% of patients with chronic diarrhea and 5.9% of patients with acute diarrhea (<i>E. bieneusi</i> in 18, <i>E. intestinalis</i> in 2); prevalence in this group one of highest in the world	103
Mucosal abnormalities	Mechanisms appear to be malabsorption caused by reduction of absorptive mucosal surface and impairment of enterocyte function	95
Epidemiology		
Waterborne outbreak	Of 338 individuals, 261 had HIV, 16 were transplant recipients, and 61 had other sources of immunosuppression; disease appears to be endemic in HIV-positive persons; 200 people involved in waterborne outbreak; no evidence of fecal contamination of water; outbreak ended several months before antiprotease era	21
Risk factors	Intestinal microsporidiosis in persons with HIV infection and ≤ 200 CD4 cells/mm ³ is associated with male homosexuality and swimming in pools, suggesting fecal-oral transmission, including sexual and waterborne routes	47
New disease manifestation		
Nodular skin disease	36-yr-old woman presented with late-stage AIDS and disseminated, nodular cutaneous lesions and underlying osteomyelitis; disseminated microsporidial infection with <i>Encephalitozoon</i> -like species diagnosed by EM; long-term clindamycin therapy cured cutaneous infection; response to clindamycin merits further study	53
Current clinical syndromes	Enteropathy, keratoconjunctivitis, sinusitis, tracheobronchitis, encephalitis, interstitial nephritis, hepatitis, cholecystitis, osteomyelitis, myositis; <i>E. bieneusi</i> is the most common cause of intestinal disease (can also disseminate); <i>E. (Septata) intestinalis</i> is associated with disseminated and intestinal disease	58
Modification of clinical course	Of 37 AIDS patients with <i>E. bieneusi</i> diarrhea, 15 showed clearance (40.5%); peripheral blood CD4 cell count of ≥ 100 /mm ³ , use of two or more antiretroviral medications, and use of protease inhibitor statistically associated with time to clearance of parasite; albendazole not associated with parasite eradication	19

^a EM, electron microscopy.

gold appearance in formalin-fixed, paraffin-embedded, routine hematoxylin-and-eosin-stained sections. Some of the difficulty may be attributed to the use of formalin; alternative fixatives are currently being tried. Spores are occasionally seen very well by using the PAS stain, the methenamine-silver stain, tissue Gram stains, or acid-fast stains. The spore has a small, PAS-positive posterior body, the spore coat stains with silver, and the spores are acid-fast variable. There is also evidence to indicate that specimens from plastic-embedded tissues are seen more

easily, regardless of the fixative used. Tissue examination by electron microscopy is still considered the best approach; however, this option is not available to all laboratories and is not that sensitive.

Techniques that do not require tissue embedding are also popular. Touch preparations of fresh biopsy material that are air dried, methanol fixed, and Giemsa stained have been used; however, screening must be performed using the 100 \times oil immersion objective. Another study, involving cytocentrifugation followed by Giemsa staining,

found that 27% of 55 AIDS patients with chronic diarrhea were positive for *E. bienersi*; all results were confirmed by electron microscopy.

Routine staining of clinical specimens (stool, urine, eye specimens) can be performed using a modified trichrome stain in which the chromotrope 2R component added to the stain is 10 times the concentration normally used in the routine trichrome stain for stool. The stool preparations must be *very* thin, the staining time is 90 min, and the slide must be examined at $\times 1,000$ (or higher) magnification. Unfortunately, there are many objects within stool material that are oval, stain pinkish with trichrome, and measure approximately 1.5 to 3 μm . If this stain is used for the identification of microsporidia in stool, positive control material should be available for comparison. The newest approach for the identification of spores in clinical specimens uses antisera in an IFA procedure. Fluorescing microsporidial spores were distinguished by a darker cell wall and by internal visualization of the polar tubule as diagonal lines or cross lines within the cell. In another study with this same antiserum, 9 (33%) of 27 patients diagnosed as having cryptosporidiosis (8 AIDS patients and 1 non-AIDS but immunodeficient patient) were found to have *E. bienersi* in the stool. Although there is some cross-reactivity with bacteria, this technique offers a more sensitive approach than routine staining methods currently available for the examination of stool specimens. As clinicians begin to suspect these infections and laboratorians become more familiar with the diagnostic methods, the number of positive patients, particularly those who are immunocompromised, may increase dramatically.

Although *E. bienersi* appears to be the most common human microsporidian, serologic evidence is based primarily on results for *Encephalitozoon cuniculi* as the parasite antigen. Whether these surveys reveal actual infections with this organism or whether there is cross-reactivity with other microsporidians is unknown. However, the data strongly suggest that latent infections with microsporidia occur in a number of groups, ranging from patients with other infections such as tuberculosis, typhoid fever, leprosy, malaria, schistosomiasis, toxoplasmosis, Chagas' disease, and toxocariasis to normal individuals and a group of homosexual men (44). Serologic evidence of human infection with the microsporidia has been reviewed elsewhere (44). Microsporidian infections in immunocompetent patients may result in a self-cure following mild symptoms over a short time frame, a situation similar to that seen with both cryptosporidiosis and isosporiasis. As awareness of this infection increases and more sensitive diagnostic techniques are developed, we may find that these infections are not uncommon in immunocompetent hosts.

The vast majority of human cases of microsporidiosis have been reported during the past 20 years, in patients

with HIV/AIDS, while only relatively rare cases have been described in immunocompetent individuals. However, microsporidial infections are being increasingly found in patients following solid-organ transplantation, where the main symptom has been diarrhea. The first case of pulmonary microsporidial infection in an allogeneic bone marrow transplant recipient in the United States and only the second case in the world has recently been reported (79).

Leishmania spp.

Visceral leishmaniasis (VL) continues to increase in frequency in patients who are HIV positive. The majority of cases of leishmaniasis in AIDS patients have been seen in France, Spain, Italy, and Portugal. Like other opportunistic infections, subclinical VL can be found at any stage of HIV-1 infection, but symptomatic cases appear mainly when severe immunosuppression is present. HIV-*Leishmania* coinfection is being seen more and more frequently in the Mediterranean basin (Table 19.14; Figure 19.11).

Over 850 coinfection cases have been recorded where 7 to 17% of HIV-positive individuals with fever have amastigotes. This finding strongly suggests that individuals infected with *Leishmania* spp. without symptoms will express symptoms of leishmaniasis if they become immunosuppressed. Based on the patient's general health status and prior exposure to the infection, leishmaniasis may be seen as an early opportunistic infection or may be seen as a complication late in the course of AIDS. Clinical signs of VL usually occur in the later stages of AIDS. The majority of AIDS patients present with the classic picture of VL; however, asymptomatic cutaneous, mucocutaneous, diffuse cutaneous, and post-kala azar dermal leishmaniasis (usually caused by *L. infantum*) can be seen. Cutaneous lesions in VL are being detected increasingly frequently in patients with HIV infection, and their significance is still somewhat unclear. Lesions often do not present a uniform or specific appearance and have been seen as erythematous papules and hypopigmented macules on the dorsa of the hands, feet, and elbows; small subcutaneous nodules on the thighs; and erythematoviolaceous, scaly plaques on the face. Also, the digestive and respiratory tracts are often parasitized, as well as the pleura and peritoneum. Lesions can also be coinfecting with other organisms, such as *Mycobacterium avium-intracellulare*.

CD4 T-lymphocyte counts are usually less than 50/mm³ and are almost always less than 200/mm³. Many physicians think that VL does not cause severe symptoms in these patients but is just one of several opportunistic infections that may coinfect AIDS patients. However, VL can manifest atypical aspects in HIV-positive patients depending on the degree of immunosuppression, and it

Table 19.14 *Leishmania* infections in immunocompromised patients

Underlying condition	Disease manifestation ^a	Comments ^a	Reference
AIDS	VL (southern Spain)	HIV-1 carriers (291) underwent bone marrow aspiration (regardless of symptoms); 32 (11%) showed VL and 13 of these (41%) had subclinical cases; female sex negatively associated with VL; i.v. drug use high, but not independent association; high proportion of cases subclinical; symptomatic cases evident when deep immunosuppression is present	85
AIDS	VL (Mediterranean area)	<i>Leishmania</i> -HIV coinfection common in Mediterranean area; most common species is <i>L. infantum</i> ; most frequent if CD4 count is <200/mm ³ and in parenteral drug addicts; chronic development with relapses is frequent; most effective diagnostic method is bone marrow culture (NNN); low sensitivity for serologies; PCR useful in asymptomatic cases, for therapeutic control, and in relapses; treatment similar to that in immunocompetent patients; generally necessary to use secondary prophylaxis; mortality rate is high (~25%)	72
AIDS	VL and possible dissemination	WHO estimates that 2–9 in 100 HIV patients in Africa and Asia will develop <i>Leishmania</i> -HIV coinfection; VL most common; unusual locations suggest multiorgan spreading in absence of host immune response; high incidence of recurrence; follow-up required; clear picture of prophylaxis not yet developed	62
AIDS	VL	Since 1990, 1,616 cases of coinfection reported, mainly from southern Europe (Spain, southern France, Italy); coinfecting patients mainly young adults, i.v. drug users; 272 isolates showed 18 different zymodemes, 10 of which were found only during HIV coinfection; new foci emerging (Brazil and East Africa)	24
AIDS	VL (and mucocutaneous disease in areas where <i>L. donovani</i> is not endemic)	15 AIDS patients in Germany, all of whom were severely immunocompromised; 1 was diagnosed at autopsy; 1 mucocutaneous case was diagnosed by nasal biopsy; others were diagnosed by bone marrow (13/13), liver (3/3), and gastrointestinal mucosa (4/4) biopsies; serology positive in only 6/13; VL must be ruled out in every patient with fever and/or pancytopenia and appropriate travel history	4
AIDS	Case mimicking VL	HIV-positive patient presented with picture of VL coinfection; bone marrow biopsy performed on admission; amastigote forms seen in bone marrow, and organisms grew in culture as promastigotes; molecular analysis revealed that the organisms were not <i>Leishmania</i> , but were <i>Leptomonas pulexsimulantis</i> , a trypanosomatid found in dog fleas; thus, opportunistic infection with an insect trypanosomatid was suspected and confirmed	80
Immunosuppressive drugs for organ transplantation or cancer	VL	Immunosuppressive therapy results in reactivation of asymptomatic VL or facilitates new infections	24
AIDS	CL (Brazil)	IRIS has been found in AIDS patients since the introduction of HAART; syndrome is characterized by clinical manifestations of opportunistic infections when signs of immune reconstitution are observed during therapy; leishmaniasis, suggestive of HAART-induced IRIS, in 2 patients with AIDS was seen; after beginning HAART, 1 patient presented with disseminated CL lesions,	87

(continued)

Table 19.14 (continued)

Underlying condition	Disease manifestation ^a	Comments ^a	Reference
AIDS (continued)	CL (Brazil)	whereas the other patient's preexisting lesions worsened and became more extensive; however, their CD4 ⁺ T-cell counts were increasing and viral loads were decreasing significantly; the lesions healed with anti- <i>Leishmania</i> therapy	
AIDS	CL (French Guiana)	In French Guiana, CL in moderately immunosuppressed HIV-infected subjects (CD4 ⁺ T-cell count, >200/mm ³) is characterized by a higher rate of recurrence or reinfection and is more difficult to treat than that in HIV-negative subjects	22
AIDS	CL (Italy)	Patient was HIV infected, an i.v. drug user, with an unusual disseminated CL after an initial visceral disease and after a 13-month maintenance treatment with liposomal amphotericin; severe concurrent immunosuppression probably played a role in leading to this atypical cutaneous form, characterized by diffuse, nonulcerated, nonscabby maculopapular lesions	14

^a CL, cutaneous leishmaniasis; HAART, highly active antiretroviral therapy; IRIS, immune reconstitution inflammatory syndrome; i.v., intravenous; NNN, Novy-MacNeal-Nicolle medium; WHO, World Health Organization.

should be listed among AIDS-defining conditions. The most common symptoms are fever, splenomegaly, hepatomegaly, and pancytopenia.

Data from Spain provide some interesting outcome figures regarding *Leishmania* infections in persons with or without HIV infections. In spite of a good initial response to treatment for VL, 60.6% of the patients had relapsed by the end of 1 year. Mortality from the first episode was 18.5%, and 24% died in the first month after diagnosis of any VL episode. The mean survival of the 29 patients who died was 10.27 months. Survival in patients with and without AIDS at the time of the first episode of VL was compared at 30 months and found to be 30.5 and 53.7%, respectively. A diagnosis of AIDS

Figure 19.11 *Leishmania donovani* in bone marrow (note the individual amastigotes, each one containing the bar and nucleus); specimen stained using Giemsa stain.

at the time of the first episode of VL and thrombocytopenia were the only risk factors found to be related to survival. Certainly in AIDS patients, VL is a recurrent disease that is highly prevalent and whose clinical course is modified by HIV. VL is a very prevalent disease among HIV-1-infected patients in southern Spain, with a high proportion of cases being subclinical. Symptomatic cases appear mainly when severe immunosuppression is present. There is also an association between VL and the male sex and intravenous drug use. In HIV-infected patients, VL occurs in late stages of HIV disease and often has a relapsing course. Secondary prophylaxis reduces the risk of relapse.

In HIV-1-infected patients with active VL, the sensitivity of a peripheral blood smear is about 50%, because of the high parasitemia in these patients. However, in HIV-1-infected patients with subclinical VL, the sensitivity of a routine blood smear is <10%. Unfortunately, in these patients serology and *Leishmania* skin tests have low sensitivities and are little help. Cultures have proven to be effective in diagnosis of VL in patients who are coinfecting with HIV-1.

A clinical diagnosis of Old World VL is often made based on clinical findings and local epidemiologic factors. However, confirmation of the diagnosis requires demonstration of the amastigotes in tissues or clinical specimens (blood, buffy coat preparations) or the promastigotes in culture. Detection of parasite genetic material or antigen detection is also sufficient for confirmation. Leishmaniasis should be suspected in individuals who have resided in or traveled to areas where the disease is endemic. The

diagnosis would be supported by findings of remittent fevers, hypergammaglobulinemia with anemia, circulating immune complexes, rheumatoid factors, weight loss, leukemia, and splenomegaly. The differential diagnosis of late-stage VL is limited to hematologic and lymphatic malignancies. The diagnosis of early disease is more difficult, and the differential would include malaria, brucellosis, enteric fevers, bacterial endocarditis, generalized histoplasmosis, chronic myelocytic leukemia, Hodgkin's disease and other lymphomas, sarcoidosis, hepatic cirrhosis, and tuberculosis. Also, patients with multiple myeloma and Waldenström's macroglobulinemia have monoclonal hypergammaglobulinemia. Mixed cryoglobulinemia secondary to VL has also been reported.

Although the usual route of transmission is through the bite of infected sand flies, parasites can be transmitted in other ways including blood transfusion, sexual contact, congenital transmission, occupational exposure, and shared needles. Apparently, *L. infantum* can circulate intermittently and at low density in the blood of healthy seropositive individuals, who appear to be asymptomatic carriers; this certainly has implications for the safety of the blood supply in certain areas of the world, including southern France, where coinfection with HIV is a problem.

Strongyloides stercoralis

In the life cycle of the intestinal nematode *Strongyloides stercoralis*, the larvae migrate through the heart and lungs, pass up the trachea, are swallowed, and finally grow to maturity in the gastrointestinal tract (see chapter 10) (Tables 19.3, 19.4, and 19.15; Figure 19.12). One significant feature of the *Strongyloides* life cycle is an internal autoinfection capability. Noninfective rhabditiform larvae, which normally pass out in the stool, may transform to infective filariform larvae while still within the gastrointestinal tract or perhaps on the perianal surface. These larvae can then penetrate the bowel wall or skin and reinitiate the life cycle. This cycle can maintain itself at a very low level over a period of many years in an individual without causing symptoms. The only unusual finding in the patient may be an unexplained eosinophilia. Patients who contracted the original infection many years earlier can become severely ill when they become immunosuppressed (Table 19.4). In the compromised patient, the number of larvae and adult worms may increase rapidly, leading to the hyperinfection syndrome and disseminated strongyloidiasis.

Patients in whom systemic *S. stercoralis* infections have been found include those with various leukemias and lymphomas, chronic infections such as leprosy and tuberculosis, and miscellaneous conditions such as kidney disease, organ transplantation, asthma, systemic lupus

erythematosus, and various fungal infections. Other conditions include malnutrition, alcoholism, chronic renal failure, and achlorhydria. When migrating *Strongyloides* larvae begin to increase in numbers in the compromised host, the patient may present with abdominal complaints and there may be repeated episodes of unexplained bacteremia or meningitis with enteric bacteria. This occurs when the larvae penetrate the bowel and reinitiate the cycle. In doing so, they carry members of the bowel flora with them. The other consistent finding in these patients is an unexplained eosinophilia, which may range from 10 to 50%. Like *G. lamblia*, *S. stercoralis* resides in the duodenum, and recovery of the larvae in the stool is difficult in patients with low worm burdens. For this reason, additional techniques like the Entero-Test string capsule and the duodenal aspirate may be used (see chapter 29). Other techniques for concentrating and recovering *Strongyloides* larvae include the Harada-Mori and petri dish culture techniques, as well as the Baermann apparatus.

In individuals with preserved immune function, direct development of *S. stercoralis* is favored, whereas in individuals with lesser immune function, indirect development is relatively more common. These results may explain the notable absence of disseminated strongyloidiasis in patients with advanced HIV disease. Because disseminated infection requires the direct development of infective larvae in the gut, the observed tendency toward indirect development in individuals immunosuppressed by advancing HIV disease is not consistent with the promotion of disseminated infection.

The typical rhabditiform larvae of *S. stercoralis* are characterized by a short buccal capsule or mouth opening and the presence of a genital primordial packet of cells. In contrast, the rhabditiform larvae of hookworm have a much longer buccal capsule and essentially no genital primordial cells present.

Whenever one is working with material from a patient suspected of having strongyloidiasis, one should use extreme care because of possible filariform larvae in the specimen. Gloves must be worn to prevent skin penetration by these larval forms.

As we prolong life for more individuals, the medical community must become aware of some of the parasitic infections that may pose a threat to the life of the compromised patient. Awareness is the first step in preventing more serious disease.

Crusted (Norwegian) Scabies

Scabies is a highly contagious infestation of the itch mite, *Sarcoptes scabiei*. Symptoms are related to pruritic dermatitis, and apparently transmission can occur through

Table 19.15 *Strongyloides stercoralis* infections in immunocompromised patients

Underlying condition	Disease manifestation	Comments	Reference
AIDS and non-Hodgkin's lymphoma	Disseminated disease	After chemotherapy, patient complained of retrosternal pain, dysphagia, dry cough, and upper abdominal discomfort; eosinophilia was 41%; recurrence of lymphoma ruled out; treatment for disseminated atypical mycobacterial infection; biopsy exam of duodenal fluid revealed worms and larvae; albendazole therapy successful	75
Idiopathic pulmonary fibrosis therapy	Disseminated disease	64-year-old man with pulmonary fibrosis was admitted for shortness of breath and cough; immunosuppressed due to steroids; repeated sputum and stool positive for <i>S. stercoralis</i> ; died suddenly from severe cardio-respiratory failure while on mebendazole therapy	61
Nephrotic syndrome therapy	Disseminated disease	Patient with nephrotic syndrome developed disseminated strongyloidiasis after steroid therapy; renal biopsy, time course, resolution of nephrotic syndrome after thiabendazole suggested causal relationship between chronic strongyloidiasis and nephrotic syndrome; early diagnosis important to good clinical outcome	118
Nephrotic syndrome therapy	Glomerulonephritis	Glomerulonephritis documented	116
Nephrotic syndrome therapy	Disseminated disease	Problems after administration of steroids	74
Chronic renal failure	Intestinal disease	Vomiting, diarrhea predominant symptoms; albendazole effective	104
Immunosuppressive drugs for kidney transplantation	Disseminated disease	Development of strongyloidiasis in renal transplant recipients following cyclosporin A has not been described; <i>Strongyloides</i> hyperinfection occurred immediately after cyclosporin A was discontinued; possible transmission by kidney transplant	81
Adult HTLV-1 infection	Intestinal or disseminated disease	Onset usually follows long period of viral latency; strongyloidiasis is considered a cofactor of leukemogenesis; hypereosinophilia is also seen, could be associated with parasites or leukemic process; cofactors might be important in HTLV-1-associated leukemogenesis; hypereosinophilia affects prognosis	86
Adult HTLV-1 infection	Intestinal disease	Prevalence of both HTLV-1 and <i>Strongyloides</i> increased with age, especially over 50 yr; prevalence of <i>S. stercoralis</i> infection significantly higher in HTLV-1 carriers; IgE level low in HTLV-1 carriers and significantly lower in HTLV-1 carriers with <i>Strongyloides</i> infection	40
Adult HTLV-1 infection	Disseminated disease	Strongyloidiasis progresses to hyperinfection or disseminated disease in carriers of HTLV-1; larvae detected in stool; meningitis responded to therapy; larvae still present after thiabendazole; coinfection with <i>S. stercoralis</i> is a predisposing factor to meningitis; association may warrant preventive antiparasitic treatment in patients infected with HTLV-1	31
Adult HTLV-1 infection (Peru)	Disseminated disease including meningitis	<i>Strongyloides</i> hyperinfection among Peruvian patients highly associated with HTLV-1 infection	36
HTLV-1 infection and ATLL ^a	Intestinal or disseminated disease	ATLL represents ~50% of T-cell lymphomas in Martinique; <i>Strongyloides</i> infection during ATLL is linked with high response rate to chemotherapy and prolonged survival; p53 overexpression seen in ~50% of cases of aggressive ATLL from Martinique and is associated with resistance to chemotherapy and short-term survival	3
HTLV-1 infection	Intestinal disease	<i>S. stercoralis</i> hyperinfection syndrome and therapeutic failure in apparently healthy patients with nondisseminated strongyloidiasis may be markers of HTLV-1 infection; HTLV-1 coinfection may also impact clinical course of scabies and HIV disease	35

(continued)

Table 19.15 *Strongyloides stercoralis* infections in immunocompromised patients (continued)

Underlying condition	Disease manifestation	Comments	Reference
Advanced small noncleaved cell lymphoma	Disseminated disease	<i>S. stercoralis</i> infection in child mimics relapse (the child was on intensive multiagent chemotherapy for lymphoma, and the treatment was successful in this case); <i>S. stercoralis</i> infection in adults being treated for malignant lymphoma is frequently fatal	94
SLE ^a therapy (active disease)	Disseminated disease	Death due to massive pulmonary hemorrhage induced by filariform infection; diagnosed from bronchoalveolar lavage fluid 2 days before death; importance of checking patients for possible parasitic infections prior to starting therapy, even in areas without endemic infection	100
Cancer chemotherapy (Mexico)	Intestinal disease	In epidemiologic settings with high prevalence of intestinal parasitic infections, stool exams should be performed and antiparasitic therapy provided before initiating chemotherapy	38
Ribavirin plus interferon therapy for chronic HCV ^a infection	Disseminated disease	Ribavirin may have immunomodulatory and immunosuppressive action; severe strongyloidiasis reported after use of ribavirin and interferon therapy for HCV infection	82
Steroids	Intestinal disease	In patients on corticosteroids, vomiting and diarrhea are key symptoms; duodenal mucosa varied from being normal to having severe ulceration; symptoms may be attributed to underlying disease	104
Steroids for chronic idiopathic thrombocytopenia	Disseminated disease	Diagnosis difficult due to lack of diarrhea and eosinophilia; negative multiple stool specimens; upper endoscopy revealed larvae, as did sputum specimens; death in spite of thiabendazole therapy	106
Single-dose steroids prior to radiosurgery	Disseminated disease	Patient received single dose of dexamethasone before stereotactic radiosurgery; fatal disseminated case of strongyloidiasis	108
Steroids	Intestinal disease (mimicking ulcerative colitis), possibly leading to disseminated disease	<i>Strongyloides</i> infection mimics ulcerative colitis over long period; accurate diagnosis is essential	104
Immunosuppressive drugs	Intestinal disease	Patient with chronic <i>S. stercoralis</i> infection initially presented with generalized prurigo nodularis and lichen simplex chronicus (skin nodules, thickened skin)	49
Diabetes mellitus and malnutrition	Disseminated disease	Repeated vomiting and upper gastrointestinal bleeding; unexplained leukocytosis; pulmonary infiltrates, gastric aspirate leukocytosis, presence of adult worms, eggs, and filariform and rhabditiform larvae in stool specimens; patients died while undergoing treatment with mebendazole	43
Diabetes mellitus and eosinophilic pleural effusion	Disseminated disease	Fever, exudative type of eosinophilic pleural effusion; bronchial washings contained <i>S. stercoralis</i> larvae; patient history extremely important	27
Unknown	Intestinal disease	Patient admitted for progressive weight loss, abdominal bloating; gastroscopic exam revealed mucosal prepyloric elevations in gastric mucosa; gastric strongyloidiasis confirmed by presence of adult worms, as well as ova and rhabditiform larvae; histologically confirmed case of gastric disease	101
None (immunocompetent patient)	Eosinophilic pleural effusion	Helminth infections should be considered in cases of eosinophilic pleural effusion	37
None (immunocompetent patient)	Colitis	Diarrhea, weight loss, microcytic anemia; colonoscopy revealed pancolitis and intense eosinophilic infiltrates; biopsy revealed <i>S. stercoralis</i> larvae	5
None (immunocompetent patient)	Colitis	Poor sensitivity of stool exams, careful search needs to be made in all patients before diagnosis of idiopathic eosinophilic colitis; steroid therapy may have fatal outcome	20

^a ATLL, adult T-cell leukemia/lymphoma; HCV, hepatitis C virus; SLE, systemic lupus erythematosus.

Figure 19.12 *Strongyloides stercoralis*. (Upper) Rhabditiform larvae seen in bronchoalveolar lavage fluid specimen (larvae can also be seen in sputum in heavy infections or in the hyperinfection syndrome); (lower) rhabditiform larva from fecal concentration sediment (note the short mouth opening/buccal capsule and the packet of genital primordial cells at the bottom left).

person-to-person direct skin contact or via fomites (Table 19.3; Figure 19.13). Outbreaks of scabies in hospitals or institutions, particularly for the elderly or retarded, have been documented worldwide. These outbreaks are particularly severe when associated with Norwegian or crusted scabies; such patients may be infected with thousands of mites on the skin. This infection has been linked with cellular immune deficiencies, including AIDS. Other potential problems include a decreased awareness of itching and the use of topical corticosteroids to reduce itching. Because of the number of mites present, these patients are extremely contagious, from sloughing skin, direct contact, and environmental contamination. Another potential problem is the fact that the symptoms mimic those of many other dermatologic conditions. Burrows may not be evident, and hyperkeratotic, crusted, scaling, fissured plaques are present over the scalp, face, and back, with associated gross nail thickening. The number of documented reports, particularly in AIDS patients, suggests that crusted scabies may become more common in the future.

Crusted scabies should be considered in the differential diagnosis of a generalized cutaneous eruption in

a human T-cell leukemia virus type 1 (HTLV-1)-positive patient. Patients with crusted scabies from an HTLV-1-endemic population should be tested for a possible HTLV-1 infection. Infection with HTLV-1 is an important cofactor related to Norwegian scabies in Peru. Testing for HTLV-1 in all Norwegian scabies cases is highly recommended, especially when no other risk factors are apparent. These patients may be at increased risk of progressing to adult T-cell leukemia/lymphoma (8, 11). Definitive parasitic diagnosis can be difficult; difficulties in management have led to renewed interest in both scabies and pediculosis. The diagnosis of scabies should always be considered in patients with advanced malignancies and associated pruritus.

The diagnosis of Norwegian scabies can easily be missed. Serpiginous tracks were noted on the surface of Sabouraud's dextrose agar used for fungal culture of the skin scrapings from an elderly long-term-care facility resident. This unusual laboratory manifestation alerted clinical microbiologists to the possible diagnosis of scabies. Although many microbiology laboratories are aware of these unusual findings, personnel can forget to consider scabies in such situations.

Ivermectin is increasingly being used to treat scabies, especially crusted (Norwegian) scabies. However, treatment failures, recrudescence, and reinfection can occur, even after administration of multiple doses. Clinical and in vitro evidence of ivermectin resistance has been found in several patients with multiple recurrences of crusted scabies who had previously received 30 to more than 50 doses of ivermectin over a 4-year time frame. As predicted, ivermectin resistance in scabies mites can develop after intensive ivermectin use.

Figure 19.13 *Sarcoptes scabiei* "itch mite." (Left) Mite from skin scraping preparation (note the four pairs of legs); (right) hand of an individual with severe scabies (Norwegian scabies). (Right, Armed Forces Institute of Pathology photograph.)

Summary

Nosocomial Infections

Nosocomial infections are those that are hospital acquired or hospital associated. According to some publications, nosocomial infections are estimated to complicate the course of 5 to 10% of all hospitalized patients in acute-care facilities (4, 79). Nosocomial infections are a significant cause of morbidity, mortality, and increased hospital costs, largely as a result of the increased length of stay. Over the past few years, escalating medical costs and the introduction of outpatient surgery have resulted in shorter hospital stays and much higher volumes of outpatient surgical procedures. Unfortunately, these changes have tended to mask true surgical infection rates. Also, postoperative surgical-site infections are often not apparent until after the patient's discharge (22). Since 1976, hospital accreditation by the Joint Commission on Accreditation of Healthcare Organizations requires the use of a nurse epidemiologist or infection control nurse whose primary responsibility is to identify, track, and control infections associated with hospitalization (17).

Individuals in the institution who fall within the surveillance parameters of the nurse epidemiologist include both patients and employees. Although we usually consider patients to be more prone to infections, some microorganisms can also infect healthy adults (9).

Definition: A nosocomial infection is defined as one diagnosed during or after hospitalization that was neither present nor incubating at the time of admission (4, 79).

One of the problems with this definition is the difficulty involved in accurately differentiating community-acquired from hospital-acquired infections, particularly when employees are involved. Depending on the individual's immune status, incubation periods may also vary.

Although any organism can infect a susceptible host, the organisms most often considered to cause possible nosocomial infections, particularly in the immunologically compromised, include the following:

Fungi: *Aspergillus* spp., *Candida* spp., *Mucor* spp., *Cryptococcus neoformans*, *Nocardia asteroides*

Algae: *Prototheca* spp.

Bacteria: *Escherichia coli*, *Klebsiella* spp., *Proteus* spp., *Pseudomonas* spp., *Staphylococcus* spp., *Legionella* spp.

Viruses: Cytomegalovirus, varicella-zoster virus, human immunodeficiency virus, rubella virus, rotavirus, enterovirus

Parasites: *Giardia lamblia*, *Entamoeba histolytica*, free-living amebae, *Toxoplasma gondii*, *Cryptosporidium* spp., the microsporidia, *Strongyloides stercoralis*, *Trypanosoma* spp., *Plasmodium* spp., *Babesia* spp., *Hymenolepis nana*, *Taenia solium*

Ectoparasites: *Pediculus* spp., *Sarcoptes scabiei*, dipterous fly larvae (myiasis)

Although most nosocomial infections are bacterial, fungal, or viral in origin, a few can be caused by parasites. The patient may actually have acquired the infection (*T. gondii*, *S. stercoralis*) many years before hospitalization. These latent infections can often be reactivated when the patient becomes debilitated for some reason, particularly when the immune system is involved.

Other areas within an institution must be considered, including interaction between food service personnel and patients and employees. Public health requirements for checking food handlers have varied over the years, but as a result of cost containment measures, the general trend is to refrain from special laboratory work or routine screening procedures for employees. Parasite transmission possibilities are presented in Table 20.1. Not every organism is listed; however, those that represent actual possibilities for transmission are emphasized.

Sometimes patients are placed in isolation settings (enteric precautions), which may not be appropriate or necessary for the organism or infection involved. A good example is a patient with amebic dysentery. If the patient has diarrhea or dysentery, the organism stage being passed in the stool is the trophozoite. The trophozoite stage is noninfectious for others. The cyst form, which is passed in more normal, formed stools, is the infective stage for humans. The trophozoites do not form cysts after the stool is passed outside of the body. Therefore, this patient with amebic dysentery does not pose an infection threat to others.

An example in which the need for enteric precautions would be recommended is a patient with diarrhea caused by *Cryptosporidium*. The oocysts are infective, and often large numbers of organisms are passed in the watery, diarrheic stool. There are several reports of suspected transmission of *Cryptosporidium* from patients to health care workers (5, 21, 46, 48, 50).

Nosocomial infection with blood and tissue parasites can occur by accidental needlestick, contact with blood (open wound, mucous membranes, eye), transfusion, or organ transplantation (51). Nosocomial transmission of babesiosis has also been documented (76).

Nosocomial Gastrointestinal Infections

Nosocomial gastroenteritis can be defined as an acute infectious gastrointestinal illness acquired by a hospitalized patient, specifically unexplained diarrhea for 2 days, or the onset of infectious diarrhea somewhere in the hospital or medical center setting. In general, requests for ova and parasite identification are not indicated for patients with nosocomial diarrhea (80). Patients at highest risk for gastrointestinal infections include neonates, the elderly, patients with achlorhydria, and those who are immunosuppressed (79). Risk factors can be categorized as those within the host and those outside the host. Risk factors within the host include impaired immunity, reduced gastric acidity, and alterations in the normal intestinal flora or intestinal motility. Risk factors outside the patient include those that alter host resistance or increase the possibility of colonization. The transmission of organisms is generally via the fecal-oral route; some of the organisms can survive for long periods outside the body. Parasites that have been implicated in nosocomial infections include *Cryptosporidium* spp., *E. histolytica*, and *G. lamblia*. Although little is known about nosocomial transmission of microsporidia, potentially infectious spores can be found in the hospital environment, particularly in stools from severely immunocompromised patients (e.g., those with AIDS). The presence of infective spores in human clinical specimens suggests that precautions when handling body fluids and personal hygiene measures such as hand washing may be important in preventing primary infections in the health care setting. However, comprehensive guidelines for disease prevention will require more definitive information regarding sources of infection and modes of transmission (8).

Cryptosporidium spp.

Although cryptosporidiosis is a well-recognized occupational hazard for persons exposed to naturally infected calves and other animals, cases of cryptosporidiosis have also been reported among persons exposed to experimentally infected animals (37). Five veterinary students who had direct (four) or indirect (one) contact with experimentally infected calves became ill 6 to 7 days later and had diarrhea for 1 to 13 days; one student was hospitalized. A researcher developed gastrointestinal symptoms 5 days after a rabbit, which was infected with oocysts through a gastric tube, coughed

Table 20.1 Possible parasite transmission in a health care setting (nonlaboratory)

Organism ^a	Mode of transmission	Comments
Protozoa (intestinal)		
<i>Entamoeba histolytica</i> ^b (C)	Accidental ingestion of infective cysts, trophozoites, oocysts, or spores in food or water contaminated with fecal material (fecal-oral transmission)	These organisms could be important in a food handler situation. Treatment of carriers and excellent hygiene measures would prevent or eliminate any problems. <i>Cryptosporidium</i> would be an example where “enteric precautions” would be appropriate (severe diarrhea with stool containing large numbers of infective oocysts).
<i>Entamoeba dispar</i> (C)		
<i>Entamoeba coli</i> (C)		
<i>Entamoeba hartmanni</i> (C)		
<i>Endolimax nana</i> (C)		
<i>Iodamoeba bütschlii</i> (C)		
<i>Blastocystis hominis</i> ^b (C)		
Free-living amebae		
<i>Giardia lamblia</i> ^b (C)		
<i>Dientamoeba fragilis</i> ^b (T)		
<i>Cryptosporidium</i> spp. ^b (O)		
<i>Cyclospora cayetanensis</i> ^b (O)		
<i>Isoospora belli</i> ^b (O)		
Microsporidia ^b (S)		
Helminths (intestinal)		
<i>Enterobius vermicularis</i> (E)	Inhalation or ingestion of infective eggs	Very common in children, asymptomatic
<i>Strongyloides stercoralis</i> (IL)	Skin penetration of infective larvae from stool material	Possible, particularly in a compromised patient
<i>Hymenolepis nana</i> (E)	Ingestion of infective eggs (fecal-oral)	Could lead to infection with the adult worm in humans
<i>Taenia solium</i> (E)	Ingestion of infective eggs (fecal-oral)	Could cause cysticercosis
Blood and tissue protozoa		
<i>Leishmania</i> spp. (cutaneous)	Direct contact or inoculation of infectious material from patient's lesion could lead to infection.	A rare possibility, but it has been documented (accidental person-to-person transmission)
<i>Trypanosoma</i> spp.	Blood transfusion	Significant problem in areas of endemicity
Ectoparasites		
<i>Pediculus</i> spp. <i>Sarcoptes scabiei</i>	Transmission of lice and mites is usually seen in groups with very close contact (institutionalized settings).	Confinement in close quarters often lends itself to a transmission problem with lice and mites.
Dipterous fly larvae	Myiasis could occur anywhere.	Protection of wounds from flies would solve the potential problem.

^b Potentially pathogenic intestinal protozoa.

droplets of inoculum onto his face as he was removing the tube. The researcher's stool, which was first obtained for testing the day after he became ill, was positive for oocysts. A veterinary scientist developed flu-like symptoms 7 days after smelling for gastric odor to check the position of a gastric tube in an infected calf; she was unaware of other exposures to *Cryptosporidium*. She developed gastrointestinal symptoms 10 days after this exposure, and oocysts were found in a stool specimen about a week later.

Cryptosporidium can also be transmitted within the hospital setting. At least nine cases of occupational transmission of *Cryptosporidium* from human patients to health care workers have been reported (37). The infected staff members were symptomatic and had oocysts identified from stool examinations. These individuals included

a nurse caring for an infected bone marrow transplant recipient, a nurse doing night duty on a ward where an infected 13-month-old boy was a patient, a nurse caring for infected patients before and after renal transplantation, and five nurses caring for an infected patient with AIDS. Patient-to-patient transmission of *Cryptosporidium* in hospitals has also been reported.

Cryptosporidiosis has been implicated as one of the more important opportunistic agents seen in patients with AIDS (18, 27, 28). Unfortunately, at the time of this writing, no totally effective therapy for cryptosporidiosis has been identified, despite testing of over 100 drugs. Consequently, finding this parasite in an immunocompromised host, especially one with AIDS, usually carries a poor prognosis. Also, reports of respiratory tract and

biliary tree infections confirm that the developmental stages of this organism are not always confined to the gastrointestinal tract. The more than 4,000 published papers related to cryptosporidiosis that are currently in the literature include information on nosocomial transmission, day care center outbreaks, and a number of waterborne outbreaks.

The presence of a thin-walled autoinfective oocyst may explain why a small inoculum can lead to an overwhelming infection in a susceptible host and why immunosuppressed patients may have persistent, life-threatening infections in the absence of documentation of repeated exposure to oocysts. Oocysts undergo sporogony while they are in the host cells and are immediately infective when passed in the stool. In contrast, the oocysts of *Cyclospora cayetanensis* and *Isospora belli* do not sporulate until they are passed from the host and are exposed to oxygen and temperatures below 37°C.

Oocysts recovered in clinical specimens are difficult to see without special stains, such as the modified acid-fast, Kinyoun's, or Giemsa preparations, or the direct fluorescent-antibody, enzyme-linked immunosorbent assay, or immunochromatographic immunoassay methods (26, 30–32). The four sporozoites can be seen within the oocyst wall in some of the organisms, although they are not always visible in freshly passed specimens.

Clinical symptoms include nausea, low-grade fever, abdominal cramps, anorexia, and 5 to 10 watery, frothy bowel movements a day, which may be followed by constipation. Some patients present with diarrhea as described above, and others have relatively few symptoms, particularly later in the course of the infection. In patients with the typical watery diarrhea, the stool specimen contains very little fecal material and is mainly water and mucus flecks. Often, the organisms are entrapped in the mucus, and diagnostic procedures are performed accordingly. Generally a patient with a normal immune system will have a self-limited infection; however, patients who are compromised may have a chronic infection with a wide range of symptoms (asymptomatic to severe).

Occasionally, these patients require fluid replacement, and the diarrhea may persist for more than 2 weeks. This is particularly true in infants, in whom excessive fluid loss may last for more than 3 weeks. Failure to thrive has also been attributed to chronic cryptosporidiosis in infants. Since diarrheal illness is a major cause of morbidity and mortality in young children living in developing countries, it is likely that cryptosporidiosis plays a major role in the overall health status of these children. It has also been suggested that *Cryptosporidium* may be implicated in the respiratory disease that often accompanies diarrheal illness in malnourished children.

The duration and severity of diarrheal illness depends on the immune status of the patient. The most severely immunocompromised patients cannot self-cure, the illness becomes progressively worse with time, and the sequelae may be a major factor leading to death. The length and severity of illness may also depend on the ability to reverse the immunosuppression. In these patients, *Cryptosporidium* infections are not always confined to the gastrointestinal tract; additional symptoms have been associated with extraintestinal infections (respiratory problems, cholecystitis, hepatitis, and pancreatitis). Data for a small series of patients indicated that those with CD4 counts of 180 cells/mm³ or greater cleared the *Cryptosporidium* infection over a period of 7 days to 1 month. These data are important in predicting the natural progression of the infection and in designing therapeutic trials.

Previously, most human cases have been diagnosed after examination of small- or large-bowel biopsy material, often by both light and electron microscopy. Although examination of flotation material by phase-contrast microscopy has proven to be an excellent procedure for the recovery and identification of *Cryptosporidium* oocysts, many laboratories have neither access to such equipment nor experience with phase-contrast microscopy. Also, since the organism is considered infectious for laboratory personnel, fixed specimens can be processed by using several acid-fast stains, many of which are very satisfactory in demonstrating the organisms in stool material (29).

Respiratory cryptosporidiosis has been found in AIDS patients. Sputum specimens from immunodeficient patients with undiagnosed respiratory illness should be submitted in 10% formalin and examined for *Cryptosporidium* oocysts by the same techniques as those used for stool samples. Infection of the gallbladder and biliary tree should result in oocysts being passed in the stool.

The use of fecal immunoassays has proven to be very helpful in providing more sensitive methods of detecting organisms in stool specimens. Fluorescent-antibody procedures with good specificity and sensitivity have been developed, as have enzyme immunoassay procedures and immunochromatographic cartridges, also with excellent specificity and sensitivity. Some of these reagents, particularly the combination direct fluorescent-antibody product used to identify both *Giardia* cysts and *Cryptosporidium* oocysts, are being widely used in water testing and outbreak situations (24, 25, 29–32).

The infections tend to be self-limiting in patients who have an intact immune system (24). One method of treating patients who are receiving immunosuppressive drugs is to discontinue such a regimen. Other approaches with specific therapeutic drugs such as spiramycin have been tried, but the results to date are somewhat controversial.

Data indicate that paromomycin may be a potential therapeutic agent for extended clinical trials. Ongoing studies of immunologic intervention hold promise, but this technique currently is not widely available.

Information on the epidemiology of cryptosporidiosis is well defined, and its potential pathogenicity in humans has been widely recognized. The organism is transmitted by oocysts that are fully sporulated and infective at the time they are passed in stool. Oocysts are resistant to some of the disinfectants routinely used in medical care facilities. They are susceptible to ammonia, 10% formalin in saline, freeze-drying, and exposure to temperatures below freezing or above 65°C for 30 min. Commercial bleach in a 50% solution is effective.

Direct person-to-person transmission is likely and may occur through direct or indirect contact with stool material. Direct transmission may occur during sexual practices involving oral-anal contact. Indirect transmission may occur through exposure to positive specimens in a laboratory setting or through exposure to contaminated surfaces, food, or water.

The epidemiologic considerations for cryptosporidiosis emphasize transmission by environmentally resistant oocysts, numerous potential reservoir hosts for zoonotic transmission, documentation of person-to-person transmission in day care centers, nosocomial transmission within the health care setting, occurrence of asymptomatic infections (infective, carrier state), widespread environmental distribution resulting in the probability of waterborne transmission, and the link between cryptosporidiosis and severe, life-threatening disease in individuals with impaired immune function.

Giardia lamblia

A “debilitating bout” of giardiasis thought to have represented patient-to-staff transmission has been reported. The case involved an orthopedic surgeon caring for two preschool-age patients with giardiasis. In changing the leg cast, it was noticeably stained with moist and dry feces. The physician became ill in early May and later had giardiasis confirmed with routine stool examinations. Although he typically washed his hands before and after changing casts, he rarely wore a mask; infection may have been caused by inhalation of infectious cysts in the plaster dust.

G. lamblia is worldwide in distribution and is apparently more prevalent in children than in adults and more common in warm climates than in cool ones. It is the most commonly diagnosed flagellate in the intestinal tract, and it may be the most commonly diagnosed intestinal protozoan in some areas of the world. Despite disagreement concerning the species names *intestinalis* and *duodenalis*,

both continue to be used to describe this organism. Since the majority of health care workers within the United States are used to “*Giardia lamblia*” and continue to report the presence of the organism by using this name, it will continue to be used throughout this text to refer to organisms found in humans as well as other mammals.

The most common location of the organisms is in the crypts within the duodenum. Again, for reasons that are not totally known, cyst formation takes place as the organisms move down through the colon. The trophozoite is usually described as being teardrop shaped from the front, with the posterior end being pointed. When examined from the side, the trophozoite resembles the curved portion of a spoon. The concave portion is the area of the sucking disk. The cysts may be either round or oval, and they contain four nuclei, axonemes, and median bodies. Often, some cysts appear to be shrunk or distorted, and one may see two halos, one around the cyst wall itself and one inside the cyst wall around the shrunken organism. The halo effect around the outside of the cyst is particularly visible on the permanent stained smear.

Although the organisms in the crypts of the duodenal mucosa may reach very high densities, they may not cause any pathologic changes. The organisms feed on the mucus secretions and do not penetrate the mucosa. Although organisms have been seen in biopsy material inside the intestinal mucosa, others have been seen only attached to the epithelium. In symptomatic cases, there may be irritation of the mucosal lining, increased mucus secretion, and dehydration. Other symptoms include epigastric pain, flatulence, and diarrhea with increased fat and mucus in the stool but no blood. Weight loss often accompanies these symptoms. Although there is speculation that the organisms coating the mucosal lining may act to prevent fat absorption, this does not completely explain why the uptake of other substances normally absorbed at other intestinal levels is prevented. Occasionally, the gallbladder is also involved, causing gallbladder colic and jaundice. *G. lamblia* has also been detected in bronchoalveolar lavage fluid.

Although patients with symptomatic giardiasis usually have no underlying abnormality of serum immunoglobulins, patients with immunodeficiency syndromes, particularly common variable hypogammaglobulinemia, have a high incidence of giardiasis. Giardiasis was the most common cause of diarrhea in these patients and was associated with mild to severe villous atrophy. Successful treatment of giardiasis led to symptomatic cure and improvement in mucosal abnormalities, with the exception of nodular lymphoid hyperplasia.

With the advent of AIDS, there was speculation that *G. lamblia* might be an important pathogen in this group of individuals. However, to date, clinical findings do not seem to confirm this possibility (58, 75).

Routine stool examinations are normally recommended for the recovery and identification of intestinal protozoa. However, because *G. lamblia* organisms are attached so securely to the mucosa by means of the sucking disk, a series of even five or six stools may be examined without recovery of the organisms. The organisms also tend to be passed in the stool on a cyclical basis. The Entero-Test capsule can be helpful in recovering the organisms, as can the duodenal aspirate. Although cysts can often be identified on the wet stool preparation, many infections may be missed without the examination of a permanent stained smear (14). Material from the string test (Entero-Test) or mucus from a duodenal aspirate should be examined as a wet preparation for motility; however, motility may be represented by nothing more than a slight flutter of the flagella because the organism will be caught up in the mucus. After diagnosis, the rest of the positive material can be preserved as a permanent stain.

Immunoassays to detect *Giardia* antigen in feces have also been developed (2, 30–32). The enzyme-linked immunosorbent assay is at least as sensitive as microscopic wet examinations (61). Fluorescence methods involving monoclonal antibodies have also proven to be extremely sensitive and specific in detecting *G. lamblia* in fecal specimens (77).

Unfortunately, serodiagnostic procedures for giardiasis do not yet fulfill the criteria necessary for wide clinical use, particularly since they may indicate either past or present infection. In contrast, the detection of antigen in stool or visual identification of organisms with monoclonal antibody reagents indicates current infection. With the increase in the prevalence of *Giardia* infections and awareness of particular situations such as nursery school settings, perhaps additional detection assays will emerge as rapid and reliable immunodiagnostic procedures (1). Because giardiasis may not produce any symptoms at all, demonstration of the organism in symptomatic patients may not rule out other possibilities such as peptic ulcer, celiac disease of some other etiology, strongyloidiasis, and possibly carcinoma.

If giardiasis is diagnosed, the patient should be treated. Giardiasis can be eliminated from most patients by metronidazole (40). Tinidazole has also been used and has proven to be more effective than metronidazole as a single dose (40).

In the absence of a parasitologic diagnosis, the treatment of suspected giardiasis is a common question with no clear-cut answer. The approach depends on the alternatives and the degree of suspicion of giardiasis, both of which will vary among patients and physicians. However, it is not recommended that treatment be given without

a good parasitologic workup, particularly since relief of symptoms does not allow a retrospective diagnosis of giardiasis; the most commonly used drug, metronidazole, also targets organisms other than *G. lamblia*.

The third question involves treatment of a patient who is asymptomatic. Generally, it is recommended that all cases of proven giardiasis be treated because the infection may cause subclinical malabsorption, symptoms are often periodic and may appear later, and a carrier is a potential source of infection for others (40).

G. lamblia is transmitted by ingestion of viable cysts. Although contaminated food or drink may be the source, intimate contact with an infected individual may also provide the infection mechanism. This organism tends to be found more frequently in children or in groups that live in close quarters (16, 17, 19, 34, 43, 53, 56, 59, 72). Often, there are outbreaks due to poor sanitation facilities or breakdowns in sanitation as evidenced by infections in travelers and campers (42, 45, 53, 60). There is also an increase in the prevalence of giardiasis in the male homosexual population, probably as a result of anal or oral sexual practices (67, 71).

During the past few years, this infection has received much publicity. With increased travel, there has been a definite increase in symptomatic giardiasis within the United States (1). Various surveys show infection rates of 2 to 15% in various parts of the world.

Entamoeba histolytica

Although *E. histolytica* is not generally associated with nosocomial infections, reports indicate that transmission is certainly possible (11). Istre et al. reported on 36 cases of amebiasis during a 30-month period in patients who had received colonic irrigation therapy (38). Epidemiologic studies implicated the colonic irrigation machine; testing indicated that after routine cleaning, the machine was contaminated with *E. histolytica*. Patients at greatest risk were those who received colonic irrigation immediately after a patient with amebiasis and bloody diarrhea. Evidence supports the possibility of transmission if endoscopic equipment is not thoroughly cleaned and disinfected after use in a patient infected with *E. histolytica*.

Since *E. histolytica* can easily be confused with macrophages (trophozoites) and polymorphonuclear leukocytes (cysts) found in stool, it is important to recognize the possibility of false-positive results (in which other protozoa or human cells are confused with this organism). Recognizing the possibility of error is particularly important in a potential “outbreak” situation. These types of diagnostic errors, whereby large numbers

of patients were diagnosed with amebiasis, have been documented; in one report, on review, 34 of 36 patients who were diagnosed with amebiasis were found to be negative for *E. histolytica* (10).

Over the years, some workers came to believe that what was called *E. histolytica* was really two separate species of *Entamoeba*, one being pathogenic and causing invasive disease (*E. histolytica*) and the other being nonpathogenic and causing mild or asymptomatic infections (*E. dispar*). Although this was controversial, current knowledge indicates that pathogenic *E. histolytica* is the etiologic agent of amebic colitis and extraintestinal abscesses while nonpathogenic *E. dispar* causes no intestinal symptoms and is not invasive in humans (65). Unfortunately, with the exception of some newly introduced immunoassay procedures, most laboratories will continue to use routine methods for the identification of organisms in the *Entamoeba* genus; unless the trophozoites contain ingested erythrocytes, identification to the species level is not possible. The organisms should be reported as *E. histolytica/E. dispar* with appropriate reporting to public health agencies. In these cases, the approach to the patient will be based on clinical findings and physician decisions regarding therapy. Diagnostic reagents for confirmation of true pathogenic *E. histolytica* and for the *E. histolytica/E. dispar* group are commercially available.

Microsporidia

Although the epidemiology of the microsporidia has not yet been thoroughly defined, it is highly likely that the spores shed in human clinical specimens (stool, urine, sputum, etc.) are immediately infectious. These infectious spores can be found in hospital and laboratory environments and are associated primarily with clinical specimens from immunocompromised patients, such as those with AIDS or transplant recipients. Precautions should be used when handling body fluids from these patients. Microsporidial infections in all body sites have been documented; this fact needs to be considered when determining the housing and care of the patient. Precautions would be very similar to those used for patients diagnosed with disseminated cryptosporidiosis, in which infectious organisms could be found in multiple clinical specimens.

Specific infection control guidelines for inpatients with microsporidiosis have yet to be developed, but available information suggests that all body fluids that may contain infectious spores should be handled accordingly. Standard precautions used within the institution and laboratory environments should be sufficient to prevent accidental infection with microsporidial spores.

Isospora (Cystoisospora) belli

I. belli is thought to be the only species of *Isospora* that infects humans, and no other reservoir hosts are recognized for this infection. Transmission is through ingestion of water or food contaminated with mature, sporulated oocysts. Sexual transmission by direct oral contact with the anus or perineum has also been postulated, although this mode of transmission is probably much less common. The oocysts are very resistant to environmental conditions and may remain viable for months if kept cool and moist; oocysts usually mature within 48 h following stool evacuation and are then infectious. Although it is not considered a "common" parasite, occasional positive specimens are seen in many laboratories. Since transmission is through the ingestion of infective oocysts, there is certainly the possibility that this parasite could be transmitted within the laboratory or in the patient care setting.

Examination of a fecal specimen for the oocysts is recommended. However, wet-preparation examination of fresh material either as the direct smear or as concentrated material is recommended rather than the permanent stained smear. The oocysts are very pale and transparent and can easily be overlooked. They can also be very difficult to see if the concentration sediment is from polyvinyl alcohol-preserved stool. The light level should be reduced, and additional contrast should be obtained with the microscope for optimal examination conditions. It is also quite possible to have a positive biopsy specimen but not recover the oocysts in the stool because of the small numbers of organisms present. These organisms are acid fast and can also be demonstrated by using auramine-rhodamine stains.

Hymenolepis nana

Although *H. nana* can be transmitted by the eggs and does not require an intermediate host to complete its life cycle, the nosocomial significance of this infection is unknown. However, it is important to remember that the eggs passed in the stool are mature and infective for patients and health care workers.

Taenia solium

Nosocomial transmission of the infective eggs of *T. solium*, causing cysticercosis, has not been documented. However, an individual infected with adult *T. solium* and passing eggs could certainly serve as a potential reservoir for serious transmission potential. It is important to remember that the eggs passed in the stool are mature and infective for patients and health care workers. This is true even when proglottids are submitted to the laboratory

in preservative; the eggs within the uterine branches will remain viable and infectious.

Nosocomial Blood and Tissue Infections

Plasmodium spp.

Worldwide, transfusion malaria is the most common and significant nosocomial parasitic infection, although it is rare within the United States (7, 51). These infections have occurred after transfusion not only of whole blood but also of white blood cells, fresh plasma, and platelets (49). Nosocomial malaria infections have also originated through renal transplants (51). It is interesting that malaria infections have been transmitted from recipient to donor in a person-to-person transfusion situation in which backflow of blood has been a problem (7). Most cases of posttransfusion malaria may go unsuspected, with an incubation period of up to 4 weeks. Donors implicated in transfusion-transmitted malaria tend to be "semi-immune" with a very low parasite load; therefore, detection using antigens or PCR may not guarantee identification of the infected donor. Often the infectious dose from these donors may be 1 to 10 parasites in a unit of blood (73).

Malaria induced via contaminated needles shared among drug addicts has been well known for many years. Also, nosocomial patient-to-staff malaria transmission via needlestick injury has been documented, with most cases involving nurses or physicians who were exposed during venipuncture or preparation of blood smears (51).

A nosocomial outbreak of chloroquine-resistant *Plasmodium falciparum*, in which a multidose heparin vial was implicated as the source of infection, was reported from Venezuela. The vial was apparently contaminated by the blood of a parenteral drug abuser who had asymptomatic malaria and who had received 2 days of intravenous fluid therapy (62).

In the cases involving suspected malaria transmission by renal transplantation, the donors were strongly seropositive or had a positive blood smear. However, all three patients were from areas where malaria was endemic, and the stress of surgery and immune system suppression could have also stimulated recrudescence of the infection (51). Transmission of malaria has also been documented through liver transplantation; unfortunately, the recipient died. Based on therapeutic toxicity for *Plasmodium* spp., the use of organs from donors infected with malaria carries risks that may limit transplantation from such donors (3).

Babesia spp.

Nosocomial transmission of babesiosis through routine blood transfusion, frozen-thawed blood, and platelets has also been documented (51). Although needlestick or

open-wound transmission of *Babesia* spp. has not been reported, it is certainly possible, particularly in the health care setting. The risk of infection through contact with ticks is probably low.

Trypanosoma brucei gambiense and *T. brucei rhodesiense*

Although patients with African trypanosomiasis are usually symptomatic, those in the early stages of the infection may be asymptomatic and appear to be healthy potential blood donors. These types of patients are probably responsible for the rare transfusion cases reported. However, contaminated needlestick injuries and open-wound contact with contaminated blood are also potential means of transmission in the health care setting.

Trypanosoma cruzi

Although *T. cruzi* is normally transmitted by the feces of an infected triatomid bug, transmission of the organism via blood transfusion is the second most common means of acquiring the infection. In areas where infection is highly endemic, as many as 62% of blood donors are seropositive for *T. cruzi* antibody (54). One study from Los Angeles County of 1,027 consecutive blood donations found 2.4% to be seropositive for *T. cruzi* antibody by an indirect fluorescent-antibody assay (P. Kerndt, H. Waskin, F. Steurer, L. V. Kirchhoff, J. Nelson, I. Shulman, G. Geliert, and S. Watermen, *Program Abstr. 28th Intersci. Conf. Antimicrob. Agents Chemother.*, abstr. 669, 1988). Considering this information, concerns regarding the safety of the blood supply are reasonable and understandable (44). Transmission via kidney transplants has also been well documented (23).

The entry of large numbers of immigrants from Central America has contributed to growing concerns, particularly with respect to transfusion-related transmission of *T. cruzi* in areas of the world where the infection is not endemic or, if endemic, has not been a problem. Since there are triatomid bugs capable of becoming infected with *T. cruzi* within the southwestern United States, the presence of more people with latent infections also presents some concerns.

Transmission of *T. cruzi* through donor kidneys has been documented in Latin America, where serologic screening of organ donors and recipients is not standard practice. Three cases of recipient infection have been reported in the United States; the cases involved kidney and pancreas, kidney alone, and liver transplant from the same donor from Central America. One of the recipients died of myocarditis (3).

Leishmania donovani

Although transfusion-induced visceral leishmaniasis has been described only rarely, like other infections mentioned above, it may be underreported in areas of endemicity where confirmation of the route of infection may be difficult. Certainly, exposure to contaminated blood or animals would represent a potential source of infection.

Toxoplasma gondii

Nosocomial infection with *T. gondii*, primarily in cardiac or renal transplant patients, has been documented (51). However, the efficacy of trimethoprim-sulfamethoxazole for the prevention of toxoplasmosis transmission dramatically reduces the risk to organ recipients from infected donors. Most serious infections in immunocompromised patients result from reactivation of a latent infection. Transmission from a patient to a health care worker via needlestick injury or exposure to blood (open wound) has not been documented.

Nosocomial Infections with Ectoparasites

Ectoparasites of nosocomial significance include lice (head, body, pubic), scabies and other mites, and myiasis. Head and pubic lice and scabies are fairly common in many parts of the world, including the United States. These infestations are generally not serious problems within the health care setting, with the exception of scabies, which has the potential to cause large outbreaks.

Pediculus spp. and *Phthirus pubis*

Infection with lice belonging to the genus *Pediculus* are common and are usually found on one part of the body such as head, body, or pubic hair. The head louse, *Pediculus humanus capitis*, is found most often in school-age children, and nosocomial transmission is generally not a problem, with possible exceptions characterized by close patient-to-patient contact in pediatric wards or institutional settings.

Pediculus humanus corporis (body louse) is well known for its association with poverty and poor personal hygiene. Since transmission is through contact with or exchange of contaminated clothing or bedding, this does not seem to represent a large potential problem. However, the potential for transmission varies throughout the world.

Phthirus pubis (pubic louse) infestation occurs most commonly in sexually active adults, with a direct skin-to-skin transfer. It is unlikely that transmission within the health care setting would cause any problems.

Sarcoptes scabiei

Scabies is a highly contagious infestation of the itch mite, *Sarcoptes scabiei*. Symptoms are related to pruritic dermatitis, and apparently, transmission can occur through person-to-person direct skin contact or via fomites. Outbreaks of scabies in hospitals or institutions, particularly for the elderly or retarded, have been documented worldwide (52). These outbreaks are particularly severe when associated with Norwegian or crusted scabies; such patients may be infected with thousands of mites on the skin. This infection has been linked to cellular immune deficiencies, including AIDS (74). Other potential problems include a decreased awareness of itching and the use of topical corticosteroids (52). Because of the number of mites present, these patients are extremely contagious via sloughing skin, direct contact, and environmental contamination. Another potential problem is the fact that the symptoms mimic those of many other dermatologic problems. Burrows may not be evident, and hyperkeratotic, crusted, scaling, fissured plaques are present over the scalp, face, and back, with associated gross nail thickening (69). The number of documented reports of scabies, particularly in AIDS patients, suggests that nosocomial scabies may become more common in the future.

Although outbreaks of other mites, including the pigeon mite *Dermanyssus gallinae*, have been described, it is not clear whether these infestations are a problem. It has also been suggested that these cases may be misdiagnosed as scabies (52).

Myiasis

Myiasis refers to infestation of the body by larvae of a number of fly species. These cases occur when flies are attracted to patient blood or body tissue fluids and deposit eggs into an open wound or patient body opening such as the nose or ear. Often, these patients are not totally conscious, or they may be debilitated or immobile. It is generally thought that these cases are underreported for a number of reasons, some of which are related to institutional risk management decisions. A study from Brisbane, Australia, reported 14 infestations, 6 of which were nosocomial, during a period of 17 months (55).

Ophthalmomyiasis, caused by infestation of the eye by dipterous fly larvae, can result in symptoms ranging from minor irritation to blindness, disfigurement, or death. Infestations with the sheep botfly, *Oestrus ovis*, are normally associated with normal hosts, while infestations with others, including *Cochliomyia hominivorax*, seem to occur more commonly in compromised hosts (12).

Nosocomial Infections in the Pediatric Patient

Specific infections that can be acquired in the pediatric patient include those caused by *Cryptosporidium* spp., *G. lamblia*, *P. humanus capitis*, and *S. scabiei*. Although less is known about microsporidia, the infective spores could be transmitted in a hospital setting, particularly if spores are present in stool specimens, urine, or other body fluids from immunocompromised patients.

Cryptosporidium spp.

Cryptosporidium infection is discussed above in the section on nosocomial gastrointestinal infections. It is also important to remember that this organism has been isolated from other body sites, particularly in severely immunocompromised patients. Cryptosporidiosis has also been linked to infections in nursery schools and should certainly be considered in this setting.

Giardia lamblia

Infection has been well documented in the pediatric population. Giardiasis is most frequently associated with nursery school outbreaks and is thoroughly discussed above in the section on nosocomial gastrointestinal infections.

Pediculus humanus capitis

Although pediculosis is a well-known problem among young children, lice are not as likely to be spread to other patients except in chronic ambulatory-care situations such as psychiatric wards or pediatric ward playrooms. Under these circumstances, patients should be screened prior to admission.

Sarcoptes scabiei

Prevalence of the itch mite infection, or scabies, varies among young children; sexually active adolescents and adults are also susceptible to infection. The small size of the mite contributes to the problem and to possible transmission to medical staff and other patients. Although intimate contact is considered the most likely mode of transmission, fomite transmission is an alternative method, particularly with Norwegian scabies. It is generally recommended that if two or more patients and one or more staff members exhibit the symptoms of scabies (pruritus with or without crusting or scaling) or have positive skin scrapings, total treatment should be given. It is also important that posttreatment surveillance and testing be continued for at least 3 months.

Nosocomial Infections in the Compromised Patient

Compromised patients have poor host defenses, usually for one of three reasons: underlying disease (immunosuppression or immunodeficiencies in either the cellular or humoral mechanisms of the immune system or both), therapy for disease (chemotherapy, radiation), or hospital-based procedures and contact with infected persons (catheterization, broad-spectrum antibiotics, nebulizers, inhalation procedures, person-to-person contact, food sources, contaminated equipment, etc.).

In addition to *Cryptosporidium*, *E. histolytica*, *G. lamblia*, and microsporidia as mentioned above, *S. stercoralis*, free-living amebae, and *Leishmania* spp. cause severe disease in the compromised patient and can be transmitted in the hospital setting.

S. stercoralis has become extremely important, particularly with respect to compromised patients (41) and military personnel and travelers who may have been in an area of endemic infection many years before (64). More than 30 to 40 years after acquisition of the original infection, persistent undiagnosed disease can be found in these individuals. If, for any reason, they become immunocompromised, the result can be disseminated disease leading to the hyperinfection syndrome and death (33, 78).

The life cycle of *S. stercoralis* is one of the more complex parasite cycles. Human infection is acquired by skin penetration of the filariform larvae (infective larvae) from the soil. After penetration of the skin, the larvae are carried via the cutaneous blood vessels to the lungs, where they break out of the pulmonary capillaries into the alveoli. They then migrate via the respiratory tree to the trachea and pharynx, are swallowed, and enter the mucosa in the duodenum and upper jejunum. Development usually takes about 2 weeks, after which the females begin egg production. The eggs are oval and thin shelled and measure 50 to 58 μm by 30 to 34 μm (generally a bit smaller than hookworm eggs). The eggs usually hatch, and the rhabditiform larvae (noninfective larvae) pass out of the intestinal tract in the feces. These larvae are passed out onto the soil in the feces and develop into free-living male and female worms, eventually producing infective filariform larvae (egg, noninfective larvae, and infective larvae). In temperate climates, the free-living male and female worms do not develop; however, the rhabditiform larvae that pass out in the stool develop into the filariform (infective) larvae, which are then ready to infect the next host through skin penetration.

In situations in which autoinfection occurs, some of the rhabditiform larvae that are within the intestine develop into the filariform larvae while passing through the bowel. These larvae can then reinfect the host by (i) invading the intestinal mucosa, traveling via the portal

system to the lungs, and returning to the intestine or (ii) being passed out in the feces and penetrating the host on reaching the perianal or perineal skin.

It is generally accepted that the life cycle presented above is correct; the skin-penetrating larvae travel from the skin to the intestine via an obligatory route that includes the blood, lungs, trachea, and upper gastrointestinal tract (the standard pulmonary route). It is also assumed that following autoinfection, the larvae follow the same route to return to the duodenum, where they mature. However, review information and data from Schad et al. (70) indicate that the pulmonary route is just one of several possible pathways to the duodenum, regardless of whether the larvae penetrated the skin or the intestine. In spite of some caveats, these studies definitely challenge the current accepted understanding of the life cycle. The pulmonary migration route for all skin-penetrating nematodes may not be as universally applicable as was once thought (66).

As judged from the life cycle, the three areas of primary involvement are the skin (cutaneous), the lungs (pulmonary), and the intestinal mucosa (intestinal).

Initial skin penetration usually causes very little reaction, although there may be some pruritus and erythema if the number of penetrating larvae is large. With repeated infections, the patient may mount an allergic response that will prevent the parasite from completing the life cycle. The larvae may be limited to skin migration or larva migrans.

Larval migration through the lungs may stimulate symptoms, depending on how many larvae are present and the intensity of the host immune response. Some patients are asymptomatic, whereas others present with pneumonia. With a heavy infective dose or in the hyperinfection syndrome, individuals often develop cough, shortness of breath, wheezing, fever, and transient pulmonary infiltrates (Loeffler's syndrome). Cases in which the larvae could even be found in the sputum have been reported (13, 36).

In heavy infections, the intestinal mucosa may be severely damaged with sloughing of tissue, although this type of damage is unusual. The symptoms may mimic peptic ulcer with abdominal pain, which may be localized in the right upper quadrant. Radiographic findings may mimic Crohn's disease of the proximal small intestine (6). In an immunocompetent patient, there is a leukocytosis with a peripheral eosinophilia of 50 to 75%, while in patients with chronic infections, the eosinophilia may be much lower. Some of these chronic infections have lasted over 30 years as a result of the autoinfective capability of the larvae (67). One case of chronic strongyloidiasis persisted for approximately 65 years (49).

Autoinfection is probably the mechanism responsible for long-term infections that persist for years after the person has left the area of endemic infection. The parasite

and host reach a status quo so that neither suffers any serious damage. If for any reason this equilibrium is disturbed and the individual becomes immunosuppressed, the infection proliferates, with large numbers of larvae being produced and found in every tissue of the body. Several conditions, including the increased use of immunosuppressive therapy, predispose an individual to the hyperinfection syndrome (16, 63, 74). In addition to suffering tissue damage from the migrating larvae, the patient may die from sepsis, primarily as a result of the intestinal flora. Other causes of death include peritonitis, brain damage, and respiratory failure. Few cases of reactive arthritis have been reported, and the number of cases may be underestimated. A case of reactive arthritis combined with uveitis associated with a long-standing, heavy *Strongyloides* infection was detected in a 32-year-old patient positive for human T-cell leukemia virus type 1. Treatment with thiabendazole and ivermectin resulted in rapid improvement (63).

Confirmation of the infection depends on recovery and identification of the adult worms, larvae, or eggs from the stool, duodenal material, or sputum. Fecal specimens may not be positive, even after performance of the routine ova and parasite examination, including the concentration procedure. The number of larvae found in the stool also varies from day to day.

Some reports indicate that sampling of duodenal contents may recover larvae if stools are negative (33), while others indicate that duodenal sampling may not be effective (15). Special techniques that have been recommended for the recovery of duodenal contents include the Entero-Test capsule (see chapter 29). There are also special concentration techniques (Baermann) and methods for larva culture (Harada-Mori, petri dish), which are discussed in detail in chapter 28. These techniques provide a means of larval recovery from large amounts of stool material, and often the filariform larvae are recovered. To differentiate the *Strongyloides* filariform larvae from those of hookworm, one should examine the tail under the microscope. *Strongyloides* filariform larvae have a slit in the tail, while hookworm filariform larvae have a pointed tail.

Agar plate cultures are also possible; stool is placed onto agar plates, and the plates are sealed to prevent accidental infections and then held for 2 days at room temperature. As the larvae crawl over the agar, they carry bacteria with them, thus creating visible tracks over the agar. The plates are examined under the microscope for confirmation of larvae, the surface of the agar is then washed with 10% formalin, and larval identification is confirmed via wet examination of the sediment from the formalin washings. Details can be found in chapter 28.

Debililitated or compromised patients should always be suspected of having strongyloidiasis, particularly if there are unexplained bouts of diarrhea and abdominal pain, repeated episodes of sepsis and/or meningitis with intestinal bacteria, or unexplained eosinophilia. However, a recent comparative study of the occurrence of *Strongyloides* infection in 554 AIDS and 142 non-AIDS patients demonstrated similar prevalences of infection in the two groups, thus indicating no significant statistical differences (20).

At present, the recommended drug of choice is thiabendazole; specific dosages are provided in chapter 25. In some cases repeated therapy is necessary, and the cure rates range from 55 to 100% (35). Patients with the hyperinfection syndrome should be hospitalized during therapy for proper monitoring.

Contact with contaminated infective soil, feces, or surface water should be avoided. Individuals found to have the infection should be treated. *All patients who are going to receive immunosuppressive drugs should be screened for strongyloidiasis before therapy.*

Laboratory Infections

Safety precautions tend to be emphasized in clinical laboratories, particularly microbiology laboratories (standard precautions; see chapter 35). However, general safety regulations pertaining to laboratory coats, hand washing, and use of disinfectants, as well as to not eating, drinking, and smoking, fail to address the specifics of possible parasite transmission.

In laboratories where extensive diagnostic testing is performed, exposure to possible infectious parasites may result from the handling of specimens, drawing of blood, various types of concentration procedures, organism cultures, and animal inoculation studies. Relevant parasites and their possible routes of infection are presented in Tables 20.2 and 20.3. Information on resistance to anti-septics and disinfectants can be found in Table 20.4 (57).

Intestinal Protozoa

Intestinal protozoa such as *G. lamblia*, *E. histolytica*, microsporidia, and the coccidia, particularly *Cryptosporidium* spp., cause human disease, and the protozoan cysts, oocysts, and spores can be accidentally transmitted from one person to another. The cysts, oocysts, and spores are resistant to many disinfectants. Of those currently available, ozone is the most effective protozoan cysticide, followed by chlorine dioxide, iodine, and free chlorine, all of which appear to be more effective than the chloramines (39, 47). Cyst forms, including oocysts, are the most resistant to chemical disinfection. Although the exact mechanisms of resistance are not thoroughly understood, these resistant

stages probably take up fewer disinfectant molecules from solution than do stages like the trophozoite.

Relatively few cases of laboratory-acquired infections with intestinal protozoa have been reported; however, a few cases have been detected. A worker who “checked in several hundred stool specimens, stamping numbers and dates on report cards, many of which had been contaminated from leaky containers,” became infected with *G. lamblia* (37). The infection was confirmed by finding the flagellates in the stool. A laboratory technician who examined numerous stool specimens from a patient infected with *I. belli* became ill about a week later, and *I. belli* was confirmed to be present in his stool. While infecting a rabbit using a capsule containing about 400 *Isospora* oocysts, two researchers were sprayed in their faces with droplets when the rabbit regurgitated the material and vigorously shook its head; both individuals became ill about 2 weeks later (37).

Free-Living Amebae

A number of studies have investigated the responses of trophozoites and cysts of *Acanthamoeba* spp. to disinfectants in various solutions used to disinfect contact lenses; infections with these organisms have led to serious eye infections, particularly keratitis. These infections can be very difficult to treat if not recognized early, and eradication of the free-living amebae is also very difficult. These protozoa are capable of forming biofilms on contact lenses and could adversely affect the effectiveness of chemical agents used for disinfection.

Plasmodium spp.

In a series of 34 cases of laboratory-acquired malaria, 15 were due to *P. falciparum*, 10 were due to *P. cynomolgi*, and 9 were due to *P. vivax*. The majority of cases were reported from the United States and Europe, with 19 being vector borne, 10 being parenteral, and 5 occurring through a break in the skin. All patients were symptomatic (37, 68).

It has also been documented that research workers can be accidentally infected from a mosquito, possibly one that escaped from a mosquito colony. Strict containment measures should be in place. Another possible route of infection involves mosquito dissection, during which infective sporozoites could be accidentally injected.

Trypanosoma brucei gambiense and *T. brucei rhodesiense*

Cases of laboratory-acquired African trypanosomiasis can result from contact with blood or tissue from infected persons or animals. Six laboratory-acquired cases have

Table 20.2 Possible parasite transmission in a health care setting (laboratory)

Organisms ^a	Mode of transmission	Comments
Protozoa (intestinal)		
<i>Entamoeba histolytica</i> ^{b,c} (C)	Accidental ingestion of infective cysts, trophozoites, oocysts, or spores in food or water contaminated with fecal material; also, direct transfer of stool material via fomites (fecal-oral transmission)	Transmission becomes more likely when fresh stool specimens are being processed and examined; submission of fecal specimens in preservatives or fixatives would decrease risks.
<i>Entamoeba dispar</i> (C)		
<i>Entamoeba coli</i> (C)	Contamination of hands, eyes handling free-living ameba cultures; inhalation of infectious aerosols; splashes to eyes or mucous membranes	Wearing gloves, using capped centrifuge tubes, and working in biological safety cabinet would decrease the risk of acquiring <i>Cryptosporidium</i> infections. <i>Not recommended</i> : use of potassium dichromate as collection fluid and use of sugar flotation on fresh stool.
<i>Entamoeba hartmanni</i> (C)		
<i>Endolimax nana</i> (C)	Free-living amebae	Immunocompromised employees must be educated regarding risk factors; they may elect not to work with certain organisms or perform certain procedures.
<i>Iodamoeba bütschlii</i> (C)		
<i>Blastocystis hominis</i> ^b (C)		
<i>Giardia lamblia</i> ^{b,c} (C)		
<i>Dientamoeba fragilis</i> ^b (T)		
<i>Cryptosporidium</i> spp. ^{b,c} (O)		
<i>Cyclospora cayatanensis</i> ^b (O)		
<i>Isospora belli</i> ^{b,c} (O)		
Microsporidia ^b (S)		
Helminths (intestinal)		
<i>Enterobius vermicularis</i> (E) ^c	Inhalation or ingestion of infective eggs	Very common in children, asymptomatic
<i>Strongyloides stercoralis</i> (IL) ^c	Skin penetration of infective larvae from stool material	Exposure would be very possible or even likely when working with stool cultures or concentrates for larva recovery.
<i>Hymenolepis nana</i> (E)	Ingestion of infective eggs (fecal-oral)	Ingestion of infective eggs can lead to the adult worm in humans.
<i>Taenia solium</i> (E)	Inhalation or ingestion of infective eggs (could lead to cysticercosis)	Exposure very likely when working with gravid proglottids (ink injection for identification of worm to species level).
Blood and tissue protozoa		
<i>Leishmania</i> spp. ^c	Direct contact or inoculation of infectious material from patient lesion; accidental inoculation of material from culture or animal inoculation studies	Culture forms and organisms from hamster would be infectious.
<i>Trypanosoma</i> spp. ^c	Same as for <i>Leishmania</i> spp.; also handling arthropod vectors	Cultures and special concentration techniques would represent possible means of exposure.
<i>Plasmodium</i> spp. ^{c,d}	Accidental inoculation could transmit any of the four species; mosquito transmission	Blood and culture material should always be handled carefully (avoid open cuts, etc.).
<i>Toxoplasma gondii</i> ^c	Inhalation or ingestion of oocysts in cat feces (veterinary situation); accidental inoculation of tachyzoites from culture, tube of blood, or animal isolation (mouse peritoneal cavity); needles, spills, mucous membrane contamination; tissue culture work	Although many people already have antibodies to <i>T. gondii</i> , indicating past exposure, there have been documented laboratory accidents in which the individual became ill because of the large infecting dose.
Ectoparasites		
<i>Pediculus</i> spp.	Specimens submitted on hair could be easily transmitted in the laboratory.	Careful handling and fixation of the arthropods would prevent any potential problems with transmission.
<i>Sarcoptes scabiei</i>	Transmission via skin scraping, etc., would be possible but not that likely.	Careful handling and preparation of specimens with KOH would tend to prevent any problems.
Dipterous fly larvae (myiasis)	Transmission could occur anywhere.	Protection from flies would solve the potential problem.

^a C, cyst; T, trophozoite; O, oocyst; IL, infective larvae; E, egg; S, spore.^b Potentially pathogenic intestinal protozoa.^c Laboratory infections documented: *Leishmania* spp., *Trypanosoma cruzi*, *Trypanosoma brucei gambiense*, *Trypanosoma brucei rhodesiense*.^d Mosquito transmission.

Table 20.3 Potential exposures to laboratory-acquired parasitic infections^a

Parenteral or aerosolization
Recapping a needle
Removing a needle from the syringe
Leaving a needle on the counter, point up
Dropping a syringe
Breaking hematocrit tube while pressing the end into clay
Performing venipuncture on agitated patient
Sudden animal movement during an inoculation procedure
Creating aerosols during tapeworm proglottid injection
Creating aerosols while working with cultures (blood parasites, free-living amoebae)
Animal or vector bites
Being bitten by an infected animal (mouse, hamster)
Being bitten by infected mosquito (mosquito colony)
Skin exposure
Not wearing gloves during procedure
Not wearing laboratory coat (closed sleeves, closed front over clothes)
Accidentally touching face or eyes during handling of infectious materials
Exposing of eyes, nose, and mouth to potential aerosols
Ingestion
Mouth pipetting
Being sprayed with inoculum droplets from coughing or regurgitating animal
Other reasons for potential exposures
Working in disorganized laboratory bench setting
Working too fast
Not receiving proper training
Assuming that the agent is not infectious to humans
Assuming that the agent(s) is no longer viable
Using defective equipment

^aAdapted from a number of sources, including reference 37.

been caused by *T. brucei gambiense*, and two have been caused by *T. brucei rhodesiense*. In these cases the route of exposure was usually parenteral, and all patients were symptomatic.

Trypanosoma cruzi

Infection can occur from exposure to the feces of infected triatomine bugs, by handling cultures or blood specimens, and possibly by inhaling aerosolized organisms. The predominant stage of the parasite in culture is the epimastigote stage; however, the infectious trypomastigotes can also be found. *T. cruzi* can infect laboratory personnel through needlestick injuries, through preexisting microabrasions of the skin, or through intact mucous membranes.

Sixty-five cases of laboratory-acquired *T. cruzi* infection have been reported, although in many cases, the actual geographic site was unknown. While the route of exposure for many of the cases was unknown, parenteral infection was identified for 11 individuals. The clinical status of the infected individuals was generally unknown; however, 24 of 47 were symptomatic, with 9 severe cases and 1 death (37, 68).

Leishmania spp.

In laboratory settings, leishmaniasis could be acquired through contact with an infected sand fly; containment measures for infected flies should be strictly followed. Transmission can also occur through contact with parasite cultures or clinical specimens from infected persons or animals (e.g., needlestick injuries or microabrasions of the skin). Although fewer parasites are found in patient blood specimens than in cultures or infected tissues, blood should be handled with care.

Twelve cases of laboratory-acquired leishmaniasis caused by six different species have been reported. Although most of the infected persons developed cutaneous leishmaniasis, sometimes with associated local lymphadenopathy, one person developed visceral leishmaniasis and one developed mucosal leishmaniasis as a sequela of cutaneous leishmaniasis. All patients were symptomatic, with two having severe disease (37).

Toxoplasma gondii

Infection can occur through ingestion of sporulated oocysts from feline fecal specimens or through skin or mucosal contact with tachyzoites or bradyzoites in tissue or culture. All *Toxoplasma* isolates should be considered pathogenic for humans. Procedures for separating oocysts from feline feces and for infecting mice have been described; fecal concentrations should be performed before oocysts sporulate and become infectious. Laboratory equipment and glassware that have been in contact with oocysts should be sterilized, since the oocysts are not easily killed by chemical exposure. Immunocompromised persons and *T. gondii*-seronegative women who are pregnant or might become pregnant should be counseled about the risks associated with *T. gondii* infection (e.g., central nervous system infection and congenital infection) and given the option of not working with live *T. gondii* and of not working in a laboratory in which others do so.

Of the 47 cases of laboratory-acquired toxoplasmosis, the majority were in the United States and Europe. The most common route of exposure was parenteral; however, in 10 of the cases no specific accident or route

Table 20.4 Resistance to antiseptics and disinfectants, from most to least resistant

Type of organism	Example(s)
Prions	Creutzfeldt-Jacob disease, bovine spongiform encephalopathy
Coccidia	<i>Cryptosporidium</i> spp.
Spores	<i>Bacillus</i> , <i>Clostridium difficile</i>
Mycobacteria	<i>Mycobacterium tuberculosis</i> , <i>M. avium</i>
Cysts	<i>Giardia lamblia</i>
Small nonenveloped viruses	Poliiovirus
Trophozoites	<i>Acanthamoeba</i>
Gram-negative bacteria (nonsporulating)	<i>Pseudomonas</i>
Fungi	<i>Candida</i> , <i>Aspergillus</i>
Large nonenveloped viruses	Enteroviruses, adenovirus
Gram-positive bacteria	<i>Staphylococcus aureus</i> , <i>Enterococcus</i>
Lipid-enveloped viruses	Human immunodeficiency virus, hepatitis B virus

of exposure could be identified. Although 9 patients were asymptomatic, 38 were considered to be symptomatic if they had lymphadenopathy. Four individuals had encephalitis, two of whom had myocarditis, and one patient with both conditions died (37).

Specimen Handling

Another consideration involves the handling of specimens from patients with AIDS. Although the agent, human immunodeficiency virus, is considered to be a very fragile virus that does not survive in the environment, specimen-handling precautions are advised. Some laboratories suggest that stool specimens being processed for *Cryptosporidium* (often diagnosed in AIDS patients) be handled in a biological safety cabinet and be centrifuged in capped centrifuge tubes. These types of precautions will help diminish the chances of an accidental laboratory infection.

Summary

Although there are real possibilities for nosocomial and laboratory transmission of parasites, proof of such transmission is usually very difficult to document. Depending on the area of the country and the number of endemic parasites present in the community, documentation can be particularly difficult. In areas where many organisms are endemic, it is almost impossible to differentiate between a community-acquired infection and one acquired in the work setting.

Some of the infectious agents being handled in the laboratory present a potentially more serious problem. Although many laboratories do not handle all of these agents, their personnel may still be at risk when performing certain techniques or handling certain specimens. For these reasons, it is very important that everyone become aware of possible hazards when working in the field of diagnostic medical parasitology. The information presented in Tables 20.1 through 20.3 provides specific, practical information concerning safety precautions in the laboratory.

American trypanosomiasis

Malaria

Summary

For many years, there has been extensive research in immunoparasitology directed at the identification, isolation, purification, and characterization of parasite antigens. Antigens are required for immunodiagnosis, clarification of immunopathology, quantitation of various immune responses in the host, and evaluation of potential vaccines. Antibodies to defined antigens are used for typing of reagents, the study of antigenic variability, passive immunization, and in vitro inhibition studies. Without the use of defined antigens and antibodies, a thorough understanding of the immunologic aspects of the host-parasite relationship is unlikely. Table 21.1 contains information on the various categories of parasite antigens, while Table 21.2 lists various methods of antigen analysis.

It is important to understand the factors influencing the immune responses of the host, including (i) genetics; (ii) state of the host at exposure, including nutrition, age, health status, and underlying diseases; and (iii) the size, route, and frequency of the parasite loading dose. Also, there are several types of resistance, which include natural resistance (how refractory the host is to a particular parasite), acquired resistance (either specific or nonspecific), and immunoregulation (Table 21.3).

Innate Immune System. The immune system is made up of two interrelated parts, the innate and acquired systems. The innate response is the first to be activated during the response to invading organisms and is due primarily to phagocytic cells. This response is related primarily to immediate recognition and response to pathogen invasion. Phagocytes include polymorphonuclear leukocytes or neutrophils, monocytes, and macrophages. Secondary phagocytes can include dendritic cells, fibroblasts, and epithelial cells. Macrophages are found in all tissues and represent the first line of defense against pathogenic invasion of the host (Table 21.4). In order to thrive, parasites must be able to survive the innate response. Complement activation represents a first line of defense against extracellular parasites. Once the membrane attack complex is formed, parasite lysis can occur while complement components opsonize parasites for phagocytosis. One of the most important cytokines in cell-mediated innate resistance is interleukin-12 (IL-12). IL-12 activates natural killer (NK) cells, which in turn produce gamma interferon (IFN- γ), which is responsible for activation of effector mechanisms that control replication of intracellular parasites.

Table 21.1 Parasite antigens^a

I. Immunologic criteria
A. Importance of the induced immune response to the parasite or host (relevant or functional antigens versus incidental antigens)
1. Host-protective antigens ^b : related to induction and expression of host-protective immunity
2. Immunodiagnostic antigens: related to detection of antibodies, skin test sensitivity (both immediate or delayed), detection of circulating or urinary antigens
3. Immunopathologic antigens ^c : related to induction and expression of immunopathology
4. Parasite-protective antigens: related to induction and expression of parasite-protective immunity
B. Immunogenicity in different animals
1. Natural antigens: infection of natural hosts or immunization of natural hosts with or without adjuvants
2. Novel antigens (heteroantigens): immunization of unnatural hosts with or without adjuvants, or infection of nonpermissive hosts
C. Type of lymphocyte involved, e.g., T-cell-stimulating carrier determinant, B-cell-stimulating haptenic determinant, allergen, T _c -stimulating determinant
II. Parasitologic criteria
A. Origin and location
1. Soluble exoantigens: released from living parasites, parasitized cells, or cultured cell lines and called excretory/secretory (ES), excretory/secretory/tissue turnover (EST), or metabolic antigens
2. Soluble somatic antigens: extracted from parasites or parasitized cells; may be surface or internal
3. Dead parasites, fragments or secretory blebs
4. Whole living parasites
5. Body fluids of nematodes
6. Cystic fluids of larval cestodes
B. Parasite population and life cycle
1. Genus-, species-, strain-, and stage-specific antigens
2. Molting antigens
III. Biochemical criteria
A. Composition (protein, lipid, carbohydrate, glycoprotein, glycolipid, etc.)
B. Characteristics (size, chain structure, determinant number and type, etc.)
C. Molecule function (enzyme, metabolite, receptor, recognition structure, etc.)
D. Future sources (expression of cloned DNA, chemical synthesis, stimulation of anti-idiotypic antibodies)

^a Data from reference 4.

^b It is not the host antigens themselves but the immune responses that these antigens induce which are host protective.

^c Immunopathologic immune responses depend on the genotype of the host and may also have beneficial effects.

Acquired/Adaptive Immune System. Although innate immunity is critical in resistance to acute parasitic infections, the acquired, or adaptive, response is necessary for long-term protective immunity. Adaptive T- and B-cell responses following infection depend on accessory cells that present antigen, provide costimulation, and produce cytokines, all of which impact the onset, duration, strength, and type of the adaptive immune response. CD4⁺ helper T cells are divided into two subsets, Th1 (type 1 response) and Th2 (type 2 response), each of which produces different cytokines and has different functionalities (Table 21.5). At times, both type 1 and type 2 responses may be used to eliminate the same parasite. These two mechanisms may be functional at the same time, during different stages of the parasite life cycle, or in different locations within the body.

Immunopathologic Reactions in the Host. It is important to have a basic understanding of the types of

immunopathologic reactions in the host which are responsible for disease. These are often classified into four categories or pathways by which the host responds. They have been categorized as (i) type I reaction (anaphylactic), initiated by the antigen reacting with tissue cells (basophils and mast cells) passively sensitized by antibody produced elsewhere (release of pharmacologically active substances); (ii) type II reaction (cytotoxic or cell stimulating), initiated by the antibody reacting with an antigenic component of or antigen associated with a cell or tissue element (damage occurring in the presence of complement or certain mononuclear cells); (iii) type III reaction (antigen-antibody complexes), initiated when the antigen reacts with precipitating antibody (forming microprecipitates in and around small vessels, interfering with membrane function, and forming soluble circulating complexes); and (iv) type IV reaction (delayed, tuberculin type, cell mediated), initiated by reaction of active lymphocytes

Table 21.2 Methods of antigen analysis

Gel precipitation techniques	
1.	Double diffusion
2.	Ouchterlony
3.	Immunoelectrophoresis
4.	Autoradiography of precipitin lines
5.	Counterimmunoelectrophoresis
6.	Counterradioimmunoelectrophoresis
Immunoprecipitation and gel analysis	
1.	Anti-immunoglobulins
2.	Sodium dodecyl sulfate-polyacrylamide gel electrophoresis
3.	Isoelectric focusing
4.	Nonequilibrium pH gradient electrophoresis
5.	Fluorography
Gel overlay or transfer techniques	
1.	Direct application of antiserum to the surface of one- or two-dimensional gels
2.	Direct application of antiserum to a paper transfer of the gel
3.	Passive binding to nitrocellulose sheets
4.	Covalent bonding to diazobenzyloxymethyl paper
5.	Filter affinity transfer
Identification of surface antigens	
1.	Antigen labeling (intrinsic or extrinsic)
2.	Antigen solubilization
3.	Antigen fractionation
4.	Demonstration of cell surface location
Hybridoma-derived antibodies	
1.	Production of monoclonal antibodies
2.	Screening procedures for hybridoma culture supernatants
Recombinant DNA	
1.	Clarification of genomic rearrangements related to antigenic variation
2.	Identification of nucleic acid sequence data
3.	Production of potentially useful parasite polypeptides

Table 21.3 Immunoregulatory systems in the host

Antibody-mediated mechanisms

	Nonspecific suppressor cells

in response to allergen, release of lymphokines, and/or cytotoxicity (infiltration of cells). These are listed in Table 21.6. The overall immune response to the presence of any parasite is no different from the responses seen with any infectious agent, all of which begin with the organism infecting the host and being recognized by the cells of the immune system. Once the parasite is recognized as foreign by the immune system, a series of steps are initiated (Figure 21.1; Table 21.7).

Parasites have three basic characteristics that make it very difficult for the host to control them: parasite size, complicated parasite life cycles, and antigenic complexity. There are also a number of ways in which parasites avoid the host immune system responses; these include (i) location within body sites that are relatively protected from the immune response, (ii) various modifications of surface antigens, and (iii) different mechanisms that can modify the host immune response. A number of these evasion mechanisms are listed in Table 21.8.

All human parasites elicit immune responses, both humoral and cellular. Specific antibodies belonging to the immunoglobulin M (IgM), IgG, IgA, and IgE classes have been found, indicating the body's recognition of parasite antigens (Table 21.9). Cell-mediated immune responses have also been clearly documented. However, in both cases, there may be little or no correlation between responses and protection of the host.

Although the immune system functions in the same way for parasites as for other organisms, there are some dramatic differences based on the complexity of the response. As parasites progress through their normal life cycle stages, many different antigens are expressed at each different stage. This leads to the development of many different antibody-dependent and -independent responses. In some cases, the immune system of the host actually becomes confused, leading to situations where the host is harmed rather than helped.

Although the host response to protozoa is quite different from the host response to helminths, some general statements apply to both situations. When a parasite and the host interact, there are several possible outcomes: (i) the parasite fails to become established in the host; (ii) the parasite becomes established and kills the host; (iii) the parasite becomes established and the host eliminates the infection; (iv) the parasite becomes established and the host, in trying to eliminate the organism, becomes damaged itself; and (v) the parasite becomes established, and the host begins to overcome the infection but is not totally successful (12). Some representative parasites are presented in this chapter. Obviously, some human parasites have been studied more than others, and these differences are reflected in the amount of available information related to parasite immunology.

Table 21.4 Macrophage functions

Macrophage functions	Mechanisms
Protective	
Detection of pathogen invasion	Opsonic receptors for microbes Complement and antibody receptors Nonopsonic receptors Membrane-bound pattern recognition receptors (C-type lectins, leucine-rich proteins, scavenger receptors, and integrins)
Control of microbial spread	Phagocytosis, granuloma formation, intracellular killing
Recruitment of immune cells	Release of cytokines and other inflammatory mediators
Lymphocyte activation	Antigen presentation, costimulatory molecules, cytokines
Effector cells for cell-mediated immunity	Increased phagocytosis, increased intracellular killing, clearance of apoptotic cells
Participation in humoral immunity	Receptors for antibody and complement
Nonprotective	
Tissue damage	Extracellular release of toxic oxidants, hydrolytic enzymes Inflammatory mediators (TNF- α , IL-1) Fever, wasting, septic shock
Dissemination of pathogens	Transport throughout the host
Autoimmune disease	Presentation of microbial epitopes to lymphocytes, which cross-react with self molecules

Amebiasis

With the development of axenic culture and antigen purification techniques, *Entamoeba histolytica* infections and subsequent host immune responses have been more thoroughly investigated. However, although both humoral and cellular responses occur in amebiasis, the role of immunity is still not completely understood.

Pathogenic *E. histolytica* is now well recognized as a separate species from the morphologically identical but nonpathogenic *E. dispar*. *E. histolytica* uses different virulence factors, including a surface membrane GalNAc lectin that allows adherence and induces cytolysis plus a cysteine protease. Cysteine proteases contribute to tissue invasion, causing degradation of the extracellular

Table 21.5 Differences between Th1 and Th2 CD4⁺ T helper cells

Th1—Type 1 Responses	Th2—type 2 responses
Produce IFN- γ and IL-2; induction of cytolytic activity by CD8 ⁺ T cells; production of complement-fixing antibodies	Produce cytokines (IL-4, IL-5, IL-10, and IL-13); associated with high levels of neutralizing and cell-bound antibodies, mast cell activation, eosinophilia, suppression of type 1 responses
IL-12 associated with resistance to protozoa and susceptibility to various helminths	IL-4 plays important role in development of Th2-type responses: associated with resistance to helminths (expulsion of intestinal nematodes) and susceptibility to protozoa
Produce lymphotoxin; promote macrophage activation and generation of cell-mediated immunity	Support maturation of B cells to immunoglobulin-secreting cells (activation of humoral immune mechanisms)
Resistance to intracellular pathogens requires Th1 proinflammatory response	Resistance to extracellular pathogens requires Th2 response
Prevention: IFN- γ , IL-12, IL-10 also cooperate to keep Th2 response in check	Prevention of Th1 response from overproduction: IL-10, transforming growth factor- β , IL-4
Problems: effector molecules detrimental if produced too long: nitric oxide, reactive oxygen intermediates (IL-1, IFN- γ , TNF)	Problems: strong antibody responses = antigen/antibody complexes, complement activation, eosinophils = immediate hypersensitivity; can cause hepatic fibrosis, portal hypertension, chronic morbidity

Table 21.6 Allergic reactions responsible for disease in parasitic infections^a

Infection	Clinical disease	Reaction type
Malaria	Nephrotic syndrome	Immune complex (III)
	Anemia	Cytotoxic (II)
Chagas' disease	Myocarditis	Cytotoxic (II)
Leishmaniasis	Spectral disease	Cell mediated (IV)
Schistosomiasis	Swimmer's itch	Anaphylaxis (I)
		Cell mediated (IV)
	Katayama fever	Immune complex (III)
	Granulomatous disease	
	<i>Schistosoma mansoni</i>	Cell mediated (IV)
	<i>Schistosoma haematobium</i>	Cell mediated (IV)
Filariasis	Elephantiasis	Cell mediated (IV)
	Tropical pulmonary eosinophilia	Anaphylaxis (I)
Echinococcosis	Leaky hydatid fluid	Anaphylaxis (I)

^a Data from references 11 and 81.

matrix, and they participate in the induction of apoptosis (programmed cell death) in cells contacted by the amebae (7). They also assist in circumventing the host immune response through cleavage of secretory IgA and IgG and activation of complement (64). Cysteine proteases are encoded by a number of genes present in *E. histolytica* but not *E. dispar*. A detailed study of cysteine proteases may eventually provide the key to the design of specific inhibitors that could serve as new chemotherapeutic agents.

Humoral Immunity

Coproantibodies can be detected in approximately 80% of patients with amebic dysentery, with a steady decline to about 55% over a period of weeks. During the same time frame, a rise in the level of antibodies in serum can be demonstrated. These data may represent a transient secretory response followed by invasion and penetration of the intestinal mucosa with production of circulating antibody. Once invasive amebiasis has been established, a serologic response can generally be demonstrated within a week after the onset of symptoms. These titers tend to be high and can persist for several years, even after invasive disease has healed or a subclinical infection has been controlled. However, this humoral response during the invasive phase of the disease apparently has little impact on potential reinfections or in the healing process.

IgM is produced, although IgG is found at a higher concentration, with the predominant subclass being IgG2 (60). Data indicate that cleavage of IgG by the extracellu-

lar cysteine proteinase of *E. histolytica* trophozoites may limit the effectiveness of the host humoral response (78). The production of anti-ameba IgE is controversial, and its role in *E. histolytica* infections is unclear. A cytotoxic effect on the trophozoites is produced, and organisms lose motility when in contact with serum containing specific antibodies. Also, introduction of antibodies to cultures inhibits growth, and antibody-treated organisms do not induce liver abscess in susceptible animal models.

It is also interesting that sera from healthy individuals with no evidence of past or present amebiasis also have the same effects on organisms as immune sera do. Even after absorption with *E. histolytica* trophozoites, the effects persist, suggesting that they are due to causes other than the presence of natural antibodies. Complement activation is involved, via classic and alternative pathways, and apparently does not require antibodies. Activation of complement pathways results in lysis of the trophozoites. It has been reported that highly virulent strains of *E. histolytica* are more resistant to complement-mediated lysis; thus, complement may also play a role in natural resistance to infection by causing a potential reduction in invasive capacity. However, it is not known if reduced complement activity plays a role in the susceptibility of certain individuals to infection or whether it may be related to host defenses.

Although the data are limited, a suppression of humoral response to sheep erythrocytes in hamsters has been documented when extracts of *E. histolytica* were used. The effect is enhanced when the erythrocytes and amebic extract

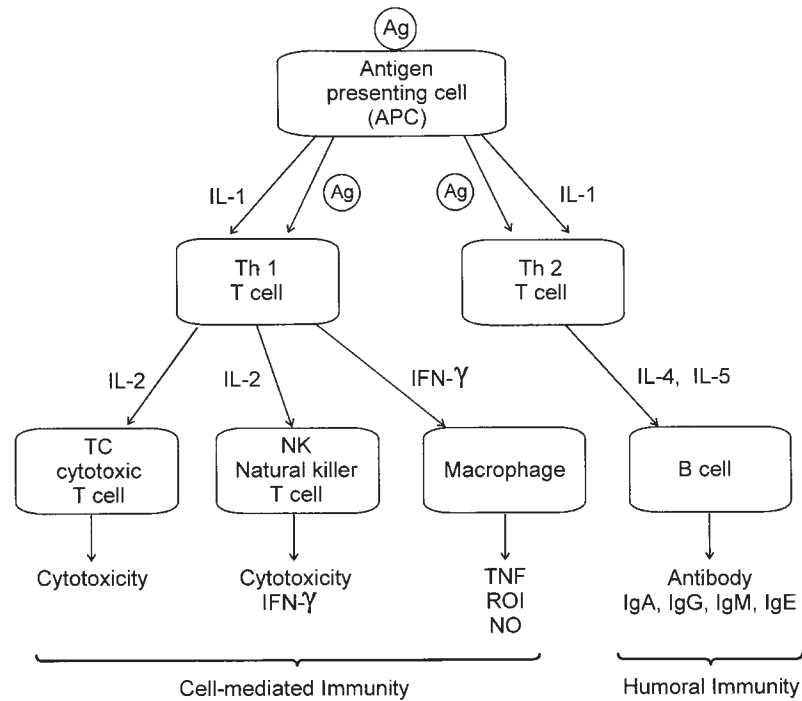

Figure 21.1 Representation of the immune response. Antigen (Ag) is recognized and processed by antigen-presenting cells (APC) and presented to Th1 or Th2 cells that carry receptors for the antigen. At the same time, the APCs release IL-1, a cytokine that activates resting Th1 and Th2 cells. Activated Th1 cells produce IL-2, which activates cytotoxic T (TC) or natural killer (NK) cells. Cytotoxic T cells kill target cells carrying the original antigen in a major histocompatibility complex-restricted way, while NK cells kill target cells nonspecifically. Another product of the Th1 cells is IFN- γ , which activates resting macrophages to become more phagocytic and to release TNF, reactive oxygen intermediates (ROI), and nitric oxide (NO). Both ROI and NO are involved in killing intracellular parasites or those in close proximity to the activated macrophage. The Th2 cells release IL-4 and IL-5, which are involved in B-cell activation and the release of antibodies specific to the antigen. IL-5 also activates eosinophils. Antibodies may cooperate with macrophages and eosinophils to serve as a bridge bringing the activated cell and the parasite together; they may also support the release of toxic molecules directly onto the surface of the parasite. *Note:* It is important to remember that some of the cytokines exert both a positive and negative influence on the immune response at the same time; this diagram is designed to show the main features of the overall immune response. (Adapted from reference 15.)

are injected on the same day; however, the primary response only is involved. Suppression of the primary response has also been documented with ovalbumin as the antigen.

Survival mechanisms allow the survival of the parasite, often in spite of both natural and immune defenses. One of these mechanisms is capping, i.e., surface redistribution of membrane antigens in amebae, which may circumvent the effect of surface-bound specific antibodies. Antibodies to the amebae bind to the organism and induce a polar redistribution of surface components. The surface becomes

an accumulation of folded membranes that extrude as a cap, containing most of the antibodies that were originally bound to the surface. The cap is then released, probably by constriction of a limiting membrane region.

In spite of the production of high levels of antibody in response to an infection with *E. histolytica*, it appears that the humoral response is not protective to the host. This is confirmed by the ease with which reinfection occurs and the fact that high antibody levels can be seen in patients who remain symptomatic with amebiasis.

Table 21.7 Immune system “alphabet soup” and definitions^a

Term ^b	Definition	Comments
APC	Antigen-presenting cell	Processes the foreign antigen and presents it to the T helper cells
B cell	Lymphocyte; precursor of plasma cell; expresses immunoglobulins on its surface but does not release them	B lymphocyte; short life; responsible for production of immunoglobulins
T cell	Lymphocyte; helper, killer, suppressor cells	T lymphocyte; long life; responsible for cell-mediated immunity; soluble products are lymphokines
Th	T helper cell; both Th1 and Th2 carry same CD4 ⁺ or CD8 ⁺ surface markers	T lymphocyte; Th1 produces IL-2 and IFN- γ ; Th2 produces IL-4 and IL-5; may be antagonism between products of Th1 and Th2; Th1 drives immune response toward antibody-independent immune responses; Th2 drives immune response toward antibody production
Lymphokine	Hormone-like peptide, released by activated lymphocytes	Mediates immune responses
Cytokine	Hormone-like low-molecular-weight protein that regulates the intensity and duration of immune responses and is involved in cell-to-cell communication	Interferon (IFN), interleukin (IL), lymphokines; released from spleen, thymus, epithelial, endothelial, and mast cells and by fibroblasts and lymphocytes
Interferon (IFN)	Small glycoproteins; classified into three groups (alpha, beta, and gamma); can regulate many cell properties and functions	IFN- α 2A and -2B used as antineoplastic agents; IFN- β elaborated by fibroblasts; IFN- γ elaborated by T lymphocytes in response to specific antigen or mitogenic stimulation
Interleukin (IL)	Name given to cytokines once their amino acid structure is known	IL-1: from mononuclear phagocytes; enhances proliferation of Th and growth and differentiation of B cells IL-2: from Th; causes proliferation of T cells and activated B cells (T-cell growth factor) IL-3: from monocytes, fibroblasts, and endothelial cells; increases the production of monocytes (multi-colony-stimulating factor) IL-4: from T4 lymphocytes; causes differentiation of B cells (B-cell differentiation factor) IL-5: from T cells; causes activation of B cells and differentiation of eosinophils IL-6: from fibroblasts, macrophages, and tumor cells; increases synthesis and secretions of immunoglobulins by B cells (B-cell-stimulating factor 2, IFN- β 2) IL-7: from bone marrow cells; causes proliferation of B and T cells IL-8: from endothelial cells, fibroblasts, keratinocytes, macrophages, and monocytes; causes chemotaxis of neutrophils and T cells IL-9: from T cells; causes growth and proliferation of T cells IL-10: from helper T cells, B cells, and monocytes; inhibits IFN- γ secretion by T cells and mononuclear cell inflammation IL-11: from bone marrow endothelial cells, macrophages, and preadipocytes; stimulates increased concentrations of acute-phase proteins (C-reactive proteins), mannose-binding protein, serum amyloid-P component, α_1 -antitrypsin, fibrinogen, ceruloplasmin, and complement components C9 and factor B in plasma IL-12: from B cells, T cells, and macrophages; induces IFN- γ gene expression in T cells and NK cells IL-13: from Th cells; inhibits mononuclear cell inflammation IL-14: from T cells; stimulates B-cell proliferation and inhibits immunoglobulin secretion IL-15: from T cells; stimulates T-cell proliferation and NK cell activation

(continued)

Table 21.7 Immune system “alphabet soup” and definitions^a (continued)

Term ^b	Definition	Comments
NK cell	Natural killer cell; heterogeneous collection of lymphocytes; neither B nor T cells; activated by IL-12	Kills target cells nonspecifically; does not involve MHC ^b class I molecules; is being increasingly implicated in protection against parasitic infections
Cytotoxic T cell	T lymphocyte	Kills target cells carrying original antigen in an MHC-restricted manner; often involved in viral infections but seldom in parasitic infections
TNF	Tumor necrosis factor; a cytolytic factor that is produced by CD4 and CD8 T cells after exposure to antigen; also produced by macrophages	A polypeptide hormone; has the ability to modulate adipocyte metabolism, lyse tumor cells in vitro, and induce hemorrhagic necrosis of certain transplantable tumors in vivo
ROI, NO	Reactive oxygen intermediates; nitric oxide	Both are involved in intracellular killing of ingested parasites or destruction of parasites in close proximity to the activated macrophage

^a Adapted from reference 13.

^b MHC, major histocompatibility complex.

The identification and structural characterization of three amebic antigens, the serine-rich *E. histolytica* protein (SREHP), the 170-kDa subunit of the Gal/GalNAc-binding lectin, and the 29-kDa cysteine-rich protein, indicate that they all show promise as recombinant antigen-based vaccines to prevent amebiasis (20, 28, 50, 75). Recent data confirm that DNA vaccination with SREHP can provide high levels of protection against amebic liver abscess in animal models of disease (84).

Cellular Immunity

Most research on cell-mediated immunity in amebiasis has been conducted with animal models of amebic liver abscess. However, a number of different approaches to clarify the role of cellular immunity in humans have been taken. One example involved the use of skin test antigens obtained from *E. histolytica* culture. This procedure detects amebiasis long after the patient has recovered from

the infection, and it has been useful in epidemiologic studies; patients with invasive amebiasis exhibit a typical delayed-type hypersensitivity reaction, although the reaction is usually negative during the acute phase of an untreated liver abscess (60).

Macrophage migration-inhibition assays have shown results similar to those obtained with skin test antigens during invasive disease. Results were negative during the early phases of liver abscesses but became positive after therapy. A number of different animal model studies also confirm that cell-mediated immunity plays an active role in the overall immune response to infection with *E. histolytica* (60).

Concanavalin A (ConA)-induced lymphocyte transformation with cells from both patients with amebic liver abscess and healthy controls is comparable; similar results have also been demonstrated with phytohemagglutinin (PHA). However, studies with infected hamsters indicated reduced reactivity to ConA and PHA; other reports

Table 21.8 Various methods used by parasites to evade the host immune response

1. Become intracellular (<i>Plasmodium</i> spp.)
2. Enter immunologically protected site soon after infection (<i>Plasmodium</i> spp.)
3. Leave site of established immune response during life cycle (<i>Ascaris lumbricoides</i>)
4. Become disguised with host antigen(s) (<i>Schistosoma</i> spp.)
5. Survive in macrophages (<i>Leishmania</i> spp., <i>Trypanosoma cruzi</i> , <i>Toxoplasma gondii</i>)
6. Live in lymphocytes (<i>Theileria</i> spp.)
7. Inactivate host lymphocytes (<i>Schistosoma mansoni</i>)
8. Cause polyclonal stimulation of lymphocytes (<i>Trypanosoma brucei</i> subspp., <i>Plasmodium falciparum</i> , <i>Babesia microti</i> , <i>Entamoeba histolytica</i> , <i>Trichinella spiralis</i>)
9. Activate macrophages (<i>Leishmania</i> spp., <i>Toxoplasma gondii</i> , <i>Trichinella spiralis</i> , <i>Nippostrongylus brasiliensis</i>)
10. Shed antigens (<i>Trypanosoma brucei</i> subspp., <i>Entamoeba histolytica</i> , <i>Ancylostoma caninum</i>)
11. Undergo antigenic variation (<i>Plasmodium falciparum</i> , <i>Trypanosoma brucei</i> subspp.)
12. Inhibit cell or antibody binding (<i>Schistosoma mansoni</i>)
13. Suppress immune system (<i>Trypanosoma cruzi</i> , <i>Trypanosoma brucei</i> subspp., <i>Leishmania donovani</i> , <i>Plasmodium</i> spp.)

Table 21.9 Immune system antibodies (neutralization, agglutination, complement activation, and facilitated opsonization)

Antibody	General comments	Functionality
IgA	Occurs as 2 subclasses (IgA1 and IgA2); can occur in monomeric, dimeric, or polymeric forms; found in secretions, where it protects the mucous surfaces of the gut, respiratory tract, and urogenital tract; occurs in breast milk	Neutralization of bacterial toxins; inhibition of invasion of the mucosa by agglutinating infectious agents or preventing attachment to the host cell
IgG	Found in serum and extravascular spaces; occurs as 4 subclasses, IgG1, IgG2, IgG3, and IgG4	Most common antibody in secondary immune response; all subclasses can agglutinate microorganisms; IgG1, IgG2, and IgG3 activate complement, with IgG3 being the most effective; IgG1 and IgG4 can cross the placenta; IgG1 and IgG3 can bind to macrophages via their Fc portions
IgM	Found in serum and extravascular spaces; pentameric immunoglobulin; single subclass	First antibody produced in response to antigenic stimulation; agglutinates microorganisms with repeated epitopes; activates complement via classic pathway
IgE	Has an affinity for mast cells, basophils, and eosinophils, to which it binds via the Fc portion	When bound to an antigen, it causes cross-linking, resulting in the release of active substances from the cell to which it is bound

indicate that *E. histolytica* extracts are mitogenic for murine lymphocytes. Induced blastogenesis in lymphocytes from patients with amebic liver abscess has been shown with aqueous *E. histolytica* extracts and a subcellular antigenic fraction, thus indicating *in vivo* sensitization of T lymphocytes to amebic antigens (60).

According to Ortiz-Ortiz (60), all arguments in favor of protective immunity in amebiasis are based on cellular immunity, hence the emphasis on studies involving the *in vitro* interaction of *E. histolytica*, T lymphocytes, and macrophages. A compilation of some of these studies can be seen in Tables 21.10 and 21.11. It is apparent from these studies that cell-mediated immunity limits the clinical manifestations of amebic liver abscess and protects against recurrent infections.

Most studies reinforce the idea that cell-mediated immunity is the most important factor in acquired protective immunity. A number of factors support this conclusion: (i) cellular anergy that supports the initial *E. histolytica* invasion; (ii) increased incidence of invasive amebiasis after T-cell suppression or splenectomy; (iii) protective impact of T-cell stimulants; (iv) after recovery from amebic liver abscess, appearance and persistence of a delayed-type hypersensitivity reaction to amebic antigens; (v) transfer to immunity via sensitized T cells; and (vi) the lysis effect of cytotoxic T cells stimulated with antigen and activated macrophages.

Anergy during the course of amebic liver abscess is well documented. Animal models reveal tissue destruction with minimal inflammatory reaction surrounding these abscesses. One explanation for this anergy might be a temporary desensitization caused by circulating antigen; it is not thought to be due to decreased T-cell numbers, since

normal levels have been detected in patients with amebic liver abscesses (60).

Phagocytosis by both peripheral blood polymorphonuclear leukocytes and monocytes is reduced in various circumstances related to amebiasis. Phagocytic function in polymorphonuclear leukocytes was more depressed in patients with amebic liver abscess than in patients with other manifestations of *E. histolytica* infection or in healthy controls. In evaluating the functional capacity of monocytes, phagocytosis was significantly depressed in both liver and intestinal amebiasis and bactericidal function was depressed even more in liver amebiasis.

Studies of patients with amebic liver abscess that had been healed for a minimum of 9 weeks indicated that the CD4⁺ (helper, inducer T-cell) lymphocyte subpopulation was smaller and the CD8⁺ (suppressor, cytotoxic T-cell) subpopulation was increased, resulting in a lower cell ratio in patients with amebic liver abscess than in controls (71). However, when the same group of patients was checked a year later, four of five demonstrated an increased CD4⁺ cell percentage and three of five showed an increased ratio of CD4⁺ to CD8⁺ cells. Since T lymphocytes from patients cured of amebic liver abscesses have been shown to destroy *E. histolytica* after activation with parasite antigens, this may have an impact on host resistance in these patients.

Giardiasis

Giardia lamblia is probably the most commonly diagnosed flagellate in the intestinal tract and may be the most commonly diagnosed intestinal protozoan in many areas of the world. Although various criteria have been used to

Table 21.10 Interaction between *Entamoeba histolytica* and T lymphocytes in vitro

Study	Comments	Reference
Virulent <i>E. histolytica</i> with lymphocytes from patients who have recovered from amebic liver abscess	Parasite lysis (also with lymphocyte supernatant fluids)	45
<i>E. histolytica</i> with lymphocytes, peritoneal cells, or spleen cells from infected hamsters	Parasite lysis; may have been caused by lymphokine-activated macrophages	30
Lymphocytes (treated amebic liver abscess patients) with ameba antigen or nonimmune T cells (PHA stimulated)	Parasites killed	70
<i>E. histolytica</i> with supernatant fluids of stimulated T cells	Inhibition of DNA and protein synthesis; not toxic	8

differentiate species of *Giardia*, there is still disagreement about classification and nomenclature. On the basis of different species names for different animal hosts, there are approximately 50 *Giardia* species. However, there are data to suggest either biological or antigenic differences among many of these species.

Studies during the last 15 years have confirmed that *Giardia* organisms elicit an immune response that probably plays a role in the variable host response generated to the presence of the parasite. Early data indicating a lower incidence of symptoms in individuals who were repeatedly exposed to the organism suggested the presence of an immune response. Subsequent studies with humans and experimental animals have confirmed the presence of both humoral and cellular immune responses to *Giardia* spp.

In giardiasis a diffuse loss of microvillous brush border, usually combined with villous atrophy, is responsible for malabsorption, which ultimately causes diarrhea. Other mucosal changes include crypt hyperplasia and increased infiltration of intraepithelial lymphocytes. The loss of brush border surface area, reduced disaccharidase activities, and increased crypt/villus ratios are mediated by

CD8⁺ T cells, while both CD8⁺ and CD4⁺ small mesenteric lymph node T cells regulate the influx of intraepithelial lymphocytes (6).

Antigenic variation has been documented in giardiasis, and variation at the surface membrane of trophozoites occurs frequently. These antigens are composed of cysteine-rich proteins, and B-cell-dependent mechanisms are probably responsible for the surface antigen switch (24). Apparently, individual organisms express only one variant-specific protein at a time; the detection of multiple surface-labeled bands in some of the studies resulted from subpopulations of trophozoites expressing several different variant surface protein types (1).

Humoral Immunity

The majority of infected patients produce detectable levels of *Giardia*-specific antibodies; however, the biological role played by these antibodies in the host immune response to the infection is unclear. Diagnostic procedures have been developed for the detection of short-lived IgM anti-*Giardia* antibodies and IgG antibodies that may remain at high titers for many months after the patient

Table 21.11 Interaction between *Entamoeba histolytica* and macrophages in vitro and in vivo

Study	Comments	Reference(s)
Virulent <i>E. histolytica</i> with nonactivated macrophages	Lysis of mammalian cells; no harm to amebae	72
Virulent <i>E. histolytica</i> with activated macrophages (lymphokines induced with ameba soluble protein, ConA, or PHA)	Amebae killed; dependent on cell-cell contact, time, and oxidative and nonoxidative processes; decrease in macrophage viability, possibly owing to lysis by <i>E. histolytica</i> toxic products	72
Silica poisoning of macrophages or use of antimacrophage serum	Increased susceptibility to amebic liver abscess; larger abscesses; dissemination to other tissues (hamsters, guinea pigs)	31, 33
Bacillus Calmette-Guérin-stimulated macrophages	Decreased susceptibility to amebic liver abscess; smaller abscesses; less dissemination (to hamsters, guinea pigs)	31, 32
Congenitally athymic nude mice (<i>nul/nul</i>), macrophage dependent	Resistant to invasive amebiasis; can limit development of liver abscess	10, 76

has been treated and cured. Specific anti-*Giardia* IgM responses in serum were found in 100% of human volunteers experimentally infected with human-source *Giardia* spp. (58). Some studies indicate a correlation between the presence of antibody and symptoms in the patient. Other studies, using different antigens and antibody detection procedures, fail to confirm this correlation.

In asymptomatic patients, the presence of antibody may play a protective role or serve merely as an indicator of infection. Certainly, data indicate that people who are repeatedly exposed to the parasite will tend to be asymptomatic and will have high levels of *Giardia*-specific antibody in serum and breast milk. Patients with hypogammaglobulinemia also have a high rate of diarrhea, often due to *Giardia* spp., and children with chronic diarrhea and giardiasis have an increased incidence of hypogammaglobulinemia. Also, AIDS patients who have giardiasis but no specific antibody also have acute symptomatic infections (40). In contrast to this group of AIDS patients, those who have giardiasis with circulating *Giardia*-specific antibody may have symptoms unrelated to their *Giardia* infection.

Giardia-specific IgA may also be important in both defense against and clearance of the parasite. In one study, patients with symptomatic giardiasis had higher levels of IgA in serum than did uninfected controls and none of the patients were IgA deficient (40). The degree of protection of breast-fed infants against *Giardia* infection also depends on the level of IgA-specific antibodies in breast milk. In the intestine, IgA antibodies may influence the local immune response by inhibiting parasite adherence, tissue invasion, or penetration of the mucosa by parasite antigens (40). IgA anti-*Giardia* antibodies are the most common Ig type found in acutely ill patients with giardiasis, and they have been detected in persons exposed to a waterborne outbreak in Vermont and villagers in Thailand (40). The jejunal-plasma immune response to *Giardia* involves a decrease in the number of IgA cells and an increase in the number of IgM cells. The large population of antibody-producing plasma cells that are secreting mainly IgA is evidence of the importance of mucosa-associated lymphoid tissue in giardiasis.

Cellular Immunity

Antibodies to *Giardia* spp. work together with cellular immune mechanisms. Cellular responses to giardiasis occur at the level of the intestinal mucosa, and a number of inflammatory changes may occur during the infection. Histologic changes during giardiasis include infiltration of polymorphonuclear leukocytes into the epithelium and mononuclear leukocytes into the lamina propria, development of shortened villi, loss of the brush border, damage to epithelial cells, and an increase in epithelial cell mitosis

(40). In rare cases, giardiasis is associated with changes that mimic celiac sprue and include complete villous atrophy, dense mononuclear cell infiltration, and flattening of the epithelial cells. This accumulation of inflammatory cells in the intestinal mucosal cells of patients with giardiasis suggests that cellular responses play a role in the overall immune response to *Giardia* infection. However, while these histologic findings suggest a cellular immune response, they may also represent a nonspecific inflammatory response stimulated by the presence of an intraluminal infection.

Experimental animal studies provide evidence that T lymphocytes and Peyer's patch helper T lymphocytes play a role in the host immune response. In athymic mice, which are deficient in both T lymphocytes and Peyer's patch helper T lymphocytes, inoculation with *G. muris* results in a chronic infection with large numbers of organisms. In contrast, immunocompetent mice clear the parasite and may develop resistance to reinfection.

Reports also indicate that human mononuclear phagocytes are capable of killing *Giardia* organisms and phagocytizing *Giardia* trophozoites (40). Also, gut-associated lymphoid tissue provides the precursor cells that migrate to the mammary gland and become cells capable of secreting the Ig components of milk. Despite the number of studies on the immunology of giardiasis, the actual effect of antibody or cellular components on the organism itself is unclear. Future studies on defining specific antigens to which the host immune system responds will play a major role in our understanding of this very common infection. For reviews of current information, see references 24 and 40.

Toxoplasmosis

The gastrointestinal route appears to be the most common site of infection with *Toxoplasma gondii*, and, after disruption of the host cells, the organisms invade adjacent cells and are spread throughout the body via the lymphatics and bloodstream. Since the advent of AIDS, the impact of toxoplasmosis as a major opportunistic infection has led to extensive research in the field of immunology. Infection with *T. gondii* stimulates the development of both humoral and cellular immune responses, with the cell-mediated response being the more predominant. These immune responses of the host can dramatically affect the course and severity of the infection.

Adhesion to the host cell is facilitated by secreted proteins, and invasion uses an actin-myosin-based process. Within the cell, the parasite remains inside the parasitophorous vacuole; the organism prevents the cell from fusing with lysosomes. Eventually the tachyzoites transform

into bradyzoites and encyst. Ongoing encystment depends on an ongoing type 1-mediated immune response; IFN- γ and CD4⁺ and CD8⁺ cells play a protective role. Although this immune response limits the tissue invasion of the parasite, it also aids the survival of *Toxoplasma* by converting it into a bradyzoite, the resistant form (26).

Humoral Immunity

In spite of the very high antibody titers to *T. gondii* often seen in human infections, humoral antibody plays a secondary role in contributing to protective immunity. The classic approach to the diagnosis of toxoplasmosis has always been based on the detection of immunoglobulins, specifically IgM and IgG. In infected humans, IgM usually appears within 2 weeks after infection whereas IgG antibodies appear later and their levels peak at approximately 2 months postinfection. The IgG titer decreases gradually to a low level and remains at this level thereafter. For this reason, the presence of IgG demonstrates proof of a prior infection with *T. gondii*. Although detection of IgM has always been considered an indicator of acute infection, the development of more sensitive diagnostic methods means that IgM can now be detected months to years after the initial acute infection. Unfortunately, these findings also complicate the interpretation of serologic test results in patients with toxoplasmosis.

IgA antibodies can be detected early in infection, and their level decreases between 3 and 9 months after infection. The detection of both IgA and IgM at the same time indicates the acute phase of toxoplasmosis and is currently used for risk evaluation of pregnant women. Apparently, IgE antibodies also appear early in infection and then their level begin to decline; the detection of IgE could also serve as an indicator for acute disease. One study indicated the presence of IgE in 86% of infected patients (62). The presence of IgE in immunosuppressed individuals appears to be correlated with the onset of complications such as adenopathies, chorioretinitis, and disease reactivation (80).

Unfortunately, in spite of what is currently known about the humoral response in toxoplasmosis, routine serologic tests are often inadequate for the diagnosis of congenital disease. Specific IgG can persist in a child for months and cannot be differentiated from maternal IgG. However, both IgM and IgA antibodies do not cross the placenta and can be detected in infected fetuses as early as the second trimester of pregnancy, assuming that the mother became infected soon after conception (19). Since children at 1 year of age have only 20% of the level of IgA in adults, early synthesis of specific IgA might also be an indicator of congenital infection (23).

A number of attempts have been made to confer resistance to *T. gondii* by passive transfer of immune ho-

mologous or heterologous antisera. The results of these studies have indicated conflicting outcomes; some investigators have reported no protection, whereas others have reported significant protection. The results appear to be related to the choice of experimental host species, specific parasite strains, and transfer of small volumes of high-titer antisera. It appears that anti-*Toxoplasma* antibody can be protective under carefully controlled conditions.

When extracellular tachyzoites are exposed to antibody in the presence of complement in vitro, their morphology is altered: the cells become vacuolated and coarse, collapse, and lyse. The changes in dye permeability in the Sabin-Feldman dye test are based on these changes seen with a combination of antibody and complement. However, the in vivo intracellular location of the parasite protects it from the circulating antibody.

Cellular Immunity

Cellular immunity is the key component of the host's immune reaction to toxoplasmosis. Macrophages, T lymphocytes, and NK cells, as well as the cytokines, are major components of the immune response (26). A number of studies have shown that there is a lower level of lymphocyte transformation in patients with acute disease than in chronically infected patients. In the presence of parasite antigens, lymphocytes from patients with evidence of infection for more than 1 year proliferate whereas lymphocytes from seronegative patients do not (26).

Animal studies have confirmed the key role of T lymphocytes in protective immunity against *T. gondii*. In infected mice, depletion of CD4⁺ T lymphocytes reactivates toxoplasmosis in the central nervous system. These cells also play a role in the development of host resistance and in controlling brain cyst development. Apparently, in the mouse model there is a synergistic relationship between CD4⁺ and CD8⁺ T-cell subsets, with CD4⁺ cells participating in the development of resistance during vaccination or acute infection and CD8⁺ cells being involved in the maintenance of a protective immune response and the inhibition of cyst formation. CD4⁺ and CD8⁺ cells are the key players involved in host resistance in toxoplasmosis. The CD8⁺ cells are activated by IL-2 secreted by the CD4⁺ cells, and they exhibit cytotoxic activity against tachyzoites or cells infected with *T. gondii*.

Studies of patients with acute toxoplasmosis have shown a significant elevation in levels of suppressor T cells in patients with symptoms lasting more than 4 weeks. A reversed CD4⁺/CD8⁺ cell ratio is also seen and persists for 2 to 4 months after infection. By using flow cytometry and differential leukocyte counts, an increase in the absolute number of CD8⁺ T cells was confirmed

in patients with symptomatic toxoplasmosis, with no significant change in CD4⁺ cell levels. Also, cloned CD4⁺ and CD8⁺ cells from a symptomatic patient produced less IFN- γ after stimulation with *T. gondii* antigen than did T cells from an asymptomatic patient.

Immunosuppression

Although information is still somewhat incomplete, CD8⁺ cells can be stimulated by *T. gondii* antigen to suppress lymphocyte proliferation; both the suppression and increase in the level of the CD8⁺ T-cell subset correlate with a more severe and prolonged clinical course (51). This study also supports the suggestion that suppressor T cells play a role in prolonging the symptoms of toxoplasmosis. Lymphadenopathy and elevated numbers of CD8⁺ T cells have been found in patients with lymphatic toxoplasmosis; the same picture is also seen in patients with viral infections known to cause mononucleosis (Epstein-Barr virus and cytomegalovirus). Overall, the immunosuppressive effect seen in toxoplasmosis is apparently limited to the T-cell responses, while B-cell functions are unaffected.

In congenital infections, T-cell functions are also impaired; studies indicate that most congenitally infected infants demonstrate specific immunologic tolerance to *T. gondii* (55). The presence of the parasite at a critical stage of fetal development results in production of lymphocytes that are unable to distinguish immunologically between parasite and self. It is possible that increased numbers of suppressor T cells that occur during fetal life could induce tolerance by the inhibition of other lymphocytes and production of less IFN- γ and IL-2. Also, in symptomatic babies, these diminished responses to *T. gondii* antigens usually correlate with more severe disease.

In normal, unstimulated macrophages, *T. gondii* tachyzoites can continue to multiply; however, in activated macrophages, vacuoles containing living tachyzoites fuse with lysosomes and the parasites are killed. Both oxygen-dependent and oxygen-independent mechanisms are involved in parasite killing.

There is also evidence to indicate that platelets are cytotoxic for tachyzoites when direct cell-to-cell contact is established, even in the absence of antibody. These findings certainly suggest a role for platelets as one of the mechanisms in host defense against toxoplasmosis.

In two studies, a protective effect of vaccination of mice with a combination of antigen and IL-12 or IL-15 has been demonstrated. In the study using a recombinant surface antigen (rSAG1) plus IL-12, this combination reduced the parasite load in the brain by 40% (48). The second study indicated that the $\gamma\delta$ T-cell response to *T. gondii* was enhanced by the administration of exogenous IL-15 in the presence of parasite lysate antigen; the survival time after lethal challenge were lengthened (47). In this study, IgG1

and IgG2a antibody titers were increased, as was splenocyte lymphoproliferation.

African Trypanosomiasis

According to recent data, 50 million people are at risk of contracting trypanosomiasis. Also, in Africa, the extensive distribution of the vector, the tsetse fly, makes 10⁷ km² of potential grazing land unavailable for livestock and approximately one-third of the cattle are at risk of trypanosomiasis. On the basis of isoenzyme studies, *Trypanosoma brucei gambiense* is considered a subspecies; however, it is really not clear whether *T. brucei gambiense* and *T. brucei rhodesiense* should be subspecies or variants of a single species. In this infection, the trypanosomes live in the bloodstream, where they are directly affected by the production of antibodies by the host.

Humoral Immunity

In reviewing the immune system response of the host to the presence of these parasites, it is important to understand the concept of antigenic variation. It has been long recognized that African sleeping sickness is characterized by a series of parasitemia peaks in the blood. This successive wavelike pattern is due to the appearance of trypanosomes expressing a different antigenic identity. Organisms that have changed their antigenic identity can escape the host immune response and can initiate another increase in the level of parasitemia. The success of this infection depends on the parasite's ability to select between hundreds of genes that encode the variant surface glycoprotein (VSG), or variant surface protein (VSP). Both designations are correct. As the host immune response produces high levels of antibody against one variant, parasites expressing a different VSG gene begin to proliferate. These organisms persist until they are killed by the immune response, and this pattern is repeated multiple times (22).

The factors that induce VSG switching have not been totally defined; however, the presence of host antibodies is not necessary for the changes to occur. The number of variable antigenic types that can occur in any one trypanosome population is quite large (100 or more), and more than 1,000 VSG genes have been detected. There is evidence to indicate that the VSG-specific antibodies represent a mixture of T-dependent and T-independent antibodies directed at different epitopes (66). Unfortunately, although these antibody responses play a role in the successive wavelike growth patterns of the organisms, they do not generate long-lasting immunity.

Specific changes in the humoral component of the immune response to trypanosomes include an increase in the cellularity of the spleen and lymph nodes, an increase in the proliferation of spleen cells, an increase in the number

of B cells (not T cells), an increase in the IgM level, the appearance of antibodies reacting with nontrypanosome antigens, and the appearance of autoantibodies, rheumatoid factors, and immune complexes (74).

Cellular Immunity

Studies of tumor necrosis factor alpha (TNF- α) have shown that it is involved in many physiologic functions, and it has been implicated in the pathogenesis of septic shock and systemic inflammatory reactions. Increased levels have been seen in sera from patients with other parasitic infections such as malaria and leishmaniasis; in patients with malaria, increased levels of TNF- α correlate with disease severity. In a recent study, an increase in the level of TNF- α was observed in sera from patients with African trypanosomiasis compared with controls. Patients were classified as being in the early stage (blood, lymphatic) or late stage (meningoencephalitic) of the disease. An increase in the level of TNF- α was also noted in late-stage patients compared with those in the early stages of the disease. Data indicated that levels of TNF- α in the serum of patients with African trypanosomiasis were definitely correlated with disease severity (signs of inflammation or presence of major neurologic signs), indicating that TNF- α could be involved in at least some aspects of physiopathology in human African trypanosomiasis (*T. brucei gambiense*) (59).

Immunosuppression

It is also well documented that another key feature of African trypanosomiasis is suppression of the host immune system. Increased incidence of opportunistic infections in patients with African trypanosomiasis is well recognized and has been known since the early 1900s. Both T-cell and B-cell functions can be severely suppressed.

Animal studies have demonstrated two different pathways, one that is suppressor cell dependent and one that is suppressor cell independent. Consequently, suppression has been attributed to polyclonal activation of B cells and to the generation of suppressive cells, two different pathways that are probably coexisting mechanisms.

Prostaglandins also play a large role, not only in immunosuppression but also in other areas such as immune system modulation and pathogenesis. It has been shown that prostaglandins in cerebrospinal fluid from patients with sleeping sickness are probably responsible for sleep induction (61).

American Trypanosomiasis

American trypanosomiasis (Chagas' disease) is caused by *Trypanosoma cruzi* and is one of the major health problems in Latin American countries. It is estimated that 100 million persons are at risk of infection, of whom 16

million to 18 million are actually infected, and there are approximately 50,000 deaths per year due to Chagas' disease. In certain areas of endemicity, approximately 10% of all adult deaths are due to Chagas' disease. In addition to humans, numerous species of wild and domestic mammals can harbor the infection and serve as an enormous parasite reservoir.

Shortly after infection, both humans and animals develop an immune response to the presence of the parasites; this is clearly demonstrated by the development of parasite-specific antibodies and hypersensitivity reactions. As with many other parasite infections, these immune responses do affect the outcome of the infection; however, host protection is limited. Both antibody-mediated and cell-mediated mechanisms are involved. It has also been shown that autoantibodies directed against laminin, tubulin, and nervous tissue are present; however, whether these autoantibodies contribute to disease is somewhat unclear.

Humoral Immunity

During the initial phase of the infection, IgM is predominant, whereas later, IgG and IgA become the major antibody classes represented. Antigenic variation, which is characteristic of infections with African trypanosomes, is less common in *T. cruzi* infection. In spite of humoral and cellular immunity to *T. cruzi*, the infection is able to persist in the host.

Reviews of serologic test results show that patients can be divided into four categories: (i) uninfected, (ii) indeterminate (seropositive but asymptomatic), (iii) cardiac (symptomatic with palpitations, dyspnea, syncope, and pulmonary embolus, with findings consistent with chagasic cardiomyopathy), and (iv) mega-gastrointestinal (symptomatic with dysphagia, constipation, and abdominal pain, with documented visceromegaly of the esophagus or colon determined by barium or surgical exploration). Individuals with both cardiac and mega-gastrointestinal disease were categorized as both (9). There were no significant differences in the levels of antitrypanosomal antibodies among the various clinical groups of chronically infected individuals. Titers obtained by hemagglutination, indirect fluorescent-antibody assay, and enzyme-linked immunosorbent assay allowed a clear distinction between seropositive and seronegative individuals.

The use of recombinant *T. cruzi* antigens greatly improves the early diagnosis of congenital Chagas' disease, especially through the detection of IgM. Although detection of IgM has proven to be very helpful, additional studies related to IgA will be justified, particularly since some congenitally infected infants, who do not produce IgM, may develop specific IgA (49).

Glycoinositolphospholipids are some of the major glycolipids of the *T. cruzi* surface that activate B cells.

Apparently, *T. cruzi* glycoinositolphospholipids can directly stimulate NK cells and can induce immunoglobulin production in the absence of T cells and NK cells. These studies indicate that this *T. cruzi*-derived molecule may be one of the stimulators that lead to NK cell activation during infection (17).

Cellular Immunity

Cell-mediated immunity has also been implicated as a cause of the tissue destruction, including cardiomyopathy and megacolon, seen in Chagas' disease. In animal studies, the transfer of lymphocytes from chronically infected mice to uninfected mice can destroy cardiac cells and the T-cell lines can recreate some of the neuropathologic changes seen in chronic disease (9).

Decreased cell-mediated immune responses have been found in symptomatic patients compared with asymptomatic patients. Future work will probably be focused on T-cell suppression factors or selective cell depletion as possible mechanisms for cell-mediated immunity alterations.

CD8⁺ T cells are critical to the control of *T. cruzi* infection and function in multiple ways, the most important being the production of IFN- γ ; IL-12 is also involved in protection against *T. cruzi* (46, 54, 79). This cytokine is produced early by NK cells and later by T cells. Cytokine responses in *T. cruzi*-infected children have been partially clarified; the children were 5 to 14 years of age and were from an area of endemic infection in Paraguay. This age group tends to be the most severely affected by the early phases of infection. Acutely infected children showed a distinct Th1-type IFN- γ cytokine response to infection. The cytokine pattern seen in the seropositive, asymptomatic group was the Th0 type (expression of both IFN- γ and IL-4). It was suggested that selective induction of a Th0-type cytokine pattern is important for the development of cell-mediated and humoral responses that suppress the parasite burden, thus prolonging the onset or limiting the disease severity of chronic Chagas' disease years later (73). Also, the frequency of IFN- γ -producing T cells in patients with chronic Chagas' disease seems to be associated with a history of recent exposure and with the clinical status of the patient (43).

Reduced production of IFN- γ by CD8⁺ T cells is associated with increased severity of Chagas' disease in humans. In chronic infection, CD8⁺ T cells serve as effector memory cells, undergo rapid expansion, and demonstrate effector functions following reexposure to antigen. However, these responses appear to develop relatively slowly, and the effector function of the CD8⁺ cells is compromised in some tissues, including muscle (54).

In several patients coinfecting with *T. cruzi* and human immunodeficiency virus (HIV) with high parasitemia, no clinical or parasitological evidence of *T. cruzi* reactivation

was seen. CD4⁺ T-cell counts decreased over time in two patients, and the lymphocyte proliferative response to the parasite was very low in all patients. Thus, *T. cruzi* infection appears to have a long silent course in immunocompromised HIV-infected patients (15).

In group of 23 patients with AIDS and *T. cruzi* infection, 20 patients developed severe multifocal or diffuse meningoencephalitis with necrosis and hemorrhage associated with numerous tissue parasites (69). The second most severely affected site was the heart, with myocarditis in 7 of the 23 patients. Both acute myocarditis and meningoencephalitis are thought to be caused by relapses of chronic *T. cruzi* infection, but this hypothesis is not universally accepted. Since immunologic defense against *T. cruzi* is mediated mainly by T lymphocytes and since the CD4⁺ population of T cells is depleted in AIDS patients, it appears in certain circumstances that AIDS may be responsible for reactivation of *T. cruzi* infections. In patients who do not have AIDS but have fatal, acute infections with *T. cruzi*, meningoencephalitis is uncommon and is seen most often in children younger than 4 years. Cases of Chagas' disease in immunosuppressed individuals have been described as having pseudotumoral presentations. There are expanding mass lesions in the cranial cavity, causing intracranial hypertension, and they mimic various neoplasms such as gliomas, lymphomas, or metastases (69). The United States, with the largest HIV-infected population reported by the World Health Organization up to 1987, is also known to have a significant number of individuals with Chagas' disease (35).

Studies of IL-12 indicate that this cytokine can act as a more selective amplifier of *T. cruzi* reactive cells than IL-2 does. By enhancing parasite antigen-specific immunity, IL-12 could be potentially therapeutic, with the ability to control reactivated *T. cruzi* infections associated with AIDS or other immunosuppressive conditions (18).

Immunosuppression

Suppressed delayed-type hypersensitivity has been reported to occur during acute Chagas' disease. *T. cruzi* also exerts a direct suppressive effect on human lymphocytes. Abnormalities in activated human lymphocytes may be involved in immunosuppression. These changes occur, regardless of whether the parasites and cells are in physical contact. There is also evidence that a soluble *T. cruzi* product mediates the suppressive effects. This trypanosomal immunosuppressive factor is a protein and can be purified from sera from chronic chagasic patients but not healthy individuals (42).

B cells isolated at the acute stage of infection have shown marked impairment in their response to polyclonal activators in vitro. Studies suggest that B-cell apoptosis and cell cycle arrest could be the mechanisms that control

intense B-cell expansion but at the same time could be delaying the emergence of a specific immune response to *T. cruzi* (85).

Splenomegaly, lymphadenopathy, depression of immune system responses to unrelated antigens, hypergammaglobulinemia, and autoimmunity are all indications of immune system physiopathologic changes in Chagas' disease. Minoprio et al. (56) also think that specific antigenic challenges could elicit "nonspecific" immune responses greater than the antigen-specific components of the response. Underlying mechanisms might include as examples the production of cytokines, the nonspecific "stickiness" of antigens to lymphocyte surfaces, the expression of major histocompatibility complex and other cell surface components (probably IFN- γ and IL-4), and the nonspecific lymphocyte mitogens released by *T. cruzi* or superantigens which could bind to T-cell receptors and trigger accessory cell-dependent T-cell activation.

Studies have shown that there appears to be no correlation between natural killer (NK) and lymphokine-activated killer (LAK) cell functions in the same individual. Neither NK nor LAK cell functions seem to be involved in the immunosuppression associated with chronic Chagas' disease (77).

Autoimmunity

Chagas' disease cardiomyopathy (CCC) is one of the few examples of postinfectious autoimmunity, where *T. cruzi* triggers molecular mimicry-related target organ immune damage. Heart tissue destruction in CCC may be caused by autoimmune recognition of heart tissue by a mononuclear cell infiltrate, often many years after the initial infection. Indirect evidence indicates that there may be cross-reactivity between *T. cruzi* and cardiac tissue. There is also evidence for immune system recognition of cardiac myosin in CCC; the presence of an anti-cardiac myosin-cross-reactive *T. cruzi* antigen is suspected as the cause. Studies demonstrate sequence homology to a recombinant *T. cruzi* protein (B13) in several positions of cardiac myosin heavy chain. This recognition of a heart-specific *T. cruzi* cross-reactive epitope in close association with the presence of chronic heart lesions suggests the involvement of cross-reactivity between cardiac myosin and B13 in the pathogenesis of CCC (14, 38). It has been proposed that phagocytic removal of infected apoptotic cardiomyocytes, combined with signaling through innate immune receptors, may be required to initiate immune responses that damage the heart (21).

Studies demonstrate the presence of antibody to myelin basic protein in the serum of mice chronically infected with *T. cruzi*. Studies of the overlapping peptides from the myelin basic protein identified two regions responsible for the

cross-reactivity with *T. cruzi* (3). This may provide further evidence to help explain why chronic Chagas' disease is characterized by inflammatory infiltrates in myocardial and nervous tissues, with virtually no demonstrable parasites.

Another study suggests that fraction IV-*T. cruzi* (parasite antigen acidic fraction) and sciatic nerve components have some epitopes, possibly carbohydrate, in common. Thus, infection in patients with Chagas' disease could override tolerance to self components and lead to autoimmunity (29).

The scarcity of parasites in the chronic phase of the disease contrasts with the severe cardiac pathology seen in approximately 30% of chronically infected patients. Antigen-specific and non-antigen-specific mechanisms have been suggested to explain T- and B-cell activation leading to autoimmunity. However, the issue of autoimmunity versus parasite persistence as the cause of Chagas' disease pathology continues to be hotly debated.

Malaria

Human malaria is caused by infection with any of four species of *Plasmodium*, with *Plasmodium falciparum* being the most pathogenic. The other three species are *P. vivax*, *P. ovale*, and *P. malariae*. Symptoms of malaria infections include fever and malaise; however, infections with *P. falciparum* can be fatal. This is particularly true in untreated, nonimmune individuals. Despite the high fatality rate in nonimmune or partially immune individuals, people who live in areas of endemic infection for long periods generally acquire immunity and may be asymptomatic or have very mild symptoms. Why and how this slow development of immunity occurs is not completely understood, particularly when reviewing the very complex life cycle of these organisms.

The vector for malaria is the female anopheline mosquito. When the vector takes a blood meal, sporozoites contained in its salivary glands are discharged into the puncture wound. A surface protein, the circumsporozoite protein, in combination with thrombospondin-related adhesive protein allows recognition of glycosaminoglycans in the liver, thus providing the targeting mechanism that allows the *Plasmodium* sporozoite to reach the correct liver cells. Within an hour, these infective stages are then carried via the blood to the liver, where they penetrate parenchymal cells and begin to grow, thus initiating the preerythrocytic or primary exoerythrocytic cycle. The sporozoites become round or oval and begin dividing repeatedly, resulting in large numbers of exoerythrocytic merozoites that leave the liver and invade the red blood cells (RBCs) (erythrocytic cycle). In *P. vivax* and *P. ovale*, a secondary or dormant schizogony may occur from organisms that remain quiescent in the liver until a later

time (hypnozoites). Merozoite surface proteins facilitate recognition of and adhesion to the RBC.

The situation in which the RBC infection is not eliminated by the immune system or by therapy and the number of RBCs begins to increase again with subsequent clinical symptoms is called a recrudescence. All species may have a recrudescence. The situation in which the erythrocytic infection is eliminated and a relapse occurs because of a new invasion of the RBCs from liver merozoites is called a recurrence or true relapse and theoretically occurs only in *P. vivax* and *P. ovale* infections.

Once the erythrocytes and reticulocytes have been invaded, the parasites grow and feed on hemoglobin. As the nucleus begins to divide, the trophozoite is called a developing schizont. The mature schizont contains merozoites, whose number depends on the species, which are released into the bloodstream and invade RBCs, in which a new cycle of erythrocytic schizogony begins. After several erythrocytic generations, some of the merozoites begin to develop into the male and female gametocytes.

The asexual and sexual forms just described circulate in the bloodstream in infections with three species of *Plasmodium*. However, in *P. falciparum* infections, as the parasite continues to grow, the RBC membrane becomes sticky and the cells tend to adhere to the endothelial lining of the capillaries of the internal organs. Thus, only the ring forms and the gametocytes (occasionally mature schizonts) normally appear in the peripheral blood.

If gametocytes are ingested when the mosquito takes a blood meal, they mature into gametes while in the mosquito gut. The male microgametes undergo nuclear division (exflagellation), in which they break out of the RBC, become motile, and penetrate the female macrogamete; the fertilized stage is then called the zygote. The zygote becomes elongate and motile and is called the ookinete; it migrates to the mosquito midgut, secretes a thin wall, and grows into the oocyst, which extends into the insect's hemocele. Within a few days to 2 weeks, the oocyst matures and hundreds of sporozoites are formed. When the oocyst ruptures, the sporozoites are released into the hemocele and dispersed throughout the body, and some make their way into the salivary glands. When the mosquito next takes a blood meal, the sporozoites are injected with saliva into the host.

Each phase of the life cycle is associated with the expression of many stage- and species-specific proteins, many of which are found within the surface membrane of the parasite. These surface proteins are highly polymorphic and antigenically variable. Two hypotheses have been developed to explain the slow development of immunity: (i) immunity is strain specific, and so the individual would not become immune until exposed to

all the major antigenic variants circulating within the area of endemicity, and (ii) acute malaria causes extreme immunosuppression, which delays the development of protective immunity. Also, antidiarrheal immunity may be very different from antiparasite immunity. Even continuous exposure to malaria parasites rarely produces sterile immunity, and blood-stage parasites can be detected by PCR in all age groups (25). The wide range of malarial surface antigens helps explain why the development of clinical immunity requires years of repeated infections. Two mechanisms contribute to antigenic diversity, one being the genetic nucleotide replacement and recombination and the second being antigenic variation. Since different antigens are expressed during various parts of the life cycle, naturally acquired immunity tends to be stage specific. Both humoral and cellular components are required for naturally acquired immunity. CD4⁺ and CD8⁺ T cells are effective against intracellular liver-stage organisms, while antibodies may interfere with host cell invasion by sporozoites and merozoites. Also, antibodies to variant surface antigens expressed on the RBC surface may facilitate phagocytosis of the infected cells and prevent their adhesion to endothelial receptors.

Apparently, internal antigens are less variable and are partially conserved among different malarial species. When released during the rupture of mature schizonts, these internal antigens appear to stimulate the cytokine cascade, which leads to various symptoms and pathologic changes. (Table 21.12).

Humoral Immunity

Malarial infection leads to production of high levels of TNF and other proinflammatory cytokines; other findings include elevated immunoglobulin production, activation of complement, and redistribution of lymphocytes from the peripheral circulation to the spleen and other organs. Antibodies can confer protection against *P. falciparum* and *P. vivax*; neonates and infants are protected by maternal antibodies and, in clinical treatment trials, by immune serum or purified immunoglobulins. Animal studies involving passive transfer of whole serum or purified IgG can have a dramatic impact on the erythrocytic cycle by extending the prepatent period, reducing the parasitemia, and leading to spontaneous cure.

Levels of antimalarial antibodies in humans increase during childhood, become maximal during early adulthood, and subsequently remain fairly constant. However, there appears to be little correlation between antibody levels and protection against infection or clinical disease. Also, some of the antibodies are not directed against *Plasmodium* organisms. These antibodies may represent the degree of past exposure rather than functional immunity.

Table 21.12 Updated information on immune responses seen in malaria infections

Immune response ^a	Comments ^a	Reference
Parasite antigen-specific IL-10 and antibody responses predict accelerated parasite clearance in <i>P. falciparum</i> malaria	Parasite antigen-specific IL-10-mediated antibody responses may play a role in the control of asexual-stage parasite multiplication	53
<i>P. falciparum</i> -merozoite surface protein 1 antigen (MSP119): induction of small T-cell response (IL-4), significantly increased by addition of IL-2; if IFN- γ , IL-12, or neutralizing anti-IL-4 antibody present, T-cell responses abolished	Recombinant MSP119 is leading malaria vaccine candidate, can prime nonimmune human lymphocytes	27
Correlation of T-cell response and lymphokine profile with RESA peptides of <i>P. falciparum</i> containing a universal T-cell epitope and an immunopotentiator, polytuftsin	Cytokine profile is suggestive of a CD4 ⁺ Th1 type of immune response; ideal for killing intracellular pathogens like plasmodia	44
TNF- α , IL-1 β , IL-6 implicated in pathogenesis of severe <i>P. falciparum</i> malaria; exogenous IL-10 inhibited malarial antigen-induced cytokine production; maximal inhibition when IL-10 used in first 2 h of stimulation of PBMC	TNF- α , IL-1 β , IL-6 produced within 2–4 h of stimulation; IL-10 produced after 8 h; findings suggest that IL-10 counterregulates proinflammatory response to <i>P. falciparum</i> ; severe falciparum malaria may be associated with inadequate negative feedback response by IL-10	36
IFN- γ responses associated with resistance to reinfection with <i>P. falciparum</i> in young African children	Differences in Th1/Th2 cytokine balance may be linked to ability to control parasite multiplication, helping explain marked differences in both susceptibility to infection and clinical presentation	52
PfEMP-1 molecule expressed on surface of RBC infected with trophozoite or early gametocyte parasites; IgG antibodies to PfEMP-1 increased with age, mirroring decline in both prevalence and density of asexual stages and gametocytes in RBCs	Immunity to PfEMP-1 may influence malaria transmission by regulation of gametocyte production; mechanisms may be (i) controlling asexual proliferation and density and (ii) affecting gametocyte maturation	63
Cell-mediated immunity and cytokines involved in pathogenesis of malaria; MM and CM cases in children monitored	Both groups (MM, CM) had significantly higher levels of IL-6, IL-10, and TNF- α than did controls; 24 h after admission, IL-10 and IL-6 levels much higher in CM patients; findings suggest activation of monocyte-macrophage system during early stage of clinical malaria	5

^a CM, cerebral *P. falciparum* malaria; PBMC, peripheral blood mononuclear cells; MM, mild *P. falciparum* malaria; PfEMP-1, *P. falciparum* erythrocyte membrane protein 1; RESA, ring-infected erythrocyte surface antigen.

Cellular Immunity

Animal studies indicate that T-cell-dependent immune mechanisms are required for the development of effective immunity. Although animal model results vary and may not always mimic human immune responses, it does appear that the human antimalarial response is both T-cell dependent and independent (47).

In the erythrocytic portion of the parasite life cycle, T cells are thought to serve at least two functions in immunity: (i) assisting in antibody production and (ii) producing cytokines. The role of cytokines in malaria is very complex; they affect parasite growth and clearance, and they activate macrophages to engulf infected RBCs and to kill the malarial parasites. Elevated concentrations of TNF, IL-6, and soluble TNF receptors have been found in serum in patients with severe *P. falciparum* infections.

TNF induces nitric oxide (NO) production; NO definitely plays protective roles in malaria: (i) it acts as

a relaxing factor; (ii) it can downregulate cell adhesion molecules; (iii) it can reduce leukocyte-endothelial cell adherence; (iv) it can scavenge free oxygen radicals; (v) its inhibition can cause endothelial cell alterations, such as albumin leakage and platelet deposition; and (vi) it can reduce platelet aggregation and adhesion to endothelium (34). The role of NO in pathogenesis is somewhat less clear. It is possible that NO can mediate early changes in cerebral malaria, such as neurotransmission disturbances, but NO is probably not involved in the actual process of neurovascular damage.

Studies suggest that a systemic, excessive production of TNF, not compensated for by TNF receptors or a hyperproduction affecting vulnerable sites such as the brain, may exacerbate the disease and lead to vascular abnormalities and life-threatening malaria. On the other hand, TNF produced within the context of a specific immune response may be the major protective cytokine

in malaria infections. This demonstrates the dual role of this particular cytokine (43).

Although many of the published research reports indicate that a number of monokines and lymphokines are released during acute malaria infections, interpretation of the relevance of cytokine levels may be somewhat misleading (68). Summary information related to the elimination of infected RBCs and mechanisms by which the parasite evades the host immune system can be seen in Table 21.13.

Immunosuppression

It has been well documented that acute malaria infections lead to a decrease in host immune system functionality. These patients have been described as being temporarily immunosuppressed. Direct evidence for this decreased immune system capability has been summarized by Riley et al. (67) and includes increased susceptibility to bacterial infections, reactivation of latent viral infections, and diminished response to some vaccines in children. Indirect evidence is that children protected by chemoprophylaxis for malaria are less susceptible to other infections and tend to respond better to routine vaccinations (67). Although this evidence indicates a lowered immunocompetency level in patients with malaria, it is not known exactly which factors influence this change. It may result directly from the level of parasitemia or from the overall impact of a febrile illness, such as malaria.

During acute malaria infections, there is a decrease in the response to parasite antigens. This may be due to immunosuppression, discussed above, or may just indicate a

lack of “priming of the system” in patients with no prior exposure to the organism. Therefore, increased immune responses after cure may be due to decreased immunosuppression or increased levels of preexisting immune responses.

Several factors have been described as virulence factors with *P. falciparum*; however, formal documentation that these characteristics are always associated with virulence and significantly more likely to cause severe disease is not abundant (82). These factors include the following: (i) the multiplication capacity in which the biomass of parasites may outstrip host defense mechanisms; (ii) the RBC selectivity limiting the overall number of infected RBCs (however, this is not a big factor for *P. falciparum*); (iii) the cytoadherence and rosetting ability where all four species can cause rosetting but only *P. falciparum* can cause cytoadherence, which is thought to be linked to cerebral malaria; (iv) the potential to release cytokines; (v) antigenicity (those not recognized by the host will have an advantage); and (vi) antimalarial drug resistance, with a great deal of selective pressure against drug-sensitive parasites (82).

Numerous studies seem to emphasize that the host immune system has difficulty in controlling the infection; many unusual host responses have been described. These unusual responses may be due to host immune system overreaction, leading to inappropriate responses. The difference between protective immunity and pathology is a very delicate balance and one in which specific mechanisms are difficult to clarify (65). Specific immunopathologic complications of malaria infection are listed in Table 21.14.

Table 21.13 Mechanisms of infected red blood cell elimination and evasion of the host immune system in *P. falciparum* infections^a

Mechanism	Occurrence in <i>P. falciparum</i> infection
Infected RBC elimination	
Opsonization	Yes
Antibody-dependent cell-mediated toxicity	Yes
NK cell activity	Yes
Cytotoxic T-cell activity	No
Evasion of host immune system	
Infected RBC knob-like membrane changes	Yes
Infected RBC surface antigenic changes	
Modified host antigens	Yes
Parasite-derived antigens	Yes
Clonal antigenic variation	Yes
Cytoadherence	
Endothelial	Yes
Autoagglutination	Yes
Rosetting of both infected and normal RBCs	Yes
Upregulation of host ligands	Yes

^a Data from references 2 and 82.

Table 21.14 Immunopathological complications of malaria infection^a

Pathology	Suspected mechanism ^b	Comments ^b
Hypergammaglobulinemia	Antigen-induced cytokine production (IL-6); antigenic variation; polyclonal activation	IL-6 from fibroblasts, macrophages, and tumor cells; increases synthesis and secretions of immunoglobulins by B cells; most antibodies not directed against malaria antigens; common feature of antigenic variation is presence of successive peaks of infection, each new peak being antigenically different from the previous one; partial loss of suppressor mechanisms coupled with normal CD4 helper/inducer activity may result in high levels of immunoglobulin in serum (characteristic of people living in areas of endemic malarial infection)
Immunosuppression	Macrophage dysfunction; antigenic competition; structural disruption of germinal centers; disruption of spleen function; polyclonal activation and immune system “exhaustion”	May be due to suppressive effect of malarial pigment ingested; defects in monocyte and neutrophil chemotaxis, reduced monocyte phagocytic function
Nephrotic syndrome	Immune complex deposition; autoimmunity	In nephrotic syndrome associated with <i>P. malariae</i> , malaria antigen and immune complexes can be eluted from the kidneys
Autoimmunity	Autoantibodies; antierythrocyte antibodies; dyserythropoiesis; excessive erythrophagocytosis	Defective IL-12 production in early course of infection may result in fatal anemia; uninfected RBCs destruction occurs through phagocytosis of RBCs bound to merozoites killed as a result of malaria paroxysms (thus, dyserythropoiesis may play a minimal role in anemia); hemolysis is prime cause of anemia, although destruction of parasitized RBCs is not the sole cause of hemolytic process; bone marrow suppression may be insignificant, but preexisting iron deficiency aggravates the severity of anemia; immune recognition of “self” or “modified self” RBC antigens by B or T lymphocytes may occur
Thrombocytopenia	Excessive removal of platelets; coating of platelets with malaria antigen	May also be due to platelet inactivation; increased platelet turnover; platelet-bound antibody controversial
Hyperactive malarial splenomegaly	Genetic predisposition; hypergammaglobulinemia; chronic increase of lymphocyte proliferation	Associated with increased capacity to clear RBCs by Fc receptor-mediated mechanisms and recognition of reduced deformability; spleen may also modulate cytoadherence
Burkitt’s lymphoma	Coendemicity with EBV; polyclonal activation; antigen-induced cytokine production	In patients with <i>P. falciparum</i> malaria, loss of cytotoxic T-cell control of EBV in B cells, possibly due to destruction or dysfunction of a subset of CD4 cells responsible for induction of suppressor/cytotoxic CD8 cells, leads to activation and proliferation of foci of B cells containing EBV; the expanded pool and rapid turnover of these cells may increase the chances of malignant transformation, leading to the genesis of Burkitt’s tumor

^a Adapted from references 16, 37, 39, 41, 57, and 83.

^b EBV, Epstein-Barr virus.

Summary

Although there is evidence for acquired immunity in most protozoan infections, it is often neither fully effective nor protective. As with many organisms, the fact that the host does not die of overwhelming infections supports the concept of parasite immunity.

Since the majority of helminths do not multiply within the host, the host immune system is not faced with an overwhelming infection due to parasite multiplication as seen with protozoal infections. Many helminth life cycles include both larval and adult forms, both of which stimu-

late immune system reactions. However, adult and most larval forms are too large to be destroyed by antibody or by phagocytic cells. In this case, there may be some form of antibody-dependent cell-mediated cytotoxicity in which the parasites become coated with antibodies which bind eosinophils and other cells that destroy the parasites (12). Worm expulsion from the intestine is a CD4⁺ T-cell-mediated event associated with type 2 cytokines. There tends to be less evidence for the implication of eosinophils in host protection. While type 1 or type 2 responses may be key factors following infection with intracellular pro-

Table 21.15 Immune responses to parasites (protozoa and helminths)^a

Parasite or infection	Comments
Protozoa	
Intestinal protozoa <i>E. histolytica</i> , <i>G. lamblia</i>	Most organisms in gastrointestinal tract are nonpathogenic, i.e., do not elicit immune responses <i>Overall immune response:</i> little correlation between antibody levels and protection; repeated invasion of gut wall (amebiasis) relatively common, reinfection rare in hepatic amebiasis
Leishmaniasis Self-healing dermal forms (<i>L. tropica</i> , <i>L. mexicana</i>) Nonhealing visceral forms (<i>L. donovani</i>)	In addition to two general categories, wide spectrum of disease, immune response slow to develop (few months to >1 yr); strong immunity to homologous strain, little antibody produced; visceral infections frequently progress to death; ~25% of patients do recover <i>Overall immune response:</i> cell mediated; parasite killing is intracellular and involves production of toxic metabolites by host cell; no apparent role for antibody or complement
African trypanosomiasis	Successive waves of parasitemia; antigens differ in each wave (antigenic variation); immune response rapid, efficient <i>Overall immune response:</i> agglutination, complement-mediated lysis; cell-mediated responses involved to a lesser degree
American trypanosomiasis	Incubation, 2–3 wk; acute phase, 4–5 wk; chronic phase, '≥20 yr; latent phase/no symptoms, '≥20 yr; spontaneous recovery rare (some individuals die soon after infection) <i>Overall immune response:</i> antibody involved; immunopathology is a very important aspect
Coccidiosis	Self-limiting, immune response not that important in control but very effective against reinfection with homologous organism <i>Overall immune response:</i> antibody-mediated response probably most important; dramatic differences between immunocompetent and immunosuppressed hosts (<i>Cryptosporidium</i> spp.)
Toxoplasmosis	Antibody controls infection but will not eliminate residual organisms; no protection against reinfection, but severity reduced <i>Overall immune response:</i> probably macrophage activation reinforced by antibody; dramatic differences between immunocompetent and immunosuppressed hosts
Malaria	Time span, 2–4 yr (<i>P. vivax</i> , <i>P. ovale</i> , <i>P. falciparum</i>) or lifelong (<i>P. malariae</i>) <i>Overall immune response:</i> no immune response to exoerythrocytic stages; immunity does occur to homologous strains; antibody transfer effective (mother to child); strong correlation between antibody and parasite disappearance; antibodies stage specific; T cells probably serve at least two functions (assisting in antibody production and producing cytokines)
Babesiosis	Pathogenesis not fully understood; lasting immunity after infection, antibody mediated; splenic immune properties unrelated to specific acquired immunity <i>Overall immune response:</i> humoral system-mediated immune response present; impact on host cell-mediated response more important; activated macrophages important; also evidence for some immunosuppression of the host but may not be relevant to pathogenesis
Helminths	
Schistosomiasis	No evidence of spontaneous recovery, can resist infection <i>Overall immune response:</i> primary response against skin penetration by schistosomula, effective against reinfection; six methods have been identified: (i) IgG + neutrophils, (ii) IgG + eosinophils, (iii) IgG + macrophages, (iv) IgG + eosinophils + mast cells, (v) IgE + macrophages, (vi) IgE + eosinophils + mast cells In vitro studies indicate that eosinophils bind to schistosomula, extrude hydrolytic enzymes onto surface of worm, disrupt membrane, allow eosinophils into body and detach tegument; macrophages become involved after damage by eosinophils and neutrophils; mechanisms probably similar in human disease <i>Most important components:</i> hypersensitivity responses are initiated by eggs trapped in the tissues (granulomas and local tissue damage, particularly in the liver); blockage of blood flow can cause portal hypertension and vascular abnormalities
Cestode infections	Adult forms show no evidence of acquired immunity; in larval forms, immunity is slow to develop <i>Overall immune response:</i> larval forms evade immune response; animal studies indicate eosinophils and mast cells involved in damage to cyst, with subsequent encapsulation by various cells including macrophages; early part of immune response may be similar to that seen in schistosomiasis; larval forms exert immunosuppressive effects on the host such as larval secretions inhibiting T-cell proliferative responses and IL-2 production, preventing accumulation of inflammatory cells, and interfering with normal macrophage functions

(continued)

Table 21.15 Immune responses to parasites (protozoa and helminths)^a (continued)

Parasite or infection	Comments
Intestinal nematodes	Strong immune response to all intestinal nematodes (elicited by migrating larvae); self cure (spontaneous elimination of adult worms in gastrointestinal tract); worm infections elicit Th2-subset responses, cytokines generate inflammatory responses (IgE, mast cells, and eosinophils), which are powerful mediators of intestinal inflammation <i>Overall immune response:</i> some evidence of acquired immunity and resistance to reinfection; immune system mechanisms stage specific; possible attachment of antibody and perhaps complement followed by cell attachment which damages cuticle, followed by phagocytosis by macrophages; increased IgE levels seen
Toxocariasis	
Visceral	Prolonged and severe T-cell-dependent eosinophilia; rapid, vigorous, prolonged humoral response; elevated IgG anti-A and anti-B blood group antigen titers present; elevated IgM anti-IgG (rheumatoid factor) titers may occur; elevated IgE titers
Ocular	May not be able to demonstrate circulating anti- <i>Toxocara</i> antibody; eosinophilic granulomas seen in some infections
Filariasis	Both tissue forms and microfilariae can partially evade the immune system, immunity eventually develops; strong immune responses against adult worms responsible not for protection but host pathology <i>Overall immune response:</i> when parasites eliminated from blood, antibody can be found on surface of microfilariae; antibody initiates attack by various cells (IgG, IgE, eosinophils, neutrophils, like other helminth infections); IgE may be important in protection against larval stages but may also contribute to immunopathology via hypersensitivity reactions to adult worms; the T-cell anergy seen in patients heavily infected with lymphatic filariasis or with <i>Onchocerca</i> is probably due to downregulation of Th1 responsiveness by IL-10

^a Data from reference 120.

tozoa or gut-dwelling nematodes, the mechanisms responsible for resistance to any one organism are usually quite specific for the biological characteristics of each.

General comments on a number of different parasites, both protozoan and helminth, are presented in Table 21.15. Although not all inclusive, hopefully this chapter has provided some insight into the complex interactions between parasite and host.

Parasitic organisms infecting humans can be divided into two classes: (i) those that multiply within the host (e.g., protozoa) and (ii) those that mature within the host but never multiply (e.g., most helminths).

Infections caused by pathogenic protozoa, which multiply within the host, are similar to infections caused by bacterial, fungal, or viral pathogens. There is continuous antigenic stimulation of the host immune system as the infection progresses. In these instances, there is often a positive correlation between clinical symptoms and serologic test results.

Some helminths migrate through the body and pass through a number of developmental stages before becoming mature adults. With rare exceptions, these infections have been difficult to confirm serologically, possibly because of a limited antigenic response by the host or failure to use the appropriate antigen in the test system. Most antigens used in serologic procedures are heterogeneous mixtures that are not well defined. The result of using such antigens may be cross-reactions or inadequate sensitivity.

Although parasites and their by-products are immunogenic for the host, the host immune response is usually not protective. Any immunity that does develop is usually species specific or even strain or stage specific.

In certain parasitic infections, the standard diagnostic laboratory procedures may not be sufficient to confirm infection or specimen collection may not be practical or cost-effective. In these circumstances, alternative methods may be helpful; these include antibody, antigen, and nucleic acid detection. In some cases, serologic methods might be clinically indicated and may be very helpful, particularly if a parasitic infection is suspected and routine results are negative. However, even with the most sophisticated technology, few serologic tests for parasitic infections can be used to confirm an infection or predict the disease outcome. Interpretation of test results may also present problems, particularly when one is dealing with patients from areas of endemic infection, who may have higher baseline titers than do patients from other areas, in whom a low titer may actually be significant. Antibody detection generally indicates exposure to the parasite at some time in the past and may not necessarily reflect a current infection. This is particularly true when testing patients who have lived in an area of endemic infection for some time; their current clinical presentation may have no relationship to a positive antibody titer for a particular parasite. Although antibody levels generally decline over a period of months to years,

serologic test results neither confirm nor rule out current infection or cure.

However, a positive serologic titer to a particular parasite in a patient who has had no previous exposure to the organism is clinically relevant and probably indicates recent exposure. The importance of a complete history, including both residence and travel information, is critical for accurate interpretation of serologic test results. Specific reagents available for serologic diagnostic testing are listed in Tables 22.1 and 22.2.

Although serologic test procedures have been available for many years, they are not routinely offered by most clinical laboratories for the reasons mentioned above (sensitivity, specificity, and interpretation). Standard techniques that have been used include complement fixation (CF), indirect hemagglutination (IHA), indirect fluorescent antibody (IFA), soluble-antigen fluorescent antibody, bentonite flocculation, latex agglutination (LA), double diffusion, counterimmunoelectrophoresis (CIE), immunoelectrophoresis, radioimmunoassay, and intradermal tests. Excellent reviews of these procedures, the rationale for their use, and their advantages and limitations are provided in references 49 and 91.

During the past few years, changes in the availability of certain tests have occurred, both at the Centers for Disease Control and Prevention (CDC) and at some private laboratories. The currently available antibody and antigen detection tests are listed in Table 22.1. A number of antibody and/or antigen detection tests have been developed in the research laboratory but are not yet available commercially; these include tests for *Ancylostoma caninum*, *Angiostrongylus*, *Anisakis*, *Baylisascaris*, *Gnathostoma*, microsporidia, *Opisthorchis*, and *Trypanosoma brucei* (91). Although PCR tests have been developed for most human parasites, they are generally available only through various research laboratories. Also, the only probe test currently available for parasitic infections is for the detection of *Trichomonas vaginalis*. However, as the costs of these tests decrease and automation of the various steps is developed, there will be more interest in incorporating these methods into the routine diagnostic laboratory. CDC offers a number of serologic test procedures for diagnostic purposes, some of which are not available elsewhere. Because regulations about submission of specimens may vary from state to state, each laboratory should check with its own county or state department of public health for the appropriate

Table 22.1 Serologic, antigen, and probe tests used in the diagnosis of parasitic infections

Disease	Routine antibody test(s) ^a	Antigen or probe test(s)
Protozoa		
Amebiasis	EIA	EIA, Rapid
Babesiosis	IFA	
Chagas' disease	EIA, IFA	
Cryptosporidiosis		DFA, EIA, IFA, Rapid
Giardiasis		DFA, EIA, Rapid
Leishmaniasis	IFA, EIA	
Malaria	IFA	Rapid
Microsporidiosis		IFA ^b
Toxoplasmosis	EIA, IFA, LA	
Trichomoniasis		DFA, LA, DNA probe
Helminths

General guidelines for specimen collection can be seen in Table 22.3.

Progress has been made in the development and application of molecular methods for diagnostic purposes, including the use of purified or recombinant antigens and nucleic acid probes. The detection of parasite-specific antigen is more indicative of current disease. Many of the assays were originally developed with polyclonal antibodies which were targeted to unpurified antigens

that markedly decreased the sensitivity and specificity of the tests. Immunoassays are generally simple to perform and allow a large number of tests to be performed at one time, thereby reducing overall costs. A major disadvantage of detection of antigens in stool specimens is that the method can detect only one or two pathogens at a time. One still must perform a routine ova and parasite examination to detect other parasitic pathogens. The current commercially available antigen tests have excellent sensitivity and specificity compared with routine microscopy (Tables 22.1 and 22.4).

Protozoal Infections

Amebiasis

The causative agent of amebiasis, *Entamoeba histolytica*, is found throughout the world and is a major infectious disease in developing countries. Although this parasite is considered mainly a cause of diarrhea, the trophozoite stage can readily invade tissues, resulting in the development of extraintestinal disease.

The diagnosis of infection with *E. histolytica*/*E. dispar* is usually based on finding either trophozoite or cyst stages

Table 22.3 Specimen collection and shipment for antibody and antigen detection tests

Type of test requested	Collection	Shipment
Antibody detection		
Most parasites	Serum or plasma acceptable	All specimens can be shipped at room temperature to arrive within several days; if specimen is small (<1.0 ml), shipment with dry ice is recommended to prevent specimen evaporating during shipment; in general, acute- and convalescent-phase sera are not required; not all laboratories are equipped to perform testing on eye fluids or CSF; advisable to call to confirm availability if other than CDC
Toxocariasis, toxoplasmosis	Aqueous and vitreous eye fluids accompanied by serum	
Central nervous system infections (cysticercosis, toxoplasmosis)	CSF accompanied by serum	
Antigen detection		
Fresh or formalinized stool	Routine stool collection vials	Some diagnostic kits require fresh stool; advisable to check with the laboratory prior to specimen submission

in the stool. However, unless the trophozoites contain ingested red blood cells (RBCs), morphologic differentiation between pathogenic *E. histolytica* and nonpathogenic *E. dispar* is not possible. Antigen detection may be helpful as an adjunct to routine microscopy, either for detection of the *E. histolytica/E. dispar* group or for detection of pathogenic *E. histolytica*. In extraintestinal amebiasis, one may or may not find organisms in the stool. The diagnosis of extraintestinal amebiasis depends largely on serologic tests.

The discovery that there are two distinct but morphologically identical species of *Entamoeba* infecting humans is important. *E. dispar* is associated with the asymptomatic carrier state and is the most prevalent species, whereas *E. histolytica* is the pathogenic form capable of invading tissue and causing symptomatic disease. Through the use of RNA and DNA probes, the genetic difference between these two species has been substantiated. At present, when a form resembling *E. histolytica* is detected in fecal material, it is not possible to differentiate it from *E. dispar* unless the trophozoite contains ingested RBCs.

Antibody Detection. If immunoglobulin G (IgG) antibodies specific to *E. histolytica* are detected, tissue invasion has occurred and may represent past or present disease. Serum antibodies can be detected in 85 to 95% or more of the patients with invasive disease. In newborns, maternal antibody disappears within 3 months, and persistence of antibody after this time may indicate active extraintestinal disease.

The most commonly used serologic tests are IHA, IFA, CF, enzyme-linked immunosorbent assay (ELISA), LA, CIE, and immunodiffusion (ID). CF tests have not been widely used because of nonspecific and variable results. IHA and LA appear to detect the same antibody. Although ELISA and IHA are two of the more sensitive tests, antibody titers persist for years, making interpretation difficult in certain patients. ELISA and IHA are useful for epidemiologic surveys. IFA and ID not only are sensitive tests but also have high positive predictive values.

After successful therapy, titers in many of the patients decrease, allowing physicians to monitor the therapeutic response. Although tests for the detection of IgM antibodies specific for *E. histolytica* have been reported, their clinical usefulness is questionable because of the lack of sensitivity. Many of the current tests use crude trophozoite extracts, whereas a few use recombinant proteins (77).

IHA has for many years been the standard for the diagnosis of extraintestinal amebiasis; titers of $\geq 1:256$ are seen in 95% of patients with extraintestinal amebiasis, 70% of patients with active intestinal disease, and 10% of asymptomatic cyst passers. Unfortunately, titers can persist for many years after successful therapy, and so the presence of a titer does not automatically indicate active disease. However, false-positive results at titers of $>1:256$ rarely occur. The sensitivity of detection of specific antibodies to *E. histolytica* in serum is reported to be near 100%, which is promising for diagnosis of amebic liver abscess (ALA) (85). Serum anti-lectin IgG antibodies could be present within 1 week after the onset of symptoms in patients with amebic colitis and ALA, with a value over 95%. In most laboratories, EIA has replaced IFA; it is equally sensitive and specific.

Recombinant proteins such as the 170-kDa subunit of the galactose-inhibitable adherence lectin have been used to detect serum antibodies in more than 95% of patients with ALA. PCR and DNA hybridization assays have been used to detect specific gene sequences related to pathogenic *E. histolytica*; however, none are commercially available at this time.

Antigen Detection. Antigen-based fecal immunoassays have several significant advantages over other methods currently used for diagnosis of amebiasis: (i) some of the assays differentiate *E. histolytica* from *E. dispar*; (ii) they have excellent sensitivity and specificity; (iii) they are readily usable by most laboratory personnel; and (iv) these assays have potential use as screening tools in situations such as waterborne outbreaks. Because there are distinct genetic differences between *E. dispar* and *E. histolytica*,

commercial kits have been developed to detect their presence and differentiate them in clinical samples (Table 22.4). However, current antigen detection tests require the examination of fresh or frozen (not preserved) stool specimens, while many laboratories have switched to stool collection methods using various preservatives.

Other specimens in which amebic antigens have been detected include saliva, serum, and abscess fluid. Using ELISA, the adherence lectin antigen has been detected in saliva samples of ALA patients. This assay was found to be 22% sensitive and 97.4% specific. Amebic antigen in pus specimens from ALA patients was detected by ELISA (85).

A coagglutination test for the detection of circulating antigen in sera from patients with ALA has been reported (50). This is a simple and economical slide agglutination test. In patients with ALA, 45 (90%) of 50 sera were positive by the coagglutination test, while none of the 25 control sera were positive. However, two false-positive results were seen with two sera from patients with other parasitic and miscellaneous infection controls. Although this test is not yet commercially available, it could be used as a sensitive and specific rapid slide agglutination test for the presence of amebic antigen in the sera; it would also be useful in a routine clinical laboratory setting.

Babesiosis

Definitive diagnosis of babesiosis may be difficult because of the small number of infected RBCs, or the inability to discriminate between *Plasmodium falciparum* and *Babesia* spp. Babesiosis is transmitted by ticks, which can also transmit *Borrelia burgdorferi* and *Ehrlichia* spp. There are reports of coinfection with these three disease-causing agents (58). The serologic response to acute infection is marked by a rise in the titer to $\geq 1:1,024$ during the first few weeks followed by a gradual decline to 1:16 to 1:256 over a period of 6 months. Infections caused by a strain of *Babesia* found in the western part of the United States may not yield a diagnostic titer (69) and would represent a false-negative result. When tested for babesiosis by IFA, patients infected with malaria have been noted to yield a serologic cross-reaction, generally of low titer; however, the test is 100% specific for patients with other tick-borne infections or patients with no exposure to the organism. PCR has also been used to detect infections (65). Despite the present unavailability of commercially available screening assays, some form of serologic and nucleic acid testing for *Babesia* spp. may be justified. Assuming that interactions between humans and ticks will probably increase in the future, it is likely that both new and extant tick-borne agents pose potential threats to transfusion safety (40).

Chagas' Disease

Trypanosoma cruzi infects millions of people in Central and South America and is a significant public health problem there. Screening of blood donors in areas where Chagas' disease is endemic is very important. In addition, donor centers are concerned about contamination of the blood supply when donors are migrant workers or immigrants who resided in areas where infection is endemic. Definitive diagnosis depends on demonstration of the parasite in blood or tissues. However, examination of blood may be helpful only during the initial acute disease or during chronic exacerbation. During chronic Chagas' disease, serologic testing may be the only method of detecting the infection.

Antibody Testing. Serologic tests used for the diagnosis of Chagas' disease include CF (Guerreiro-Machado test), IFA, IHA, ELISA, and agglutination. Cross-reactions with low titers have been noted with leishmaniasis, infectious mononucleosis, lepromatous leprosy, pemphigus foliaceus, and *Trypanosoma rangeli* infections.

Although the IFA test is more sensitive than the CF test, the CF test is more specific. ELISA kits which use crude antigens have sensitivities and specificities similar to those of IFA. Use of synthetic peptides and recombinant antigens has improved the sensitivity and specificity of these diagnostic techniques (53, 64). Tri- and tetrapeptides, representing immunodominant epitopes of *T. cruzi*, have been used in the ELISA format to detect serum antibodies. These tests showed much higher rates of sensitivity and specificity and may serve as excellent alternatives to lysate for detection of anti-*T. cruzi* antibodies, as required for developing blood-screening assays (11, 43). Recombinant antigen-based assays have been used for the detection of IgM and IgA antibodies in congenital Chagas' disease and for the evaluation of therapy (56).

In one study to determine the prevalence of Chagas' disease among donors in five Mexican blood banks, two commercial serologic assays for Chagas' disease, the Abbott Chagas EIA and the Meridian Chagas' IgG ELISA, were tested. It is obvious from the data that transfusion-associated transmission of *T. cruzi* is occurring in the study areas. Serologic testing of blood donors for Chagas' disease should be performed there and in the rest of Mexico. However, the two screening assays evaluated may lack the accuracy necessary for blood donor testing when used as suggested by the manufacturers (52).

Routine blood donor screening for *T. cruzi* with a single test results in unacceptable numbers of false-negative samples in areas of highly endemic infection or in at-risk population groups. Adding a second test seems mandatory, but

selection depends on local costs and feasibility (67). Because of the risk of transfusion-related infections and the lack of adequate screening tests to detect *T. cruzi*-positive donors, PCR may become the test of choice for screening (30).

Antigen Testing. Circulating-antigen detection methods have been used to detect recently acquired and congenital infections. PCR has greater sensitivity and specificity than routine methods for the diagnosis of Chagas' disease and can detect as few as one trypomastigote per 20 ml of blood (7). PCR has been very useful in diagnosing acute and chronic Chagas' disease and in monitoring therapy (48, 92).

Cryptosporidiosis

In addition to waterborne outbreaks, *Cryptosporidium* infections commonly occur in pediatric and immunocompromised individuals. Serologic tests for the diagnosis of this infection have not been useful; however, an immunoblot assay has shown specific antigen-antibody banding patterns in individuals presumed to be infected. Using the immunoblot assay as the "gold standard," new ELISAs have been shown to be more specific and, with the 27-kDa antigen ELISA, more sensitive than the crude oocyst antigen ELISA currently being used (68). Unfortunately, these reagents are not readily available. Detection of the organism in stool specimens relies on the use of special staining techniques or fecal immunoassays. Permanent stains normally used in ova and parasite examinations do not adequately stain *Cryptosporidium* spp. A number of commercially available immunoassay kits are available and are more sensitive and specific than routine microscopic examination (32–36) (Table 22.4). Stool specimens may be fresh, frozen, or fixed; however, polyvinyl alcohol-fixed specimens are usually unacceptable for use in the fecal immunoassays.

Cyclosporiasis

Currently, there are no immunodiagnostic tests available for cyclosporiasis. However, water concentrates have been subjected to community DNA extraction followed by PCR amplification, PCR sequencing, and computer database homology comparison for the detection of *Cyclospora cayetanensis* (24).

Giardiasis

Giardia lamblia can cause chronic diarrhea and malabsorption, especially in children. The organism is one of the most easily recognized parasites when detected in the stool; however, variability in the concentration of organisms in the stool makes this infection difficult to diagnose.

Antibody Detection. Serum antibodies to *G. lamblia* have been detected in infected patients; however, because of the lack of sensitivity, they cannot be recommended for diagnosis. After successful therapy, antibodies can be detected for as long as 15 months. Studies show intriguing associations between seroprevalence, outbreak-related laboratory serologic data, and patterns of parasite contamination of drinking water. However, additional studies are required to validate the serologic approach to risk assessment of waterborne parasitic infections at a community level (45).

Antigen Detection. Antigen detection in stool, duodenal fluids, and serum by DFA, IFA, ELISA, and immunoblotting methods has been reported (32–36). These tests are reliable and as sensitive as routine ova and parasite examinations. Commercial immunoassay (Table 22.4) kits are readily available. Users will have to evaluate which kit will be most useful for their own laboratories (19). Some of the methods may require fresh specimens, and stools fixed in preservatives may not be suitable. Also, some of the kits may not detect both trophozoites and cysts of *G. lamblia* but may be selective for only one life cycle stage. PCR and DNA probes have been tried on stool specimens but have had limited success because of difficulty encountered with sample preparation and lack of sensitivity.

Leishmaniasis

Leishmania spp. are obligate intracellular parasites that are transmitted to the mammalian host by the bites of infected sand flies. Leishmaniasis is mainly a zoonosis, although in certain areas of the world there is primarily human-vector-human transmission. The World Health Organization estimates that 1.5 million cases of cutaneous leishmaniasis (CL) and 500,000 cases of visceral leishmaniasis (VL) occur every year in 82 countries. Estimates indicate that approximately 350 million people are at risk for acquiring leishmaniasis, with 12 million currently infected.

Leishmaniasis refers to a diverse group of diseases, with the spectrum of disease depending on the infecting species. Disease syndromes range from self-healing cutaneous lesions to debilitating mucocutaneous infections to subclinical viscerotropic dissemination to fatal visceral involvement. Since disease presentations vary considerably, a well-defined classification system based on clinical findings is difficult and sometimes confusing. With recent outbreaks in many areas of the world, including Brazil, India, Italy, Spain, Sudan, and Kenya, leishmaniasis has become more widely recognized as an important emerging infectious disease in many developed as well as underdeveloped countries.

The taxonomy of *Leishmania* spp. is controversial and reflects the development of multiple parameters on which classification is based. Previously, organisms were classified based on the clinical disease picture and geographic locations; with the development of criteria based on biochemical and genetic data, the taxonomic groupings no longer coincide with recognized disease entities.

Antibody Detection. A number of serologic diagnostic methods have been developed worldwide, although they are not widely available. In general, sensitivities are >90% but specificities are lower. False-positive results can be seen with other infectious diseases, following treatment for VL where antibodies persist for months, and in some asymptomatic patients. There are currently four tests in use, direct agglutination (DA), IFA, CIE, and ELISA. DA appears to be the best choice as a diagnostic tool, is very specific, and does not require expensive equipment or reagents. However, patients may still have positive sera for 1.5 to 5 years after treatment (61). DA has also been adapted to filter paper sampling, and the filter paper eluates compare well with their homologous sera and correlate strongly with antibody titers. However, newer studies using ELISA formats indicate excellent sensitivity and specificity and may be very helpful in early infections.

Currently, IFA is used to detect antibodies to *Leishmania* spp. but cannot differentiate among the various species. However, it can differentiate leishmaniasis from other similar diseases, although some cross-reactivity occurs with *T. cruzi*, the cause of Chagas' disease. Sensitivity is excellent for VL (>90%) but much less so for CL and mucocutaneous leishmaniasis. The humoral response in patients coinfecting with human immunodeficiency virus and *Leishmania* is much lower than that in immunocompetent patients; the immunoblot method appears to be sensitive, noninvasive, and specific for the diagnosis of VL in immunocompromised patients (74).

A previously described ELISA that detects patient antibodies reactive with the recombinant *Leishmania* protein K39 (rK39) has been modified to confirm suspected kala azar and to detect asymptomatic infection in a community study in Bangladesh. The sensitivity and specificity of the modified ELISA for kala azar were 97.0% and 98.9%, respectively, for sera from the study population (54).

Antigenic properties of a chimeric recombinant antigen have been evaluated by indirect ELISA using a panel of human and canine sera previously characterized by parasitologic and/or serologic techniques. Chimeric ELISA showed 99% specificity in both human and canine control groups, while the sensitivity was higher in canine VL than in human VL. Results suggest the potential use of

this new antigen for routine serodiagnosis of VL in both human and canine hosts (12).

Molecular detection methods are available in the research setting but are not yet available commercially. Detection of anti-K39 by immunochromatographic strip testing is a rapid and noninvasive method of diagnosing VL (kala azar), has excellent sensitivity (100%) and specificity (98%), and is well suited for use in field conditions (84). However, not all results using the rapid immunochromatographic strip are as promising (47). The K39 strip test is ideal for rapid and reliable field diagnosis of VL. The test has high sensitivity and specificity, but it remains positive up to 3 years after treatment.

Post-kala azar dermal leishmaniasis (PKDL) is a dermal complication of kala azar. Diagnosis of PKDL is difficult due to the low parasite burden in the lesions. The DA test was compared with those of the rK39 strip test. The sensitivities of the DA test for antileishmanial antibody detection, based on promastigote and amastigote antigens at a cutoff titer of 1:800, were 98.5% and 100%, respectively, with corresponding specificities of 96.5% and 100%. The DA test could correctly detect 100% of polymorphic cases and 95.4% of macular PKDL cases. In comparison, the rK39 strip test was able to correctly diagnose 95.6% of polymorphic and 86.0% of macular PKDL cases. A DA test based on axenic amastigote antigen provided 100% sensitivity and specificity, making it particularly useful for macular PKDL cases, which are often missed by the rK39 strip test. Thus, the DA test is simple, reliable, and inexpensive for PKDL diagnosis and has potential applicability in field conditions (79).

Antigen Detection. Diagnosis of VL is usually confirmed by demonstration of organisms in tissue smears. However, obtaining the specimens may be difficult. Antibody-based diagnostics are limited by their inability to predict active disease. A new LA test (KAtex), which detects parasite antigen in freshly voided and boiled urine, has been evaluated for use with VL patients before and after treatment. KAtex appears to be a promising test, which in this simplified and improved format could be useful in the diagnosis of VL (83). Antigen detection in urine by KAtex is appropriate for primary diagnosis of VL, for monitoring the efficacy of treatment, and for detection of subclinical infection (72).

Circulating antigens in 35 serum samples from patients with VL were successfully identified using dot ELISA, giving 100% sensitivity. With the exception of serum samples from patients infected with *Plasmodium vivax*, which has shown cross-reactivity with *Leishmania donovani* antigens, the test appeared to be specific for the detection of circulating leishmanial antigens (8).

Malaria

Malaria is known to infect more than 250 million individuals throughout the world and kills more than 1 million people a year, most of whom are children. The vector for malaria is the female anopheline mosquito. When the vector takes a blood meal, sporozoites contained in the salivary glands of the mosquito are discharged into the puncture wound. Within an hour, these infective stages are carried via the blood to the liver, where they penetrate parenchymal cells and begin to grow, thus initiating the preerythrocytic or primary exoerythrocytic cycle. The sporozoites become round or oval and begin dividing repeatedly. This schizogony results in large numbers of exoerythrocytic merozoites. Once these merozoites leave the liver, they invade the RBCs, initiating the erythrocytic cycle. It has been reported that in *P. vivax* and *P. ovale*, a secondary or dormant schizogony may occur from organisms that remain quiescent in the liver until a later time. These resting stages are termed hypnozoites. Delayed schizogony does not occur in *P. falciparum* and probably does not occur in *P. malariae*.

Clinical symptoms of malaria include anemia, splenomegaly, and the classic paroxysm, with its cold stage, fever, and sweats. Although the febrile paroxysms strongly suggest infection, many patients who are seen in medical facilities, particularly in the early stages of the infection, do not exhibit the typical fever pattern. They may have fever or several small, random peaks each day. Since the symptoms associated with malaria are so nonspecific, the diagnosis should be considered in any symptomatic patient with a history of travel to an area where malaria is endemic. The typical paroxysm begins with the cold stage and rigors, which last 1 to 2 h. During the next few hours the patient spikes a high fever and feels very hot, and the skin is warm and dry. The last several hours are characterized by marked sweating and a subsequent drop in body temperature to normal or subnormal.

Giemsa-stained thick and thin blood films have been used to diagnose malaria for many years and have always been considered the "gold standard." However, a number of alternative methods have been developed, including different approaches to microscopy, flow cytometry, biochemical methods, immunoassay, and molecular methods. The aim of these procedures has been to reduce cost, reduce the need for expensive equipment, increase sensitivity, and provide simple, rapid methods that do not require conventional microscopy.

Antibody Detection. Serodiagnosis is not recommended for the diagnosis of malaria except in cases of transfusion reaction, where the parasitemia is so low that malaria transmission via blood transfusion cannot be documented. For a patient with repeated negative blood

smears, serologic testing may be indicated, but the presence of antibody does not correlate with past or present infection.

In regions of low immunity, serologic assays offer an efficient method to identify infectious donors. The recent development of EIAs with improved sensitivity to *P. falciparum* and *P. vivax*, the predominant transfusion threats, has improved the possibility of serologic testing. Although universal serologic screening in regions where malaria is not endemic is not cost-effective, targeted screening of donors identified to be at risk based on travel-based questioning can significantly reduce wastage through reinstatement. Importantly, transfusion safety does not appear to be compromised by this approach, as evidenced by the lack of a documented transmission in France between 1983 and September 2002, where such a strategy has been used since 1976 (76).

Antigen Detection. The substitution of newer, more expensive drugs mandates rapid, accurate, and inexpensive diagnostic procedures so that directed therapy can be provided. A new *P. falciparum* antigen detection system, the ParaSight F test (Becton Dickinson), was found to be very effective in field trials. This procedure is based on an antigen capture approach and has been incorporated in a dipstick format; the entire test takes approximately 10 min. The ParaSight F+V assay improved the ParaSight F test format by incorporating a monoclonal antibody directed against a proprietary *P. vivax*-specific antigen, in addition to the antibody directed against *P. falciparum* histidine-rich protein 2 (HRP-2), which was used in the ParaSight F test. The final ParaSight F+V prototype, evaluated in 1999, had an overall sensitivity for detection of asexual *P. falciparum* parasites of 98%. The sensitivity of the device was 100% for *P. falciparum* densities of >500 parasites/ μ l, with a sensitivity of 83% for parasite densities of \leq 500/ μ l. The specificity for the exclusion of *P. falciparum* was 93%. For *P. vivax*, the overall sensitivity was 87% for the final 1999 prototype. The sensitivities calculated for different levels of *P. vivax* parasitemia were 99% for parasite densities of >5,000/ μ l, 92% for parasite densities of 1,001 to 5,000/ μ l, 94% for parasite densities of 501 to 1,000/ μ l, and 55% for parasite densities of 1 to 500/ μ l. The specificity for the exclusion of *P. vivax* was 87% (29).

The second test that detects HRP-2, the ICT Malaria Pf (AMRAD ICT), is also in the dipstick format. This test appears to perform well and is comparable to the ParaSight F test; however, its false-positive rate appears to be lower. A rapid in vitro immunodiagnostic test, the NOW ICT Malaria Pf/Pv test kit, has been used for the detection of circulating *P. falciparum* (Pf) and *P. vivax* (Pv) antigens in whole blood. Although there was full concordance between the results of blood smear mi-

croscopy and rapid antigen testing, these techniques are most useful when there is a discrepancy with microscopy findings. Accurate and rapid identification of parasites, particularly in cases of mixed *P. falciparum* and *P. vivax* infection, is extremely important for patient management, particularly in regions of chloroquine resistance (10).

The third dipstick format procedure, OptiMAL (Flow Inc.), uses monoclonal antibodies against species-specific parasite lactate dehydrogenase (pLDH). Its sensitivity and specificity appear to be similar to those of the HRP-2 assays, with similar limitations at lower parasitemias. An advantage of this method is its use in follow-up of posttherapy patients to confirm a cure; the test detects only viable parasites. The OptiMAL-IT assay is more sensitive than the ICT Malaria Pf/Pv test for monitoring therapeutic responses after antimalarial therapy since the LDH activity ceases when the malarial parasite dies (44). In a multicenter trial, the sensitivity of the OptiMAL test was 98%; its specificity was 100%, with positive and negative predictive values of 100 and 99%, respectively. Participating hospital physicians and laboratory directors independently reported that the OptiMAL rapid malaria test was accurate, easy to use, and well accepted by the laboratory staff. The overall conclusion was that integration of the OptiMAL rapid malaria test into the U.S. health care infrastructure would provide an important and easy-to-use tool for the timely diagnosis of malaria (62).

Toxoplasmosis

Toxoplasma gondii is capable of infecting a wide range of hosts, including mammals, birds, and reptiles. The first recognized case of human toxoplasmosis was described by Janko, an ophthalmologist, in 1923. The infection can be contracted by ingestion of oocysts from fecal material (animals in the cat family, Felidae), ingestion of tissue cysts from raw or inadequately cooked meat, organ transplantation, transfusions, or transplacental transmission. Human infection occurs primarily through the ingestion of raw or undercooked infected meat.

Infection or colonization by *T. gondii* appears to be common in most parts of the world, particularly where cats are found. In the United States, approximately 30% of adults have been exposed to toxoplasmosis; however, the vast majority of these adults did not have recognizable illness.

Congenitally acquired toxoplasmosis can result in serious and debilitating sequelae, including stillbirths, defects seen at birth, and infections in infants who are frequently asymptomatic at birth. In the latter cases, sequelae of congenital infection may arise later in life, most commonly between the first and third decades (71).

The incidence of congenital toxoplasmosis is virtually unknown and may be greatly underreported. The clinical severity of congenital toxoplasmosis varies considerably with the trimester of pregnancy when the maternal infection was acquired. Infections contracted during the third trimester result in a large number of congenital infections; however, most infants show no sign of disease. Although infections acquired by the mother in the first trimester result in a smaller number of infected infants, sequelae are the most severe, including a number of stillbirths. Recent evidence suggests that most infants with subclinical infection at birth will develop signs or symptoms of disease (chorioretinitis) as they approach adulthood.

The diagnosis of acute *Toxoplasma* infection can be established by the following: isolation of tachyzoites from blood or body fluids; demonstration of tachyzoites in cytologic preparations or tissue sections; lymph node histologic testing; demonstration of cysts in such tissues as the placenta or in the fetus or neonate; antigen detection; or serologic test results. In older children or adults, the isolation of *T. gondii* from tissues may reflect only the presence of cysts. However, depending on the clinical presentation, the isolation of the organism from lymph node tissue may reflect the presence of tachyzoites.

Antibody Detection. Since isolation of the parasite is not practical for most laboratories, serologic tests are routinely used for diagnosis (Tables 22.5 and 22.6). Properly interpreted serologic test results provide excellent supportive evidence for the clinician. Classically, the detection of *Toxoplasma* infections has been based on the detection of IgG and IgM antibodies. Diagnostic reagent comparisons indicate that most are comparable in the detection of anti-*Toxoplasma* IgG but vary considerably in the detection of IgM antibodies. It has been shown that specific IgA antibodies are extremely useful in the diagnosis of congenital and acute toxoplasmosis (71). Another test for detecting acute infection involves the antigen binding avidity of IgG antibodies (55). Because of the large volume of requested serologic tests for the diagnosis of toxoplasmosis, a large variety of tests are available for the detection of antibodies. These include the Sabin-Feldman dye test, CF, IHA, IFA, agglutination, ELISA, and immunoblotting. The tests most commonly used today are IFA and ELISA for the detection of IgG and IgM antibodies and, more recently, IgA antibodies.

Serodiagnosis of acute toxoplasmosis using a recombinant form of the dense granule antigen GRA6-GST in an ELISA for IgG proved to be very useful. For discrimination between the presence and absence of acute toxoplasmosis, the assay reached a specificity of 99.6% in a group of 431 sera (70). Also, the assay showed good intra- and interassay reproducibility; however, it is not yet

commercially available. In another study using recombinant antigens, the approach was effective in distinguishing *T. gondii*-infected from uninfected infants with congenital toxoplasmosis (17).

Individuals should be initially tested for the presence of *Toxoplasma*-specific antibodies to determine their immune system status. A positive IgG titer indicates infection at some point in time. Women who have a positive IgG titer before pregnancy have never been found to transmit *Toxoplasma* infection to the fetus, regardless of the antibody titer. Women who have no demonstrable antibody must be considered at risk for infection. Because the diagnosis of acute toxoplasmosis is usually based on serologic test results and is frequently considered late in the patient's clinical course, serologic titers may have already reached their peak. In these cases, examination of paired sera would be of little benefit and a single high titer may not indicate recent infection, since titers can remain high for years.

In acute and congenital toxoplasmosis, IgA and IgM antibodies are the first to be detected. Normally, IgM and IgA antibodies do not cross the placental barrier, and these antibodies have been used as the hallmark of congenital infection. The IgA and IgM titers continue to rise during the first few weeks of infection and may remain positive for a year or more (71, 91). It is possible that the

IgA and IgM titers will decrease to undetectable levels by 5 or 6 weeks postinfection; however, this is not always the case, and high levels may indicate infection within the past 3 to 5 months (66). In some cases, IgM antibodies may be detected by EIA for as long as 18 months after acute acquired infection. IgM antibody methods have given both false-positive and false-negative results because of the presence of rheumatoid factor, blocking antibody, and the induction of fetal IgM antibodies against maternal immunoglobulin. The IgM test should be performed using a method such as the IgM capture ELISA to minimize nonspecific reactions (91). It is important to remember that all IgM-positive results should be verified by a reference laboratory such as the CDC or the Toxoplasmosis Laboratory, Palo Alto Medical Research Foundation, Palo Alto, Calif.

Generally, the demonstration of either IgA or IgM serum antibody is considered diagnostic; however, the use of cord serum is unreliable because of the possible presence of maternal antibody. Both maternal and infant sera should be monitored at the same time. If both sera are positive, the infant's serum should be retested within 1 to 2 weeks. An infant IgA or IgM titer which is stable or continues to rise is diagnostic of infection. Immunocompromised patients and those with ocular toxoplasmosis may have no demonstrable antibody re-

Table 22.6 Serologic tests for detection of the presence of *Toxoplasma* antibodies^a

Antibody	Interpretation	Comments
IgG		
IgG negative	Patient has not been infected with <i>T. gondii</i>	IgG is the first test to be run in determining patient's immune status
IgG positive	Patient has been infected with <i>T. gondii</i> at some time in the past	If more information is required regarding the time of infection, IgM testing can be performed
IgM		
IgG negative, IgM positive	These results are highly suspicious	Results may represent a false-positive IgM result; redraw in 2 wk and retest both sera
IgG positive, IgM negative	Patient was infected >1 yr ago	
IgG positive, IgM low positive	May represent False-positive result Infection within the last 2 yr New infection	Confirm any positive IgM result at a <i>Toxoplasma</i> reference lab (CDC or Toxoplasmosis Laboratory in Palo Alto, Calif.)
IgG positive, IgM high positive	May represent Infection within last 3–6 mo False-positive result	Confirm any positive IgM result as indicated above

^a Data from reference 91.

sponse. AIDS patients with active toxoplasmosis, including central nervous system disease, generally have no IgM antibodies and a low to moderate level of (or occasionally no) IgG antibodies (57). Early treatment of the infection may considerably delay or reduce the normal host immune response.

Antigen Detection. Tests for the detection of circulating antigen have been used for the diagnosis of infection but have not been widely accepted (39, 71). Studies indicate that detection of some low-molecular-weight antigens is diagnostic of reactivated toxoplasmosis (4). These antigens can be detected even with normal dye test titers, and their detection improves the diagnosis of reactivated disease. They may be the result of the release of bradyzoites from ruptured tissue cysts. Because of the difficulties associated with reliable serologic methods for the diagnosis of toxoplasmosis, other methods such as molecular diagnostics have been used for diagnosis. PCR assays are available primarily in specialized research centers (41, 71). PCR will be a rapid and specific means of detecting the parasite in infected individuals who have failed to mount an immune response and allows for the infection to be detected much earlier in gestation.

A specific antibody and Western blot analyses have been used to demonstrate the presence of a highly reactive antigen of 36 kDa, not only in the extract of *T. gondii* tachyzoites but also in selected sera of women with confirmed laboratory and clinical signs of recent toxoplasmosis. The 36-kDa antigen was purified from *T. gondii* tachyzoites and human serum by using electro-

elution from preparative polyacrylamide gels. An ELISA format for the detection of target *Toxoplasma* antigen (TAG-ELISA) in human serum samples has recently been developed. The TAG-ELISA detected the target antigen in 88% of sera of acutely infected women, with 91% specificity among sera from noninfected women. The detection of 36-kDa *Toxoplasma* circulating antigen in human sera appears to be a promising alternative approach for the laboratory diagnosis of active *T. gondii* infection (5).

Trichomoniasis

The diagnosis of *Trichomonas vaginalis*, a sexually transmitted disease, relies primarily on direct microscopic examinations of wet mounts. Trophozoites can be detected in vaginal secretions, urethral specimens, or spun urine. The sensitivity of the direct wet mounts is low (50 to 85%) and can be improved by culture of the organism. DFA and LA reagents are now commercially available, and both can be used on vaginal swab specimens or fluids (15, 27). The automated Affirm VP Microbial Identification Test system is also available and is being used in physician office settings, clinics, and routine clinical laboratories. Using oligonucleotide probes, the system can detect *T. vaginalis* and *Gardnerella vaginalis* from a single vaginal swab. Sensitivity has been reported as 100% compared with wet preparation examination but only 80% compared with culture. Although there are still limitations for specimen storage conditions and times, one of the benefits is certainly flexibility for laboratories serving large outpatient populations.

Helminth Infections

Cysticercosis

The diagnosis of cysticercosis usually depends on surgical removal of the parasite and microscopic examination for the presence of suckers and hooks on the scolex. Multiple larvae are frequently present, and the presence of cysticerci in the subcutaneous or muscle tissues indicates that the brain is probably also involved. The calcified larvae can be readily seen on X-ray examination. Computed tomography (CT) scans or magnetic resonance imaging (MRI) techniques may reveal the presence of lesions in the brain. Although neurocysticercosis may be suspected, particularly in a patient living in an area of endemicity, the multiple neurologic syndromes and the various clinical presentations make it difficult to confirm the diagnosis, even with CT or MRI techniques. Human cysticercosis caused by *Taenia solium* is an important public health problem in developing nations.

Antibody Detection. Serologic tests used for diagnostic purposes include CF, IHA, IFA, ELISA, immunoblotting, ID, and radioimmunoassay (49, 80). IgG is the predominant Ig detected in patients with cysticercosis; IgA, IgE, and IgM antibodies are of little value in diagnosis and cannot be correlated with the patient's clinical condition. Serodiagnosis of cysticercosis has been a problem because of cross-reactions occurring in patients with coenurus, *Echinococcus*, filariasis, and *T. saginata* infections.

The CDC enzyme-linked immunoelectrotransfer blot (EITB) using purified *T. solium* antigens has been acknowledged by the World Health Organization and the Pan American Health Organization as the immunodiagnostic test of choice for the diagnosis of cysticercosis (90). It is 100% specific and has an extremely high sensitivity. The test employs purified glycoproteins, making it more sensitive than ELISA, and has eliminated the problems with nonspecificity noted above. Both serum and cerebrospinal fluid (CSF) can be used as diagnostic specimens. The test may be more sensitive with serum than CSF; therefore, there is no need to obtain CSF. For patients with multiple cysts (more than two cysticerci), the test has a sensitivity of $\geq 90\%$. Patients with multiple calcified cysts had a seropositivity of 82%, whereas patients with a single parenchymal cyst had a seropositivity of 50 to 70%. Several private laboratories now offer this test, which was previously available only at CDC. Several immunoassay kits are also commercially available (Table 22.2). The clinical tests for the diagnosis of cysticercosis cannot be used to distinguish between present and past infections, nor can they be used to monitor the progress of therapy.

Although the assay of choice for serologic detection of cysticercosis in humans and pigs is EITB, a Western blot assay that relies on the use of seven lentil-lectin-purified glycoproteins (LLGPs) derived from *T. solium* metacestodes, scarcity of native source material and the labor-intensive process of metacestode purification reduce its practicality. EITB antigens have now been reproduced in synthetic forms. Four chemically synthesized antigens were assayed individually using ELISA and Western blotting for immunoreactivity against sera from clinically defined neurocysticercosis patients. The sensitivity and specificity of all four antigens using the ELISA format did not meet the standards set by the LLGP EITB, while the results of the Western blot format were comparable to those of the LLGP EITB (75).

Specific *Taenia crassiceps* and *T. solium* antigenic peptides have been used for the serologic diagnosis of neurocysticercosis (16). Data indicate that the *T. crassiceps* ELISA and the immunoblotting test could be very useful in detecting relevant specific peptides (19 to 13 kDa) for *T. solium*.

Antigen Detection. An ELISA for the detection of antigen secreted by viable *T. solium* metacestodes has been used on pre- and posttreatment CSF samples from Peruvian patients with neurocysticercosis demonstrated by CT and EITB; the sensitivity was 86% (31). There was no difference between antigen levels in CSF taken before or 14 days after therapy. There was a significant positive correlation between antigen levels, the number of live cysts detected by CT, and the EITB results. In contrast, there was a negative correlation with the number of enhancing lesions by CT, supporting the hypothesis that enhancing lesions correspond to a late, dead stage of the parasite. This test approach using antigen specific for viable parasites has great clinical relevance, not only for providing information on the viability of the organisms but also for understanding the pathogenesis of neurocysticercosis before and after therapy.

Antigens and antibodies in sera from humans with epilepsy or taeniasis in an area of Mexico where *T. solium* cysticercosis is endemic have also been evaluated (21). Parasite-specific antigens and antibodies were more common among patients with epilepsy and taeniasis than among the controls. Antigens seemed to be associated with late-onset epilepsy, while the antibodies were associated with subcutaneous nodules. The sensitivities of both tests were low in terms of disease detection; however, the specificity and the positive predictive value of the antigen capture assay were high when used on sera from patients with late-onset epilepsy. Since late-onset epilepsy and neurocysticercosis are associated in areas of endemic infection, antigen capture assays may

provide a reliable method of detecting active cases of neurocysticercosis.

Hydatid Disease

In an area of endemic infection, exposure to sheepdogs, the presence of an enlarged liver, the presence of a palpable mass in the right upper quadrant of the abdomen, expectoration of a salty-tasting fluid with hemoptysis, and a round lesion on chest radiographs all support the presumptive diagnosis of hydatid disease in either the liver or lungs. Hydatid cysts in the liver may be confused with congenital liver cysts, amebic abscess, or hepatic tumors. Pulmonary symptoms may be confused with tuberculosis. Hydatid cysts should be considered in patients with abdominal masses for which there is no clearly defined diagnosis. Many asymptomatic cysts are first discovered after radiologic studies.

Antibody Detection. Immunodiagnostic tests have been very helpful in confirming the diagnosis of echinococcosis caused by *Echinococcus granulosus* (cystic disease) or *E. multilocularis* (alveolar disease). Serum antibodies to *Echinococcus* spp. have been detected by IHA, IFA, ELISA, CF, LA, immunoelectrophoresis, immunoblotting, and ID. The immune response depends on the location and viability of the cyst. Individuals harboring calcified, senescent, or dead cysts often have a negative serologic test result. Liver cysts produce a greater serologic response in the patient than do hyaline or lung cysts, and up to 50% of patients with lung cysts are serologically negative. Cysts in the brain and spleen are also associated with a decreased immune response in the host.

A dipstick assay for the serodiagnosis of human hydatidosis using camel hydatid cyst fluid was compared to EITB and Falcon assay screening test-ELISA (FAST-ELISA). For the diagnosis of hydatidosis, the sensitivity, specificity, and diagnostic accuracy of the dipstick assay and EITB were 100, 91.4, and 95.1% while those of FAST-ELISA were 96.2, 100, and 98.4%, respectively. Since the dipstick assay is easy to perform, has a visually interpreted result within 15 min, and is both sensitive and specific, it could be an acceptable alternative for use in clinical laboratories lacking specialized equipment and the technological expertise needed for EITB and FAST-ELISA (2).

Serologic cross-reactions have been noted in low titers in patients with other parasitic diseases, liver cirrhosis, and collagen diseases (49). A test involving a selected antigen called arc-5 or the 8-kDa antigen has been developed for the specific diagnosis of *Echinococcus* infections. It is recommended that serum be screened by either ELISA or IHA and all positive reactions be confirmed by immunoblotting (91). False-positive reactions with the arc-5

antigen can occur with cysticercosis; however, use of the 8-kDa antigen in the immunoblot assay eliminates this cross-reactivity. Immunoblotting using the 8-kDa antigen provides 99% discrimination between seropositive preoperative cystic hydatid disease cases and cross-reactive noncestode parasitic infections or malignancies.

Cross-reactivity can occur between species. The use of purified *E. multilocularis* antigens with either ELISA or immunoblotting methods has been helpful in differentiating infections caused by the two species (38, 46, 88, 89). Immunoblot tests have been used to monitor the therapy of patients, whereas IHA and ELISA may continue to give positive results for years. Tests for the detection of circulating antigen have been used for diagnosis of infection, but they are not readily available.

Patients with alveolar hydatid disease are usually serology positive when heterologous *E. granulosus* or homologous *E. multilocularis* antigens are used; crude antigens tend to give nonspecific reactions in alveolar disease, as seen with cystic disease. Immunoaffinity-purified *E. multilocularis* antigens (Em2) used in an EIA method give positive results in >95% of cases of alveolar disease. Tests using Em2 are also more useful for monitoring postoperative conditions than for monitoring posttherapy effectiveness.

Antigen Detection. Efforts to standardize and evaluate the LA test as a simple test for the detection of circulating hydatid antigen in serum are under way. The latex particles were sensitized with hyperimmune hydatid antiserum raised in rabbits. The LA test showed a sensitivity of 72%, a specificity of 98%, a positive predictive value of 93%, and a negative predictive value of 91%. This is the first report of use of the LA test for the detection of hydatid antigen in serum in the diagnosis of cystic echinococcosis (23).

Fascioliasis

In *Fasciola hepatica* infections, metacercarial larvae do not cause significant pathologic damage until they begin to migrate through the liver parenchyma. The amount of damage depends on the worm burden of the host. Hyperplasia of the bile ducts occurs, possibly as a result of toxic substances produced by the larvae. Symptoms associated with this migratory phase have included fever, epigastric and right upper quadrant pain, and urticaria, although no eggs are found in the stool until the worms mature, which takes 8 weeks; some patients experience no symptoms.

Once the worms have established themselves in the bile ducts and matured, they cause considerable damage from mechanical irritation and metabolic by-products as

well as obstruction. The degree of pathology depends on the number of flukes penetrating the liver. The infection produces hyperplasia of the biliary epithelium and duct fibrosis with portal or total biliary obstruction. The gallbladder undergoes similar pathologic changes and may even harbor adult worms. Adult worms may reinvade the liver parenchyma, causing abscesses.

Multiple stool examinations may be needed to detect light infections. Eggs may be detected in the stool of individuals who have eaten *F. hepatica*-infected liver, thereby yielding an erroneous laboratory result.

Antibody Detection. Serologic diagnosis using *F. hepatica* excretory-secretory antigens has been successfully used in areas of endemicity to detect patient antibodies. This approach includes both ELISA and EITB testing. Antibodies may be detected within 2 to 4 weeks after infection. Sensitivity for the FAST-ELISA was reported to be 95%, while sensitivity for the immunoblot assay using 12-, 17-, and 63-kDa antigens was 100%. However, there does appear to be some cross-reactivity with patients who have schistosomiasis. Serologic test results can be used to monitor treated patients to ensure successful therapy, after which antibody levels drop to normal within 6 to 12 months. Serologic tests are the tests of choice for the diagnosis of acute and chronic fascioliasis when few eggs can be found in the stool or when large populations are being screened.

An ELISA has been developed based on the detection of serum IgG4 antibodies reactive with *F. hepatica* cathepsin L1 (CL1). In an area of high prevalence of fascioliasis, a highly statistically significant correlation was seen when the recombinant and native proteins were used. The assays showed that 38 (59%) of the individuals tested were seropositive while only 26 were positive for *F. hepatica* eggs in the stool. All patients with egg-negative stools were also serologically negative. Also, there was no cross-reactivity with sera from patients with schistosomiasis, cysticercosis, hydatidosis, or Chagas' disease. This study indicates that recombinant CL1 shows excellent potential for use in the development of a standardized assay for the diagnosis of human fascioliasis (60). Other cysteine proteinases have also been used for the immunodiagnosis of human fascioliasis and have demonstrated excellent results (18, 20).

Immunoblotting studies showed that an 8-kDa protein reacts with sera from humans with fascioliasis but not sera from humans with other trematode infections. This result suggests that the 8-kDa protein of *F. hepatica* is one of the diagnostic antigens in human fascioliasis without cross-reaction and may be very useful in the diagnosis of fascioliasis (51).

Antigen Detection. The detection of coproantigens using an ES78 sandwich ELISA has been used;

coproantigens were detected in all patients with patent infections. The data indicate that this approach is more sensitive than stool examinations for eggs, particularly in early infections (26).

Filariasis

Lymphatic Filariasis

A wide variety of serologic tests have been used for diagnostic and epidemiologic purposes in cases of human filariasis. Except for use in patients not native to the area of endemicity, immunodiagnostic tests are of limited value. Current tests lack both sensitivity and specificity, and most people from the region of endemicity have a positive serologic response. This response may be due to exposure to nonhuman filarial antigens from infected mosquitoes, and filarial antigens may cross-react with antibodies to other parasitic diseases.

Antibody Detection. The immune response of the filaria-specific IgG4 is considerably increased in patients with active filarial infections. The detection of IgG4 antibodies also reduces the cross-reactivity of nonfilarial antibodies. IgG2 production appears to be increased in patients with elephantiasis. Studies also suggest that specific antisheath antibodies are associated with an immunologic resistance mechanism that in the endemic community is expressed with highest prevalence in young individuals before the development of patent microfilaremia. However, antibody tests cannot differentiate past from present infection, nor do they show any correlation between antibodies and worm burden.

In the simple and rapid *Brugia* Rapid (BR) test, an immunochromatographic dipstick is used to detect IgG4 antibodies that are reactive with a recombinant *Brugia malayi* antigen. When sera from 109 individuals with *Brugia* microfilaremias (12 infected with *B. malayi* and 97 infected with *B. timori*) were investigated using the BR test, all were found to be positive. In contrast, all of the 150 sera from individuals with *Onchocerca volvulus* or *Mansonella* infections were found to be negative in BR tests. Some cross-reactions were observed with sera from individuals infected with *Wuchereria bancrofti* (3 of 12 test positive) and *Dirofilaria* (1 of 9 test positive) (28).

A rapid-format, simple, and qualitative flowthrough immunofiltration test has been developed for the identification of total IgG antibodies to recombinant filarial antigen WbSXP-1. This test system employs colloidal gold-protein A reagent as the antibody capture reagent. The sensitivity was 90.8% and 91.4% with brugian and bancroftian microfilaremic patients, respectively. The test showed minimum reactivity with *Loa loa* microfilaria-positive sera

and no reactivity with *Onchocerca*-positive sera. The test was nonreactive with samples from individuals suffering from other parasitic diseases including schistosomiasis, soil-transmitted helminth infections, and protozoan infections, confirming the potential of this test as a diagnostic tool for both brugian and bancroftian lymphatic filariasis (9).

Antigen Detection. Because of the lack of sensitivity in direct-detection methods and problems with obtaining blood specimens within correct time frames, detection of circulating antigens has been used diagnostically. Antigen detection has also been used to monitor therapy. Many of these methods are not yet standardized and are not substitutes for direct-detection methods. Most are not sensitive enough to detect amicrofilaremic individuals who have clinical filariasis.

PCR assays will be a very useful diagnostic tool because they can discriminate between past and present infection and can be used to monitor therapy. In a preliminary evaluation of the diagnostic capability of PCR with diurnally collected sputum from bancroftian filariasis patients, the data were excellent; this approach appears to have excellent potential (1). New approaches for antigen detection also include (i) the ICT card test for serum specimens, (ii) the TropBio ELISA for serum specimens, and (iii) the TropBio ELISA for filter paper specimens; data from all three methods were very promising for their use as diagnostic tools in bancroftian filariasis (63, 78).

Onchocerciasis

The prepatent period of onchocerciasis in humans is 3 to 15 months. Light infections may cause no symptoms, and worms may be free in the tissue; however, in heavy infections, major disease manifestations include dermatitis, onchocercomas (subcutaneous nodules containing adult worms), lymphadenitis, and blindness. Even though there is an inflammatory reaction that causes the formation of a fibrotic capsule (onchocercoma) around the adult worm, the main pathology appears to be directed against the microfilariae.

Antibody Detection. Recombinant antigens for serologic diagnosis can help overcome the problems associated with poor sensitivity and specificity, particularly in areas where other human filarial infections overlap with those caused by *O. volvulus*. A cocktail of recombinant *O. volvulus* antigens for serologic diagnosis with the potential to predict the endemicity of onchocerciasis infection has been developed (14). When a sentinel population of 5- to 15-year-old individuals was used to compare communities, the serologic index was sufficiently sensitive to measure the changes in endemicity that would be required for control programs. However, serologic testing cannot

distinguish between current and past infection and tends to be more important in monitoring specific groups.

It has also been shown that tests based on IgE detection are more specific than those based on IgG detection. However, current tests still lack sensitivity and specificity, and the results do not correlate with past or present infection or with parasite burden.

Antigen Detection. Studies have been reported using recombinant proteins and a dipstick immunobinding assay (DSIA) for the detection of ocular microfilariae, a transblot immunobinding assay (TADA) for the detection of skin microfilariae, and a dot blot immunobinding assay (DIA) for the detection of urinary microfilariae (59). Sensitivities were 100% for DSIA, 82.5% for TADA used on samples of tears, 97% for TADA used on dermal fluids (skin snip), and 96% for DIA used on urine samples.

A recent report discussed the development and evaluation of a dot blot immunobinding assay (DIA-BA) based on the biotin-avidin binding system for the detection of *O. volvulus*-specific antigens in body fluids (87). The biotinylated probes were then used to detect *O. volvulus*-specific antigens initially blotted onto a nitrocellulose membrane. The smallest amount of blotted antigens detectable by the new test is 0.5, 1, 1, and 2 ng in urine, dermal fluid, tears, and serum samples, respectively. The test was 100% sensitive when used with urine and only 54.76% when used with serum from skin-snip-positive subjects. The specificity of the test was 100%, while the dermal fluid specificity was 97.5%. Also, there was a positive correlation between the color intensities on the blot and the skin microfilaria loads of the individuals. The DIA-BA test could be very useful for mass diagnosis of prepatent, low-level, and high-level infections due to *O. volvulus* (87).

Paragonimiasis

Humans become infected with *Paragonimus* spp. by ingesting uncooked crabs or crayfish containing metacercariae. The metacercariae excyst in the duodenum and migrate through the intestinal wall into the abdominal cavity. The larvae migrate around or through the diaphragm into the pleural cavity and the lungs. They mature to adults in the vicinity of the bronchioles, where they discharge their eggs into the bronchial secretions. Individuals with symptoms of chronic cough, vague chest pains, and hemoptysis who have resided in an area where infections are endemic and have a history of eating raw crayfish or crabs should be suspected of having paragonimiasis. *Paragonimus* eggs can be detected in sputum and in the stool, and concomitant examinations should be performed to improve the

overall detection rate. In many individuals in whom the infection is eventually confirmed, small numbers of eggs are present intermittently in the sputum and feces. For patients with light infections, up to seven sputum examinations have been recommended. Frequently, pulmonary paragonimiasis is misdiagnosed as pulmonary tuberculosis. The Ziehl-Neelsen method for detecting mycobacteria destroys *Paragonimus* eggs.

Antibody Detection. In addition to routine diagnostic methods used to recover the characteristic eggs, immunodiagnostic tests have been used to diagnose pulmonary and extrapulmonary infections and to differentiate tuberculosis from paragonimiasis. CF has been used to diagnose active infections since it was noted that the test became negative soon after the death of the worms. An immunoblot test for the detection of antibodies to *P. westermani* using adult worm homogenates was found to be highly sensitive and specific; this test has been available at CDC since 1988. Only one false-positive result has been obtained with this method: a patient with *Schistosoma haematobium* infection.

EIA using adult excretory-secretory antigens was found to be very sensitive for detecting parasite-specific IgG and IgE. Pleural effusion fluid may be more suitable than serum for detection of infections. Dot ELISA has also been used to detect parasite-specific antigen in human sera. Monoclonal antibodies to detect species-specific and stage-specific antigens are highly sensitive and specific for the detection of active infections (25). The serology-based assays are available in areas of endemicity or in specialized diagnostic centers. Most of these assays use nonstandardized reagents and have not been used in clinical trials.

An intradermal test is also available for epidemiologic surveys in areas of endemicity; however, positive reactions persist for years after parasitologic cures have been effected. Purification of antigen for intradermal tests does not improve the efficacy of screening for paragonimiasis, probably due to the nature of skin sensitization evoked by many elements of the parasite but not by a few selected components. The crude worm antigen may be valuable for screening a large population, yet the diagnosis should not depend totally on this test. The final diagnosis should be made by repeated sputum examinations over time, a comprehensive patient history, serologic testing, and radiologic testing if necessary.

Schistosomiasis

Humans become infected with *Schistosoma* spp. by penetration of cercariae through intact skin rather than by the ingestion of metacercariae. Once the cercariae have successfully entered the host, the organism is termed a

schistosomulum. After about 48 h, the schistosomulum migrates through the tissues and finally invades a blood vessel. On entry into the blood vessels, the schistosomulum is carried to the lungs and then the liver. Once within the liver sinusoids, the worms begin to mature into adults. Depending on the species, the adult worms are found in various veins. The worms form pairs (male and female), with the female lying in the gynecophoral canal of the male. Development of sexual maturity of female schistosomes depends on the presence of mature male worms.

The eggs are immature when first laid and take approximately 8 to 10 days to develop a mature miracidium. Egg deposition takes place intravascularly. Many of the eggs laid are swept downstream, where they become lodged in the microvasculature of the liver and other organs. About half of the eggs swept away by the bloodstream become embedded in the mesenteric venule wall. The presence of eggs in the tissues stimulates granuloma formation; the eggs die, calcify, and are absorbed by the host eventually.

Disease syndromes associated with schistosomiasis are related to the stage of infection, previous host exposure, worm burden, and host response. Syndromes include cercarial dermatitis, acute schistosomiasis (Katayama fever), and related tissue changes resulting from egg deposition.

Specific diagnosis of schistosomiasis by detection of eggs in stool or urine specimens is possible only after egg production has begun. Eggs may be found in feces as early as 5 weeks after infection. The ease of egg detection depends on the worm burden and the duration of the infection. Patients with a low worm burden or old (chronic) infections may have very few eggs in their feces or urine, and the infections may not be confirmed due to the use of insensitive diagnostic methods.

Antibody Detection. A large number of serologic tests have been used in the diagnosis of schistosomiasis; however, most have not been particularly useful because of cross-reactions with other helminth infections, continuation of elevated titers long after the completion of successful treatment, and the slow immunologic response of the host. Because of the complex life cycle, a large number of antigens have been used in serologic tests. Only a few have been useful. The most frequently used tests are the circumoval precipitin test, the cercaria-Hullen reaction, IFA, IHA, immunoblotting, EIA, and FAST-ELISA.

Currently at CDC, specimens are first tested by FAST-ELISA with *S. mansoni* adult microsomal antigen (MAMA). A positive reaction (>8 U/μl of serum) indicates infection with *Schistosoma* species. The sensitivity is 99% for *S. mansoni* infection, 95% for *S. haematobium* infection, and ≥50% for *S. japonicum* infection. The specificity is 99%. Because of the lower sensitivity for *S. haematobium* and

S. japonicum, immunoblot analyses relevant to the patient's travel history are performed. As with many other parasitic infections, the presence of antibody indicates infection at some time in the past and cannot be correlated with clinical status, parasite burden, egg production, or prognosis.

EIA methods with soluble adult worm or egg antigens for the detection of antibodies have been used as screening tests, with confirmation of infection performed by EITB tests. Individuals infected with schistosomes have an elevated IgE and IgG4 response, as is commonly seen with other helminthic infections. Few studies have investigated the persistence of antibodies over time after therapy. It is possible that high titers posttherapy reflect treatment failure or reinfection.

The dipstick dye immunoassay test (DDIA), developed in China for the detection of antibodies against *S. japonicum*, relies on soluble egg antigen (SEA) labeled with a colloidal dye. This assay is not only rapid, simple, and inexpensive but also particularly useful for screening in the field. Sensitivity and specificity results support the notion that the DDIA with *S. japonicum* SEA can safely be implemented for the diagnosis of *S. mekongi*; however, careful interpretation of results is mandatory when sample are obtained from areas where *Opisthorchis viverrini* is also endemic (93).

Antigen Detection. ELISA methods have also been used to detect circulating schistosome antigens in the sera and urine of infected patients and may be the preferred method of diagnosis. In addition to diagnosis of infection, antigen levels have been used to assess disease severity in terms of intensity of infection and to monitor therapy. Individuals treated with praziquantel experienced a rapid clearance of circulating anodic antigen (CAA) and circulating cathodic antigen (CCA); however, in individuals treated with other therapeutic drugs, clearance may take much longer. A dipstick assay based on the anti-CCA sandwich ELISA, on a nitrocellulose format, can detect CCA in the urine of patients with *S. mansoni* infection with a sensitivity of 92%. The results were at least as good as those obtained using ELISA or the Kato-Katz fecal smear examination. This rapid, simple approach may lend itself to more extensive use in future screening programs (82). The combination of urine CCA and serum CAA for the detection of circulating antigens and the combination of the *S. haematobium* adult worm microsomal antigen (HAMA) FAST-ELISA and the HAMA EITB for detecting antibodies has significantly improved the sensitivity of antibody and antigen detection (3). However, while CCA dipsticks are a good alternative, or complement, to stool microscopy for field diagnosis of intestinal schistosomiasis, they have no proven value for field diagnosis of urinary schistosomiasis (81). Another reagent strip assay

for the diagnosis of schistosomiasis based on detection of parasite antigens in the urine of infected individuals has been evaluated. The test uses the principle of lateral flow through a nitrocellulose strip of the sample mixed with a colloidal carbon conjugate of a monoclonal antibody specific for *Schistosoma* CCA. The strips and the conjugate in the dry format are stable for at least 3 months at ambient temperature in sealed packages, making the test suitable for transport and use in areas where schistosomiasis is endemic (86).

Using an SEA monoclonal antibody, circulating schistosome antigen was undetectable in serum from patients with other parasitic infections and in 94% of serum samples and 84% of urine samples from *S. mansoni*-infected patients. A significant reduction in circulating schistosome antigen levels was detected in serum and urine samples approximately 12 weeks after praziquantel therapy (73). In another study using a 63-kDa circulating antigen, the antigen was detected in 92% of urine samples from 330 *S. mansoni*-infected individuals, with a 16% false-positive result among 130 noninfected individuals (6).

Strongyloidiasis

Human infection with *Strongyloides stercoralis* is acquired by skin penetration by the filariform larvae (infective larvae) from the soil. These larvae are long and slender and may remain viable in soil or water for several days. After penetration of the skin, they are carried via the cutaneous blood vessels to the lungs, where they break out of the pulmonary capillaries into the alveoli. They then migrate via the respiratory tree to the trachea and pharynx, are swallowed, and enter the mucosa in the duodenum and upper jejunum. Development usually takes about 2 weeks, after which the females begin egg production. The eggs usually hatch, and the rhabditiform larvae (noninfective larvae) pass out of the intestinal tract in the feces. These larvae are passed out onto the soil in the feces and develop into free-living male and female worms, eventually producing infective filariform larvae (eggs, noninfective larvae, and infective larvae). In temperate climates, the free-living male and female worms do not develop; however, the rhabditiform larvae that pass out in the stool develop into the filariform (infective) larvae, which are then ready to infect the next host through skin penetration.

In situations in which autoinfection occurs, some of the rhabditiform larvae within the intestine develop into filariform larvae while passing through the bowel. These larvae can then reinfect the host by (i) invading the intestinal mucosa, traveling via the portal system to the lungs, and returning to the intestine or (ii) being passed out in the feces and penetrating the host on reaching the perianal or perineal skin.

Pathology present in strongyloidiasis can vary, both in severity and in the areas of the body involved. Some individuals remain totally asymptomatic, with the only abnormal clinical finding being a peripheral eosinophilia. Considering the life cycle of the parasite, the three areas of primary involvement would be the skin (cutaneous), the lungs (pulmonary), and the intestinal mucosa (intestinal).

Confirmation of the infection depends on recovery and identification of the adult worms, larvae, or eggs from the stool, duodenal material, or sputum. Fecal specimens may not be positive even after the routine ova and parasite examination, including the concentration procedure, is performed. The numbers of larvae found in the stool also vary from day to day.

Antibody Detection. Although not routinely available, EIA and immunoblot methods have been investigated for use in both the diagnosis and postchemotherapy evaluation of human strongyloidiasis. These methods appeared to be both sensitive and specific, and within about 6 months after therapy they demonstrated a significant decrease in antibody levels. However, in cases where treatment was not effective, the individuals did not show a significant fall in antibody titers. More detailed studies to determine appropriate intervals for serologic evaluation and criteria for successful cure are required before these tests become more widely used.

Currently, EIA, with a sensitivity of 84 to 92%, is recommended. Some patients may be negative, particularly those who are carriers (8 to 16%), and antibody test results cannot be used to differentiate between past and current infection. It is interesting that immunocompromised patients still tend to have detectable IgG antibodies, in spite of their immune system deficiencies.

Strongyloides ratti larval extract was used for the standardization of ELISA to detect genus-specific IgE in humans with strongyloidiasis. A significant positive correlation was found between levels of *Strongyloides*-specific IgE and total IgE in sera from patients with strongyloidiasis. *S. ratti* heterologous extract could be a useful tool for detecting genus-specific IgE by ELISA, thus helping characterize the immune response profile in human strongyloidiasis (22).

Toxocariasis

Toxocara spp. are non-human-derived ascarids that are capable of undergoing limited development in the human host. Infections with the organism have been classified into two categories: visceral larva migrans (VLM), which is a systemic infection occurring in patients with a mean age of 4.6 ± 3.6 years; and ocular larva migrans (OLM),

which also occurs in children. However, concurrent infection with VLM and OLM in the same patient is rare. Eosinophilia, which is pronounced in VLM, is almost absent in OLM. The average age of patients with OLM is also older than that of patients with VLM.

Antibody Detection. The clinical diagnosis of toxocariasis can be very difficult, and only fairly recently has a reliable immunodiagnostic test been developed. Serologic test results must be interpreted with care because of the prevalence of asymptomatic infection and the age and socioeconomic status of the individual (42). Previous serologic tests had involved adult- or larval-stage somatic extracts and whole or sectioned larvae. The EIA uses third-stage-larva secretory antigen and is superior to all other serodiagnostic tests. The test is highly specific and does not give cross-reactions with sera obtained from patients infected with other commonly occurring human parasites.

Even though EIA is an extremely sensitive test, the diagnostic predictive value for VLM is significantly different from that for OLM (91). A titer of 1:32 is considered diagnostic for VLM (sensitivity, 78%), whereas a titer of 1:8 is considered diagnostic for OLM (sensitivity, 90%). The specificity is >90% at a titer of $\geq 1:32$. This lower predictive titer for OLM raises the possibility of a false-positive diagnosis in a patient who has an asymptomatic *Toxocara* infection and ocular disease due to other etiology. In addition to serum antibody, vitreous antibody can be measured. Titers in the vitreous fluid were equal to or greater than the serum titers. Measurement of ocular fluid antibody should increase the specificity of the EIA, yielding a better definitive diagnosis for the patient.

Trichinellosis

Human infection with *Trichinella spiralis* is initiated from the ingestion of raw or poorly cooked pork, bear, walrus, or horse meat or meat from other mammals (carnivores and omnivores) containing viable, infective larvae. The tissue is then digested in the stomach. The excysted larvae invade the intestinal mucosa, develop through four larval stages, mature, and mate by the second day. By the sixth day of infection, the female worms begin to deposit motile larvae, which are carried by the intestinal lymphatic system or mesenteric venules to the body tissues, primarily striated muscle. Deposition of larvae continues for approximately 4 weeks, with each female producing up to 1,500 larvae in the nonimmune host.

The very active muscles, which have the greatest blood supply, including the diaphragm, muscles of the larynx, tongue, jaws, neck, and ribs, the biceps, and the gastrocnemius, are invaded. The cyst wall results

from the host immune response to the presence of the larvae, and the encysted larvae may remain viable for many years, although calcification can occur within less than a year. As few as 5 larvae per g of body muscle can cause death, although 1,000 larvae per g have been recovered from individuals who died from causes other than trichinosis.

Symptoms that may develop within the first 24 h include diarrhea, nausea, abdominal cramps, and general malaise, all of which may suggest food poisoning, particularly if several people are involved. Studies also indicate that the diarrhea can be prolonged, lasting up to 14 weeks (average, 5.8 weeks), with few or no muscle symptoms.

During muscle invasion, there may be fever, facial (particularly periorbital) edema, and muscle pain, swelling, and weakness. The extraocular muscles are usually the first to be involved, followed by the muscles of the jaw and neck, limb flexors, and back. Muscle damage may cause problems in chewing, swallowing, breathing, etc., depending on which muscles are involved. The most severe symptom is myocarditis, which usually develops after the third week; death may occur between the fourth and eighth weeks. Other severe symptoms, which can occur at the same time, may involve the central nervous system. Although *Trichinella* encephalitis is rare, it is life-threatening.

Antibody Detection. Serologic tests are very helpful, with the standard two being EIA and bentonite flocculation, which are recommended for trichinosis. EIA detects antigen first and is used for routine screening, and all EIA-positive specimens are tested by bentonite flocculation for confirmation. A positive reaction in both tests indicates infection with *T. spiralis* within the last few years. Often, antibody levels are not detectable within the first month postinfection. The titers tend to peak in the second or third months postinfection and then decline over a few years. Positive reactions are detected at some point during disease progression in 80 to 100% of all patients with symptomatic disease; detectable antibody usually appears between 3 and 5 weeks after infection.

Antigen Detection. A modified double-sandwich ELISA has been developed using polyclonal antibodies raised in rabbits and guinea pigs against larval somatic antigens of *T. spiralis*. The first detection of coproantigen was as early as the first day postinfection; the level of coproantigen gradually increased to reach its peak on the seventh day and then decreased to disappear completely during the third week postinfection. Another test, the coagglutination test, was used, and this test confirmed the previous results. Results suggest that the coproantigen

detection test could be used to confirm ongoing early *T. spiralis* infection (13).

Intradermal Tests

In the absence of reliable serologic diagnostic tests, skin tests have been used to provide indirect evidence of infection. Most skin tests have been used primarily for research and epidemiologic purposes. Some of the more widely used skin tests are the Casoni and Montenegro tests. In many cases, the antigens used are difficult to obtain and are not commercially available. The antigens are usually crude extracts that have not been standardized and are neither highly sensitive nor specific. They may provoke an immune response that complicates further serologic testing, and there is always the danger of provoking an anaphylactic reaction. In addition, there are ethical questions related to giving patients injections of nonstandardized foreign protein, particularly if the antigens were derived from *in vivo* materials.

Casoni Test

In the past, the Casoni test was the only means of diagnosing exposure to hydatid disease. This intradermal test, in which hydatid cyst fluid is used as the antigen, has many advantages as a result of its simplicity; its nonspecificity has been its major limitation. Diagnostic sensitivity was limited in patients who had intact or hyaline cysts. An immune response was detected more frequently in patients with liver cysts than in those with lung cysts.

False-positive reactions have occurred in patients with other parasitic and nonparasitic diseases. The Casoni antigen may also sensitize the patient, leading to antibody production, and anaphylactic reactions have also been reported. This test is rarely used for diagnostic purposes because of the ethical concerns addressed above.

Casoni's skin test and IHA are still used in Turkey. For 120 patients retrospectively studied during 1997 to 2004, results indicated that an immediate skin reaction to crude hydatid antigens was more useful than IHA (37).

Montenegro Test

The Montenegro test uses formalinized promastigotes of any species of *Leishmania* to evoke a delayed hypersensitivity reaction in infected patients. In some areas, it is the method of choice for diagnosis because of its simplicity.

Patients infected with *Leishmania donovani* (kala azar) have a negative Montenegro test during active disease. The test becomes positive after successful treatment or when

there is a spontaneous cure. Problems similar to those mentioned above for the Casoni test have occurred with the Montenegro test. The skin test may induce antibody production and may also cause anaphylactic reactions.

23

Histologic Identification of Parasites

Often, histology preparations are submitted to the clinical laboratory for review, consultation, or confirmation. Sections of tissue that contain parasites may be seen infrequently in many pathology departments; thus, consultation services are needed.

This chapter is designed not as a comprehensive presentation of histologic parasitology but rather as a review of parasite morphology, potential sites in the human host, any recommended special processing or stains, and additional helpful hints. The information is arranged in table form according to body site (Table 23.1).

Specific organisms are listed within parasite groups (protozoa, helminths, etc.). The table does not include organisms that have been reported as only rarely infecting humans. Some of these more rare infections are represented by so few cases that a physician may never see one (see chapter 18). The photographs in Figures 23.1 to 23.118 illustrate representative parasitic infections in various body tissues. Although most of the specimens are from human tissues, a few are from animals to illustrate a particular parasite and representative body tissue.

Although a great deal of information is contained in this chapter, there has been no attempt to illustrate every organism and every possible tissue involved. Also, identification of parasite adults or immature forms depends on specimen submission and subsequent preparation. If the organisms and tissues are not well preserved, identification may be difficult or impossible. Distinguishing actual organisms from artifact material may also complicate the process.

Most diagnostic procedures in medical parasitology do not require extensive patient information; however, the examination of tissues and final identification of any organisms present can be simplified by reviewing as much information as possible about the patient. Specifics would include place of residence, travel history, food preferences, recent health status, health status of family members, current symptoms, outdoor activities, animal exposure, and any possible unusual environmental exposures. If specific lesions have been identified, the source of the tissue(s) must be identified, as well as the method by which the specimen was obtained. It is particularly relevant to know anything about the status of the specimen regarding adequate fixation and/or any lag time prior to fixation that might influence the overall morphology.

Some general descriptions are provided with diagrams to illustrate specific morphologic criteria used for parasite identification. Because the protozoa are unicellular organisms with one or more nuclei and various organelles, their simplicity does not require extensive descriptive material. However, the identification of various helminths and arthropods requires a more thorough understanding of parasite morphology and appropriate terminology (Table 23.2). Tables 23.3 to 23.5 contain information on staining characteristics, nuclear and cy-

toplasmic stains, and specific stains for carbohydrates. This information provides some basic guidelines for the understanding of how various stains are categorized, used, and interpreted. Tables 23.6 and 23.7 indicate the locations within the body where human protozoal and helminth parasites are found. Table 23.8 contains very specific information on the musculature of nematodes and can be found following Figure 23.34. One can also refer to the excellent references provided with this chapter.

Table 23.1 Histologic identification of parasites^a

Body site	Organisms	Stain ^b	Comments ^b
Intestine	Protozoa		
	<i>Entamoeba histolytica</i> (cecum, ascending colon, sigmoid rectal region; other sites less common); trophozoites and cysts are normally passed in stool	H&E, PAS, trichrome or iron hematoxylin in stool	Differential between organism and histiocyte: in an organism, the nucleus may not be visible; in histiocytes, a portion of the nucleus is almost always visible; both trophozoites and histiocytes stain red with PAS (review nuclear details); histolysis of invaded tissue; flask-shaped ulcers; organisms seen in healthy ulcer margins, not in central, necrotic areas
	<i>Giardia lamblia</i> (duodenum); trophozoites and cysts are normally passed in stool; organisms can be seen in duodenal aspirates or using other sampling methods (Enterotest)	H&E, Giemsa, trichrome or iron hematoxylin in stool	Normal to mild to severe blunting of villi; loss of the brush border; infiltration of lamina propria with lymphocytes and granulocytes; chronic inflammation; tissue invasion does not occur; trophozoites may appear as sagittal sections of small, crescentic organisms that may adhere to the epithelial surface; front views will reveal the typical teardrop shape
	<i>Balantidium coli</i> ; trophozoites and cysts are normally passed in stool; tissue invasion may occur in the colon and appendix	H&E, trichrome or iron hematoxylin in stool (may be difficult to see on permanent stained smears; wet mount is best)	Simple hyperemia to marked ulcerations (large intestine); very large size (trophozoites); presence of cilia, large cytostome, and prominent macronucleus will distinguish these ciliates from other protozoa; due to large size, cut planes may not reveal all internal morphology; early lesion resembles that of <i>E. histolytica</i> , but the opening into the mucosa is larger
	<i>Cryptosporidium</i> spp. (have been recovered from mouth to anus, more common in small intestine); oocysts (4–6 μm) are passed in stool; disseminated disease can occur, with oocysts being passed in sputum	H&E, modified acid-fast stains for stool (oocysts positive)	Mild to moderate villous atrophy, increased crypt size, mild to moderate mononuclear cell infiltrates of lamina propria; organisms along brush border are small and measure 3–5 μm; other coccidia and the microsporidia develop within the cells and so are not confused with the brush border location of <i>Cryptosporidium</i> spp.
	<i>Cyclospora cayetanensis</i>	H&E, modified acid-fast stains for stool (oocysts positive, but staining variable)	Developmental stages have been seen in jejunal enterocytes, usually at the luminal end rather than at the brush border; tends to resemble developmental stages of <i>I. belli</i>
<i>Isoospora belli</i> (more common in small intestine); oocysts are passed in stool; unsporulated oocysts measure 20–33 μm long by 10–19 μm wide and may contain a single sporoblast (usually seen in cases of diarrhea)	H&E, modified acid-fast stains for stool (oocysts positive)	Same as <i>Cryptosporidium</i> spp., but development occurs within the epithelial cells; tissue eosinophilia can be seen	

Microsporidia; identification of organisms to the genus and species levels requires electron microscopy, tissue culture, immunofluorescence studies, or PCR; differentiation of spores from bacteria or small yeasts in stool is extremely difficult	H&E, tissue Gram stains, PAS, silver stains; modified trichrome and calcofluor white used for stool or urine	Developing spores seen within enterocytes; sizes of individual spores are ~1–3 μm in humans; <i>Enterocytozoon bienersi</i> and <i>Encephalitozoon (Septata) intestinalis</i> involved, primarily seen in the compromised host; both organisms can disseminate to other organs and spores can be found in liver, lungs, kidneys, CNS, and cornea
<i>Trypanosoma cruzi</i> (esophagus, colon); trypomastigote may be found in peripheral blood in the early stage of infection	H&E	Disease of ganglion cells of mesenteric plexuses; can cause severe distension and thinning of visceral wall; scarring, chronic inflammation; amastigotes may shrink, nuclei and kinetoplasts may not be visible in tissue sections and may resemble <i>Histoplasma</i> ; tissues most often involved include brain, cardiac, and smooth muscle cells
Nematodes		
<i>Enterobius vermicularis</i> (cecum, appendix, other sites; may also be found in female reproductive tract or peritoneal cavity); eggs and adult worms recovered on Scotch tape preparations or pin-worm paddles; stool not recommended	H&E	Characteristic lateral alae on worm cross sections; eggs in utero may also be visible; most often seen in appendix with little or no inflammation
<i>Ascaris lumbricoides</i> (small intestine, bile ducts, liver, peritoneal cavity); fertilized and unfertilized eggs passed in stool; adult worms may also be seen in stool; migrating larvae may be seen in sputum	H&E	Large size, characteristic muscular wall formed by long, irregular muscle fibers; sectioned (eggs may be seen with their thick, bumpy shells); the body wall has a thick, multilayered cuticle, fibrous-appearing hypodermis (expands to form large lateral chords, within which are seen excretory canals); short, muscular esophagus and simple intestinal tube with an irregular lumen; larval forms may be more difficult to identify
<i>Strongyloides stercoralis</i> (usually duodenum and upper jejunum; may be in any tissue in disseminated disease); rhabditiform (noninfectious) larvae usually seen in stool; filariform (infectious) larvae, as well as adult worms and eggs, may be seen in stool in hyperinfection cases	H&E	Sections may reveal adult females, well-segmented eggs, and numerous larvae; although the morphology of the adult female may be difficult to see in tissues, the small size of the worm and the presence of developing eggs and larvae close to the adult worm strongly suggest this diagnosis; with hyperinfection, the bowel lining becomes congested and edematous, with possible ulcerations; chronic infection may reveal bowel wall fibrosis
Hookworms (<i>Necator</i> , <i>Ancylostoma</i>) (usually upper part of small intestine); hookworm eggs normally passed in stool; eggs of both genera look the same	H&E	Relatively thick cuticle and thin hypodermis; lateral hypodermal chords are usually visible; wide-open mouth sucking the mucosa; adult <i>Necator</i> has cutting plates, while <i>Ancylostoma</i> has teeth

(continued)

Table 23.1 Histologic identification of parasites^a (continued)

Body site	Organisms	Stain ^b	Comments ^b
	<i>Trichuris trichiura</i> (large intestine); whipworm eggs normally passed in stool	H&E	Most sections reveal both the thicker body area (“whip handle”), which lies free in the lumen, and the slender anterior area (“whip”), which is firmly embedded into the mucosa; sectioned eggs may be visible
	<i>Trichinella</i> spp. (duodenum, small intestine)	H&E	Edema, chronic inflammation, hyperemia, serosa petechiae, dilatation of bowel loops; prominent Peyer’s patches; swollen intestinal villi, mucin secretion; diffuse infiltration of eosinophils (lamina propria); larvae may be seen and may resemble microfilariae
	Cestodes		
	<i>Taenia saginata</i> (most common), <i>T. solium</i> , <i>Diphyllobothrium latum</i> ; proglottids and/or eggs are normally passed in the stool	H&E	May see loose proglottids and/or eggs in appendix
	<i>Hymenolepis nana</i> ; eggs are normally passed in the stool	H&E	Both larval and adult forms may be in intestinal sections in the human
	<i>Echinococcus granulosus</i> (mesentery)	H&E, acid fast	External laminated, anuclear cyst wall; hooklets are acid fast
	Trematodes		
	<i>Schistosoma mansoni</i> , <i>S. japonicum</i> , <i>S. haematobium</i> , less common schistosomes (<i>S. mekongi</i> , <i>S. intercalatum</i>); eggs may be seen in urine and/or stool	H&E	Adults and eggs may be seen in the mesentery or mesenteric veins; egg identification may depend on demonstration of spine in section; important to determine if egg contains miracidium larva (indicates active infection); in the wall of the intestinal tract, polyp formation may occur (more eggs found in polyps)
Liver	Protozoa		
	<i>Leishmania donovani</i>	H&E, PAS	Organisms are dot-like in routine section; they are larger (2–4 μm) in tissue impression smear; kinetoplast next to nucleus is very characteristic and differentiates these organisms from <i>Toxoplasma</i> (no kinetoplast); <i>Histoplasma</i> is PAS positive, while <i>L. donovani</i> is PAS negative
	<i>Toxoplasma gondii</i>	H&E, PAS	Resting forms (bradyzoites) are pyriform with no kinetoplast (if many organisms are seen per cyst, they may appear as dots); bradyzoites within cysts are PAS positive; tissue cysts have a very thin wall; tissue cysts of <i>Toxoplasma</i> must be differentiated from <i>Sarcocystis</i> (seen most frequently in skeletal or cardiac muscle and larger than <i>Toxoplasma</i>); when reviewing animal tissues (from dogs), <i>Neospora caninum</i> may be present and will mimic <i>Toxoplasma</i>

Microsporidia	See intestine	See information on intestine
<i>Plasmodium falciparum</i> , <i>P. vivax</i> , <i>P. malariae</i> , <i>P. ovale</i>	H&E	Exoerythrocytic stages (mature tissue schizonts) measure 45–80 µm and contain 15,000–40,000 merozoites per cell; malarial pigment may be seen in Kupffer cells; capillaries may be filled with parasitized RBCs (pigment is also visible here); the host does not respond to the presence of these organisms; pigment within blood vessels can be seen with routine tissue stains, but the use of polarized light may also be helpful in demonstrating the birefringent granules of malarial pigment
Nematodes		
<i>Capillaria hepatica</i> ; eggs in human stool would be from the ingestion of parasitized livers, probably from squirrels or other animals (spurious infections—eggs disappear from the feces in a few days)	H&E, trichrome (Masson)	Liver parenchyma; eggs remain in liver and the life cycle does not continue in humans; eggs resemble those of <i>T. trichiura</i> , but the shell appears beaded or pitted; polar plugs are less pronounced than in <i>T. trichiura</i> ; intense granulomatous reaction around eggs; the general egg shape, the bipolar plugs, and striations in the thick shell make this identification relatively easy
<i>Toxocara cati</i> or <i>T. canis</i> , <i>Baylisascaris</i> spp. (visceral larva migrans); adult worms play no role in human disease (very rare exceptions)	H&E	Liver contains largest number of larvae; any organ can be affected; eosinophilic granuloma; focal necrosis may occur; larval morphology includes single lateral ala, nonpatent intestine, and large paired excretory columns; <i>Baylisascaris</i> larvae are larger than <i>Toxocara</i> larvae and have a patent gut and a predilection for the CNS
Cestodes		
<i>Echinococcus granulosus</i> ; adult worms and/or eggs found only in the small intestine of canids (primarily dogs)	H&E, acid fast, GMS, PAS	External laminated, anuclear cyst wall; thin nucleated inner layer; hooklets are acid fast; calcified cysts often reveal no hooklets; mature cysts contain brood capsules and protoscolices; degeneration of brood capsules results in “hydatid sand” (degenerating protoscolices and hooklets in the cyst fluid); some cysts are sterile
<i>Echinococcus multilocularis</i> ; adult worms and /or eggs found only in the small intestine of canids (primarily dogs and foxes)	H&E, acid fast, GMS, PAS	Alveolar structure with no limiting membrane; scolices seldom present, thus no protoscolices, hooklets, or calcareous corpuscles; laminated and germinal layers are collapsed, folded, and scattered throughout the liver
Trematodes		
<i>Schistosoma mansoni</i> , <i>S. japonicum</i> , <i>S. haematobium</i> , less common schistosomes (<i>S. mekongi</i> , <i>S. intercalatum</i>); eggs normally passed in urine and/or stool	H&E, trichrome (Masson)	Granulomatous tissue reaction around eggs (lymphocytes, plasma cells, eosinophils); trichrome demonstrates fibrotic tissue; eggs of <i>S. japonicum</i> more numerous in liver (greater egg-laying capacity); adult worms seen most frequently in cross or transverse sections within blood vessels in the wall of the intestine or in liver; often the female is seen in copula, surrounded by the larger male body

(continued)

Table 23.1 Histologic identification of parasites^a (continued)

Body site	Organisms	Stain ^b	Comments ^b
	<i>Fasciola hepatica</i> (bile duct); eggs normally passed in stool	H&E	Large size plus cross section of worm containing intestinal diverticula; eggs may also be seen but are usually collapsed or distorted
	<i>Clonorchis (Opisthorchis) sinensis</i> (bile duct); eggs normally passed in stool	H&E	May be eosinophilic infiltration and slight thickening of the duct wall; may progress to fibrosis, cirrhosis of liver, biliary obstruction, etc.; long, coiled uterus full of eggs may be seen; adult trematodes in bile ducts may suggest <i>C. sinensis</i> , <i>Opisthorchis</i> spp., <i>Dicrocoelium dendriticum</i> , and <i>Fasciola</i> spp.
Spleen	Protozoa <i>Leishmania donovani</i>	H&E, PAS	See information on liver
	<i>Plasmodium falciparum</i> , <i>P. vivax</i> , <i>P. malariae</i> , <i>P. ovale</i>	H&E	See information on liver
Gallbladder	This organ is seldom invaded by parasites; occasionally, <i>Cryptosporidium</i> , microsporidia, <i>Clonorchis (Opisthorchis) sinensis</i> , <i>Ascaris lumbricoides</i> , and <i>Fasciola hepatica</i> are found; schistosome eggs may also be found		Eggs and/or sections of adult trematodes may be seen; developmental stages of <i>Cryptosporidium</i> possible
Kidney	Protozoa Microsporidia	See intestine	See information on intestine
Urinary bladder	Trematode <i>Schistosoma haematobium</i>	H&E, acid fast	Seen within blood vessels, often near the bladder; early inflammation may progress to thickening, hyperplasia, fibrosis, and ulceration; carcinoma may be a complication; terminal egg spine may be visible; important to determine if egg contains miracidium; eggs may be distorted and collapsed; calcified eggs may also be seen; eggs are not acid fast, like those of <i>S. mansoni</i> and <i>S. japonicum</i> ; adult worms may be seen in copula within the blood vessels
Lungs	Protozoa <i>Entamoeba histolytica</i>	H&E	Usually extension of liver abscess in the right lower lobe; may occur elsewhere; nucleus is not always visible; should be area of histolysis around organisms
	<i>Toxoplasma gondii</i>	H&E	Cysts look like those in the liver; tachyzoites are crescent shaped, especially when released from the cells
	<i>Cryptosporidium</i> spp.	H&E	Organism morphology similar to that in intestine; organisms may be seen in sputum in disseminated disease

	Microsporidia	Tissue Gram stains, PAS, silver stains, H&E	Organism morphology similar to that in intestine; spores may be found in sputum
	Nematodes <i>Strongyloides stercoralis</i> , <i>Ascaris lumbricoides</i> , hookworm, <i>Toxocara</i> spp., <i>Wuchereria bancrofti</i> , <i>Brugia malayi</i> , <i>Dirofilaria immitis</i>	H&E	Migrating larvae (<i>Strongyloides</i> , <i>Ascaris</i> , hookworm, <i>Toxocara</i> spp.) may be seen; microfilariae (<i>Wuchereria</i>) may cause an eosinophilic granuloma (pneumonitis, alveolar hemorrhage, edema)
	Trematodes <i>Paragonimus westermani</i> , other <i>Paragonimus</i> spp.; eggs can be found in sputum and/or stool	H&E	Reaction by lung tissue isolates the worm in a thick, fibrous capsule containing hemorrhagic, purulent exudate and eggs; adults typically paired, surrounded by fibrous capsule; spines on tegument and typical eggs make the diagnosis relatively easy
Heart	Protozoa <i>Entamoeba histolytica</i>	H&E, PAS	May be present; pericardial tamponade may occur
	<i>Trypanosoma cruzi</i>	H&E	Amastigotes are morphologically identical to those of <i>L. donovani</i> found in the macrophages of the reticulo-endothelial system; inflammatory cell infiltrates, interstitial edema, and separation of myofibers
	<i>Toxoplasma gondii</i>	H&E	Cysts appear like those in liver (no kinetoplast as in amastigotes of <i>T. cruzi</i>)
	Microsporidia	See intestine	See information on intestine
	<i>Plasmodium falciparum</i> (most important), <i>P. vivax</i> , <i>P. malariae</i> , <i>P. ovale</i>	H&E	May be marked congestion of the capillaries; blocked with parasitized RBCs and malarial pigment; evidence of anoxia (cloudy swelling, fatty degeneration, myocardial infarcts) may be seen
Skeletal muscle	Protozoa <i>Sarcocystis</i> spp. (rare)	H&E, GMS	Cylindrical cysts (Miescher's tubes) formed (double outer membrane and transverse trabeculae separating the cyst into closed compartments packed with spores); silver stain will clearly reveal the external capsule and septa
	Microsporidia	PAS, AFB, GMS, H&E	Organisms in the genera <i>Pleistophora</i> , <i>Trachipleistophora</i> , and <i>Brachiola</i> can be found in muscle in compromised hosts (cases on record rare); atrophic and degenerating muscle fibers full of spores (<i>Pleistophora</i> in clusters of ~12 organisms); each cluster enclosed by enveloping membrane (pansporoblastic membrane); spores measure 2.8 by 3.4 μm

(continued)

Table 23.1 Histologic identification of parasites^a (continued)

Body site	Organisms	Stain ^b	Comments ^b
	Nematode <i>Trichinella</i> spp.	H&E	Diaphragm most commonly invaded; biopsy usually not performed until after day 17, when larvae present a typical, coiled appearance; old, calcified cysts may be difficult to recognize
	Cestode <i>Taenia solium</i> (cysticercosis)	H&E	May also occur in brain, eye, muscles, heart, liver, lungs, abdominal cavity; cyst is oval or round and contains one invaginated scolex with crown of hooklets and four suckers; larva is usually surrounded by tissue reaction capsule, which is wrinkled after tissue processing (very typical appearance, often diagnostic even without cross section of scolex); cysticercus has a dark-staining spiral canal and a scolex surrounded by a thin, lightly staining bladder wall; parenchymatous portion consists of the invaginated scolex with its spiral canal, four suckers, and an armed rostellum with hooks; surface of spiral canal is deeply folded; parenchyma is usually filled with calcareous corpuscles; racemose form of cysticercosis appears as multiple sections of bladder wall tegument (scolex and spiral canal not seen)
Skin and subcutaneous tissue	Protozoa <i>Leishmania</i> spp.	H&E, GMS	See information on liver
	Nematodes <i>Wuchereria bancrofti</i> , <i>Brugia malayi</i>	H&E	Adults in lymphatic vessels (may be diagnosed in tissue sections); microfilariae in blood
	<i>Loa loa</i>		Adults in subcutaneous tissue; microfilariae in blood
	<i>Onchocerca volvulus</i>		Adults in subcutaneous nodules or in loose connective tissues from deeper areas within the body; may be diagnosed in tissue sections (fibrous nodules); microfilariae in skin; accidental infections with animal species of <i>Onchocerca</i> may occur; key features of thick cuticle, transverse ridges, and striations in the middle layer of cuticle are helpful
	<i>Mansonella ozzardi</i> , <i>M. perstans</i> , <i>M. streptocerca</i> , <i>Dirofilaria</i> spp.		Adults in body cavities (abdominal, pleural) and pericardium; microfilariae in blood (<i>M. streptocerca</i> in skin)
	Hookworm larvae	H&E	Differentiate from <i>Strongyloides</i> spp. (not found in skin)

	Cestodes		
	<i>Spirometra</i> spp. (sparganosis)	H&E	Larvae often invade subcutaneous tissues or muscles (in or about the eyes); acute inflammatory reaction, which is more severe as larva dies and is absorbed; solid-bodied sparganum lacks suckers and surrounding bladder wall seen in other cysticerci
	<i>Sparganum proliferum</i>	H&E	Produces a more severe reaction with metastatic branching and spread throughout the tissues; no scolex seen
	Arthropods		
	<i>Demodex folliculorum</i> (mite)	H&E	Invades hair follicles and sebaceous glands; may be chronic inflammatory cells around mites
	<i>Sarcoptes scabiei</i> (itch mite)	H&E	Superficial skin layer (never below epidermis); preferred site is interdigital spaces, may be elsewhere (heavy infestations, i.e., Norwegian scabies)
	<i>Tunga penetrans</i> (chigoe, sand flea)	H&E	Prefers toes; causes intense itching, even pain
Lymphatic vessels	Nematodes		
	<i>Wuchereria bancrofti</i> , <i>Brugia malayi</i>	H&E	Damage ranges from inflammatory sensitization to elephantiasis (tissue hyperplasia)
Testes	Nematode		
	<i>Wuchereria bancrofti</i>	H&E	Worms may be calcified and lymphatic vessel replaced by collagen tissue
Nervous system	Protozoa		
	<i>Naegleria fowleri</i> , <i>Acanthamoeba</i> spp., <i>Balamuthia mandrillaris</i> (leptomycid amoeba), <i>Sappinia diploidea</i>	H&E	Brain lesions demonstrate congestion or hemorrhages, marked cellular infiltration (mononuclear, polymorphonuclear), and abscess formation; trophozoites have large karyosome and no chromatin on nuclear membrane; may be difficult to differentiate <i>Acanthamoeba</i> from <i>Balamuthia</i>
	<i>Entamoeba histolytica</i>	H&E, PAS	Histolysis of invaded tissue; trophozoite nucleus may not always be visible
	Microsporidia, <i>Encephalitozoon</i> spp., <i>Vittaforma</i> spp., <i>Nosema</i> spp., <i>Brachiola</i> spp., <i>Trachipleistophora</i> spp., “ <i>Microsporidium</i> ” spp.	PAS, AFB, GMS	Spores range from 2 to 4 µm and have been found in cerebrospinal fluid; appearance in tissue similar to other body sites; eye infections reported with <i>Encephalitozoon</i> , <i>Vittaforma</i> , <i>Nosema</i> , and members of the catchall genus “ <i>Microsporidium</i> ”

(continued)

Table 23.1 Histologic identification of parasites^a (continued)

Body site	Organisms	Stain ^b	Comments ^b
	<i>Trypanosoma brucei gambiense</i> , <i>T. brucei rhodesiense</i>	H&E	May be no reactive changes around organisms (brain); undulating membrane may be difficult to see
	<i>Toxoplasma gondii</i>	H&E	See information on liver; there is no cyst formation in an early acute infection (central nervous system more commonly involved)
	<i>Plasmodium falciparum</i>	H&E	Congested blood vessels containing parasitized RBCs and malarial pigment
Nematodes			
	<i>Angiostrongylus cantonensis</i>	H&E	Produces eosinophilic meningoencephalitis; cross section of worm is characterized by high muscle fibers under the cuticle with two prominent cords; cellular infiltrates composed of eosinophils and mononuclear cells
	<i>Toxocara</i> spp.	H&E	Granulomas or necrotic areas within periretinal inflammatory membrane
Cestodes			
	<i>Taenia solium</i> (cysticercosis)	H&E	May induce fibrous encapsulation; pronounced cellular reaction may occur as larva begins to die
	<i>Echinococcus granulosus</i>	H&E	Wall is finely laminated and has affinity for either acidic or basic dyes
Trematodes			
	<i>Schistosoma japonicum</i>	H&E	Hyperemia of meninges overlying granulomas in brain
	<i>Paragonimus</i> spp. (any area of brain)	H&E	Cysts may contain eggs, cellular debris, Charcot-Leyden crystals, eosinophils, plasma cells, and lymphocytes; granulomas form around eggs

^a Data from references 1–6; not every body site or every parasite is included in this table.

^b CNS, central nervous system; H&E, hematoxylin and eosin stain; GMS, Gomori methenamine-silver stain; PAS, periodic acid-Schiff; RBC, red blood cell; AFB, acid-fast bacillus.

Table 23.2 General characteristics of helminths

Characteristic	Nematodes	Cestodes	Trematodes	Acanthocephala	Pentastomes (tongue worms)
General	Elongate-cylindrical, bilaterally symmetrical with secondary triradiate symmetry at anterior end; integument nonnucleated cuticula secreted by hypodermis (may be smooth, striated, bossed, or spined); body has 3 main layers (cuticle, hypodermis, somatic muscles); four cords arise from hypodermis and project into body cavity; no circular muscles; body cavity is pseudocoel (not lined with mesothelium); all viscera suspended in pseudocoel; all separate sexes	Adult tapeworm consists of few to many egg-producing units (proglottids) which develop from distal end of scolex; chain called strobila; each proglottid contains male and female genital organs (hermaphroditic); food absorbed through integument; at surface is layer of microvilli (microtriches) over entire outer surface (comparable to brush border of host intestinal epithelium); primitive excretory system; tegument homogeneous and noncellular; circular, longitudinal muscles; proglottids filled with mesenchyme or parenchyma (loose meshwork of branched cells and fluid-filled spaces); calcareous corpuscles usually present in parenchyma	Flukes usually dorsoventrally flattened and hermaphroditic (other than schistosomes); have oral and ventral suckers; integument frequently covered by spines; mesenchyme below integument; circular, oblique, longitudinal muscles; alimentary canal is inverted Y shape; nutrients generally absorbed through tegument	Canals in tegument and arrangement of deeper layers of body wall distinctive; proboscis (retractile into proboscis sheath) armed with spines and body proper; separate sexes; probably related to tapeworms	Body elongate, tongue-like, cylindrical, or moniliform, with many pseudosegments but no separation into head, thorax, and abdomen; head with median subterminal mouth and two pairs of hollow, retractile claws; eyes lacking; sexes separate; striated muscles; have been considered highly modified annelids
Body cavity	Pseudocoelom—yes	No—parenchyma, containing calcareous corpuscles (unique to cestodes, prominent in larval forms)	No—filled with mesenchyme	Pseudocoelom—no; loose parenchymous matrix	Reduced—yes
Body tegument (wall)	Cuticle, hypodermis; cuticle has striations, annulations, or ridges; hypodermis has dorsal, ventral, and lateral chords; well-developed longitudinally oriented, smooth muscles	Smooth	Smooth or spinous, two suckers (oral and ventral/acetabulum); syncytial epithelium bounded externally by a plasma membrane and internally by trilaminated plasma membrane	Thick, multilayer; outer plasma membrane, thin fibrous layer, thick felt-like middle layer, very thick fibrous inner layer; structure of proboscis with hooks and spines on body surface key features; canals present in tegument	May have spines; cuticle may have prominent spines or may be smooth; subcuticular glands lie below cuticle, as do striated muscle fibers; cuticle contains chitin and has sclerotized openings that are diagnostic for pentastomids

(continued)

Table 23.2 General characteristics of helminths (*continued*)

Characteristic	Nematodes	Cestodes	Trematodes	Acanthocephala	Pentastomes (tongue worms)
Cuticle (nematodes)	3 layered (cortical, median, basal); surface may have longitudinal ridges (may be called alae); may also have inflations called bosses or plaques	Surface may be covered with hairy projections called microtriches	True cuticle and epidermis shed or fails to develop	NA ^a	NA
Hypodermis (nematodes)	Layer of cells lying between the cuticle and muscles; projects into the pseudocoelom at the dorsal, ventral, and lateral positions to form 4 chords; secretes the cuticle	NA	NA	NA	NA
Chords	Lateral chords most conspicuous; in some groups, lateral secretory/excretory columns lie within or associated with lateral chords	NA	NA	NA	NA
Muscle fibers	Longitudinally oriented, smooth muscles; no circular muscles	Longitudinal and circular smooth muscles	Longitudinal, circular, and diagonal smooth muscles	Longitudinal and circular smooth muscles	Striated muscle fibers
Body muscles	Somatic and specialized				
Somatic (nematodes)	Elongate, spindle-shaped cells; lie in rows under hypodermis, are parallel to and overlap each other; each cell has basal, contractile portion and cytoplasmic, noncontractile portion	Between tegument and subtegumental nuclei are 2 thin layers of muscle fibers; outer layer is circular fibers and inner layer is longitudinal; some differences among species	Outer layer of circular muscle, inner layer of longitudinal muscle; dorsoventral muscle fibers course throughout the parenchyma and surround internal organs	Outer circular and inner longitudinal fibers	Acidophilic glands can be seen in larval sections
Specialized (nematodes)	Associated with digestive and reproductive systems				
Body cavity contents	Contains digestive tube and tubular gonads	No	No	No digestive system	Yes, intestine large

Digestive system	Mouth, buccal cavity, esophagus, intestine, rectum	No	Oral opening, pharynx, esophagus which bifurcates into a pair of blindly ending tubular intestinal ceca	No—lacunar system; nutrients absorbed through body wall	Simple gut
Reproductive system	Separate sexes; simple tubular structures; usually 1 testis and paired ovaries	Hermaphroditic	Hermaphroditic; 2 testes and 1 ovary; exception is seen with schistosomes (separate sexes)	Separate sexes; 2 testes and 1 ovary, breaks up into “floating” ovaries	Separate sexes
Nervous system	Not relevant for identification	Not relevant for identification	Not relevant for identification	Not relevant for identification	Not relevant for identification
Excretory system	Referred to as secretory/excretory system; varies from large gland cell that opens to the exterior via a duct in ventral midline to being free in the pseudo-coelom	Not relevant for identification	Bilaterally symmetrical	NA	NA

^a NA, not applicable.

Table 23.3 Staining characteristics

Characteristic	Comments
Staining action	<p>Substantive: Stain that acts immediately and directly on the tissue without the intervention of any other substance</p> <p>Adjective: Tissue is first treated with an agent, which in turn attaches the stain to the tissue (mordant staining)</p> <p>Impregnation: Involves the deposition of sensitive metallic substances over selected cells and tissue structures that are rendered visible by subsequent reduction of the metal</p>
Staining time	<p>Progressive: Using the microscope, performed by watching the degree of staining at various points during the process and stopping the process when the desired staining action has been achieved</p> <p>Regressive: Used for the best sharpness of differentiation; whole tissue is stained and then differentiated to remove excess dye from the parts that should be relatively unstained</p>
Action on tissue	<p>General: Stain that colors all parts of the tissue equally, providing no significant differentiation</p> <p>Selective: Stain that differentiates between classes of tissue or between parts of cells</p>
Differentiation	<p>Using regressive staining methods, the process of removing excess stain is called differentiation; this usually provides sharp staining contrasts because the hydronium and hydroxide ions in the solvents used for differentiation diffuse more rapidly than any dye ion; some of the ways in which a tissue section may be differentiated include the use of acidic or basic medium and excess mordant, buffers, or oxidizers</p>
Staining mechanisms	<p>Capillarity and osmosis: Account for penetration of the dye into the interior of the tissue</p> <p>Absorption or solution: Passage of the dye molecule from the dye bath solution to the solution in the substance being dyed</p> <p>Adsorption: Deposition of dye on the surface of the dyed material (physical surface adsorption plus salt linkages of dye to the protein chain)</p>
Chemical factors	<p>Acid-base: Based on the fact that certain cell parts are assumed to be acidic and other parts are alkaline</p> <p>Ionic strength of dye solution: Dissolved salt, either neutral or buffered, in the dye solution influences the interaction of dye and tissue; increased ionic strength decreases the staining of both acidic and basic dyes; salt ions may compete with color ion for binding site on the protein molecules</p> <p>Dye concentration: Greater amounts of dye are bound with increasing concentrations of the dye; amount of dye bound by tissue is limited by the number of available binding sites</p> <p>Fixation of tissue: When cells are fixed, the affinity for stains increases; protein molecules are reorganized so that chemical groups are more available to the dye (characteristic shared by all fixatives); greater basic dye uptake after formalin fixation; more acidic dye uptake after fixation with mercuric chloride fixatives</p> <p>Temperature: Increase in temperature increases the diffusion rate of dye molecules; increase also causes protein molecules to swell the fibers, rendering them more open to dye penetration</p> <p>Staining equilibrium: Staining is a reversible reaction; when the solution environment is changed, the equilibrium concentration in the tissue is altered</p>

Table 23.4 Nuclear and cytoplasmic stains

Stain	Comments
Nuclear stains	
Technical classification	Reagents used: Dyes can be either natural or synthetic; natural dyes include cochineal, carmine, and hematoxylin; synthetic dyes include derivatives of substances found in coal tar, oxazines (safranin, basic fuchsin), thiazins (methylene blue, toluidine blue), crystal violets, and gentian violets How reagents are used: Depending on mordants, other solutions, etc., results will vary
Nucleic acids	DNA (nucleus): Feulgen reaction used to demonstrate DNA (periodic acid-Schiff stain) RNA (nucleolus, cytoplasm/mitochondria, ribosomes): Methyl green-pyronin used to demonstrate DNA (methyl green) and RNA (pyronin)
Cytoplasmic stains	
Definition	Usually consist of acidic dyes that contain sulfonic and carboxylic acids that combine with tissue bases, especially those proteins with an excess of the basic amino acids such as arginine, lysine, hydroxylysine, and histidine
Common cytoplasmic stains	Picric acid: Nitro dye used as a yellow contrast stain in collagen methods, as well as with hematoxylin Eosin: Used as a counterstain with hematoxylin; can be used as an aqueous or alcoholic solution
Mordant	
Definition	A substance capable of combining with a dye and the material to be dyed, thereby increasing the affinity or binding of the dye

Table 23.5 Carbohydrate stains

Carbohydrates	Stains ^a	Comments
Polysaccharides	Iodine: Starch and by-products (amylose and amylopectin) give blue color; glycogen and amyloid give a red-brown reaction PAS: glycogen strongly positive	Glycogen is the only polysaccharide that occurs in higher animals (liver cells, muscle, cartilage, certain parathyroid cells); starch occurs as carbohydrate reserves in plants; cellulose occurs in cell walls of plants
Mucopolysaccharides (acidic mucopolysaccharides, neutral mucopolysaccharides [not very relevant])	Iodine: Starch and by-products (amylose and amylopectin) give blue color; glycogen and amyloid give a red-brown reaction PAS: For carbohydrates, glycogen strongly positive, acid mucopolysaccharide does not stain, neutral mucopolysaccharide is not present in significant amounts, but chitin will stain; for lipids, glycolipids and phospholipids are PAS positive; for proteins, pale background color probably due to very small amounts of carbohydrate	Hyaluronic acid is the only example of a simple acidic mucopolysaccharide; main component of ground substance (substance that embeds collagen and elastic fibers) (eye, synovia, some pathologic conditions); for sulfated acidic mucopolysaccharides, heparin is found in a large variety of tissues (tissue mast cells are the site of production), and chondroitin sulfate is found in connective tissue and cartilage
Mucoproteins	PAS: Positive Toluidine blue for mucin: Positive	Complexes in which the protein, rather than the carbohydrate, is the principal constituent; found in blood group antigens, digestive and respiratory, etc.; the term “mucin” usually signifies mucoprotein
Glycoproteins	PAS: Positive	Similar to mucoproteins (hexosamine content, <4%); collagen, reticulin fibers; frequently synonymous with “mucoids”
Glycolipids	PAS: Positive	Contain 1 mol each of a fatty acid, sphingosine, and hexose; examples are cerebrosides and gangliosides

^a PAS, periodic acid-Schiff.

Table 23.6 Most likely, secondary, and rare body site locations for human protozoan parasites^a

Parasite	Life cycle stage ^b	Most likely site(s)	Secondary site(s)	Rare site(s)
Amebae				
<i>Entamoeba histolytica</i>	T	Colon	Liver, lungs, kidneys, skin, small intestine	Brain, heart, lymph nodes, peritoneal cavity, reproductive system, eye, spleen, bone
<i>Entamoeba gingivalis</i> ^c	T	Buccal cavity		
<i>Acanthamoeba</i> spp.	T/C	Eye, brain, skin		Lungs, bone
<i>Balamuthia mandrillaris</i>	T/C	Brain		
<i>Naegleria fowleri</i>	T	Brain		
<i>Sappinia diploidea</i>	T	Brain		
Flagellates				
<i>Giardia lamblia</i>	T	Small intestine, appendix		
<i>Leishmania</i> spp.	A	Skin, liver, spleen, bone marrow		Reproductive system, eye
<i>Trypanosoma cruzi</i>	A	Heart, bloodstream, bone marrow	Muscle, brain, colon, female reproductive system	Stomach, small intestine, lymph nodes
Ciliate				
<i>Balantidium coli</i>	T	Small intestine, appendix, colon		Lymph nodes, peritoneal cavity
Apicomplexans				
<i>Cryptosporidium</i> spp.	CO, O	Small intestine, appendix	Stomach, lungs, liver, gallbladder	
<i>Cyclospora cayatanensis</i>	CO, O	Small intestine		
<i>Isoospora belli</i>	CO, O	Small intestine		Lungs, lymph nodes
<i>Sarcocystis</i> spp.	CO	Muscle, heart, small intestine, blood vessel walls		
<i>Toxoplasma gondii</i>	B, Ta	Brain, lungs, heart, lymph nodes, eye, female reproductive system, spleen	Skin, liver, gallbladder, kidneys, pancreas, small intestine, male reproductive system, bone	Bladder, ureters
<i>Plasmodium</i> spp.	M	Bloodstream, red blood cells	Liver	
Microsporidia				
<i>Enterocytozoon bienersi</i>	S	Small intestine, colon	Lungs, liver, kidneys	
<i>Encephalitozoon intestinalis</i>	S	Small intestine, colon	Lungs, heart, liver, gallbladder, kidneys	
<i>Encephalitozoon</i> spp.	S	Small intestine, colon, eye	Lungs, heart, liver, gallbladder, kidneys, bloodstream vessels, lymph nodes	
<i>Pleistophora</i>	S	Muscle	Eye	
<i>Trachipleistophora</i> , <i>Brachiola</i>	S	Muscle	Eye	
<i>Nosema</i>	S	Eye, muscle (<i>Nosema</i> -like)		
<i>Vittaforma corneae</i>	S	Eye		
" <i>Microsporidium</i> "	S	Eye		

^a Adapted from references 1 and 5.^b A, amastigotes; B, bradyzoites; C, cyst; CO, coccidian stages; M, malarial parasites; O, oocyst; S, spores and microsporidial stages; T, trophozoite; Ta, tachyzoites.^c If found in sputum, can be misdiagnosed as *E. histolytica* from pulmonary abscess.

Table 23.7 Most likely, secondary, and rare body site locations for human helminth parasites^a

Parasite	Life cycle stage ^b	Most likely site(s)	Secondary site(s)	Rare site(s)	Comments
Intestinal nematodes					
<i>Ascaris lumbricoides</i>	A/L	Small intestine (A), lungs (L)	Liver, gallbladder, kidney, pancreas (A)	Pleural cavity	Tendency to migrate if disturbed
<i>Enterobius vermicularis</i>	A	Small intestine, colon	Peritoneal cavity, female reproductive system	Lungs	Extremely common; eggs highly infectious
<i>Trichuris trichiura</i>	A	Colon	Small intestine		“Whipworm”
<i>Capillaria philippinensis</i>	A	Small intestine			Eggs resemble <i>Trichuris</i>
Hookworms (<i>Ancylostoma duodenale</i> , <i>Necator americanus</i>)	A/L	Small intestine (A), lungs (L)			Eggs identical
<i>Trichostrongylus</i> spp.	A	Small intestine			Similar to hookworm disease
<i>Strongyloides stercoralis</i>	A/L	Small intestine (A), small intestine (L)	Lungs, colon (L)	Liver, kidneys (L)	May cause disseminated disease
Tissue nematodes					
<i>Trichinella</i> spp.	A/L	Small intestine (A), muscle (L)		Brain (L)	Pork, bear, walrus meat
<i>Baylisascaris procyonis</i>	L	Brain	Muscle, lungs, heart, liver, gallbladder		Associated with raccoons
<i>Lagochilascaris</i> spp.	A/L	Skin, buccal cavity		Lungs	Rare human infection
<i>Toxocara canis</i>	L	Eye, liver	Lungs	Brain, heart	Causes VLM and OLM
<i>Toxocara cati</i>	L	Eye, liver		Brain, heart	Causes VLM and OLM
<i>Ancylostoma</i> spp.	L	Skin	Muscle	Eye	Causes OLM
<i>Dracunculus medinensis</i>	A	Skin		Pericardium, eye, brain	“Fiery serpent”
<i>Angiostrongylus cantonensis</i>	A	Brain		Lungs, eye	Rat lungworm
<i>Angiostrongylus costaricensis</i>	A	Small intestine, peritoneal cavity			Abdominal disease
<i>Gnathostoma spinigerum</i>	L	Skin, muscle	Brain	Small intestine, eye	Larvae migrate throughout the body
<i>Anisakis</i> spp.	L	Stomach, small intestine		Peritoneal cavity	Associated with sushi and sashimi
<i>Pseudoterranova decipiens</i>	L	Stomach, small intestine		Peritoneal cavity	Associated with sushi and sashimi
<i>Capillaria hepatica</i>	A	Liver			No eggs found in stool
<i>Thelazia</i> spp.	A	Eye			Reported in California
Filarial nematodes					
<i>Wuchereria bancrofti</i>	A	Lymphatics		Lungs, eye	Elephantiasis
<i>Brugia malayi</i>	A	Lymphatics		Lungs	Elephantiasis
<i>Brugia</i> spp. (zoonotic)	A	Lymphatics		Lungs	
<i>Onchocerca volvulus</i>	A	Skin			“River blindness”
<i>Onchocerca</i> spp. (zoonotic)	A	Skin			
<i>Loa loa</i>	A	Skin, eye			African eye worm
<i>Mansonella perstans</i>	A	Peritoneal cavity		Eye

Table 23.7 Most likely, secondary, and rare body site locations for human helminth parasites^a (continued)

Parasite	Life cycle stage ^b	Most likely site(s)	Secondary site(s)	Rare site(s)	Comments
<i>Mansonella streptocerca</i>	A	Skin			
<i>Mansonella ozzardi</i>	A	Skin			
<i>Dirofilaria immitis</i>	A	Lungs	Heart	Skin	“Coin” lesions
<i>Dirofilaria repens</i>	A	Skin, eye		Lungs	
<i>Dirofilaria</i> spp.	A	Skin, eye		Bloodstream	
Unusual nematodes					
<i>Oesophagostomum</i> spp.	A/L	Colon	Peritoneal cavity		Nodular mass lesions
<i>Mammomonogamus</i> spp.	A	Lungs, buccal cavity			Y-shaped worms
<i>Diocotophyma renale</i>	A/L	Kidney (A), skin (L)			Primarily right kidney
Tissue cestodes					
<i>Taenia solium</i> (cysticercus)	L	Skin, muscle, brain, eye	Heart		Pork tapeworm
<i>Echinococcus granulosus</i> (unilocular cystic hydatid)	L	Liver, lungs	Muscle, brain, heart, kidneys, eye, spleen, bone	Peritoneal cavity	Sheep-sheepdog cycle; hydatid disease
<i>E. multilocularis</i> (alveolar cystic hydatid)	L	Liver	Brain, lungs	Peritoneal cavity	Difficult to treat
<i>Taenia/Multiceps</i> spp. (coenurus)	L	Skin, muscle, brain, eye	Peritoneal cavity		Most often in central nervous system
<i>Spirometra</i>	L	Skin, muscle	Lungs, heart, peritoneal cavity, reproductive system, bladder	Brain, eye	Use of raw, infected tissue as poultice
<i>Diphyllobothrium</i> spp. (spargana)	L				
<i>Mesocestoides</i> spp.	L	Peritoneal cavity			Approximately 20 cases
Intestinal trematodes					
Heterophyids	A/E	Small intestine	Heart (E)		Eggs almost identical
<i>Clonorchis/Opisthorchis</i>	A/E	Liver			Chinese liver fluke
<i>Fasciola</i>	A/E	Liver		Skin, peritoneal cavity	Sheep liver fluke
<i>Paragonimus</i> spp.	A/E	Lungs	Skin, brain (A/E); muscle (A/E)		Lung fluke
<i>Schistosoma mansoni</i>	A/E	Blood vessels, peritoneal cavity, mesenteries (A); colon (E)	Brain (E)	Liver, gallbladder	(E) Inferior mesenteric veins (A)
<i>Schistosoma haematobium</i>	A/E	Bladder, ureters, blood vessels (A); colon (E)			Vesicle, prostate, uterine plexuses (A)
<i>Schistosoma japonicum</i>	A/E	Peritoneal cavity, mesenteries, blood vessels	Lungs (E); brain, small intestine, colon (E)	Liver, gallbladder	(E) Superior mesenteric veins (A)
Unusual trematodes					
<i>Alaria</i> spp.	L	Skin	Stomach, lymph nodes, liver	Eye	Ingestion of poorly cooked frogs (legs)
Arthropods					
<i>Demodex</i> spp.	A/L	Skin (hair follicles)			Follicle mite
<i>Sarcoptes scabiei</i>	A/L	Skin			Itch mite, scabies

Table 23.7 (continued)

Parasite	Life cycle stage ^b	Most likely site(s)	Secondary site(s)	Rare site(s)	Comments
<i>Tunga penetrans</i>	A	Skin			Chigoe, sand flea
Pentastomes	L	Lungs, liver, peritoneal cavity	Lymph nodes, lymphatics in buccal cavity	Eye	Tongue worms
Myiasis (fly larvae)					
<i>Cochliomyia</i>	L	Nose, ear, brain			Infects living tissue; common name is New World screwworm
<i>Calliphora</i>	L	Skin, intestine, GU tract			Infects dead tissue; common name is bluebottle
<i>Cordylobia</i>	L	Skin, usually feet			Infects subcutaneous boils; common name is Tumbu fly
<i>Sarcophaga</i>	L	GI tract, skin, GU tract, vagina			Infects dead or living tissue, depending on species; common name is flesh fly
<i>Dermatobia</i>	L	Skin, boils, brain			Infects living tissues; common name is human botfly
<i>Cuterebra</i>	L	Skin, eye			Infects living tissue; common name is North American botfly
<i>Gastrophilus</i>	L	Skin, migrates to eye			Undergoes “larva migrans” cutaneous migration; common name is horse botfly
<i>Hypoderma</i>	L	Skin, eye, nasopharynx			Undergoes extensive larval wandering (limbs); common name is warble fly
<i>Oestrus</i>	L	Nasopharynx, eye, sinuses			Infects living tissue, resembles conjunctivitis; common name is sheep nasal botfly

^a Adapted from references 1, 4, and 5.

^b A, adult (for filarial nematodes, includes immature adults, not microfilariae); E, eggs; GI, gastrointestinal tract; GU, genitourinary tract; L, larva(e).

Protozoa

Figure 23.1 *Entamoeba histolytica*. Section of an amebic ulcer of the colon with characteristic undermining and partial destruction of the muscularis. The serosa is edematous and hyperemic. Multiple ulcers may develop and coalesce. Organisms would be found in the healthy tissue border, not in the necrotic material within the ulcer. $\times 7$. (Armed Forces Institute of Pathology photograph.)

Figure 23.2 *Entamoeba histolytica*. Section of an amebic ulcer of the colon with erosion of the muscularis. The characteristic “flask-shaped” ulcer, in which the opening on the surface is much smaller than the actual ulcer below, is clearly visible. Multiple ulcers are often present and may coalesce under the surface. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 23.3 (Upper) Section of colon shows diffuse invasion of muscularis by trophozoites of *Entamoeba histolytica*. $\times 85$. (Armed Forces Institute of Pathology photograph; contributed by Ruy Perez-Tamayo, Mexico, D.F.) (Lower) Higher magnification of the same specimen. Trophozoites have infiltrated the muscularis of the colon (arrows). $\times 170$. (Armed Forces Institute of Pathology photograph.)

Figure 23.4 *Entamoeba histolytica*. Trophozoite in the exudate within the ulcerated dermis. The nuclear structure is visible but does not clearly show the nucleus and karyosome. The nuclear structure is more darkly staining than the cytoplasm.

Figure 23.6 Gross image of liver abscess caused by *Entamoeba histolytica*. Note the sunken area of the abscess. (Centers for Disease Control and Prevention.)

Figure 23.5 Section of colon showing the nuclei and central karyosomes (arrows) of two invading trophozoites of *Entamoeba histolytica*. $\times 1,224$. (Armed Forces Institute of Pathology photograph.)

Figure 23.7 Section of liver at the margin of an amebic abscess showing several *Entamoeba histolytica* trophozoites (arrows) in addition to necrosis. $\times 110$. (Armed Forces Institute of Pathology photograph.)

Figure 23.8 *Acanthamoeba* spp. Cutaneous abscess on arm; nonhealing ulcer, possibly as a result of a human bite wound, that was not recognized as being caused by *Acanthamoeba* spp. Therapy with routine antibiotics was ineffective. (Courtesy of George Healy, Centers for Disease Control and Prevention.)

Figure 23.10 *Naegleria fowleri*. Trophozoites are seen in brain tissue. The organisms are shaped like amebae and have the large, characteristic karyosome. The staining of the karyosome is darker than that of the cytoplasm. The karyosome is not clearly visible in all amebae, and the overall image is not as clear as that in Figure 23.9. (Centers for Disease Control and Prevention.)

Figure 23.9 *Balamuthia mandrillaris*. Trophozoites are seen in brain tissue. The organisms are shaped like amebae and have the large, characteristic karyosome. The staining of the karyosome is much darker than that of the cytoplasm of the amebae. (Centers for Disease Control and Prevention.)

Figure 23.11 *Naegleria fowleri*. Trophozoites are seen in brain tissue (1,000 \times oil immersion). Note the very clearly delineated karyosome within the nucleus. Also note the vacuolated cytoplasm that is sometimes seen at higher magnifications. (Centers for Disease Control and Prevention.)

Figure 23.12 *Giardia lamblia* trophozoites seen as very small sickle-like profiles over the intestinal epithelium. $\times 127$. At this magnification, it is very difficult to identify the organisms, but the shape and appearance of the organisms are strongly suggestive of *G. lamblia*. (Armed Forces Institute of Pathology photograph.)

Figure 23.14 *Giardia lamblia* trophozoites seen as teardrop-shaped organisms; note the two “eyes” (nuclei) looking back at you. At this magnification ($1,000\times$ oil immersion), the nuclei, median bodies, and axonemes are visible. Duodenal smear.

Figure 23.13 *Giardia lamblia* trophozoites seen as teardrop-shaped organisms. $\times 645$. Although the teardrop shape is visible for some of the trophozoites, the internal structures (nuclei, median bodies, and axonemes) are not visible at this magnification. (Armed Forces Institute of Pathology photograph.)

Figure 23.15 *Balantidium coli* trophozoites within the intestinal wall (arrows). Normally, the ulcers involve the mucosa and submucosa; however, invasion of the muscular layer may occur, as well as bowel wall perforation. Ulcers tend to be flask shaped (like *E. histolytica*) and shallow and have a wide opening. Extraintestinal dissemination can occur but is rare. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

Figure 23.16 Necrotic gangrenous colon showing *Balantidium coli* trophozoites in a venule. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*. Photograph courtesy of R. B. Holliman.)

Figure 23.18 *Toxoplasma gondii* cyst in brain (note organisms within the cyst); non-AIDS patient. $\times 645$. (Armed Forces Institute of Pathology photograph.)

Figure 23.17 *Toxoplasma gondii* cysts in brain tissue (dark, round objects) of a non-AIDS patient. The presence of these cysts may be an accidental finding at autopsy and may not be the cause of the patient's illness. $\times 129$. (Armed Forces Institute of Pathology photograph.)

Figure 23.19 *Toxoplasma gondii* cysts in tissue. Some of the organisms appear to be more oval or crescent shaped. While these cysts occur in tissue, their presence may or may not be relevant to the patient's clinical condition.

Figure 23.20 *Toxoplasma gondii* cyst in tissue. In this cyst, the individual organisms can be clearly seen. Cysts in brain tissue tend to be more round than those seen in striated muscle.

Figure 23.22 *Sarcocystis* spp. Note the septa which are visible in this low-power image. Bradyzoites of *Toxoplasma gondii* in striated muscle resemble *Sarcocystis* spp. However, the *Sarcocystis* bradyzoites are usually more rounded at both ends, and they are contained in larger cysts than those of *Toxoplasma*.

Figure 23.21 *Toxoplasma gondii* tachyzoites in bone marrow from a 5-year-old child with leukemia. Note the oval or crescent-shaped organisms. (Centers for Disease Control and Prevention.)

Figure 23.23 The *Sarcocystis* septa are visible, as are the crescentic spores. The sarcocyst wall varies from thin and smooth to thick and striated. Although sarcocysts may be confused with cysts of *Toxoplasma*, sarcocysts tend to be larger and contain larger bradyzoites. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

Figure 23.24 *Cryptosporidium* parasites in the rectum. Note the upper left section with organisms (dark spots) against the brush border. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*. Photograph courtesy of K. Lewin.)

Figure 23.26 *Cryptosporidium* parasites in the colon. Note the organisms right at the edge of the brush border. The organisms are within parasitophorous vacuoles and hence are enclosed within membranes of host cell origin. The mucosal architecture tends to be abnormal, with marked shortening of the villi and hypertrophy of the crypts. (Centers for Disease Control and Prevention.)

Figure 23.25 *Cryptosporidium* parasites in the rectum (higher magnification than Figure 23.24). Previously, most human cases were diagnosed after examination of small or large bowel biopsy material, often using both light and electron microscopy. However, because biopsy specimens may not originate from the infected area of the mucosa, immunoassays for the detection of antigen in the stool are being widely used. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*. Photograph courtesy of K. Lewin.)

Figure 23.27 *Cryptosporidium* spp. Transmission electron microscopy of organisms within parasitophorous vacuoles on the intestinal mucosa. (U.S. Department of Agriculture.)

Figure 23.28 *Cryptosporidium* spp. Scanning electron microscopy of organisms at the brush border. Note the sporozoites being released from the cell. (U.S. Department of Agriculture.)

Figure 23.29 Microsporidia in a corneal lesion; note the periodic acid-Schiff-positive dot at the end of each spore (arrows). Routine histologic testing can be performed by using tissue Gram stains or silver stains. Touch preparations can be methanol fixed and stained with Giemsa stain. Plastic-embedded tissues stained with periodic acid-Schiff, silver, acid-fast, and routine hematoxylin-eosin stains generally stain better than paraffin-embedded tissues. This finding may be related to the use of formalin as a tissue fixative (1,000 \times oil immersion).

Figure 23.30 Microsporidia in the intestine; note the spores. When seen in stool, the spores measure approximately 1 to 3 μm . (A) Lower magnification; (B) higher magnification. The microsporidia multiply extensively within the host cell cytoplasm; the life cycle includes repeated divisions by binary fission (merogony) or multiple fission (schizogony) and spore production (sporogony). Both merogony and sporogony can occur in the same cell at the same time. During sporogony, a thick spore wall is formed, providing environmental protection for this infectious stage of the parasite. Microsporidia are characterized by having spores containing a polar tubule, which is an extrusion mechanism for injecting the infective spore contents into host cells. To date, seven genera have been recognized in humans: *Brachiola*, *Encephalitozoon*, *Enterocytozoon*, *Pleistophora*, *Trachipleistophora*, *Vittaforma*, and “*Microsporidium*,” a catchall genus for those organisms not yet classified.

Figure 23.31 Microsporidia in various stages of development in the intestinal enterocytes (1,000 \times oil immersion).

Figure 23.32 Microsporidia in various stages of development in the intestinal enterocytes. Note the cells that have evacuated their contents into the lumen of the gut (1,000× oil immersion).

Figure 23.33 Microsporidia. Note the spores within the kidney. Dissemination to the kidneys is not uncommon, particularly with *Encephalitozoon* spp. Any patient with suspected microsporidiosis should have both stool and urine examined for spores. Both *Enterocytozoon bieneusi* and *Encephalitozoon* spp. can disseminate from the gut to other body sites, including the kidneys.

Helminths—Roundworms

Figure 23.34 Diagram of roundworm musculature morphology in tissue. (A) Polymyarian type. (B) Meromyarian type. (C) Homomyarian type. C, cuticle; DVC, dorsal-ventral chord; IN, intestine; LA, lateral alae; LC, lateral chord; M, muscle; OV, ovary. See Table 23.8 below. (Illustration by Sharon Belkin.)

Table 23.8 Musculature of nematodes^a

Characteristic	Polymyarian	Meromyarian	Homomyarian
No. of rows of muscle cells	More than 5	Between 2 and 5	Does not exceed 2
Size of cells	Small, uniform	Large, various shapes	Very small, uniform
Arrangement of cells	Projecting into body cavity	Irregular	Regular
No. of cells	Many in each quarter	2 or 3 in each quarter	Many in complete circle
Lateral chords	Present	Present	Absent
Parasites with this type of musculature	<i>Ascaris</i> , filaria, <i>Dracunculus</i> , <i>Angiostrongylus</i> , <i>Anisakis</i>	<i>Enterobius</i> , hookworms	<i>Trichuris</i> , <i>Trichinella</i>

^a Adapted from references 1 to 6.

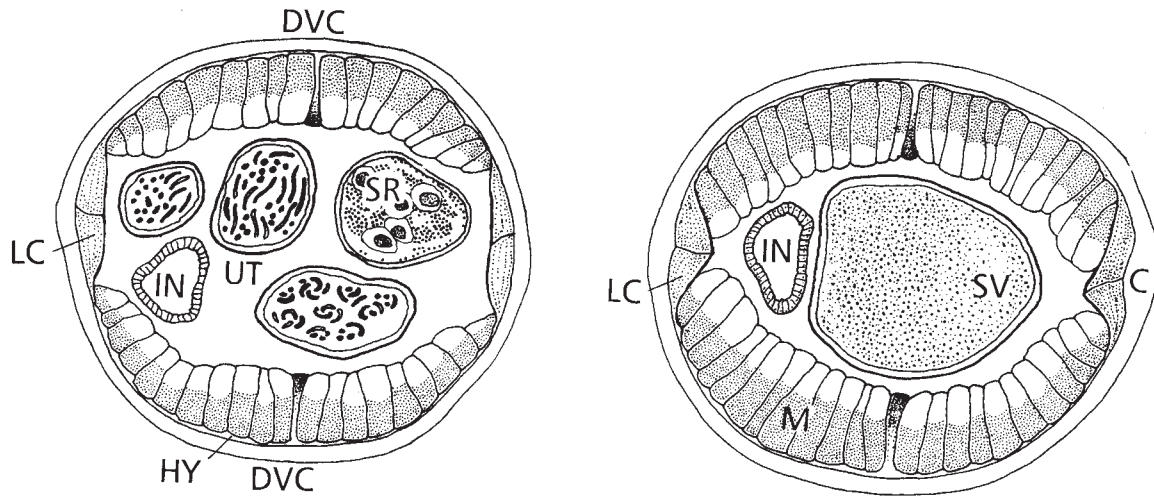

Figure 23.35 Diagram through *Loa loa* (female on the left, male on the right) (polymyarian type of musculature). Note the well-developed muscle layer divided into four bands separated by the lateral, ventral, and dorsal chords. The muscle cells project into the body cavity. C, cuticle; DVC, dorsal-ventral chord; HY, hypodermis; IN, intestine; LC, lateral chord; M, muscle; SR, seminal receptacle; SV, seminal vesicle; UT, uterus. (Illustration by Sharon Belkin.)

Figure 25.36 Diagram through *Anisakis* (left) and *Baylisascaris procyonis* (right) (polymyarian type of musculature). In *Anisakis*, note the well-developed muscular esophagus (ES) and the Y-shaped lateral chords (LC). In *B. procyonis* (brain tissue), one section is through the esophagus (ES) while the other is through the middle of the body, showing the excretory columns (EC), intestine (IN), and large lateral chords (LC). Note that the lateral alae (LA) are visible in each section.

Figure 23.37 Adult *Ascaris lumbricoides* in a dilated bile duct. $\times 12$. At this low magnification, the individual polymyarian muscle cells are somewhat more difficult to see but the large lateral chords are clearly visible. (Armed Forces Institute of Pathology photograph.)

Figure 23.39 Three transverse sections of *Ascaris lumbricoides* larvae in the lung, causing bronchopneumonia. $\times 157$. Even in this low-magnification image, the muscle structure (polymyarian) appears to be divided into quadrants by the lateral chords. (Armed Forces Institute of Pathology photograph.)

Figure 23.38 Cross section of an *Ascaris lumbricoides* adult female. The outer cuticle is partially detached from the parasite. The hypodermis and musculature are visible below the cuticle. Central to the musculature, the flattened tube is the gut and the round tubes are reproductive structures. The large round tubes are egg-containing uteri; the others are sections through ovaries and oviducts. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 23.40 *Baylisascaris procyonis* larva (polymyarian type of musculature) and inflammation in the corpus callosum of an infected rabbit. *B. procyonis* is an ascarid normally found in raccoons, has a normal ascarid-like life cycle, and causes a very serious zoonotic disease in humans. Human infections result from ingestion of eggs that are passed in very large numbers (millions of eggs/day) in the feces of infected raccoons. Rather than developing to adult worms as occurs in the raccoon, the larvae migrate extensively throughout the body tissues, causing visceral larva migrans (VLM) and/or neural larva migrans (NLM). (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of K. R. Kozacos.)

Figure 23.41 *Lagochilascaris* (polymyarian type of musculature) encapsulated larvae in the submucosa of a resected tonsil. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*. Photograph courtesy of D. Botero and M. D. Little.)

Figure 23.43 *Anisakis* in the stomach wall. Note the typical polymyarian type of musculature and the Y-shaped lateral chords. Human infection is acquired by the ingestion of raw, pickled, salted, or smoked saltwater fish. The larvae often penetrate the walls of the digestive tract (frequently the stomach), where they become embedded in eosinophilic granulomas. The throat is occasionally involved. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*.)

Figure 23.42 *Toxocara* larva present in the skin. Since these are not photographed from a cross section, the typical musculature arrangement is not visible. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*.)

Figure 23.44 *Dirofilaria* sp. Note the polymyarian type of musculature and the clearly delineated lateral chords. Also note the longitudinal ridges in the cuticle (bumpy appearance). (Courtesy of Marjorie R. Fowler and Andrea Linscott.)

Figure 23.45 *Dirofilaria* sp. (higher magnification than Figure 23.44). Note the typical polymyarian type of musculature and the more clearly delineated longitudinal ridges on the inner surface of the cuticle. The cuticle is relatively thick and multilayered. The very prominent lateral chords are also visible; although ventral and dorsal chords are present, they are usually inconspicuous. (Courtesy of Marjorie R. Fowler and Andrea Linscott.)

Figure 23.46 *Capillaria hepatica* eggs in liver. These eggs resemble those of *Trichuris trichiura*, but the shells in *Capillaria* eggs are striated. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 23.47 Diagram through *Enterobius vermicularis* (both images are of females) (meromyarian type of musculature). Note the very conspicuous lateral alae (LA). The muscle cells (M) are large, of various shapes, and irregular; there are fewer cells per quadrant than seen in the polymyarian type (Figure 23.35). The lateral chords (LC), intestine (IN), ovary (OV), and uterus (UT) are also visible. (Illustration by Sharon Belkin.)

Figure 23.48 Appendix containing two transverse sections of a female *Enterobius vermicularis* worm (arrows). $\times 13$. Although this nematode has the meromyarian type of musculature, this magnification is too low to see any details. (Armed Forces Institute of Pathology photograph.)

Figure 23.50 Colon containing *Enterobius vermicularis*, non-gravid female, midbody. Note the lateral alae (arrows). $\times 166$. Also note the typical meromyarian musculature, with large, differently shaped, irregular cells (two or three cells in each quadrant). (Armed Forces Institute of Pathology photograph.)

Figure 23.49 Cross section of adult *Enterobius vermicularis* worms in the appendix. Note the characteristic football-shaped eggs (arrows). The lateral alae are also visible. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

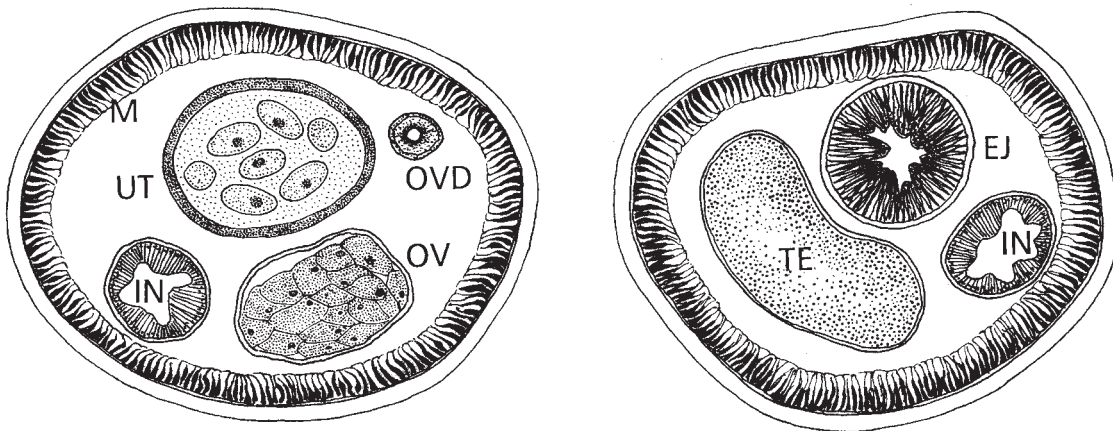

Figure 23.51 Diagram through *Trichuris trichiura* (female on the left, male on the right) (homomyarian type of musculature). Note the very small, uniform muscle cells (M) with a regular arrangement, with many cells arranged in a complete circle. Note also the absence of lateral chords. The ejaculatory duct (EJ), intestine (IN), ovary (OV), oviduct (OVD), uterus (UT), and testis (TE) can also be seen. (Illustration by Sharon Belkin.)

Figure 23.52 Several sections of adult male and female *Trichuris trichiura* worms in the colon, showing the narrow anterior portion of the worm within the mucosa (“whip”) (arrows) and the thicker posterior portion (“handle”) free in the lumen. $\times 15$. (Armed Forces Institute of Pathology photograph.)

Figure 23.53 *Trichuris trichiura* in cross section. Note the smaller sections that represent the head end, which is embedded in the mucosa, while the larger sections represent the tail portion (whip handle).

Figure 23.54 *Trichuris trichiura* in the canine cecum. Cross sections through the thin “whiplike” anterior portion and the thick posterior “handle” are seen. Note the musculature of the body wall beneath the cuticle, the gut, and the uterus filled with eggs (arrows). The musculature is of the homomyarian type, with very small, uniform, regular cells with many cells in a complete circle. No lateral chords are present. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 23.56 Adult *Ancylostoma caninum* in the canine intestine. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 23.55 *Ancylostoma caninum*. There are three pairs of teeth in the mouth of this adult hookworm. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 23.57 *Trichinella spiralis* encysted larvae in muscle. *Trichinella* forms a complex of at least five species, all of which appear to be the same morphologically but, on the basis of DNA studies and comparative features, are quite different. The five recognized *Trichinella* spp. are *T. spiralis*, *T. nativa*, *T. nelsoni*, *T. britovi*, and *T. pseudospiralis*; a sixth species, *T. papuae*, has also just been proposed. Although *Trichinella* spp. have the homomyarian type of musculature, the magnification of this image is insufficient to show the details.

Figure 23.58 *Trichinella spiralis* encysted larva in muscle. Squash preparation of tissue biopsy specimen.

Helminths—Cestodes

Figure 23.59 Diagram of a transverse section of a *Taenia* proglottid. Under the thick tegument, the underlying parenchyma is divided into cortical (CO) and medullary (ME) layers by a thick band of longitudinal muscles (M). The excretory columns (EC) are clearly visible. Branches of the uterus (UT) and testes (TE) are also seen. (Illustration by Sharon Belkin.)

Figure 23.60 (Left) Diagram of a cysticercus of *Taenia solium*. The extensively folded spiral canal and a scolex with two large suckers are clearly visible. The denser tissue of the rostellum (between the two suckers) is also visible. In this particular section plane, the hooklets are not visible. Host tissue forms a fibrous capsule around the cysticercus. (Right) Diagram of a unilocular hydatid cyst of *Echinococcus granulosus*. The outer thick fibrous wall is visible (FW) and is produced by the host. Within the fibrous layer is the thinner laminated layer (LL), while right below that layer is the thin germinal epithelial layer (GL) from which daughter cysts and multiple protoscolices arise. Multiple protoscolices within a brood capsule are visible in this illustration. Note that the middle laminated layer is acellular and the thin germinal layer contains some calcareous corpuscles. (Illustration by Sharon Belkin.)

Figure 23.61 *Taenia solium* cysticercus in pig muscle. The cysticercus consists of a fluid-filled bladder containing a single protoscolex. The cysticerci (*T. solium*) have a thick bladder wall, and the rostellum has two rows of hooklets (13 each). Each cysticercus measures 5 to 15 mm long by 4 to 12 mm wide. A convoluted spiral canal leads to the rostellum. The parenchyma usually contains calcareous corpuscles. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*. Photograph courtesy of P. M. Schantz.)

Figure 23.63 *Taenia solium* subcutaneous nodule from a patient (higher magnification than Figure 23.62). (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*. Photograph courtesy of K. Juniper, Jr.)

Figure 23.62 *Taenia solium* subcutaneous nodule from a patient. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*. Photograph courtesy of K. Juniper, Jr.)

Figure 23.64 *Taenia solium* cysticercus. Low magnification.

Figure 23.65 *Taenia solium* cysticercus (higher magnification than Figure 23.64; same specimen).

Figure 23.67 Scolex of a cysticercus showing a sucker and hooklets of *Taenia solium* (arrows). $\times 148$. (Armed Forces Institute of Pathology photograph.)

Figure 23.66 *Taenia solium* cysticercus in the brain, surrounded by fibrous tissue. The scolex is invaginated with two of the four suckers (arrows), and several hooklets are visible. The scolex is surrounded by fluid and the cyst wall. $\times 42$. (Armed Forces Institute of Pathology photograph.)

Figure 23.68 *Taenia solium* racemose cyst in the brain. Autopsy gross specimen. (From a Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 23.69 *Taenia solium* racemose cyst in the brain; the bladder wall of the racemose cysticercus has three separate layers. The tegumental surface has wartlike protuberances and is acidophilic. Beneath the tegument are small, rounded, pyknotic nuclei. The innermost layer is made up of loose connective tissue.

Figure 23.71 *Hymenolepis nana* cysticerci in the villi of a mouse. When mature, these cysticerci emerge, attach to the intestinal wall, and develop into the adult worm (same life cycle seen in humans). (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of B. Gueft; specimen courtesy of M. Yoeli.)

Figure 23.70 *Taenia solium* racemose cyst in the brain (higher magnification than Figure 23.69; same specimen).

Figure 23.72 *Hymenolepis nana* cysticerci in the villi of a mouse. Note the curved suckers (arrows). (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of B. Gueft; specimen courtesy of M. Yoeli.)

Figure 23.73 *Hymenolepis nana* cysticerci in the villi of a mouse. Note the hooklets (arrow). (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman*. Photograph courtesy of B. Gueft; specimen courtesy of M. Yoeli.)

Figure 23.75 Wall of the *Echinococcus granulosus* cyst, which has a laminated membrane (arrow). The germinal layer and scolexes are also visible. $\times 35$. (Armed Forces Institute of Pathology photograph.)

Figure 23.74 *Echinococcus granulosus* brood capsules (arrow) arising from the germinal layer. The fibrinous wall of the host and the laminated membrane are also seen. $\times 84$. (Armed Forces Institute of Pathology photograph.)

Figure 23.76 *Echinococcus granulosus*, magnification of the protoscolices.

Figure 23.77 Coenurus from a human eye. *Taenia* species with multiple scolices; no daughter cysts develop in a coenurus. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of P. J. Fripp.)

Figure 23.79 Coenurus. Note the section through all four suckers. Coenurosis is caused primarily by two species of *Taenia*, *T. multiceps* and *T. serialis*, formerly known as *Multiceps multiceps* and *M. serialis*. A coenurus consists of a viscous, fluid-filled bladder into which multiple scolices invaginate. Cysts measure from a few millimeters to a few centimeters in diameter. Protoscolices can number >100, each having four suckers and an armed rostellum. These tend to be much less common than the typical cysticerci caused by *T. solium*.

Figure 23.78 Coenurus from a human eye (higher magnification of hooklets than Figure 23.77; same specimen). (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of P. J. Fripp.)

Figure 23.80 *Taenia* coenurus. Note the sectioned hooklets. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 23.81 *Spirometra sparganum* larva in tissue. Spargana are larval forms of various tapeworms in the genus *Spirometra*. Spargana are white and ribbonlike in shape, range from a few millimeters to >30 cm in length, and are actively motile. The solid sparganum lacks suckers and bladder walls; there are irregular bundles of muscle fibers, typical folded tegument, and calcareous corpuscles in the parenchyma. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

Figure 23.82 *Spirometra sparganum* larva (higher magnification than Figure 23.81; same specimen). Some of the calcareous corpuscles are visible. They appear as small, outlined bodies within the parenchyma. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

Helminths—Trematodes

Figure 23.83 Diagram of the cross section of a trematode. Note the coiled uterus (UT) containing eggs, the lobed ovary (OV), intestinal caeca (IC), and excretory canals (EC). Also, note the large ventral sucker (VS). (Illustration by Sharon Belkin.)

Figure 23.84 (Left) Diagram of male and female *Schistosoma* trematodes. The female worm is lying with the male worm in copulo. Note the small tuberculations on the dorsal tegument of the male worm. (Right) Sections of adult *Clonorchis sinensis* in the common bile duct. Note that in different sections, different structures are visible, including the intestinal caeca, the ovary, and parts of the testis. Also note the marked proliferation of the bile duct epithelium. (Illustration by Sharon Belkin.)

Figure 23.85 Two *Paragonimus westermani* parasites within a lung cavity. Note the dark, small spots of the vitellaria just within the tegument. The dark openings represent the ceca, with clear portions of the uterus. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 23.86 *Paragonimus westermani* adult worms in the lung. In this image, the vitellaria are also visible, as are portions of the uterus, the intestinal caeca, and the ventral sucker (seen in the right cross section). (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 23.87 *Paragonimus westermani* eggs in the lung. Note the granuloma surrounding one of the eggs. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 23.89 Adult *Fasciola hepatica* in the liver. Note that the intestinal ceca and portions of the testes are clearly visible. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman; photograph courtesy of B.C. Walton.)

Figure 23.88 Adult *Fasciola hepatica* embedded in the intestinal wall. The parasite presents as an oval to round mass limited by a spined cuticle. The parasitic parenchyma is punctuated by multiple sections through the gut. The two centrally located tubular structures, separated by a light-staining muscular sucker (arrow), are part of the reproductive apparatus of the parasite. A marked inflammatory response is present in the adjacent host tissues, and fresh red blood cells can be seen near the parasite. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman; photograph courtesy of B. C. Walton.)

Figure 23.90 *Clonorchis sinensis* eggs in the adult worm within the bile duct. Note the operculum that is visible on the egg(s) in the left upper portion of the photograph. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 23.91 *Echinostoma* adult worm in the bowel wall. The spines around the oral sucker are seen in cross section. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

Figure 23.93 *Schistosoma* adults in the lung. In the lower left worm cross section, the smaller portion is the female worm; however, it is somewhat difficult to tell that the female worm is lying within the gynecophoral canal of the male. In the right upper section, the male worm is clearly seen. Note that the female worm is not visible in the upper left image and may not be present with the male worm (in copulo). (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

Figure 23.92 *Schistosoma japonicum* eggs in the appendix. The eggs are acid fast. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.* Photograph courtesy of I. Miyazaki, Fukuoka, Japan.)

Figure 23.94 *Schistosoma* adults in tissue. Note that the smaller female worm is lying within the gynecophoral canal of the male worm. The intestinal ceca are visible within both male and female worms. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

Figure 23.95 *Alaria americana* in an autopsied human lung, showing hemorrhagic pneumonia and the etiologic agent, a mesocercaria. Note the evidence of both the oral sucker and the acetabulum (ventral sucker). (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of R. S. Freeman.)

Figure 23.96 *Alaria americana* (higher magnification than Figure 23.95; same specimen). Note the oral sucker at the anterior end. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of R. S. Freeman.)

Blood Parasites

Figure 23.97 Malaria. Section through the cerebrum showing more congestion of the white matter than of the gray. (Armed Forces Institute of Pathology photograph.)

Figure 23.98 Cerebral malaria showing cerebral capillaries congested with parasitized erythrocytes (arrows). $\times 269$. Parasitized erythrocytes stick to the endothelium and occlude the capillaries. (Armed Forces Institute of Pathology photograph.)

Figure 23.99 A ring hemorrhage in the brain surrounding a thrombosed vessel. The thrombus contains many parasitized erythrocytes. The erythrocytes in the hemorrhagic area do not contain parasites, a feature which contrasts the low percentage of parasitized erythrocytes in the circulating blood with the high percentage of parasitized erythrocytes in the thrombosed capillaries. $\times 305$. (Armed Forces Institute of Pathology photograph.)

Figure 23.101 Cerebral malaria. Note the capillary containing parasitized erythrocytes. In cerebral malaria, the brain is edematous and heavy and has broadened and flattened gyri. Microscopically, the capillaries and small veins are congested and many of the erythrocytes are parasitized. Parasitized erythrocytes stick to the endothelium and occlude the capillaries. Not only are the rings visible, but pigment grains are also seen within the erythrocytes (Armed Forces Institute of Pathology photograph.)

Figure 23.100 Malarial pigment present in the spleen. The spleen is enlarged to about 500 g during an acute attack and is soft, diffusely pigmented, congested and has rounded edges. The phagocytic cells lining the splenic sinuses contain malarial pigment, free parasites, and parasitized erythrocytes. During an acute attack, malarial pigment is evenly disbursed throughout the spleen.

Figure 23.102 Diagram of amastigotes. (Left) *Leishmania donovani* amastigotes in a spleen smear. Each amastigote contains the dark, round nucleus and the bar-shaped kinetoplast. When cells are packed with amastigotes, often the complete morphology for each amastigote is not visible. (Right) *Trypanosoma cruzi* amastigotes in cardiac muscle. Each amastigote contains the nucleus (round, dark) and the kinetoplast (small bar). (Illustration by Sharon Belkin.)

Figure 23.103 Smear of bone marrow showing many intracellular and extracellular *Leishmania* organisms. The amastigotes (Leishman-Donovan bodies) appear larger in smears than in tissue sections. The nuclei and kinetoplasts are distinct in these organisms. $\times 850$. In some amastigotes, both the nucleus and kinetoplast (bar) are visible. (Armed Forces Institute of Pathology photograph.)

Figure 23.104 *Leishmania donovani*. Section of liver showing dilated sinusoids and greatly enlarged Kupffer cells (arrow). $\times 140$. (Armed Forces Institute of Pathology photograph.)

Figure 23.105 Enlargement of the Kupffer cell illustrated in Figure 23.104 (arrow). The cytoplasm contains *Leishmania* organisms. $\times 1,530$. The individual amastigotes are packed into the cell; organism characteristics (nuclei and kinetoplasts) are not clearly visible. The amastigotes appear as very small dots. (Armed Forces Institute of Pathology photograph.)

Figure 23.107 *Leishmania* spp. (cutaneous leishmaniasis). Biopsy specimen taken through the margin of an ulcer showing necrosis, hyperplastic epithelium, and inflammatory cells in the dermis. $\times 61$. (Armed Forces Institute of Pathology photograph.)

Figure 23.106 Wilder's reticulum stain of the same liver as shown in Figures 23.104 and 23.105. The small black dots within Kupffer cells are *Leishmania* organisms. $\times 374$. At this magnification, individual organism characteristics are not visible. (Armed Forces Institute of Pathology photograph.)

Figure 23.108 *Leishmania* spp. (cutaneous leishmaniasis). Inflammatory cell infiltrate, which is composed of histiocytes, lymphocytes, and plasma cells. Some of the histiocytes contain amastigotes. $\times 259$. (Armed Forces Institute of Pathology photograph.)

Figure 23.109 *Leishmania* spp. (cutaneous leishmaniasis). Reticulum stain showing the nuclei and kinetoplasts (arrows) of the many amastigotes within histiocytes. $\times 1,530$. It is difficult to see the outlines of the actual amastigotes, but the nuclei and kinetoplast are visible in some of the amastigotes within the histiocytes. (Armed Forces Institute of Pathology photograph.)

Figure 23.111 *Trypanosoma cruzi*. Acute chagasic myocarditis with a myofiber filled with amastigotes (arrow). $\times 400$. At this magnification, the amastigotes look like very small dots. (Armed Forces Institute of Pathology. Photograph contributed by the Gorgas Memorial Laboratory.)

Figure 23.110 *Trypanosoma cruzi*. Chronic chagasic cardiopathy with scarring and chronic inflammation, left ventricle. $\times 40$. (Armed Forces Institute of Pathology photograph.)

Figure 23.112 *Wuchereria bancrofti* microfilariae in the epididymis. Note the thin, threadlike structures in the lower right portion of the photograph. Various lengths are seen, depending on the actual tissue cut. Although these helminths are nematodes, they are shown with the blood parasites, since blood is the primary specimen for diagnostic purposes.

Figure 23.113 *Wuchereria bancrofti* microfilariae (higher magnification than Figure 23.112; same specimen). In this image, the “stringy” microfilariae are easily visible; there is the suggestion of cellular nuclei within the larval worm.

Figure 23.115 Dermis. Longitudinal section of a *Loa loa* microfilaria within a capillary shows the cephalic space (arrow). $\times 336$. (Armed Forces Institute of Pathology photograph.)

Figure 23.114 Microfilaria of *Wuchereria bancrofti* (arrows) in the lung. $\times 510$. In this image the elongated microfilaria is seen and the cellular nuclei within the organism are also visible. (Armed Forces Institute of Pathology photograph.)

Figure 23.116 *Mansonella streptocerca* in a section of skin. Note the long, slender microfilariae in utero. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

Figure 23.117 *Onchocerca volvulus* nodule containing adult worms; note the microfilariae in utero (cross sections of the slender microfilariae). (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

Medically Important Arthropods

Arthropods and their relationship to disease

Biological vectors of microorganisms

Bites and envenomation

Tissue invasion

Entomophobia and delusory parasitosis

Class Insecta (insects)

Order Diptera (flies, mosquitoes, and midges)

Myiasis

Order Hemiptera (true bugs)

Order Coleoptera (beetles)

Order Siphonaptera (fleas)

Order Anoplura (sucking lice)

Order Mallophaga (biting and chewing lice)

Order Hymenoptera (bees, wasps, and ants)

Order Blattaria (cockroaches)

Class Arachnida (ticks, mites, spiders, and scorpions)

Subclass Acari (ticks, mites, and chiggers)

Subclass Araneae (spiders)

Subclass Scorpiones (scorpions)

Other arthropods

Class Chilopoda (centipedes)

Class Diplopoda (millipedes)

Class Crustacea (copepods, crabs, crayfish, etc.)

Control of arthropods of medical importance

Physical control

Biological control

Chemical control

Over one million species in the Animal Kingdom are found in the phylum Arthropoda. These invertebrates are characterized by the possession of an exoskeleton, an internal hemocele that is filled with hemolymph and the internal organs, and a body that is usually divided into the head, thorax, and abdomen. Arthropods develop through a process called metamorphosis, often involving three or four stages: egg, nymph, and adult (bedbugs, sucking lice, and cockroaches); egg, larva, pupa, and adult (flies, fleas, mosquitoes, and bees); or egg, larva, nymph (one or more), and adult (ticks and mites). Classification of the medically important arthropods is shown in Table 24.1 (17, 43, 47).

The importance of this group is due primarily to the morbidity and mortality of the various diseases they transmit, as well as their wide geographic distribution. Arthropods can transmit disease via mechanical transmission, in which the arthropod vector is not a part of the life cycle of the organism, and biological transmission, in which the arthropod vector is an integral part of the life cycle of the organism (multiplication or development or both in the vector). Vector-borne parasitic human infections are listed in Table 24.2. In addition to serving as vectors of various infections, certain arthropods may cause some degree of pathologic changes as a result of their bites, stings, or presence on or in the body. Examples are given in Table 24.3. Specific diagnostic tests and recommended therapy for the more common arthropods are listed in Table 24.4. Specific terms related to the identification of specific arthropods can be found in Table 24.5. The relative sizes of some of the more important arthropods can be seen in Figure 24.1.

Arthropods and Their Relationship to Disease

Biological Vectors of Microorganisms

As biological vectors, arthropods can serve as intermediate hosts for human infections or can accidentally carry microorganisms from one host to another. They can transmit various protozoa (the agents of malaria, leishmaniasis, and trypanosomiasis, and *Babesia* spp.), helminths (filarial worms, lung flukes, and tapeworms), bacteria (*Yersinia pestis* and *Francisella tularensis*), rickettsiae (the agents of typhus, trench fever, and bartonellosis), chlamydias (the agents of trachoma, lymphogranuloma venereum, and psittacosis), spirochetes (the agents of relapsing fever, yaws, and Lyme disease), and viruses (arboviruses).

Table 24.1 Classification of medically important arthropods^a

Class	Order	Common name	
Insecta	Diptera	Blackflies	
		Sand flies	
		Mosquitoes	
		Biting midges	
		Deerflies	
		Botflies	
		Warble flies	
		Houseflies	
		Tsetse flies, etc.	
		Flesh flies	
		Blowflies	
		Kads	
		Louseflies	
		Hemiptera	Assassin bug
	Bedbugs		
	Beetles		
	Coleoptera	Beetles	
	Siphonaptera	Fleas	
	Anoplura	Sucking lice	
	Mallophaga	Biting lice	
	Hymenoptera	Honeybees	
Wasps			
Ants			
Cockroaches			
Blattaria	Acari (S)	Hard ticks	
		Soft ticks	
		Itch mites	
		Chiggers	
		Follicle mites	
		Spiders	
	Araneae (S)	Spiders	
		Scorpions (S)	Scorpions
	Pentastomida		Tongue worms
	Diplopoda		Millipedes
Chilopoda		Centipedes	
Crustacea (SP)	Copepoda (S)	Water fleas	
	Decapoda	Crabs, crayfish	

^a S, subclass; SP, subphylum.

As vectors, arthropods may serve as mechanical vectors of the etiologic agent, merely transporting the organisms from one host to another or from the environment to a host. However, most agents of arthropod-borne disease use the arthropod as a biological vector, requiring a period of incubation or development in this host. Although most vectors ingest the etiologic agent of disease, they transfer

the organisms to humans in several ways, including via an arthropod-derived vomit drop on food or drink or in a puncture wound. Fecal pellets may also contain the infecting organism, as can the hemolymph if the vector is crushed on the skin. Salivary secretions can also contain the infective organisms.

A number of criteria must be fulfilled before an arthropod can be considered a disease vector. The suspected vector must be known to bite humans in a geographic area where human infections are documented. Second, the geographic distribution of the suspected vector must include the distribution of the disease in humans. Third, the causative agent of disease must be isolated from wild-caught vectors and must be the same species as that causing disease in humans. Fourth, it must be shown that naturally or experimentally infected vectors can maintain the infection throughout the complete life cycle of the parasite. Finally, experimental transmission of the parasite by a bite is generally considered proof of the vector's ability to transmit the organism.

Bites and Envenomation

Most individuals have come in direct contact with arthropods which are problems because of their bites and human sensitivity to their saliva or toxins. Human contact occurs when arthropods are feeding or bite in self-defense. Generally these bites do not cause serious problems, unlike stings, for which the reaction may be more severe. The outcome depends on a number of factors, including the arthropod involved, the amount of toxic substance introduced into the body, the physical condition of the bite victim, and possible previous exposure. Individual responses can vary from mild itching and redness to life-threatening reactions.

Arthropods usually associated with the introduction of saliva during the act of biting include the Acari (ticks and mites), Anoplura (sucking lice), Araneae (spiders), Chilopoda (centipedes), Diptera (flies, mosquitoes, and biting midges), Hemiptera (true bugs: bedbugs, kissing bugs, and triatomid bugs), and Siphonaptera (fleas).

Envenomation is usually associated with stings; however, some groups can introduce venom during a bite. These include some of the spiders, particularly the widow spiders, violin spiders, and some tarantulas. Human contact with some groups of urticating caterpillars (which have body hairs that can inject venom) may also produce mild to serious skin conditions (Figures 24.2 to 24.5). Eye disease has also been linked to this type of contact (5, 20).

Tick-induced paralysis is also seen and is caused by the injection of toxin from gravid female ticks embedded in the flesh of the host. A review of 33 cases of

Table 24.2 Vector-borne human infections

Type of infection and disease	Causative agent	Vector (common name)
Protozoal infections		
Malaria	<i>Plasmodium</i> spp.	Mosquitoes
Leishmaniasis	<i>Leishmania</i> spp.	Sand flies
Chagas' disease	<i>Trypanosoma cruzi</i>	Triatomid bugs
East African trypanosomiasis	<i>T. brucei rhodesiense</i>	Tsetse flies
West African trypanosomiasis	<i>T. brucei gambiense</i>	Tsetse flies
Babesiosis	<i>Babesia</i> spp.	Ticks
Helminthic infections		
Filariasis	<i>Wuchereria bancrofti</i>	Mosquitoes
Filariasis	<i>Brugia malayi</i>	Mosquitoes
Filariasis	<i>Dirofilaria</i> spp.	Mosquitoes
Filariasis	<i>Mansonella perstans</i>	Biting midges
Filariasis	<i>M. streptocerca</i>	Biting midges
Filariasis	<i>M. ozzardi</i>	Biting midges
Onchocerciasis	<i>Onchocerca volvulus</i>	Blackflies
Loiasis	<i>Loa loa</i>	Deerflies
Dog tapeworm infection	<i>Dipylidium caninum</i>	Dog lice, dog fleas, human fleas
Rat tapeworm infection	<i>Hymenolepis diminuta</i>	Rat fleas, beetles, grain beetles
Dwarf tapeworm infection	<i>Hymenolepis nana</i>	Grain beetles (rare)

tick-induced paralysis in Washington state showed that most of the patients were female (76%) and most cases (82%) occurred in children younger than 8 years; two of the children died (14). Onset of illness occurred from 14 March to 22 June, and nearly all cases indicated probable exposure east of the Cascade Mountains. Of the 28 patients for whom information was available, 54% were hospitalized. When tick identification to species was reported, *Dermacentor andersoni* was consistently reported. Certainly tick-induced paralysis is a preventable cause of illness and death, and if diagnosed early, it requires simple, low-cost intervention (tick removal).

Stinging arthropods can be found in the following groups: Hymenoptera (ants, bees, hornets, and wasps) and the Scorpiones. Individuals vary in their reaction to these stings; certainly, anaphylaxis has been seen in cases related to bee stings. The frequency of mass bee attacks has dramatically increased in the Americas following the introduction and spread of the aggressive Africanized "killer" bee (*Apis mellifera scutellata*). Currently there is no specific therapy available. However, an antivenom for the treatment of mass bee attacks has been developed; venoms from European and Africanized bees appear to be almost, if not, identical (26). Scorpion stings are usually no more severe than bee stings; however, there are exceptions, and each year there are numerous deaths in Mexico as a result of scorpion stings. The venom is thought to be a toxalbumin that affects the nervous and pulmonary systems.

Some millipedes produce secretions that can cause contact vesicular dermatitis. These fluids can be squirted from glands located on the body segments. Blister beetles can also produce these types of fluids, leading to skin blisters within hours after contact.

Although death is rarely attributable to these types of injuries, small children and the very old may demonstrate severe reactions to both arthropod bites and stings.

The fire ant, *Solenopsis invicta*, is an example of an arthropod that has proven to be relatively dangerous, particularly in certain patients; the stings cause a fiery, burning sensation (Figure 24.6). Severe allergic reactions, particularly in children, may require immediate attention. In the southeastern United States, the continued spread of these ants has caused agricultural problems, changes in the ecosystem, and increasing numbers of people with sting sequelae, including hypersensitivity reactions, secondary infections, and rare neurologic problems. Apparently, evolutionary changes have facilitated their expansion northward into Virginia and westward into California; further expansion is also anticipated (29). Because of their resistance to natural and chemical control, fire ants can overwhelm their environment, causing destruction of land and animals. They can also cause a variety of health problems in humans, ranging from simple stings to overwhelming anaphylaxis and death. Although deaths caused by imported fire ant stings are rare, they

Table 24.3 Medically important arthropods and their potential effect on humans

Representative species	Common name	Geographic distribution	Effect(s) on humans
Insecta			
Anoplura (sucking lice)			
<i>Pediculus humanus humanus</i>	Body louse	Worldwide	Skin reactions to bites; vectors of rickettsiae and spirochetes
<i>P. humanus capitis</i>	Head louse	Worldwide	Skin reaction to bites
<i>Phthirus pubis</i>	Crab louse	Worldwide	Skin reaction to bites
Mallophaga (biting lice)			
<i>Trichodectes canis</i>	Dog louse	Worldwide	None—can transmit <i>Dipylidium caninum</i>
Hemiptera (true bugs)			
<i>Cimex lectularius</i>	Bedbug	Worldwide	Skin reaction to bites
<i>C. hemipterus</i>	Tropical bedbug	Tropical and subtropical	Skin reaction to bites
<i>Triatoma infestans</i> , <i>Rhodnius prolixus</i> , <i>Panstrongylus megistus</i>	Kissing bug, conenose bug	Tropical and subtropical regions of the New World	Skin reaction to bites; vectors of <i>Trypanosoma cruzi</i> , the cause of Chagas' disease
Hymenoptera (bees, wasps, ants)			
<i>Apis mellifera</i>	Honeybee	Worldwide	Painful sting, potential anaphylaxis
<i>Bombus</i> spp.	Bumblebee	Worldwide	Painful sting, potential anaphylaxis
Various genera and species of the family Vespidae	Wasp, hornets, yellow jackets	Worldwide	Painful sting, potential anaphylaxis
<i>Solenopsis</i> spp.	Fire ant	Tropical America, southeastern United States	Painful bite and multiple stings, potential anaphylaxis
Diptera (flies, mosquitoes, and their relatives)			
<i>Culicoides</i> spp.	Biting midge	Worldwide	Serious biting pest; skin reaction to bites; vectors of several filarid nematodes
<i>Leptoconops</i> spp.			
<i>Phlebotomus</i> spp.	Sand fly	Worldwide	Skin reaction to bites; vectors of leishmaniasis, bacteria, and viruses
<i>Lutzomyia</i> spp.	Sand fly	Tropical region of New World	
<i>Simulium</i> spp.	Blackfly, buffalo gnat	Worldwide	Serious biting pests; skin reaction to bites; vectors of <i>Onchocerca</i> and <i>Mansonella</i> spp.
<i>Aedes</i> spp.	Mosquito	Worldwide	Serious biting pests; skin reaction to bites; vectors of viruses, protozoa, and filaria
<i>Anopheles</i> spp.	Mosquito		
<i>Culex</i> spp.	Mosquito		
<i>Culiseta</i> spp.	Mosquito		
<i>Mansonia</i> spp.	Mosquito		
<i>Tabanus</i> spp.	Horsefly	Worldwide	Biting pests; painful bite followed by skin reaction
<i>Chrysops</i> spp.	Deerfly	Worldwide	Biting pests; vectors of tularemia and <i>Loa loa</i>
<i>Glossina</i> spp.	Tsetse fly	Africa	Biting pests; vectors of African trypanosomes
Siphonaptera (fleas)			
<i>Ctenocephalides canis</i> , <i>C. felis</i>	Dog flea, cat flea	Worldwide	None—can transmit <i>Dipylidium caninum</i>
<i>Pulex irritans</i>	Flea	Worldwide	Dermatitis, ulcerations
<i>Xenopsylla cheopis</i>	Rat flea	Worldwide	None—can transmit <i>Hymenolepis diminuta</i>
<i>Tunga penetrans</i>	Chigoe flea	Tropical and subtropical	Nodular swelling with subsequent ulceration
Orthoptera (cockroaches, grasshoppers, and their relatives)			
<i>Blattella germanica</i>	German cockroach	Worldwide	Mechanical disseminator of pathogens; intermediate host of certain helminths
<i>Periplaneta americana</i>	American cockroach	Worldwide	
Various genera	Cockroach	Worldwide	
Coleoptera (beetles)			
Various genera and species	Beetles	Worldwide	Mechanical disseminators of pathogens

(continued)

Table 24.3 Medically important arthropods and their potential effect on humans (*continued*)

Representative species	Common name	Geographic distribution	Effect(s) on humans
Various species of the family Meloidae	Blister beetles	Worldwide	Blistering of skin after contact with adult
<i>Tenebrio</i> spp.	Grain beetles	Worldwide	Intermediate hosts of tapeworms— <i>Hymenolepis</i> spp.
Lepidoptera (moths and butterflies)			
Various genera and species	Caterpillar	Worldwide	Urticating spines and hairs may cause reaction when handled or inhaled
Arachnida			
Scorpionida (scorpions)			
Various genera and species	Scorpion	Tropical and subtropical	Initially painful sting, often followed by systemic reactions
Araneidae (spiders)			
<i>Lactrodectus mactans</i>	Black widow spider	Americas	Bite usually painless, delayed systemic reaction
<i>Lactrodectus</i> spp.	Widow spider	Worldwide	Bite usually painless, delayed systemic reaction
<i>Loxosceles reclusa</i>	Brown recluse spider	Americas	Initial blister at wound site followed by sometimes extensive necrosis and slow healing
<i>Loxosceles laeta</i>	South American brown spider	South America	
Acarina (ticks and mites)			
<i>Ornithodoros</i> spp.	Soft tick	Worldwide	Skin reactions to bite; tick paralysis; vectors of relapsing fever
<i>Amblyomma</i> spp.	Hard tick	Worldwide	Skin reactions to bite; tick paralysis; vectors of rickettsias, viruses, bacteria, and protozoa
<i>Dermacentor</i> spp.			
<i>Ixodes</i> spp.			
<i>Demodex folliculorum</i>	Follicle mite	Worldwide	Found in sebaceous glands and hair follicles, occasional skin reactions
<i>Sarcoptes scabiei</i>	Human itch mite	Worldwide	Burrows in skin, causing severe itching
<i>Trombicula</i> spp.	Chigger, red bug	Worldwide	Intense itching at site of attachment; vectors of rickettsias
Crustacea			
<i>Cyclops</i> spp.	Copepod	Worldwide	Intermediate hosts of guinea worm and broadfish tapeworm
<i>Diaptomus</i> spp.			
Chilopoda			
<i>Scolopendra</i> spp.	Centipede	Tropical and subtropical	Painful bite
Pentastomida			
<i>Linguatula serrata</i>	Tongue worm	Tropical	Endoparasitic in internal organs

may become more common as the fire ant population expands (40). Two alkaloid components of imported fire ant venom cause cardiorespiratory depression and elicit seizures in rats. Such effects identify these alkaloids as toxic compounds and may explain the cardiorespiratory failure seen in some individuals who experience massive fire ant stings (23).

S. invicta and *S. richteri* are not the only ant species to cause serious allergic or adverse reactions. Ant

species belonging to 6 different subfamilies (Formicinae, Myrmeciinae, Ponerinae, Ectatomminae, Myrmicinae, and Pseudomyrmecinae) and 10 genera (*Solenopsis*, *Formica*, *Myrmecia*, *Tetramorium*, *Pogonomyrmex*, *Pachycondyla*, *Odontomachus*, *Rhytidoponera*, *Pseudomyrmex*, and *Hypoponera*) have this capability. Awareness that species other than imported fire ants may cause severe reactions should lead to more rapid patient evaluation and treatment (31).

Table 24.4 Common arthropods: diagnostic procedures and recommended therapy

Name	Symptoms	Diagnostic procedure	Recommended therapy
Fly larvae			
Cutaneous, mucocutaneous	Painful, indolent ulcers; furuncle-like sores; dermal lesions like creeping eruption	Remove larvae, place in petri dish (blood agar plate). Identification will depend on examination of the larval stigmal plates and/or the adult fly (should often be referred to an experienced entomologist).	Local palliatives, often including antibiotics for secondary infections
Nose	Obstruction of nasal passages, facial edema, and fever		
Ear	Crawling sensations, buzzing noises, foul-smelling discharge		
Eye	Severe irritation and pain		
Intestinal	Severe nervous symptoms as well as internal irritation		Treatment with castor oil will expel these larvae
Bedbugs	Asymptomatic, edema, inflammation, indurated ring at site of feeding, asthma, anxious concern	Examination and identification of adult bug	Local palliatives and insecticides, thorough washing of all bedding
Reduviid bugs, (kissing bugs, cone-nose bugs)	Local swelling and induration, oozing of blood from puncture site, generalized urticaria (bites commonly on exposed parts of skin, face, outer area of eye, lip)	Examination and identification of adult bug	Local palliatives
Fleas			
<i>Tunga penetrans</i>	Adult female burrows into skin (often toes and feet), causing nodular swelling, subsequent ulceration and festering sores	Examination and identification of adult flea	Wearing shoes, flea removal aseptically with needle, bathing of wound and treating with antiseptic
<i>Pulex irritans</i> (human), <i>Xenopsylla cheopis</i> (rat), <i>Ctenocephalides canis</i> (dog)	Asymptomatic; roseate raised lesion, frequently edematous, indurated, or pustular (bites are more common on lower extremities)		Local palliatives, use of recommended insecticides
Lice			
<i>Pediculus</i> spp., <i>Phthirus pubis</i>	Cutaneous lesions, roseate elevated papule, intense pruritus, lesions may become secondarily infected by bacteria	Examination and identification of adult and/or eggs on hair shaft	Shampoo or ointment (1% lindane); dusts with 1% malathion; bedding can be fumigated with ethyl formate; remaining nits can be removed with fine-toothed comb
Ticks			
Tick paralysis	Generalized toxemia, fever (104°F), rapid ascending flaccid paralysis, difficulty in swallowing and respiration, and death; little or no change in white cell count	Careful examination of body, particularly back of the neck and along spinal column	Prompt removal of the engorging female tick will usually limit progression of paralysis (due to toxin in tick saliva)
Other ticks and bites	Inflammatory infiltration of tissues, local hyperemia, edema, hemorrhage (histolysis at the bite site as a result of salivary secretions)	Examination and identification of adult tick	Anterior portion should be grasped with forceps close to the skin and pulled <i>straight out</i> ; leaving mouth parts may cause severe tissue reactions and possible secondary infections

(continued)

Table 24.4 Common arthropods: diagnostic procedures and recommended therapy (*continued*)

Name	Symptoms	Diagnostic procedure	Recommended therapy
Mites			
<i>Sarcoptes scabiei</i> (itch mite)	Small skin vesicles; scratching results in bleeding and scab formation followed by secondary infection	Skin scraping (avoid excoriated lesions); get material from early papule or burrow (between fingers, wrists, elbows, axillae, penis, scrotum, buttocks, backs of knees, ankles, toes, under breasts)	Topical application of 1% lindane in lotion or ointment (may require one to three applications); should be applied after scrubbing and soaking in warm water to expose lesions
Spiders			
Black widow spider	Symptoms will depend on amount of venom injected; may include abdominal cramps, hypertension, and convulsions	History and/or identification of spider	Specific antivenom is available (patients should be tested for horse serum sensitivity before use); other supportive therapy depending on symptoms
Violin spider, brown recluse spider	Bite may be painless; mild to severe pain within hours; erythema, vesicle formation, and itching followed by chills, headache, and nausea; the lesion becomes necrotic, spreads, and heals very slowly; kidney damage and death may also occur	Identification of spider	Prompt administration of steroids, early surgical excision of lesion (skin grafting may be necessary), treatment of secondary infections

Tissue Invasion

A number of arthropods are capable of actual tissue invasions, some of which may occur in the superficial tissues and some in deep body sites. These groups include Acari (ticks and mites), Diptera (flies, mosquitoes, and biting midges), Pentastomida (tongue worms) (see chapter 18), and Siphonaptera (fleas). The pentastomes are wormlike parasites that are related to the arthropods. On ingestion of eggs by humans, larvae migrate to the tissues, where they develop into nymphs and become encapsulated. Although most of these infections are asymptomatic, clinical manifestations can occur and include inflamed and enlarged lymph nodes, abdominal pain, jaundice, and ocular lesions (see chapter 18).

Various ticks, mites, and fleas tend to invade tissues at the superficial levels; these include *Sarcoptes scabiei* (itch mite), *Tunga penetrans* (chigoe flea), and members of the Argasidae (soft ticks) and the Ixodidae (hard ticks). Not only do these arthropods cause painful bites, but also they are responsible for transmission of diseases caused by bacteria, viruses, and rickettsia.

When we consider arthropod tissue invasion, we usually think of myiasis, i.e., infestation with fly larvae (maggots). Clinically, myiasis is often categorized according to the part of the body invaded: cutaneous, mucocutaneous, intestinal, and genitourinary. Some larvae develop only in living tissue, while others prefer dead or necrotic tissue. Entry sites for egg or first-stage larva deposition can include unbroken skin, open wounds or lesions, nose or ears, mouth with subsequent swallowing, and genitourinary

openings. There are three general groups of myiasis-causing flies: (i) those that require a host for the development of their larval stages, (ii) those that develop in a host if entry occurs via wounds or sores but development in a host is not required, and (iii) those that accidentally invade a host but generally complete larval development without a host.

Entomophobia and Delusory Parasitosis

Fear of insects, entomophobia, is sometimes seen and may become an issue in mentally disturbed individuals (17). These patients may report insect infestations, describing in great detail the presence of tiny insects in or on the skin. Symptoms may be described as crawling or biting sensations and are often accompanied by excessive scratching by the patient.

Delusory parasitosis usually represents a more serious emotional disorder in which patients believe that they have parasites in or on the body. These patients often describe many physician visits and consults with unproductive results; laboratory findings are consistently negative. They are absolutely convinced that they have legitimate problems and continue to try and get confirmation of problems that are imaginary rather than real. They tend to bring in small bits and pieces of skin, debris, pictures, drawings, etc., none of which demonstrate true infestation. Often, these bits and pieces of debris are of nonanimal origin (string, paper, plant material, etc.). We have received complete notebooks filled with 8-by-10-in. photographs of “parasites”—none of which depict anything that can be recognized as possible arthropods

Table 24.5 Common terms used in discussing arthropods

Term	Definition
Antennae	Segmented appendages located in the lateral side of the head
Capitulum	“False-head” found in arachnids; basal portion of structure is “basis capituli”
Cell	Area of wing enclosed by veins
Cerci	Appendages (slender, two) at terminal abdominal segment
Chelicerae	Appendages (grasping or cutting) in place of jaws; found in arachnids
Claw	Appendage (sharp, curved) at end of leg
Complete metamorphosis.	Cycle of development (e.g., egg, larva, pupa, adult); each stage distinct from others
Compound eye.	Visual elements (large number) grouped on each side of head
Costa	Thickening of the anterior edge of the wing
Coxa	Proximal segment of the leg
Ecdysis	Shedding of larval skin during transformation from one stage to another
Emergence	Appearance of winged insect from the pupal stage
Epipharynx	Organ attached to inner part of labrum
Exoskeleton	External skeleton
Fat body.	Group of cells (widely distributed, food store); contains protein, fats, glycogen
Festoons.	Notches seen at posterior part of body of hard ticks
Gill.	Specialized respiratory organ seen in aquatic insects
Haltere.	Club-shaped structure in place of second pair of wings in Diptera
Hypopharynx.	Tongue-shaped structure; lies between labrum and labium; connected to salivary duct
Hypostome.	Lower lip which takes the form of an elongated structure armed with teeth or hooks in ticks
Incomplete metamorphosis	Morphology between adults and immature stages similar; stages resemble each other
Labial palpi	Pair of appendages arising from each side of the labrum
Labium.	Lower lip which forms floor of mouth
Labrum	Upper lip which forms roof of the mouth
Longitudinal veins	Series of six veins following the subcosta; numbered in sequence
Maggot	Common name given to larva of some Diptera (flies)
Mandibles	Pair of upper jaws
Maxillae.	Pair of lower jaws
Mesonotum	Dorsal surface of second thoracic segment
Myiasis.	Infestation of human and animal tissues with fly maggots
Nymph.	Immature stage in insects undergoing incomplete metamorphosis
Ocellus.	Simple eye
Ovipositor	Tubular structure through which eggs are laid
Palmate hairs	Fan-shaped hairs on dorsal surface of anopheline larva
Pedipalp.	Second pair of appendages which arise from cephalothorax in arachnids
Pleuron.	Lateral part of a segment
Pronotal comb	Anterior segment of thorax
Pronotum.	Dorsal surface of first thoracic segment
Prothorax.	Anterior segment of thorax
Pseudotracheae.	Small tubes found on labella (through which fluid is sucked) in houseflies and members of the Tabanidae
Pygidium	Pincushion-like structure seen on ninth segment of fleas
Scutellum	Small posterior section of the tergum
Scutum	Chitinous shield seen on the dorsum of Acarina
Sensilla.	Hairs which have sensory function
Setae.	Hairlike structures which are hollow internally
Spermatheca.	Sperm-storing organ in lower genital tract of females
Spiracles.	Respiratory openings
Subcosta.	Vein lying posterior to the costa
Tergum.	Dorsal plate on thoracic segment
Tissue invasion.	Infestation (superficial tissues); infection (deeper tissues)
Tracheae.	Ringed breathing tubes
Vector	Transmitter of infection (arthropods)

Scorpion	—————	30-40 mm
Centipede	—————	30-40 mm
Triatomid bug	—————	25 mm
Black widow	—————	20 mm
Fly larva	—————	15-20 mm
Violin spider	—————	9-15 mm
Soft tick	—————	~12 mm
Tse Tse fly	—————	12 mm
Deer fly	—————	8-12 mm
Hard tick	—————	4-10 mm
Bedbug	—————	~5 mm
Sandfly	—————	~5 mm
Mosquito	—————	~4 mm
Black fly	—————	4 mm
Biting midge	—————	1-2.5 mm
Flea	—————	1.5 mm
Body louse	—————	1.5 mm
Crab louse	—————	1 mm
Itch mite	—————	~.25 mm

Figure 24.1 Relative sizes of various arthropods. (Illustration by Sharon Belkin.)

or any other type of parasite. These patients search out specific medical professionals, often by making multiple telephone calls and calling medical and other scientific societies. Unfortunately, they can benefit only from psychiatric treatment. However, patients with delusions of parasitosis

Figure 24.2 Caterpillars that sting (A and B) or cause dermatitis (C and D). (A) Io moth, *Automeris io*; (B) puss caterpillar, *Megalopyge opercularis*; (C) saddleback caterpillar, *Sibine stimulea*; (D) brown tail moth, *Euproctis chrysorrhoea*. (Illustration by Sharon Belkin.)

Figure 24.3 Saddleback caterpillar (*Sibine* sp.), which may cause dermatitis and necrosis. The irritant is in the barbed rigid nettling hairs. (Armed Forces Institute of Pathology photograph.)

generally reject psychiatric referral. The diagnosis of delusions of parasitosis can often be made on the basis of the history alone, but it is important to ensure that the patient does not have an organic skin disorder and that the delusion is not secondary to another mental or physical illness.

In spite of these psychiatric problems, it is still appropriate to check all possibilities: bites from unrecognized mites or other insects either at home or in the workplace or potential exposure to other allergic stimuli that may be unrelated to insect or organism contact need to be considered. Unfortunately, in many of these patients, the presentation is so convincing that it is difficult at first to recognize the situation as a mental rather than actual physical problem.

Class Insecta (Insects)

Some of the more important orders are presented in this section. Adults have a segmented body composed of the head, thorax, and abdomen; one pair of antennae; three

Figure 24.4 Caterpillars. *Monema flavescens* (left) and *Parasa* sp. (right). The small knobs on the body segments carry the stinging hairs, which are too small to be seen in the photograph. (Armed Forces Institute of Pathology photograph.)

Figure 24.5 *Megalopyge opercularis*, the puss caterpillar. Dermatitis is caused by venom introduced into human skin by hollow larval poisonous spines and occurs 24 h after exposure. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

pairs of legs; and, in some cases, wings. The exoskeleton is composed of hard plates (sclerites) separated by flexible membranes (conjunctivae or arthroal membrane) or grooves (sutures).

Order Diptera (Flies, Mosquitoes, and Midges)

The order Diptera contains numerous kinds of flies, mosquitoes, and midges. The members of this group have two pairs of wings, one pair of which, the halteres, are vestigial and are used for balance only.

Sand Flies (Leishmaniasis)

Sand flies occur mainly in the tropics and subtropics, limited to areas where the temperatures are above 15.6°C for a minimum of 3 months of the year. They are found

Figure 24.6 Severe reaction to multiple stings from a fire ant, *Solenopsis invicta*, on the arm of a male in Mississippi. (Armed Forces Institute of Pathology photograph.)

Figure 24.7 Sand fly (*Phlebotomus* and *Lutzomyia* spp., vectors of *Leishmania* spp.), ~5 mm. (Illustration by Sharon Belkin.)

in a number of habitats, from below sea level to 2,800 m above sea level or higher. Sand flies are small, long-legged flies that are about 5 mm long (Figure 24.7). These small flies are able to pass through ordinary mosquito netting. Two genera (*Phlebotomus* in the Old World and *Lutzomyia* in the New World) are of medical importance (Figure 24.8). Only the females feed on blood, usually that of mammals; such feeding normally occurs at night. The bite site is usually indurated and inflamed, with a wheal 1 to 2 cm in diameter, and is accompanied by pruritus. Some patients even respond with a systemic allergic reaction, including fever, nausea, and malaise. Although many sand flies can fly extended distances, they usually move in short, jerky hops along walls and ceilings. Spraying with residual insecticide is somewhat effective; however, elimination of larval habitats would be a more important control measure.

Sand flies are a geologically old group, being identified from about 120 million years ago, prior to the origin of mammals. They probably originally fed on reptiles, and their ancient status led to the evolution of different groups in the New and Old Worlds. Their main importance is as vectors of *Leishmania* spp., causing human cutaneous, mucocutaneous, and visceral disease. About 80 of 700 known sand fly species are known vectors of *Leishmania* spp. Two species of *Lutzomyia* occur in south and central Texas, as well as parts of Mexico, and are probably the vectors of cutaneous leishmaniasis in Texas. It is interesting that lectins and toxins in the plant diet of *Phlebotomus papatasi* can kill *Leishmania major* promastigotes in the sand fly and in culture; these vegetation components may decrease parasite transmission in certain areas (24). Control measures against the adult flies include the use of the bacterial insecticide, *Bacillus thuringiensis* (52).

Figure 24.8 Sand fly (*Phlebotomus* sp.). (Photograph courtesy of Duane J. Gubler, Centers for Disease Control and Prevention.)

Blackflies (Filariasis [*Onchocerca* and *Mansonella* spp.]

Blackflies (buffalo gnats, turkey gnats, Kolumbtz flies) transmit *Onchocerca volvulus* worldwide; in the Old World these vectors are limited to Africa, while in the New World the vectors are found in various parts of Central and South America. Blackflies are small flies (*Simulium* spp.), measuring 1 to 5 mm long and usually having a stout body and humped back (Figure 24.9). Only the females suck blood, and swarms may attack humans as well as domestic

Figure 24.9 Blackfly (*Simulium* sp., vector of *Onchocerca volvulus* and *Mansonella* spp.), 4 mm. (Illustration by Sharon Belkin.)

and wild mammals, usually during the daytime; the blood meal is required for egg development. Although not usually that painful, the bite is accompanied by intense itching and the development of a raised, ulcerative lesion at the site, most probably caused by the saliva in the puncture wound. Individuals who are particularly susceptible may experience severe pruritus and body swelling (blackfly fever), which is seen predominantly in children in rural areas of the northeastern United States. Similar to Hymenoptera, a Simuliidae bite occasionally results in extreme hypersensitivity and should be considered in appropriate cases.

These flies normally do not bite indoors and may fly long distances from their habitats. A massive control effort is now under way in West Africa to lower the intensity of *Onchocerca* transmission to a level of infection that does not lead to visual impairment. Because flight distances are long and the larvae develop in water, control measures are difficult at best. Development occurs in fast-running streams, often very deep; one species was found breeding at depths down to 190 ft (ca. >50 m).

Simuliids have to survive periods when the temperature is too low to sustain routine activities and when the rivers dry up during the off season. They can apparently reduce their respiratory rate and replace trehalose in the hemolymph by high polyhydric alcohols, thus remaining dormant below 4°C. Once the temperature rises, the reverse process is rapidly completed and growth resumes. These flies may not be present in sufficient numbers to be pests, but they can still be important vectors of the filarial worm causing onchocerciasis or “river blindness.”

Deerflies (Filariasis [*Loa loa*])

Adult flies (*Chrysops* spp.) are medium sized to large (about the size of a housefly or larger) and stoutly built, and they have large eyes and dull-colored bodies (Figures 24.10 and 24.11). Only the female is adapted to take a blood meal. The bite site can become a painful wound that takes a long time to heal; individuals may also respond with an allergic reaction to the saliva of the fly. Day-biting flies transmit the human form of disease with *L. loa*, a disease that affects up to 13 million people. This biting time preference coincides with the peak microfilaremia in humans. The adult flies live high in the forest canopy and descend to the forest floor to feed on humans. While most blood-sucking insects are repelled by wood fire smoke, apparently in Africa the flies are attracted to wood fires. Control measures have not been particularly successful, and loiasis continues to be a significant problem in West Africa.

Tsetse Flies (African Trypanosomiasis)

An estimated 60 million people are at risk for African trypanosomiasis, with 300,000 to 500,000 new cases

Figure 24.10 Deerfly (*Chrysops* sp., vector of *Loa loa*), 8 to 12 mm. (Illustration by Sharon Belkin.)

each year, primarily in the Democratic Republic of Congo, Angola, and Sudan. Tsetse flies (*Glossina* spp.) are robust, honey-brown flies measuring 6 to 15 mm long (the size of a housefly) (Figure 24.12). The genus habitat is limited to the African continent south of the Sahara. Both sexes are voracious blood feeders, and both can transmit parasites. Adult flies of the important vectors are daytime feeders and are attracted to moving animals and humans. The flies use movement and smell to find appropriate hosts. Although they can fly long distances, their flight pattern is generally limited to the closest available host and back to particular vegetation, where they spend long periods of rest. The wings have the characteristic “hatchet” cell, which is cleaver shaped (Figure 24.12).

The adults are long-lived and fly long distances, usually along a preferred flight line; they live in areas called fly belts. Some species live by rivers, and others are usually found in the savanna. They feed on many animals as well as humans. This fact, along with their long life

Figure 24.11 Deerfly (*Chrysops* sp.). (Photograph courtesy of Duane J. Gubler, Centers for Disease Control and Prevention.)

Figure 24.12 Tsetse fly (*Glossina* sp., vector of African trypanosomes), 12 mm. The characteristic “hatchet” cell is seen within the circle. (Illustration by Sharon Belkin.)

span, makes vector control difficult; it sometimes involves such drastic measures as killing off game animals in close proximity to humans or moving whole villages out of these fly belts. The use of insecticides has also proven to be somewhat successful. Wherever there are tsetse flies, it is impossible to keep cattle without regular chemotherapy. Trypanosomiasis has inhibited or totally prevented the development of a cattle-raising industry in much of tropical Africa. Currently, cattle ranches are still impractical in the savanna areas of Africa. Also, there is increasing resistance to melarsoprol, the key drug for central nervous system involvement in African trypanosomiasis.

Stableflies, Houseflies, and Horseflies (Potential Carriers of Infectious Organisms)

Flies in the genus *Stomoxys* (stableflies) (Figures 24.13 and 24.14) resemble the housefly. Both male and female flies can be tremendous pests with an impressive bite (causing a stabbing pain), which involves ripping open the skin through which the biting apparatus is inserted. Along the southeast coast of the United States, these flies breed in decaying seaweed and can be a tremendous tourist problem during fly season. Although control of the larvae has been difficult, insecticides are effective against the adult flies. Residual insecticides are initially effective, but these flies rapidly develop resistance.

Houseflies can harbor >100 different pathogens, most of which can be transmitted. They range from viruses to helminths and include protozoan cysts, oocysts, spores, and helminth eggs. There are several ways in which they can disseminate pathogens. The surface of the body can be contaminated; pathogens can be regurgitated onto food through the fly’s vomit drop; or pathogens can pass through the gut of the fly and be deposited in its feces.

Figure 24.13 Stablefly (*Stomoxys* sp.), 6 to 15 mm long. (Photograph courtesy of Duane J. Gubler, Centers for Disease Control and Prevention.)

It is interesting that in areas such as northern Africa where tsetse flies are not found, domestic animal trypanosomes, *T. evansi* and *T. vivax vivax*, are transmitted mechanically by horseflies (*Tabanus*) and stableflies (*Stomoxys*). These flies can spread trypanosomes within domestic animal herds, causing epidemics with tremendous financial loss.

Biting Midges (Filariasis [*Mansonella* spp.]

Biting midges (*Culicoides* spp.) are the smallest of the biting flies, measuring between 1 and 4 mm (Figure 24.15). They are also known as “punkies,” “no-see-ums,” “gnats,”

Figure 24.14 Stablefly (*Stomoxys* sp.), 6 to 15 mm long. (Photograph courtesy of Duane J. Gubler, Centers for Disease Control and Prevention.)

or “flying teeth.” Only the females feed on blood, and swarms may attack humans or other mammals, usually at dusk, when the air is still. Screen and netting controls are difficult because of the small size of the adult fly. The genus *Culicoides* is widely distributed throughout the world and ranges from sea level to almost 14,000 ft in Tibet. Members of the 1921 Everest expedition complained of being bitten continually from base camp almost to the summit. These biting midges can cause acute discomfort, particularly on warm, humid days; in spite of their small size, the bite often produces a severe local reaction. Females make small cuts in the skin, and the saliva contains an anticoagulant. Once the blood pools, it is sucked up. It was calculated in the early 1980s that because of the tremendous number of bites to which a human can be subjected, a person spending 1 h per day on the beach in Trinidad in the early morning would receive 38 bites infective for *Mansonella ozzardi* in the course of a year. However, with the tremendous tourist industry impact, control measures are constantly being revisited.

Mosquitoes (Malaria, Filariasis, and Arbovirus Infections)

Mosquitoes are slender, delicate insects that are distributed worldwide, number over 3,000 species, and have aquatic larval and pupal stages (Figure 24.16). They are the most important group of arthropods in terms of disease transmission and, as pests, produce an irritating dermatitis. To be effective vectors for malaria, female *Anopheles* mosquitoes must feed frequently on humans, must be relatively susceptible to the malarial gametocytes, must live long enough for the malaria parasite to complete the life cycle, and must be present in sufficient numbers to maintain transmission of the parasite (Figure 24.17). Blood feeding follows a circadian rhythm, with most species feeding at night or during the twilight hours, either right after sunset or before sunrise. The biting cycle has control implications, since mosquito nets are effective against nocturnal species, especially those that bite after midnight. Mosquitoes are not limited to ground level elevation but in the forests can be found from ground level up into the canopy, where birds and primates live.

In the tropics, breeding usually continues throughout the year. Important species within the United States include *Aedes aegypti* (yellow fever, dengue fever), *Aedes albopictus* (yellow fever, dengue fever, LaCrosse encephalitis virus), *Ochlerotatus (Aedes) sollicitans* (Eastern equine encephalitis [EEE]), *Aedes vexans* (EEE), *Anopheles quadrimaculatus* (malaria in the eastern United States in the early 20th century), *Culex nigripalpus* (St. Louis encephalitis [SLE]), *Culex quinquefasciatus* (SLE, West Nile virus [WNV]), *Culex salinarius* (SLE, WNV, EEE), and *Culex tarsalis* (Western equine encephalitis [WEE], SLE).

Figure 24.15 Biting midge (*Culicoides* sp., vector of *Mansonella* spp.), 1 to 2.5 mm (usually 1 to 4 mm long). (Illustration by Sharon Belkin; adapted from E. C. Faust, R. F. Russell, and R. C. June, ed., *Clinical Parasitology*, 8th ed., Lea & Febiger, Philadelphia, Pa., 1970.)

Myiasis

Myiasis is the infestation of live human and vertebrate animals with dipterous larvae which feed on the host's dead or living tissue, liquid body substances, or ingested food (Tables 24.6 and 24.7). Maggots can infest any organ or tissue accessible to fly oviposition; most cases probably occur when a female fly lands on a human host and deposits either eggs or larvae.

Human infestations have been found in the breast, urinary bladder, colon, penis, gums, brain, carcinoma of the scalp, and various skin lesions (1, 19, 25, 27, 50). It is also important to realize that nosocomial transmission can occur; myiasis cases have occurred in hospital patients,

Figure 24.16 Mosquito, ~4 mm. (Illustration by Sharon Belkin.)

Figure 24.17 *Anopheles* mosquito. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

often those who are debilitated (12, 13, 36, 44, 51, 58). Specimens should be killed, preserved in hot (60°C) 70% alcohol, and then submitted to the laboratory for identification. Myiasis-producing members of the Diptera of medical importance can be seen in Table 24.6 and Figure 24.18.

For business or pleasure, more people than ever before are traveling throughout the world. Since 3 to 10% of these travelers experience skin, hair, or nail disorders related to their travels, it is more and more likely that Western physicians will be expected to treat exotic infections imported from different countries. Tungiasis and furunculoid myiasis are two typical disorders of intertropical regions. These are conditions induced by the presence of arthropod larvae or eggs in the skin. It will become more important for physicians to recognize these and other conditions, many of which they may have not seen previously (54).

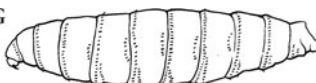

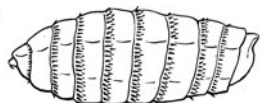

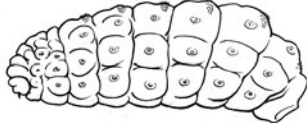

The identification of larvae found in human tissues is based on a number of morphologic characters, including (i) structure of the chitinized mouthparts, (ii) abdominal spiracles, and (iii) structures of the cuticle (these vary depending on the particular instar larva and the number of molts). Occasionally, if living mature larvae are submitted for examination, they can be held until they pupate and hatch; the adult flies can then be examined for identification. Doppler ultrasonography has also been used to evaluate the number of larvae present per lesion; this approach helps avoid misdiagnoses and treatment delays (41).

Pseudomyiasis refers to the accidental ingestion of dead or living fly larvae with no associated pathologic changes or symptoms. The term “sanguivorous myiasis” has been used to refer to superficial attachment of larvae during blood sucking.

Medicolegal Forensic Entomology

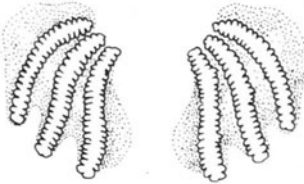

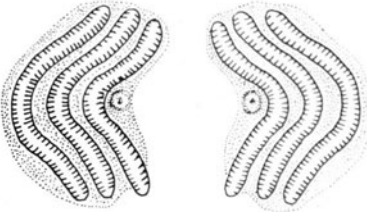

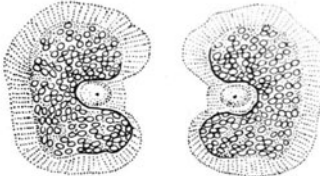

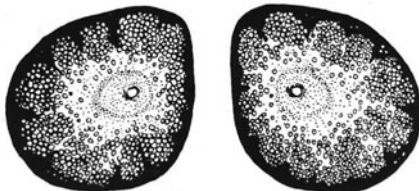

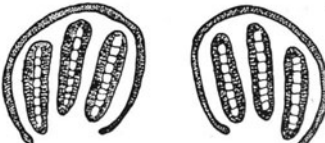

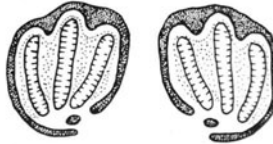

Forensic entomology has become a recognized discipline that is concerned with the application of information on

Table 24.6 Diptera of medical importance in myiasis

Scientific and common names	General habits	Body site(s) ^a	Diagram
Calliphoridae			
Calliphorinae (metallic group)			
<i>Chrysomya bezziana</i> , Old World screwworm (A)	Living tissues	Any body site, eye, erosion of bone	
<i>Cochliomyia hominivorax</i> , New World screwworm (B)	Living tissues	Nasal, aural sites, brain penetration	
<i>Lucilia</i> spp., greenbottles	Dead tissues	Skin, GI tract, GU tract	
<i>Calliphora</i> spp., bluebottles (C)	Dead tissues	Skin, GI tract, GU tract, nose	
<i>Phormia regina</i> , black blowfly (D)	Wounds	Traumatic myiasis	
<i>Cynomyopsis cadaverina</i> , blowfly	Wounds	Traumatic myiasis	
Calliphorinae (nonmetallic group)			
<i>Auchmeromyia senegalensis</i> , Congo floor maggot (E)	Sucks blood from skin	Does not penetrate, detaches after feeding	
<i>Cordylobia anthropophaga</i> , Tumbu fly (F)	Subcutaneous boils, sloughing, gangrene	Penetrates unbroken skin, usually feet	
Sarcophaginae			
<i>Wohlfahrtia</i> spp., flesh flies	Wounds, normal tissue (head)	Skin, sense organs	
<i>Wohlfahrtia magnifica</i> , Old World flesh fly (G)	Most common in humans		
<i>Sarcophaga haemorrhoidalis</i>	Dead tissues	GI tract, also skin, GU tract, nose, sinuses	
<i>Sarcophaga carnaria</i>	Living tissues	Vagina	
Cuterebridae			
<i>Dermatobia hominis</i> , human botfly (H)	Living tissues	Skin, subcutaneous boils, brain	
<i>Cuterebra</i> spp., North American botflies		Skin, eye	
Gasterophilidae			
<i>Gastrophilus</i> spp., horse (stomach) botflies (I)	“Larva migrans” cutaneous migration	Skin, migrate to eye	
Hypodermatidae			
<i>Hypoderma</i> spp., warble flies (J)	Skin penetration, extensive larval wandering (limbs)	Skin, eye, nasopharynx, chest, back, limbs, etc.	
<i>Hypoderma lineatum</i> , lesser cattle warble fly			
<i>Hypoderma tarandi</i> , reindeer warble fly			
<i>Cephenemyia ulrichii</i> , moose throat botfly		Eye	
Oestridae			
<i>Oestrus ovis</i> , sheep nasal botfly (K)	Living tissues, resembles conjunctivitis	Nasopharynx, eye, sinuses	

^a GI, gastrointestinal; GU, genitourinary.

insects and other arthropods to legal issues. The most common applications deal with the determination of death, manner of death, movement of the corpse, and other aspects of the investigation. Insects occurring in carrion can be assigned to four groups. Those that feed on the carrion, including blowflies, arrive within a few hours of death. They are followed by species that feed on the body, species that feed on its inhabitants, and species that use the corpse as an extension of their natural environment. Various stages are identified in the decomposition of the corpse and are important in helping set the time of death: (i) autolytic and microbial decomposition, during which blowflies oviposit; (ii) active decomposition by insects; (iii) advanced decomposition, primarily by coleopteran beetle larvae; (iv) microbial decomposition, which takes over when coleopteran beetle larvae leave and ends in mummification; and (v) separation of the skeleton into individual bones, when the time of death can no longer be determined (9).

The entomologist must determine the time the insect attack began; many factors influence the confirmation of this time: cadaver location (whether it was exposed to sun or shade); whether the cadaver was covered, buried, or open to the elements; whether it was wet or dry; and ambient and ground temperatures. Often a pig is used to simulate the corpse conditions and to determine various rates of decomposition and insect activity; this is particularly helpful if conditions in a particular ecoclimate are not known.

Because the length of the oldest maggots recovered from a body often provides an accurate estimate of the time of death, it is important to ensure adequate fixation without subsequent shrinkage. Studies have shown that maggot shrinkage can lead to underage errors, thus leading to differences of many hours. It has been found that maggots killed in boiling water and then placed in appropriate preservatives do not shrink. The length of the larval crop, which can be useful in age estimates of post-feeding larvae, is not altered significantly when using this approach. Standardized handling and fixation of maggots at the crime scene are critical to valid and consistent interpretations (48).

It is also possible that fly pupae may contaminate forensic entomology samples at death scenes if they

originate from animal carcasses or other decomposing organic material rather than from human remains. These contaminants may falsely increase postmortem estimates if no pupae or puparia are actually associated with the body (3).

To permit rapid identification of arthropods, random amplified polymorphic DNA typing has been used to support classic morphologic and forensic analysis of maggots found on a human corpse. This approach has been used to determine if maggots found on the body match those on the outside of the body bag or wrap or if they match the pupae found on the floor or the ground under the corpse. This type of methodology can discriminate between closely related flies and beetles found on corpses (7). This approach has been very helpful in setting the time of death for bodies found less than 1 month after death. At this point, larval insects can be very difficult to identify morphologically when the stages are immature and only fragments of pupae and first-instar larvae are found. An easy and objective method of insect identification is DNA typing; this new approach provides excellent information in a relatively short time (35).

Another relatively new approach involves forensic analysis of DNA recovered from a larva's gut, which can be used to identify the larval food source. This method for associating a maggot with a corpse could be useful, particularly in situations where remains were removed from a suspected crime scene, when an alternative food source is near the scene or the body, or in a chain-of-evidence dispute. However, since maggot gut content analysis represents a new approach, many of the limitations of the technique have not yet been identified. In spite of possible limitations, it appears that third-instar larvae actively feeding on a corpse could be considered an excellent source of human DNA (8, 59).

Insects can also assist in determining the cause of death and can serve as reliable alternate specimens for toxicologic analyses in the absence of tissues and fluids normally used for such purposes. The presence of drugs and/or toxins in decomposing tissues may alter the rate and patterns of development of arthropods feeding on these tissues. Insects can also accumulate heavy metals and toxic compounds, or their by-products, in their tissues (21).

Types of Myiasis Categorized According to Affected Tissues

Cutaneous and Mucocutaneous Tissues (Eye, Nose, and Ear). Larval penetration of cutaneous and mucocutaneous tissues causes various degrees of pathologic abnormalities, ranging from an irritating pruritus to invasion of the eyes, brain, nasopharynx, bones, ear canal, vagina, tongue, and open wounds. The only known therapeutic

procedure, other than applying local palliatives, is surgical removal and treatment for secondary bacterial or fungal infections (if these occur). Examples of representative fly larvae and their stigmal plates are seen in Table 24.7. The stigmal plates or spiracles (respiratory openings) from mature fly larvae are characteristic for each species and can be valuable in identification. The larvae orient themselves so that these spiracles are normally at the surface of the host skin, etc., to allow oxygen exchange by the larvae.

Intestinal Tissues. Female flies often deposit eggs or larvae on food that is then eaten by humans. Occasionally, some eggs or larvae survive, become temporarily lodged in the intestinal crypts and folds, and partially or completely develop before being passed in the stool (1).

Other Sites. There are reports of larvae recovered from urine, the vagina, and the lungs (accidental inhalation of either a gravid female fly or airborne eggs) (5).

Types of Myiasis Categorized According to Tissue Viability

Specific Myiasis. The larvae attack only living tissues of humans and animals, usually cutaneous and subcutaneous areas but also the nose, mouth, sinuses, eyes, ears, anus, and vagina. There are generally six dipterous families represented in this type of infestation (Table 24.6).

Semispecific Myiasis. The larvae breed on the bodies of dead animals and attach to dermal and subdermal areas and cavities. This type of myiasis is represented by four families of dipterous flies (Table 24.6).

Accidental Myiasis. Infestations are usually accidental and occur infrequently. They are usually in the gastrointestinal tract and are acquired by ingesting food contaminated with larvae. Although the eggs are usually digested or fail to hatch, some may survive, become lodged in the crypts, and develop through part of their life cycle before leaving the body. They may also invade the ears, nose, sinuses, and urinary passages. There are approximately 15 families of flies whose members are implicated in this type of infestation.

Dipterous Flies Involved in Cases of Myiasis

Calliphorid Flies (Blowflies) (*Cochliomyia*, *Phaenicia*, and *Phormia* spp.). The adults feed on material found in wounds or decaying flesh; females lay their eggs in batches of 200 to 300 in the flesh of dead animals. The eggs usually hatch within 24 h and feed on exudates of wounds or decaying flesh; they penetrate the tissue

by using powerful oral hooks, hence the name “screw-worm” (Figure 24.19) (5). Human ophthalmomyiasis has been reported, with one review specifically discussing infection with *Cochliomyia hominivorax* (11). Adult flies have been known to lay eggs on scabs, sores, scratches, pimples, or dried blood; in the healthy mucous membranes of the eyes, nose, mouth, or vagina; and in the umbilicus of neonates. Recent human infestations with *C. hominivorax* include the axilla, nose, palate, and mastoid cells. Blowflies often appear shiny or coppery green to shiny black.

Another unusual case of *Phormia regina* myiasis of the scalp was reported in 1988. *P. regina*, the black blowfly, causes facultative myiasis, usually invading wounds, benign and malignant ulcers, and other diseased tissue; rarely are normal tissues involved. However, in this case, there were no recognizable associated infected wounds or tumor. The patient was a 64-year-old homeless woman who had numerous scratches on her scalp. There is speculation that infection started with the repetitive scratching and that the open suppurative scalp wounds, which were never washed, were likely sites for egg deposition. *P. regina* is very common throughout the United States, especially during April to September.

Flesh Flies (*Sarcophaga*, *Wohlfahrtia*, and *Parasarcophaga* spp.). The adult flies feed on feces or decaying meat or fish (5); females deposit 40 to 80 first-stage larvae. The

Figure 24.20 Flesh fly, which causes myiasis in humans. (Adapted from M. T. James, *U.S. Department of Agriculture Miscellaneous Publication 631*, 1947.)

Figure 24.21 Flesh fly. (Photograph courtesy of Duane J. Gubler, Centers for Disease Control and Prevention.)

larvae penetrate the tissue, thus causing problems depending on the body site (Figures 24.20 and 24.21).

Medically important genera of flesh flies include *Wohlfahrtia* and *Parasarcophaga*. *W. magnifica* never develops in carrion, but is found in wounds and natural orifices of warm-blooded animals, including humans. *W. vigil* occurs in northern North America, and the larvae are not as invasive, usually being limited to dermal tissues and causing a boil-like lesion. The first reported case of human aural myiasis caused by the flesh fly *Parasarcophaga crassipalpis* was reported in 1987. The patient was a 16-year-old, mentally retarded, nonresponsive Caucasian boy at a public institution in Adelaide, South Australia. Some blood was noticed in the left external ear canal, and 2 weeks later, dark blood was seen discharging from the ear. The physician detected movement in the ear, and that evening a single maggot emerged from the ear. No other maggots were found, and there was no tissue damage in the external ear canal.

Botflies (*Dermatobia hominis*, *Gastrophilus* spp., *Hypoderma* spp., *Cuterebra* spp., and *Oestrus ovis*) (Cutaneous, Ophthalmic, Nasal, and Aural Myiasis).

The adult female *Dermatobia hominis* fly never feeds but uses food stored up during the larval stage for egg production. Once the eggs are developed, the female fly captures a mosquito or other blood-sucking arthropod and glues the eggs to the abdomen of the arthropod. When the arthropod lands on a warm-blooded host, the young larvae emerge from the egg membranes and, within less than an

hour, invade the skin. Lesions commonly occur on the unprotected skin; the tunnel produced is generally perpendicular to the surface and is occupied by a single larva. Eventually, local tissue destruction and accumulation of toxic waste produce throbbing pain and intense itching. The lesion may resemble a bacterial infection with seropurulent fluid (Figures 24.22 through 24.27). *D. hominis* is not found within the United States; however, cases are seen in travelers returning from areas of endemic infection that include parts of Mexico and Central and South America.

Although human infestation with *Gastrophilus* larvae is uncommon, the lesion is usually cutaneous. The larvae may advance in the tunnel, with the lesion resembling that of *Ancylostoma braziliense* (cutaneous larva migrans). Ophthalmomyiasis due to *Gastrophilus intestinalis* has also been reported.

Flies of the genus *Hypoderma* most commonly cause dermal myiasis in humans in the United States. The lesions are less serpiginous than those caused by *Gastrophilus* spp., particularly since the larvae bore more deeply into the subcutaneous tissues and produce a more inflamed lesion. However, since the larvae do migrate, they can appear many centimeters from the original site in a month's time. It is important to try and remove the larva before it dies and thus causes a more severe problem due to infection and pus formation.

The genus *Cuterebra* contains more than 20 species of flies native to North America, and the larvae occur

Figure 24.22 Myiasis. Nodule from the pubis of a 24-year-old woman. She was bitten while in a banana grove in Colombia 2 weeks before this nodule was removed. The fly larva is coiled in a cyst that communicates with the surface. The cyst and tract are lined in part by squamous epithelium. This lesion is characteristic of the “warble” or boil of *Dermatobia hominis*, although the species could not be determined from the section studies. (Armed Forces Institute of Pathology photograph.)

as dermal parasites of rodent and rabbit hosts. A case of cutaneous myiasis of the eyelid as a result of a *Cuterebra* larva has been reported. The patient was a 28-year-old man with a 3-week history of a swollen, tender nodule on his right upper eyelid. Apparently, 2 weeks before symptoms appeared, he was bitten on his shoulder by an insect. Redness and swelling developed and spread into the neck, face, and right upper eyelid during the following week. The patient was treated for periorbital cellulitis and a secondary *Pseudomonas* infection in the lesion, with no improvement. Two days after the lesion was finally incised, an oval larva emerged and was identified as a second-stage *Cuterebra* larva.

Gravid females of *Oestrus ovis* deposit their first-stage larvae onto the conjunctiva, the outer nares, or the lips or into the buccal cavity. These larvae have large oral hooks and spines that assist their penetration through the mucous membranes. The larvae may burrow into the eyelid, conjunctival sac, or lachrymal duct. Human ophthalmomyiasis is common in the former USSR, northern Africa, and Israel; however, it is rare in Western Europe and the United States. Invasion of the nasal sinuses may result in congestion accompanied by pruritus and frontal headache. Generally, with the exception of the eye, the larvae spontaneously leave the tissues. In cases in which the eye is involved, patients may present with ocular

Figure 24.23 Myiasis. Higher magnification of the lesion in Figure 24.22. The larva is surrounded by an intense inflammatory cell infiltrate composed of neutrophils, lymphocytes, plasma cells, and eosinophils. Magnification, $\times 9.7$. (Armed Forces Institute of Pathology photograph.)

symptoms of foreign-body sensation, irritation, redness, and photophobia. Topical antibiotics and steroid eye drops can be used. Patients may also develop nasal symptoms such as sneezing, nasal discharge, and epistaxis. Larvae can be removed from the conjunctival sac under local anesthetic with no difficulty. Otolaryngology follow-up may demonstrate nasal myiasis as well. Some patients have been treated with ivermectin (34).

Order Hemiptera (True Bugs)

Bedbugs (*Cimex lectularius*)

Bedbugs measure about 5 mm long by 3 mm wide, are mahogany brown, and have only vestigial wings (Figures 24.28 and 24.29). The adult bugs may resemble unengorged ticks or very small cockroaches. Although they can mechanically transmit pathogenic microorganisms, there is no conclusive evidence that they are natural biological vectors for the transmission of organisms causing diseases.

Figure 24.25 Myiasis in the skin of a leg of a patient in Panama. This is the warble of *Dermatobia hominis* of about 1 month's duration. The shiny black spot in the center is the posterior end of the larva. This lesion was over the tibia and was painful. (Armed Forces Institute of Pathology photograph.)

Figure 24.26 Myiasis. Brain of a child in Panama who died of malaria. There were several warbles on the scalp. The larva in the cavity entered through a 4-mm hole that it had bored through the anterior fontanelle. The shape and spines of the larva are consistent with *Dermatobia hominis*. (Armed Forces Institute of Pathology photograph.)

Figure 24.27 Fly larva removed from a man living in Lynchburg, Va. The patient had a pruritic “mosquito bite” on the chest, which became red and then enlarged to about 4 cm. A “head” developed, from which the patient expressed this larva. The larva was identified as *Cuterebra* sp. Magnification, $\times 22$. (Armed Forces Institute of Pathology photograph.)

Medical problems associated with these bugs include itching and inflammation caused by their bites. Bedbugs are nocturnal and reach their peak activity before dawn; they tend to hide in cracks during the day. They respond to warmth and carbon dioxide in their search for hosts and will respond to a body that is 2°C or more above ambient temperature. They produce an aggregation pheromone that brings them together. The nocturnal biting of bedbugs can be debilitating to humans, whose sleep is interrupted every night. The presence of the bugs can be suspected by finding their specks of feces and their odor. Bedbugs are very common in Third World countries and are becoming more common even in the United States. Travelers may import bugs in their suitcases or belongings, and the bugs then “make themselves at home” in cracks and crevices, behind baseboards, and under mattresses.

Triatomid, Reduviid, Kissing, or Conenose Bugs (Chagas’ Disease)

Triatomid bugs have well-developed wings, are larger than bedbugs, and have a cone-shaped head (Figures 24.30 and 24.31). These bugs are usually brown or black with orange and black markings on the abdomen where it extends beyond the folded wings. All species feed on blood, either mammalian or avian. Most species are hematophagous, feeding primarily on mammalian or avian blood. The infective forms of *Trypanosoma cruzi* (Chagas’ disease) are found in the bug’s feces. In areas where the infection is more prevalent, the bugs tend to defecate very soon after

Figure 24.28 Bedbug (*Cimex* sp.), 5 mm. (Illustration by Sharon Belkin; based on an illustration from H. H. Najarian, *Textbook of Medical Parasitology*, The Williams & Wilkins Co., Baltimore, Md., 1967.)

taking a blood meal. Since the bug’s saliva contains an irritant, the person tends to scratch, thus scratching in the infective forms from the bug feces. The time of the blood meal and the number of feeds during engorgement in relation to defecation are important epidemiologically and are directly related to infection potential.

The earlier a bug defecates during or after feeding, the more likely it is to be an efficient vector. Most triatomid bugs are nocturnal and feed on sleeping inhabitants of the house. They are attracted to the host by warmth, carbon dioxide, and odor. The bites are relatively painless, hence the name “kissing bug.” Obviously it would not be advantageous for the person to wake up before the bugs complete their blood meal and subsequent defecation. However, some individuals have an allergic reaction to the bite approximately 24 to 48 h later; in some cases it is serious. Edema of the eyelids and conjunctivitis may occur

Figure 24.29 Bedbug (*Cimex* sp.).

Figure 24.30 Triatomid bug (*Triatoma* sp.), 25 mm. (Illustration by Sharon Belkin.)

(Romaña's sign). The edema does not pit on pressure, and the skin is dry. Although Romaña's sign is thought to be almost pathognomonic for early Chagas' disease, in an analysis of 300 patients with early disease, unilateral periorbital edema was found in only 48.7%. Currently, it is estimated that 16 million to 18 million people are infected with *T. cruzi* and 90 million to 100 million are at risk. Although most cases occur in Mexico and Central and South America, indigenous cases have been reported from Texas, Tennessee, and California. Serologic evidence places *T. cruzi* as far north as Oklahoma. Five species of kissing bug are found within different parts of the United States: *Triatoma protracta*, *T. gerstaeckeri*, *T. sanguisuga*, *T. rubida*, and *T. rubrofasciata*.

In addition to an irritant, the bug saliva contains an anticoagulant, so that the blood remains unclotted when stored within the bug. This ensures that the blood remains fluid for easier passage into the digestive system of the

Figure 24.31 Triatomid bug.

midgut. In areas of endemic infection, the number of bugs may vary tremendously in houses that harbor the triatomids. When a heavily infested house in Venezuela was torn down, nearly 8,000 triatomid bugs were recovered. It was calculated that in that house the feeding rate was 58 bugs per person per day. The loss of blood per person per month can range from 0.7 to 40 ml; however, in that particular house, it exceeded 100 ml (30).

Most reduviids kill other insects; the name "assassin bugs" is used as a general term. However, bugs associated with the transmission of *T. cruzi* are referred to as kissing bugs. While assassin bugs may bite humans, producing painful lesions, they are not associated with parasite transmission. Often the general names are used interchangeably, thus confusing the issue of actual parasite transmission.

Order Coleoptera (Beetles)

The majority of beetles, representing over 40% of all insects, are not harmful to humans. In some cases, the adult beetles contain vesicating substances such as pederin (an alkaloid within body fluids) and cantharidin (a volatile terpene found in the hemolymph). When beetles are accidentally crushed against the skin, serious blistering may occur (Figures 24.32 through 24.34). Most of these beetles are seasonal and may be found in large numbers in some fields at certain times of the year. Important beetles in the family Meloidae are in the genus *Lytta*, which contains the infamous "Spanish fly" from which the well-known aphrodisiac powder is obtained. Often, beetles in the genus *Paederus* are attracted to the light and, on contact with the skin, can secrete a highly acidic liquid that produces a painful blister. There is usually no immediate response to the fluids, but in 24 to 48 h a weal appears

Figure 24.32 Blister beetles. (A) Margined (*Epicauta pestifera*); (B) ash gray (*Epicauta fabricii*). (Illustration by Sharon Belkin.)

Figure 24.33 *Paederus laetus*, a beetle of Central America which elaborates a vesiculating toxin. Magnification, $\times 4$. (Armed Forces Institute of Pathology photograph.)

and is followed by blisters. The erythema may last for several months, and the conjunctivitis can cause temporary blindness. The toxin pederin is the most complex nonproteinaceous insect secretion known and has been used in Chinese medicine for over 1,000 years.

Occasionally, reactions occur as a result of contact with the larvae of beetles in the family Dermestidae. However, contact with adult beetles in various families within the Coleoptera represents the most common situation in which humans are involved.

Order Siphonaptera (Fleas) (*Ctenocephalides* spp., *Xenopsylla cheopis*, *Pulex irritans* [Human Flea], *Tunga penetrans*, *Nosopsyllus fasciatus*, *Echidnophaga gallinacea*, and “Sand Fleas”)

Fleas are wingless ectoparasites of mammals and birds; whereas lice are usually host specific, fleas parasitize a number of hosts. It is this ability to move from one host to another that facilitates the transfer of disease from animals, primarily rats, to humans. Fleas are laterally flattened and have no wings. The legs are long and muscular, which allows them to jump (Figures 24.35 and 24.36). They are hosts and transmitters of several pathogenic organisms including the agents of plague and murine typhus and *Dipylidium caninum*, the dog tapeworm. Also, their bite or presence in the skin causes dermatitis or ulcerations. Medically important fleas include *Tunga penetrans* (Figures 24.37 and 24.38), *Pulex irritans*, *Ctenocephalides canis*, *C. felis*, and *Xenopsylla cheopis*.

Generally the flea bites begin with a wheal around each site within about 5 to 30 min. Itching is common, with the production of an indurated papule within about 12 to 24 h. In people who are sensitive to the bites, a delayed reaction appears in about 12 to 24 h and lasts for

Figure 24.34 Contact dermatitis from staphylinid beetle, *Paederus* sp., on the body of a man in Ethiopia. (Armed Forces Institute of Pathology photograph.)

Figure 24.35 Flea, 1.5 mm. (Illustration by Sharon Belkin.)

a week or longer. The intense itching is often sufficient cause for the patient to consult a physician.

Cat and dog fleas, *C. felis* and *C. canis*, are major domestic pests in many parts of the world, including North America and Australia. However, the cat flea is most often found within the United States; both types of fleas can feed on either animal. Dogs tend to be more allergic to flea saliva than are cats, but both can have severe reactions to heavy infestation. Cats can remove about 50% of their fleas in a single week, but insecticide dust, spray, shampoo, or other options may be required for removal of all fleas. Flea larvae are very sensitive to drying, and outdoor environments do not generally support survival, which requires a relative humidity of $>50\%$. In the transmission of *D. caninum*, the tapeworm eggs are ingested by the larval stages of the dog, cat, or human flea, where they develop into cysticercoid larvae. When these fleas are then ingested by the definitive host (dogs, cats, or humans), the adult worm develops within 3 to 4 weeks. Most of these infections have been found in children.

Figure 24.36 Flea. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Figure 24.37 Flea (*Tunga penetrans*, chigoe flea), 1.5 mm. (Illustration by Sharon Belkin.)

Although *Echidnophaga gallinacea* (the sticktight flea) is associated with poultry, it may also feed on humans. Chickens are commonly seen with flea “patches” around the comb, wattles, or even the eyes.

“Sand fleas” is a general term that is used for a number of arthropods, only some of which are actually fleas. In the northern United States, sand fleas are usually dog or cat fleas associated with stray animals. In the western United States, cat or human fleas associated with a number of different animals are called sand fleas. Along the coastal areas, small amphipod crustaceans found in seaweed are also called sand fleas.

Order Anoplura (Sucking Lice)

The order Anoplura contains the blood-sucking lice (*Pediculus* and *Phthirus* spp.), which have legs with claws adapted for clinging to hairs or fibers. There are three nymphal stages prior to the adult, and all stages feed on blood. In general, the biting lice respond to warmth and smell, avoid high humidity, and are negatively phototactic.

Figure 24.38 Tungiasis. Multiple and irregularly confluent tunga craters on the foot of an African. The nonpressure areas (instep and between the toes) are the most severely involved. The weight-bearing portion of the sole tends to be spared. This patient died of tetanus. (Armed Forces Institute of Pathology photograph.)

(i.e., they move toward dark objects). There are several types of human lice: the head louse, the body louse (Figures 24.39 and 24.40), and the pubic or “crab” louse (Figures 24.41 and 24.42). The head and pubic lice deposit and cement eggs onto the hair shaft (Figure 24.43), whereas the body louse deposits eggs on clothing, particularly in the seams. Although they do not specifically transmit any parasites, they do transmit epidemic typhus and louse-borne relapsing fever. Prevention involves both treatment of individuals and mass control, both of which can be difficult in situations such as jails, refugee camps, army barracks, and schools (5).

Body Lice

In a stable population of the body louse, *P. humanus*, more than two-thirds of the lice are present as eggs, about one-fourth are present as nymphs, and only 6 to 7% are present as adults. The adults measure 2 to 3 mm for the male and 2.4 to 3.6 mm for the female. Body lice can cause severe skin irritation; there may be swelling and the development of papules at the bite sites, as well as mild or severe itching. Some individuals may become sensitized to antigens introduced during louse feeding, and they can experience generalized allergic reactions. Removal of skin during itching can also lead to secondary infection. The lice tend to attach to cloth fibers along the seams inside of underwear or other places where clothes touch the body; they tend to prefer wool clothing. *P. humanus* can be removed from clothes by heating the clothes to $>60^{\circ}\text{C}$ for 15 min; this could be accomplished by placing clothes in the clothes drier for about 20 to 30 min.

Head Lice

Head lice (*P. humanus capitis*) live on the skin among the hairs on the patient’s head. Their life span is about 1

Figure 24.39 Body louse (*Pediculus* sp.), 1.5 mm. (Illustration by Sharon Belkin.)

Figure 24.40 Body louse (*Pediculus* sp.).

month if they are not removed from the body, and the life cycle from egg to adult takes about 3 weeks. Washing the hair reduces the number of nymphs and adult *P. capitis*, and combing with a finely toothed comb removes most of the eggs; combing should be done when the hair is damp. During the washing process, the lice feces are also removed; they can also serve as an irritant during the infestation. It is important to remember that if one person in the family has head lice, the entire family should be treated, since others in the family may be infested but may not be aware of it. Most of the products designed for louse removal are effective, provided that directions are followed. In refugee camp situations where body lice can multiply and spread quickly and easily, DDT dust can be applied to clothing; however, resistance to DDT has arisen, and other insecticides may be required for control.

Pubic or Crab Lice

The two distinct species of *Phthirus* occur on separate hosts, the human and the gorilla. Adult pubic lice are dark gray to brown and have a typical “crab” shape. *P. pubis* occurs on the hair in the pubic and perianal areas of the human body and occasionally the axillae, eyebrows, and beard. The incidence of this infestation has been on the increase, and some think that it may be the most contagious sexually transmitted disease. However, this infection is often found in association with other venereal diseases, including gonorrhea and trichomoniasis. Transmission can occur by sleeping in the same bed as another infested individual. In patients with an infestation of *P. pubis*, there tend to be blue or slate-gray macules on the skin (maculae caeruleae); these are thought to be either altered patient blood pigments or possibly substances occurring in the salivary glands of

Figure 24.41 Crab louse (*Phthirus* sp.), 1 mm. (Illustration by Sharon Belkin; based on an illustration from H. H. Najarian, *Textbook of Medical Parasitology*, The Williams & Wilkins Co., Baltimore, Md., 1967.)

the lice. Once these lice have left the host, their survival time is relatively short, with death occurring in less than 48 h at 15°C. If infestation occurs on the eyelids, there may be inflammation of the eyelids. These lice live only on humans, require human blood for survival, and do not infest rooms, carpets, beds, or pets. Because the lice tend to die fairly quickly once they are off the host, it is not necessary to use insecticidal sprays or fogs in the home, work, or school environment.

Order Mallophaga (Biting and Chewing Lice)

Biting lice are morphologically similar to other lice and are not very important in human medicine, although they serve as the intermediate host for the dog tapeworm, *Dipylidium caninum*. Infestations are more common in puppies, very old dogs, or those that are sick or debilitated. None of these lice live on humans but are primarily ectoparasites of birds and mammals, feeding on feathers, hairs, and epidermal scales (5).

Figure 24.43 Louse. (Upper) Eggs on hair shaft; (lower) enlargement of egg on hair shaft. (Photographs courtesy of Duane J. Gubler, Centers for Disease Control and Prevention.)

Order Hymenoptera (Bees, Wasps, and Ants)

The order Hymenoptera contains insects with two pairs of membranous wings, reduced veins in the wings, and hind wings smaller than the fore pair and interlocked with the latter by means of hooklets (Figure 24.44). There are more than 100,000 described species. Many members of species within this order live together in great structured societies, and reproduction is performed either by many of the female members or, in some cases, by a single in-

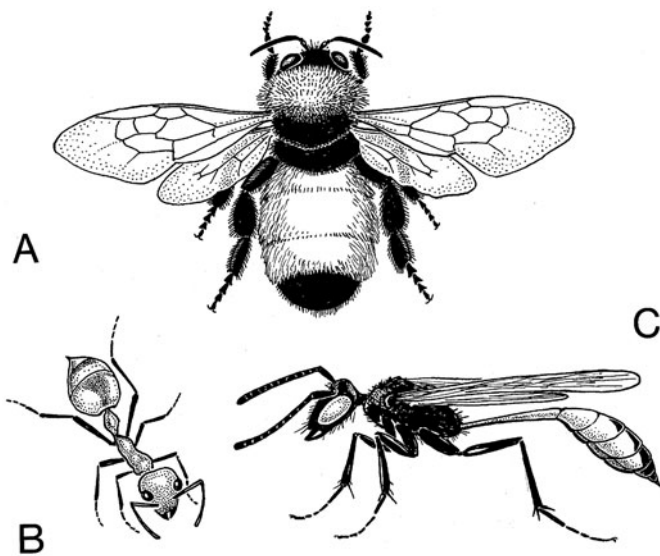

dividual known as the queen. Members of the group or colony tend to attack intruders.

Bees

Although stings of members of this order normally cause only temporary pain and swelling, anaphylaxis may occur in patients who are sensitized. Within the United States, approximately 50 to 100 individuals die each year from severe anaphylactic reactions to bee and wasp stings (17). Honeybees are not necessarily aggressive, but they tend to be everywhere outdoors during the summer months. During the stinging process, pheromones are released that cause other bees in the vicinity to attack the victim. When a person has been stung, the stinger should be removed, the site should be disinfected, and ice packs should be applied to slow the spread of venom. The stinger can be removed by scraping with a knife or fingernail to prevent further venom from being injected. If the person experiences a severe local reaction, oral antihistamines and topical application of corticosteroids can be used. Systemic allergic reactions can be a life-threatening emergency requiring immediate medical help.

The spread of the Africanized honeybee to Brazil and then to other areas of South and Central America and the southern United States has been accompanied by extensive publicity. These bees can be easily irritated and provoked to protect the hive, resulting in hundreds of stings, severe reactions, and death. Although the public has received information regarding these bees, the “killer” bees are difficult to differentiate from normal honeybees, particularly visually.

Figure 24.44 (A) Bee; (B) fire ant; (C) wasp. (Illustration by Sharon Belkin.)

In comparison to the European honeybee, the Africanized bees tend to attack more readily, remain angry for extended periods, and display massive group stinging behavior in defense of the colony and territory. Although their stings are no more toxic than those of domestic bees, death can result from the cumulative effects of numerous stings, numbering from 400 to 1,000 stings, or from anaphylactic shock. It is very likely that we will continue to see more problems and possible deaths due to the Africanized honeybees as their geographic area continues to expand within the United States. As an example, in Venezuela in 1978, before the Africanized honeybees arrived, there were 12 deaths attributed to bee stings; however, after 1978, there were 100 deaths per year. Stings can be treated in the same way; however, in the case of multiple stings, excessive histamine release may result from venom action and not necessarily from an allergic reaction. *Physicians need to be aware of this fact and the possible need to treat for histamine overdose* (20).

Bumblebees also sting when disturbed; however, they are neither as aggressive nor as prevalent as honeybees. Treatment for stings is the same as for honeybee stings.

Fire Ants

Ants can bite as well as sting; however, most do little harm. One exception is the fire ant, *Solenopsis invicta*, which is endemic in the southeastern United States. The presence of fire ants can usually be recognized by seeing their characteristic mounds, which are earthen mounds with a diameter of 24 in. and a height of 18 to 24 in. surrounded by relatively undisturbed vegetation (Figure 24.45) (20). When even slightly disturbed, the ants tend to boil out of their mounds. The ants measure about 4 to 6 mm long and are reddish brown (red form) or black (black form). The workers attach to the skin by biting with their mandibles and then lowering their abdomen to inject the stinger; thus, the victim receives both a bite and a sting. The symptom of a sting has been described as a “burning itch.” Within about 24 h, a pustule develops and may remain for about a week (Figure 24.6). Although some individuals have sustained thousands of stings with no toxic or allergic reactions, some people with hypersensitivity to fire ant venom may have severe reactions from just a few stings. At least 250 million acres within the United States are infested, now reaching as far west as New Mexico, Arizona, and California. In some heavily infested areas, 50 to 400 or more mature colonies may be found per acre. There are actually two species, *S. invicta*, the red form imported from Brazil, and *S. richteri*, the black form imported from Uruguay. The geographic range for *S. richteri* in the United States is much more limited, occurring in northeastern Mississippi, northwestern Alabama, and part of Tennessee (20).

Figure 24.45 Typical mound of the fire ant; the height can reach 2 ft.

Harvester Ants

Harvester ants, *Pogonomyrmex* spp., are ant species that sting both animals and humans. These ants are red to dark brown and are two or three times as large as fire ants. Harvester ant mounds are usually flat or slightly elevated, measure about 3 to 9 ft in diameter, and are surrounded by no vegetation (Figure 24.46). There is only one harvester ant species east of the Mississippi River, and it is found throughout the Southeast. In the western United States, about 20 species occur, 3 of the most serious being the red harvester ant (*P. barbatus*), the California harvester ant (*P. californicus*), and the western harvester ant (*P. occidentalis*). The reaction to harvester ant stings is not always localized but may spread along the lymphatics. This causes severe pain in the lymph nodes in the axilla or groin some time after the pain from the original sting has gone. Systemic allergic reactions tend to be uncommon.

Order Blattaria (Cockroaches)

Cockroaches are among the most ubiquitous pests throughout the world. A number of the 3,500 species have become adapted to living with humans and are referred to as “domestic” species that will breed anywhere. They are very active, nocturnal insects; anyone who has turned on the lights in the kitchen late at night remembers the surprise at seeing all the visitors! Cockroaches are flattened dorsoventrally and have long, multisegmented antennae, biting mouthparts, two pairs of wings, two cerci, and legs adapted for running (17). They feed on human food, excreta, sputa, and even bookbindings, paper, and leather.

Figure 24.46 Typical flat mound of the harvester ant; the flat area with no vegetation can range from 3 to 9 ft.

Mechanical Transmission of Organisms. Although certain flies and dung beetles have been implicated as mechanical vectors of *Cryptosporidium* oocysts, there is every reason to suspect that cockroaches could also do the same (22). When cockroaches feed on infected material, their mouthparts and legs become contaminated; they can then introduce these contaminants into human surroundings. Also, organisms can pass through the cockroach gut and remain fully viable. Some investigators have speculated that the cockroach may be a more significant vector of human pathogens than houseflies, transmitting viruses, bacteria, and parasites to human hosts. In one study of 234 cockroaches trapped from different sites (toilets, parlors, kitchens, and bedrooms) in houses with pit latrines and water systems, bacterial, fungal, and parasitic isolates were identical irrespective of the site and included *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus vulgaris*, *Proteus mirabilis*, *Citrobacter freundii*, *Enterobacter cloacae*, *Salmonella* spp., *Pseudomonas aeruginosa*, *Serratia marcescens*, *Staphylococcus aureus*, *S. faecalis*, *S. epidermidis*, *Aeromonas* spp., *Candida* spp., *Rhizopus* spp., *Aspergillus* spp., *Mucor* spp., cysts of *Entamoeba histolytica*; oocysts of *Cryptosporidium* spp., *Cyclospora cayetanensis*, and *Isospora belli*; cysts of *Balantidium coli*; ova of *Ascaris lumbricoides*, *Ancylostoma duodenale*, *Enterobius vermicularis*, and *Trichuris trichiura*; and larvae of *Strongyloides stercoralis* (49). Some humans also become allergic to cockroach allergens. Control involves good sanitation, prevention of new entry, and a combination of various pesticides including bait, strips, sprays, and dusts.

Several important species include *Blatella germanica* (German cockroach), *Blatta orientalis* (Oriental cockroach), *Supella longipalpa* (brown-banded cockroach), and *Periplaneta americana* (American cockroach) (Figure

24.47). These different cockroaches prefer different habitats, with some preferring warm, moist conditions (German cockroach) and others preferring cooler locations (Oriental cockroach). The most common cockroach throughout the United States is the German cockroach, which can be found infesting most buildings. Adult German and brown-banded cockroaches are approximately 15 mm long, while the American and Oriental cockroaches measure 30 to 50 mm long.

Cockroach Allergens. In addition to the mechanical transmission of many types of bacteria, fungi, and parasites, their excrement and cast skins contain a number of antigens that cause allergic responses. Urban allergens include the cockroach, mouse, and rat. Cockroach allergy is common among inner city children with asthma, and exposure to cockroach allergen is associated with more severe disease. Cockroach allergens are one of the major etiologic risk factors for immunoglobulin E-mediated allergic respiratory illness throughout the world. A high prevalence of cockroach hypersensitivity in atopic (20 to 55%) and asthmatic (49 to 60%) populations has been documented (4, 57). In a survey of day care facilities

in North Carolina, detectable levels of indoor allergens were commonly found, including cockroach allergens. For many young children and day care staff, day care facilities might be a source of clinically relevant exposures to indoor allergens (2). Cockroach allergen avoidance begins with effective pest control, followed by thorough and repeated cleaning. At least 1 to 2 months is required to eliminate cockroaches, and an additional 4 to 6 months is required to remove residual allergen. Once allergen levels have been reduced, continued efforts are necessary to maintain the home free of allergen sources. The school environment can also be an important site of exposure to cat, dog, dust mite, and cockroach allergens, which have been detected in the settled dust of many schools. In industrialized nations, the school environment has a lower potential for exposure than the home environment, but schools are significant for allergic individuals whose home environment has been addressed to the extent possible. From a public health perspective, the school environment should be considered a target for primary and secondary prevention.

Class Arachnida (Ticks, Mites, Spiders, and Scorpions)

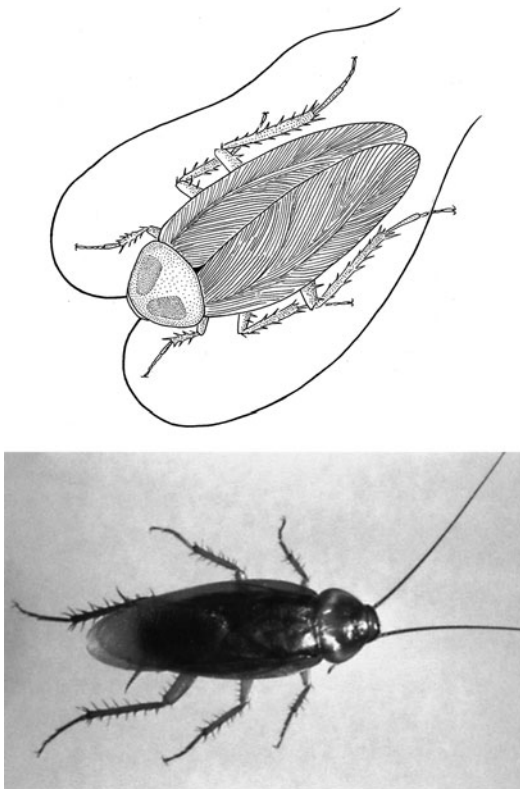

Subclass Acari (Ticks, Mites, and Chiggers)

The subclass Acari contains the soft and hard ticks, mites, and chiggers.

Soft and Hard Ticks

The soft and hard ticks are ectoparasites adapted to blood-sucking (mammals, birds, and reptiles) (18, 28, 45, 46). There is no hard dorsal plate in the soft tick, and the mouth parts are ventral to the anterior extremity (Figures 24.48 and 24.49; Table 24.8). In the hard tick, the dorsal plate or shield covers the entire surface of the male but only the anterior portion of the female (Figures 24.50 and 24.51). The dorsal surface of a tick's body often has color patterns, furrows, or sculpting that allows species determination. Ticks are responsible for the transmission of viral, bacterial, rickettsial, and protozoan (*Babesia* spp.) pathogens. The salivary secretions of some ticks may produce systemic toxemia (tick paralysis) that can cause death. Paralysis can occur from a tick attached to any part of the body, although the symptoms may be more serious when the tick injects toxin at the back of the neck or along the spinal column. Symptoms may include elevated temperature, rapid ascending flaccid paralysis, and difficulty in breathing and swallowing, and death may result. The onset may be very sudden, within 24 h, or may not appear for several days. The most likely tick involved is *Dermacentor andersoni*, the Rocky Mountain wood tick. Human cases tend to occur in the spring

Figure 24.47 (Upper) American cockroach (*Periplaneta americana*) (illustration by Sharon Belkin); (lower) *Periplaneta americana*.

Figure 24.48 Soft tick, ~12 mm. (Illustration by Sharon Belkin; based on an illustration from H. H. Najarian, *Textbook of Medical Parasitology*, The Williams & Wilkins Co., Baltimore, Md., 1967.)

Figure 24.49 Soft tick. (Photograph courtesy of Duane J. Gubler, Centers for Disease Control and Prevention.)

and early summer, when ticks are most active and are seeking a blood meal. Tick paralysis can be particularly dangerous for children; after playing in underbrush or bushes, the child should have all clothing removed and should be carefully examined for the presence of ticks, particularly around the neck and shoulder area (under the hair). The most likely geographic area is in western Montana, Idaho, and Oregon, although cases have been reported from other states including Georgia, Tennessee, Louisiana, and the Atlantic seaboard. Ticks in the genera *Amblyomma* and *Dermacentor* have been involved in cases outside of the western United States, while in other parts of the world *Ixodes*, *Rhipicephalus*, *Hyalomma*, and *Ornithodoros* have been implicated in tick paralysis.

Argasidae (soft ticks)	Ixodidae (hard ticks)
1. Do not have dorsal shield (scutum)	1. Do have dorsal shield (scutum)
2. Capitulum is located on ventral surface and does not project anteriorly	2. Capitulum is located on anterior margin

Ticks feed by making a cut in the host epidermis, inserting the hypostome into the cut, and attaching to the host. Blood is kept flowing through the use of an anticoagulant from the salivary glands of the tick. Some hard ticks form a cement cone around the mouthparts and bite site. Female

hard ticks undergo a growth feeding phase characterized by slow continuous blood intake followed by a rapid engorgement phase occurring during the last 24 h of attachment. Hard ticks have the ability to expand considerably, often resembling a soft tick. Many hard ticks attach themselves to grasses or weeds, waiting for a host to come along; they are also attracted to carbon dioxide. Hard ticks are generally found in brushy, wooded, or weedy areas containing deer, cattle, dogs, small mammals, and other hosts. Hard ticks have to conserve moisture, and so their activity and survival are influenced by temperature as well as humidity.

Differentiation between the soft ticks and hard ticks is relatively easy once an engorged hard tick is recognized as such. However, identification to the species level among the hard ticks can be difficult. Currently there is a great deal of interest in identifying the ticks that transmit Lyme disease. In the northeastern United States, the primary vector for Lyme disease caused by *Borrelia burgdorferi* is *Ixodes scapularis*, the black-legged tick (formerly known as *I. dammini*, although it now appears that they are a single species) (38, 53). The life cycle takes 2 to 4 years. Larvae are active from August to October, when they are feeding on *Peromyscus leucopus*, the white-footed mouse. The infection rate in mice is approximately 25% and occurs from May to June. Human cases tend to peak in July. A tick needs to feed for 48 h for successful transmission of *B. burgdorferi*; although 50 to 100% of the adult *I. scapularis* ticks are infected, most are removed from the human host prior to 48 h. *I. scapularis* is found in dense brush on islands off the northeast coast and in heavily for-

Figure 24.50 Hard tick, 4 to 10 mm. (Illustration by Sharon Belkin; based on an illustration from H. H. Najarian, *Textbook of Medical Parasitology*, The Williams & Wilkins Co., Baltimore, Md., 1967.)

ested areas inland. In Wisconsin, these ticks occur in areas between the northern coniferous-hardwood and southern deciduous forests.

In western North America, the primary vector of *B. burgdorferi* is *I. pacificus*, the western black-legged

Figure 24.51 (Upper) Hard tick (photograph courtesy of Duane J. Gubler, Centers for Disease Control and Prevention); (lower left) *Dermacentor* sp.; (lower right) *Ixodes* sp.

tick. These ticks range from sea level to >6,000 ft and are found from California to British Columbia and east to Nevada, Utah, and Idaho. Larvae and nymphs are active from March to June, and adults are found on humans from November to May. The infection rate of *I. pacificus* is about 1.5%. Studies looking at the prevalence of anti-arthropod saliva antibodies among residents in a high-risk community revealed a 79% positive rate compared with control groups (33). In the San Francisco Bay Area, the figure was 36%. In the study group, seropositivities for *I. pacificus* and for *B. burgdorferi* were significantly correlated. Experimental and field evaluations of two acaricides for control of *I. pacificus* in northern California appear very promising, and these substances can be a beneficial component of an overall control program (37).

The morphologic differences between *I. pacificus* and *I. scapularis* are minimal (Figures 24.53 and 24.54). Both species have no white markings on their dorsal side and no eyes or festoons. Adults are dark brown, and the mouthparts are moderately long. Occasionally, *I. scapularis* appears light brown or orangish from the dorsal view (39). The difference between the nymph and the adult can be seen in Figure 24.52. Descriptions of the more common ticks are given in Table 24.9.

Itch Mites (Mange Mites), Follicle Mites, and Dust Mites

Itch Mite. Several genera infect the skin of mammals, with *S. scabiei* being found in humans, although some mange mites of animals occasionally cause a pruritic rash

Figure 24.52 *Ixodes* spp. Diagram of the female (A) and male (B) adult ticks and the nymph (C) (bar, 3 mm). (Illustration by Sharon Belkin; based on information in reference 28.)

Figure 24.53 (Left) *Ixodes scapularis*. Scutum (the dorsal shield, being small in the female and almost covering the dorsal surface in the male) and the terminal capitulum, which is attached to the anterior end of the body of Ixodidae. Note that the scutum is nearly circular, with punctuations larger peripherally. The cornua (arrowhead) is small but definite for *I. scapularis*. (Right) *Ixodes pacificus*. Scutum and the terminal capitulum. Note that the scutum is oval with uniformly distributed small punctuations (arrowhead), and the cornua is absent. (Illustration by Sharon Belkin; based on information in reference 28.)

in humans (56). *S. scabiei* is microscopic and lives in cutaneous burrows, where the fertilized female deposits eggs (Figures 24.55 and 24.56). Scabies is transmitted by close contact with infested individuals, including touching, shaking hands, sexual contact, and contact in day care centers with children and the elderly. The usual skin sites that are susceptible to infection are the interdigital spaces, backs of the hands, elbows, axillae, groin, breasts, umbilicus, penis, shoulder blades, small of the back, and buttocks (Figures 24.57 and 24.58) (5). The outstanding clinical symptom is intense itching. Scratching commonly causes weeping, bleeding, and sometimes secondary infection. A form of the infestation, called Norwegian scabies, can occur in immunosuppressed or anergic individuals; many mites are present in keratotic excrescences on the body and extremities, but pruritus is usually absent (Figures 24.59 to 24.61). This infestation is highly contagious and has been reported to be the cause of hospital epidemics. Scabies occurs worldwide, with at least 300 million cases each year. Oral ivermectin at a dose of 300 $\mu\text{g}/\text{kg}$, given as a single dose and repeated after 7 days, proved effective for the treatment and prophylaxis of scabies in an infected institutional environment (42). Specific techniques for recovery of the mites are listed below.

Skin-scraping technique. The diagnosis can be confirmed by demonstration of the mites, eggs, or scybala (fecal pellets). Because the mites are located under the surface of the skin, scrapings must be made from the infected area.

1. Place a drop of mineral oil on a sterile scalpel blade. (Mineral oil is preferred to potassium

Figure 24.54 (Upper) *Ixodes scapularis*. (Left) Adult female. (Right) Adult male. Note that there are no white markings on the dorsal surface and no eyes or festoons (Table 24.8). (Lower) *Ixodes pacificus*. (Left) Adult male. (Right) Adult female.

hydroxide solution or water. Mites adhere to the oil, skin scales mix with the oil, the refractility differences are greater between the mite and the oil, and the oil does not dissolve fecal pellets.)

2. Allow some of the oil to flow onto the papule.
3. Scrape vigorously six or seven times to remove the top of the papule. (There should be tiny flecks of blood in the oil.)
4. Transfer the oil and scraped material to a glass slide (an applicator stick can be used).
5. Add 1 or 2 extra drops of mineral oil to the slide and stir the mixture. Any large clumps can be crushed to expose hidden mites.
6. Place a coverslip on the slide, and examine (first on low power). The adult mites range from approximately 215 to 390 μm in length, depending on sex. The eggs are 170 μm long by 92 μm wide, and the fecal pellets are about 30 by 15 μm . The fecal pellets are yellow-brown.

Table 24.9 Descriptions of some of the more common hard ticks found in the United States

Tick	Description	Comments
<i>Amblyomma americanum</i> (Lone Star tick)	Reddish-brown tick species; adult stages have long mouth parts visible from above; adult females have distinct white spot on their back (scutum); males have no single spot but have inverted horseshoe-shaped markings at the posterior edge of their dorsal side	Central Texas east to the Atlantic; north to Iowa and New York; northern Mexico; probably most aggressive and common tick in southern United States; transmits tularemia, possibly ehrlichiosis
<i>Amblyomma maculatum</i> (Gulf Coast tick)	Somewhat similar to American dog tick, except with metallic instead of white markings, long mouth parts; adult females with metallic white or gold markings on scutum, males with numerous, mostly connected linear spots of golden white	Portions of Atlantic and Gulf Coast areas (100–200 miles inland, south into Mexico); increasingly a pest in southern United States; nuisance only
<i>Dermacentor andersoni</i> (Rocky Mountain wood tick)	Adults have shorter mouth parts than <i>Amblyomma</i> ; usually dark brown or black with bright white markings on the scutum	Western counties of Nebraska and Black Hills of South Dakota to Cascade and Sierra Nevada Mountains; northern Arizona and northern New Mexico to British Columbia, Alberta, and Saskatchewan; transmits RMSF, ^a Colorado tick fever, tularemia; tick paralysis in United States and Canada
<i>Dermacentor variabilis</i> (American dog tick)	Adults dark brown or black; short, rounded mouth parts; dull or bright white markings on scutum	Medically important; primary vector of RMSF in the central and eastern United States; transmits tularemia, maybe tick paralysis; deticking dogs may lead to infection
<i>Ixodes pacificus</i> (western black-legged tick)	No white markings on dorsal side, no eyes or festoons, adults dark brown; moderately long mouth parts; appears almost identical to <i>I. scapularis</i>	Along Pacific coastal margins of British Columbia and the United States, possibly extending into Baja California and Mexico; most cases of Lyme disease in California are transmitted by this tick
<i>Ixodes scapularis</i> (black-legged tick)	Adults have no eyes, festoons, or white markings on dorsal side; dark brown but may appear light brown or orangish	Northern form in New England states and New York, south into New Jersey, Virginia, and Maryland; upper Midwest and Ontario; southern form around southern Atlantic Coast states, Texas, Oklahoma, and Mexico
<i>Rhipicephalus sanguineus</i> (brown dog tick)	Light to dark brown, no white markings on dorsal side; have both festoons and eyes	Most widely distributed tick; almost worldwide in Western Hemisphere; transmits RMSF; found indoors around pet bedding areas; strong tendency to crawl upward (walls of infested houses)

^a RMSF, Rocky Mountain spotted fever.

Plastic box or petri dish method. If mineral oil preparations of skin scrapings fail to demonstrate the mites, the encrusted skin scrapings, etc., can be placed in a small plastic box or small petri dish. The container should be left undisturbed at room temperature for 12 to 24 h. Away from the living host, the mites drop to the bottom of the box or dish and can be seen with a magnifying glass or dissecting microscope.

Follicle Mites. Two species of follicle mites parasitize humans; each has its own particular habitat. *Demodex folliculorum* is found in the hair follicles above the sebaceous glands, and *D. brevis* occurs in the sebaceous

glands. Both are found in the epidermis of the nose, nasolabial fold, forehead, and adjacent regions of the face; these mites have also been associated with dermatitis of the scalp. These follicle mites can be considered more of a nuisance than a true pathogen and are considered to be harmless saprophytes; symptoms may include a mild rosaceous pruritus and a fibrous tissue response around the mites. Estimates of human infection range from 25 to 100%. The two species have similar morphology, with *D. brevis* being somewhat shorter. They are elongated wormlike mites with rudimentary legs (Figures 24.62 and 24.63). Most humans acquire mites early in life, often by mother-to-child transmission.

Figure 24.55 Itch mite (*Sarcoptes* sp.), ~0.25 mm. (Illustration by Sharon Belkin; based on an illustration from H. H. Najarian, *Textbook of Medical Parasitology*, The Williams & Wilkins Co., Baltimore, Md., 1967.)

House Dust Mites. Although house dust mites in the genus *Dermatophagoides* are not commonly seen or submitted to the laboratory for confirmation, it is important to realize that these mites are directly linked to allergic reactivity that can be detected in patients with atopic eczema. Powerful allergens can be found in the mites *D. pteronyssinus* and *D. farinae*, as well as in their fecal pellets and secretions. Allergic rhinitis, asthma, and childhood eczema are attributable to these mites. The mites feed on shed human skin scales, but they also eat mold, fungal spores, pollen grains, feathers, and animal dander.

Figure 24.56 Itch mite. (From *A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.*)

Figure 24.57 Scabies of hand, thorax, and abdomen of a Zairian child. Lesions are complicated by scratching and secondary bacterial infection. (Armed Forces Institute of Pathology photograph.)

Active treatment includes Gore-Tex bags for all bedding elements such as the mattress and box springs, a high-power vacuum cleaner, and a spray containing benzyl alcohol and tannic acid to kill mites and denature allergens. These measures are highly effective, particularly the Gore-Tex

Figure 24.58 Scabies of buttocks of a Brazilian child. There is evidence of scratching and secondary bacterial infection. (Armed Forces Institute of Pathology photograph.)

Figure 24.59 Norwegian scabies over the buttocks of a 19-year-old Zairian. Scaling and crusting were severe about the elbows and from the lower trunk to the knees. (Armed Forces Institute of Pathology photograph.)

Figure 24.61 Close-up of two *Sarcoptes scabiei* mites in a section of skin shown in Figure 24.60. They are at the keratoepidermal junction. On the cuticle of the uppermost parasite, there are six dorsal spines. Magnification, $\times 275$. (Armed Forces Institute of Pathology photograph.)

bed bags (16). This approach was associated with clinical improvement in most patients with atopic eczema, particularly those who were the most severely affected. However, some of the acaricide applications are required at 2- to 3-month intervals to maintain optimal effectiveness (10). Also, treatments are different for different allergens (55).

Subclass Araneae (Spiders)

The subclass Araneae contains the spiders, only a few of which can cause pathologic changes in humans. All true spiders produce venom, although few types of venom cause more than a local irritation at the bite site. Those that can cause tissue damage are categorized as causing systemic arachnidism or primarily necrotic arachnidism.

Systemic Arachnidism (Black Widow, Other Widow Spiders)

Widow Spiders. The black widow spider (*Lactrodectus mactans* and other species) has the typical shiny black abdomen with a red hourglass shape on the ventral surface (Figures 24.64 and 24.65). However, it is important to realize that the typical hourglass-shaped marking on the underside of the abdomen may not look like the textbook description, and there are at least five species of “widow” spiders within the United States. Some black widow spiders have bright red hash marks on the dorsal surface in addition to the red hourglass on the underside. Also, the hourglass marking may appear “broken” and not complete (20). There may also be red or white marks on the dorsal side of the abdomen. The color patterns on the underside of the abdomen can vary quite a bit, with what appear to be dots, stripes, or a combination of the two. The immature spiders are tan to gray with little to no

Figure 24.64 Black widow spider (*Lactrodectus* sp.), 20 mm. (Illustration by Sharon Belkin.)

black color. The males and immature black widow spiders bite, but symptoms are mild due to the smaller amount of venom injected. The venom is neurotoxic, acting at both adrenergic and cholinergic junctions (11). Although serious systemic sequelae (abdominal cramps, hypertension, reduced heartbeat and feeble pulse, convulsions, shock, delirium, and death) can occur, uncomplicated recovery is the usual outcome (weakness, myalgia). Following recovery, the individual usually develops complete systemic immunity to subsequent bites, although there may be a local reaction. At the bite site, two small red spots may be visible, representing the skin penetration sites.

The black widow spiders tend to avoid strong light and prefer dark areas behind or underneath appliances,

Figure 24.65 Black widow spider (*Lactrodectus* sp.). (Photograph courtesy of Duane J. Gubler, Centers for Disease Control and Prevention.)

furniture, closets, etc. These spiders are very reclusive and will not bite unless provoked; generally, they attempt to escape. They are more active in the summer months. After mating, the female kills the male only if she is not well fed, thus ensuring the survival of the eggs; as many as 2,000 offspring may be produced in a single year.

The wound should be cleaned and ice packs should be applied to limit the spread of the venom. In cases of more severe reactions, the patient should seek medical attention; the use of intravenous solutions, antivenom, and tetanus vaccine are relevant considerations. Children, the elderly, and patients with underlying medical conditions may require hospitalization.

Necrotic Arachnidism (Violin or Brown Recluse Spider, Hobo Spider, Funnel Web Spider, Tarantula Spider)

Violin Spiders. The violin spider (*Loxosceles reclusa* and other species) is commonly found inside human habitation rather than in the outdoor areas where the black widow spider can be found (as well as indoors) (15). These spiders are of medium size (0.9 to 1.5 cm long), are yellowish to dark brown, and tend to have a fiddle-shaped marking on the dorsal surface (Figures 24.66 and 24.67). One of the signs of a brown recluse spider bite is the tendency of the lesion to extend downward; the direction of the lesion depends on the patient's position as vessel damage occurs. This bite presentation is apparently rare with other arthropod bites. Mild to severe pain can occur immediately after the bite or within a few hours. Extensive tissue necrosis can occur, with extended spread, very slow healing, and severe disfigurement (Figure 24.68). If a large dose of venom is injected, there may also be systemic complications, such as hemolytic anemia, hemoglobinuria, hematuria, jaundice,

Figure 24.66 Violin spider (*Loxosceles* sp.), 9 to 15 mm. (Illustration by Sharon Belkin.)

Figure 24.67 Violin spider (*Loxosceles* sp.). (Armed Forces Institute of Pathology photograph.)

and fever. There is a high mortality rate associated with systemic complications, which can include hematuria, anemia, fever, rash, nausea, vomiting, coma, and cyanosis. If systemic symptoms occur, they usually appear several days after the bite; as an example, hemolysis has been documented to occur from 24 h to 3 days after a bite.

The brown recluse is nocturnal and is generally found in bathrooms, bedrooms, cellars, attics, clothing folds, boxes, and storage areas, and under rubble, etc. Like the black widow spider, it is not aggressive but will bite when bothered. These spiders are found from Minnesota to Maine south to Florida and west to Arizona and Wyoming. In South America, there is a close relative of the brown recluse, *L. laeta*, which also causes a severe necrotic lesion; these spiders have been introduced and are now well established in Los Angeles, Calif., and at

Figure 24.68 Tissue necrosis caused by *Loxosceles* sp. (Armed Forces Institute of Pathology photograph.)

Harvard University in Cambridge, Mass. (20). Other species found mostly in the Southwest include *L. refescens*, *L. deserta*, *L. devia*, and *L. arizonica*.

As with any spider bite, if possible the spider should be collected and submitted for identification. In the case of the brown recluse, prompt medical attention is recommended. Although a specific antivenom has been used, it is not generally available. Treatment is somewhat controversial, ranging from ice packs to complete surgical excision of the bite site. Antibiotics such as cephalosporin or erythromycin have been used, as well as dapsone; however, the side effects of dapsone may also mimic symptoms resulting from the spider bite.

Hobo Spiders. Hobo spiders are large, fast spiders, about 45 mm long with distinct chevron stripes on the abdomen. They build funnel-shaped webs in or around houses. They are also now recognized as causing necrotic lesions, particularly the males, which are responsible for most bites. Reports of bites in Washington, Oregon, and Idaho continue to increase. Although the bites were originally thought to be from brown recluse spiders, this was never confirmed. It appears that the bite of these hobo spiders can cause lesions similar to those seen with bites by the brown recluse. The species involved is *Tegenaria agrestis*. Although the bite is usually painless at first, the same types of lesions and symptoms occur as seen with bites by the brown recluse. Some of these lesions can take years to heal, and systemic symptoms can also be seen.

Funnel Web Spiders. Funnel web spiders are large, dark-colored, and very aggressive; they have prominent fangs and are found in and around Sydney, Australia. They are glossy dark brown to black, while the abdomen is dark plum to black; including the legs, they measure 45 to 60 mm. They tend to build funnel webs in burrows, rotting logs, tree holes, or rock crevices; colonies can number more than 100 spiders. These are very dangerous spiders, and the bite can cause death in as little as 15 min. The bite can become very painful, and systemic symptoms such as hypotension and apnea can begin to occur within just a few minutes.

It is important for first aid to be administered immediately, including a pressure bandage and immobilization of the limb with splints. Patients are usually hospitalized and monitored for signs and symptoms indicating that venom has or has not been injected with the bite. These systemic symptoms can include mouth numbness, tongue spasms, nausea, vomiting, profuse sweating, salivation, and muscle spasms. Appropriate administration of antivenom is indicated; however, it is important to carefully monitor patients for possible allergic reactions to the antivenom.

Figure 24.69 Tarantula. (Note the hairy legs.)

Tarantula Spiders. Tarantulas occur throughout different areas of the world and become aggressive only if provoked or handled inappropriately. They are large, hairy spiders (Figure 24.69). The 30 species found in the southwestern United States have a leg span of approximately 18 cm, while the South American species found in the jungles measure 24 cm. Bites can vary from being relatively painless to causing a deep, throbbing pain that may last for hours. Individuals who are hypersensitive may present with more serious symptoms. Tarantulas sold for pets within the United States are generally species of *Abhonopelma*, which tend to be very colorful.

Subclass Scorpiones (Scorpions)

Scorpions are characterized by having large pedipalps that end in stout claws and a tail ending in a hooked stinger (Figures 24.70 through 24.72). Venom is discharged through the stinger. Humans usually come into contact with scorpions by stepping on them or touching them in the dark. Species considered to be dangerous occur throughout the world. Some species can even penetrate the soles of the feet and inject venom, causing symptoms which can be serious, particularly in children younger than 5 years (aching pain radiating from the site; lymphadenitis; generalized numbness; throbbing and twitching of fingers, toes, and earlobes; profuse sweating; glossopharyngeal involvement; vomiting; abdominal muscle spasms; convulsions; mental disturbances; partial paralysis; blindness; electrocardiographic changes; and death from respiratory paralysis).

Children younger than 5 years are most commonly exposed and have the most severe sequelae. It has been reported that in Trinidad, the death rate in exposed children can reach 25% (5). Usually, the death rate in exposed adults is very low.

Figure 24.70 Scorpion, 30 to 40 mm. (Illustration by Sharon Belkin.)

Scorpions are nocturnal and generally are hidden during the day. Around homes, they are often found under houses or in attics. When actively seeking water, they may be found in kitchens or bathrooms, occasionally in the sink or bathtub. In the southwestern United States, the common striped scorpion, *Centruroides vittatus*, is found; it has a sting similar to that from a wasp or bee. *C. vittatus* is found in Texas, while *C. exilicauda* is found in southern Arizona and western New Mexico.

Most stings are not serious, and the burning sensation and wheal disappear without any intervention. However, after a sting by one of the more dangerous species, it is important to minimize the spread of the venom. Ice packs are recommended, and medical treatment may be required. Areas of the world where dangerously venomous

Figure 24.71 Scorpion. Although painful, scorpion stings are rarely fatal. Exceptions are infants and children who sustain multiple stings. The venom is contained in two venom glands in the tail.

Figure 24.72 Scorpion sting. This blister has formed at the site of a scorpion sting. (Armed Forces Institute of Pathology photograph.)

scorpions are found include (Old World) Algeria, Egypt, Iraq, Israel, Jordan, Morocco, South Africa, Sudan, and Turkey and (New World) Argentina, Brazil, Guyana, Mexico, Trinidad, United States (Arizona and New Mexico), and Venezuela (20).

Other Arthropods

Class Chilopoda (Centipedes)

Centipedes are usually not considered dangerous, and their importance is related to their occasional painful bites. These arthropods like to live in dark, damp environments such as debris and rubbish. They have a long, slender, segmented body with a single pair of legs per segment except for the last two segments (Figure 24.73) (6). The appendages of the first body segment are modified into poison claws. Although the poison injected is not harmful in the temperate areas of the world, the bite of *Scolopendra* spp. within the tropics and subtropics can be very painful and can cause edema, blistering, and necrotic lesions. In some cases, systemic reactions such as fever, nausea, vomiting, and headache also occur, particularly with *Scolopendra gigantea*. Rarely, some species have been recovered from the human nares and frontal sinuses or from the digestive tract; in each case, the centipede was an accidental invader of the human body (5).

Most bites are mild and self-limiting. The bite site should be thoroughly washed, with subsequent application of an ice pack and analgesics for pain. If the lesion becomes inflamed, antibiotics may be recommended.

Figure 24.73 Centipede, 30 to 40 mm. (Illustration by Sharon Belkin.)

Class Diplopoda (Millipedes)

Millipedes also have a long, slender, segmented body, but unlike the centipedes, they have two pairs of legs per segment in the abdominal region (Figure 24.74). Also, they tend to be more round and “wormlike” in shape. They do not have piercing mouthparts, and they are not poisonous. However, some of the body secretions can result in a burning sensation, discoloration, and blister formation when applied to human skin. Severe conjunctivitis can also occur when the eyes come in contact with these fluids (17). Apparently, these secretions contain hydrogen cyanide as well as other aliphatic acids (5).

Class Crustacea (Copepods, Crabs, Crayfish, etc.)

The crustaceans are primarily gill-breathing arthropods of both freshwater and saltwater. Only a few are of medical importance, and these tend to be found in freshwater. Some of the members of this group serve as intermediate hosts for various human helminth parasites. Copepods, or water fleas, serve as intermediate hosts for several helminth infections. Species of *Cyclops* carry the larval forms of *Dracunculus medinensis* (Guinea worm), *Diphyllobothrium latum* (broad fish tapeworm), and *Gnathostoma spinigerum* (uncommon nematode infection). Species of *Diaptomus* are important first intermediate hosts of *D. latum*. Prevention of contamination and boiling or filtration of contaminated water will prevent these infections.

The larger crustaceans (decapods) include crabs and crayfish, which serve as the second intermediate hosts of *Paragonimus* spp. (lung fluke). Although the crabs incriminated in the transmission of *Paragonimus* spp. are freshwater forms, they can also survive in brackish water.

Figure 24.74 Millipede, 30 to 40 mm. (Illustration by Sharon Belkin.)

Thorough cooking of crabs and crayfish will help eliminate some of these infections.

In the South Pacific, prawns may be paratenic hosts of the nematode *Angiostrongylus cantonensis*, which can cause eosinophilic meningitis and cerebral damage in the human host.

Control of Arthropods of Medical Importance

Measures for the control of medically important arthropods usually involve a number of different options, including physical control, biological control, and chemical control. Although chemical means are generally the most widely used, they rarely succeed in providing a permanent solution to the problem. Often, a combination of methods provides the most effective control (32). A general dichotomous key for the identification of some of the arthropods can be found in Table 24.10, and a key to the important myiasis-producing larvae is provided in Table 24.11.

Physical Control

A number of control measures are related to the environment and may affect arthropod life cycles. An excellent example is demonstrated by the elimination of larval habitats of mosquitoes; this is basically water management. This approach could include rerouting of water, elimination of standing water, and ditch filling. With periodic monitoring, these should be long-term changes and should require little to no maintenance. Other approaches would include proper disposal of sewage, garbage, manure, and trash. Screens, bed nets, and protective clothing have become widely used and appreciated as preventive measures against flying insects. Although several other methods have been tried, these approaches are somewhat questionable, at best. One example is the use of pet products such as flea collars. Unfortunately, the use of flea collars for humans has not been approved by the Food and Drug Administration and may be dangerous due to the potential for pesticide absorption through the skin.

Biological Control

A number of programs are currently being used and include (i) use of specific viruses, bacteria, protozoa, nematodes, and fungi, all of which are pathogenic for various arthropods; (ii) genetic manipulation of arthropod populations, including release of sterile males and use of insect growth regulators; and (iii) release of actual

Table 24.10 Dichotomous key to some of the arthropods important in human disease and/or disease transmission^a

A.	Legs:	Three or four pairs	B
	Legs:	Five or more pairs	V
B.	Legs:	Three pairs; antennae present	C
	Legs:	Four pairs; antennae absent	L
C.	Wings:	Well developed	D
	Wings:	Absent or rudimentary	L
D.	Wings:	One pair (Diptera : flies, mosquitoes, midges)	E
	Wings:	Two pairs	F
E.	Wings:	Scales present (Diptera : mosquitoes)	
	Wings:	Scales absent (Diptera : flies)	
F.	Mouth parts:	Sucking (long proboscis present)	G
	Mouth parts:	Chewing (long proboscis absent)	H
G.	Wings:	Scales present; proboscis coiled (Lepidoptera : butterflies, moths)	
	Wings:	Scales absent; proboscis not coiled (Hemiptera : bedbugs, kissing bugs)	
H.	Wings:	Both pairs membranous, size may vary	I
	Wings:	Front pair leathery or shell-like, covers second pair	J
I.	Wings:	Both pairs similar in size (Isoptera : termites)	
	Wings:	Hind wing smaller than front wing (Hymenoptera : bees, hornets, wasps)	
J.	Wings:	No distinct veins; front wings horny or leathery; meet as straight line in middle	K
	Wings:	Distinct veins; front wings horny or leathery; overlap in middle (Blattaria : cockroaches)	
K.	Abdomen:	Prominent cerci or forceps, longer than wings (Dermaptera : earwigs)	
	Abdomen:	No prominent cerci or forceps, covered by wings (Coleoptera : beetles)	
L.	Abdomen:	Three long terminal tails (Thysanura : silverfish and firebrats)	
	Abdomen:	No terminal tails	M
M.	Abdomen:	Narrow waist (Hymenoptera : ants)	
	Abdomen:	No narrow waist	N
N.	Abdomen:	Prominent pair of cerci or forceps (Dermaptera : earwigs) (see also K)	
	Abdomen:	No cerci or forceps	O
O.	Body:	Flattened laterally; antennae folded into head grooves (Siphonaptera : fleas)	
	Body:	Flattened dorsoventrally; antennae project from side of head	P
P.	Antennae:	Nine or more segments	Q
	Antennae:	Three to five segments	R
Q.	Pronotum:	Covers head (Blattaria : cockroaches) (see also J)	
	Pronotum:	Does not cover head (Isoptera : termites) (see also I)	
R.	Mouth parts:	Tubular jointed beak; three- to five-segmented tarsi (Hemiptera : bedbugs)	
	Mouth parts:	Retracted into head or chewing type; one- or two-segmented tarsi	S
S.	Mouth parts:	Retracted into head, adapted for sucking blood (Anoplura : sucking lice)	
	Mouth parts:	Chewing type (Mallophaga : chewing lice)	

(continued)

Table 24.10 Dichotomous key to some of the arthropods important in human disease and/or disease transmission^a (*continued*)

T.	Body:	Oval, consisting of a single saclike region (Acari : ticks and mites)	
	Body:	Divided into two distinct regions, cephalothorax and abdomen	U
U.	Abdomen:	Joined to cephalothorax by slender waist (Araneae : spiders)	
	Abdomen:	Joined broadly to cephalothorax, stinger present (Scorpiones : scorpions)	
V.	Legs, swimmerets:	Five to nine pairs of legs or swimmerets; one or two pairs of antennae (Crustacea : copepods, crabs, crayfish)	
	Legs, swimmerets:	Ten or more pairs of legs; swimmerets absent, one pair of antennae	W
W.	Legs per body segment:	One pair (Chilopoda : centipedes)	
	Legs per body segment:	Two pairs (Diplopoda : millipedes)	

^a Adapted from references 5, 17, 20, 28, 43, and 47.

Table 24.11 Key to the important myiasis-producing larvae^a

1.	Body with spinous or fleshy processes laterally and dorsally or terminally	<i>Fannia</i>
	Body smooth or with short spines, but <i>never</i> having long fleshy lateral processes	2
2.	Body with a long slender tail or caudal process capable of some extension and retraction	<i>Eristalis</i>
	Body sometimes narrowed posteriorly, but <i>never</i> with a long flexible caudal process capable of some extension and retraction	3
3.	Larvae more or less grub-like; most species slightly flattened dorsoventrally	4
	Larvae maggot-like, or typical “muscoïd” shape, tapering anteriorly, broadly truncate at the posterior end; cross section more or less circular at all points	5
4.	Posterior spiracular plate with three distinct slits	<i>Dermatobia</i>
	Posterior spiracular plate with many fine openings	<i>Hypoderma</i>
5.	Posterior spiracles within a well-chitinized and complete ring encircling the button area; spiracles <i>never</i> in a distinct depression	6
	Posterior spiracles with the button very slightly chitinized or absent; chitinized ring incomplete; spiracles in a distinct depression or flush with surface	8
6.	Button area with spiracular slits nearly straight	7
	Button area with spiracular slits sinuous, with at least a double curve	9
7.	Principal transverse subdivisions of spiracular slits well marked, usually not more than six; both ring and button heavily chitinized, the ring thickened into points at two places between the slits	<i>Calliphora</i>
	Transverse subdivisions of spiracular slits less distinctly marked, from 6 to 20 in number, ring and button less heavily chitinized, the ring thickened into point at only one place between the slits	<i>Phaenicia</i>
8.	Posterior spiracles in a more or less distinct pit or depression, vestigial button usually present; integument rather smooth	<i>Sarcophaga</i>
	Posterior spiracles flush with surface; integument rather spiny (Western Hemisphere)	<i>Cochliomyia</i>
9.	Posterior spiracular plates D-shaped, each slit thrown into several loops	<i>Musca</i>
	Posterior spiracular plates triangular, with rounded corners; spiracular slits S-shaped; button indistinct, centrally placed	<i>Stomoxys</i>

^aAdapted from B. F. Prendergast (ed.), *Filth Flies, Technical Guide 30*. Armed Forces Pest Management Board, Washington, D.C., 2002 (reviewed and validated 2004).

predators such as the small fish *Gambusia affinis*, which feeds on mosquito larvae. The introduction of the irradiation technique for sterilizing males of the screwworm fly, *Cochliomyia hominivorax*, has dramatically limited the development of progeny of this myiasis-producing fly throughout the southern United States. Chemosterilants are also being used, in some cases eliminating the need for radiation techniques. Insect growth regulators generally cause reproductive dysfunction or inhibit development of the adult stage.

Chemical Control

Although chemical control measures dramatically increased after World War II, the current approach involves combination methods rather than relying on chemical means alone. Concerns have been raised about a number of chemicals, particularly in terms of their possible contamination of the food chain. Also, different chemicals and approaches vary considerably throughout the world, often depending on location and financial considerations.

Most insecticides currently in use include inorganic compounds (arsenicals and fluorine compounds), botanicals (pyrethrins from pyrethrum flowers), chlorinated hydrocarbons (DDT, lindane, chlordane, dieldrin, and methoxychlor), and organophosphorus (malathion, dicrotophos, and parathion) and carbamate (Baygon, Sevin, and Bendiocarb) compounds. A great deal of emphasis has been placed on the residual action of certain insecticides, compounds that remain stable on surfaces for long periods but which are effective at very low concentrations. These residual sprays are quite different than those that are sprayed ("space sprayed") for short-term effectiveness.

Unfortunately, as with all animal populations, susceptibility and resistance to these insecticides will vary; arthropods that are resistant will survive. Crossbreeding of these survivors often tends to enhance the resistance. This has occurred with insects exposed to chlorinated hydrocarbons and organophosphorus compounds.

Insecticides can be applied as sprays (immediate action or residual), aerosols (the insecticide remains suspended in air for a long time), ultra-low-volume concentrates (essentially no solvents are used), dusts (10% insecticide in talc or pyrophyllite inert carriers), granules (inorganic carrier such as vermiculite), or bait (houseflies, cockroaches, ants). Repellents and acaricides can also be used for those who are exposed to arthropods in infested areas. True repellents do not kill the arthropods but discourage them from landing or biting.

Treatment of Parasitic Infections

Chemotherapy plays a very important role not only in reducing patient morbidity and mortality but also in reducing transmission of the parasitic infection. Many of the drugs used to treat parasitic infections have serious side effects; therefore, before initiation of therapy, it is important to consider the following factors: health of the patient, parasite drug resistance, accuracy of the original dose, potential drug toxicity, and the need for follow-up examinations to monitor therapy. The mechanisms of action of most antiparasitic drugs are not well known, including those involving potential drug toxicity to the patient. Because of the limited resources of developing nations, where a majority of parasitic infections occur, there is little commercial incentive for developing effective therapeutics or vaccines. For some drugs such as triclabendazole, used extensively in veterinary practices, less is known about adverse side effects or toxicity to humans. Specific information can be obtained from the Centers for Disease Control and Prevention, CDC Drug Service, Atlanta, Ga. [day, (404) 639-3670; evenings, weekends, and holidays, (404) 639-2888]. One can also obtain drugs from CDC that are not commercially available in the United States.

Tables 25.1 and 25.2 provide information on the most commonly used drugs for treating parasitic infections (1, 4, 5, 8–10, 12–16, 19, 23, 24, 26); not all drugs are included, and some drugs listed are not available in the United States. Information on drug resistance and susceptibility testing can be seen in Table 25.3.

Albendazole (Albenza) (GlaxoSmithKline)

Preparation

The drug is available as 200-mg tablets and is used for the treatment of neurocysticercosis and hydatid disease.

Administration

The drug is given with meals. It is poorly absorbed from the gastrointestinal tract due to its low aqueous solubility. Concentrations in plasma are negligible or undetectable because it is rapidly converted to the sulfoxide metabolite prior to reaching the systemic circulation. The systemic anthelmintic activity has been attributed to the primary metabolite, albendazole sulfoxide. Oral bioavailability appears to be enhanced when albendazole is coadministered with a fatty meal (estimated fat content, 40 g) as evidenced by higher (up to

Table 25.1 Drugs and dosages for treating parasitic infections^a

Organism or infection	Drug	Dosage ^b	Follow-up ^b and comments
<i>Acanthamoeba</i> spp. Meningoencephalitis	Amphotericin B and Sulfadiazine	1 mg/kg/day i.v., uncertain duration 1 mg QID intrathecally	Monitor clinical course; usually susceptible in vitro to pentamidine, ketoconazole (Nizoral), and flucytosine (Ancobon)
	or Sulfisoxazole	50 mg/kg i.v.	
Keratitis	Pentamidine isethionate	4 mg/kg/day i.v.	Monitor clinical course; combination therapy highly recommended; PHMB available at Leiter's Park Ave. Pharmacy, San Jose, CA (800-292-6773) (www.leiterrx.com)
	Polyhexamethylene biguanide (Baquacil) (PHMB)	0.02% applied topically hourly for 3 days, then every 4 h	
	plus/or Propamidine isethionate (Brolene) plus Neomycin-polymyxin B-gramicidin	0.1% applied topically Ophthalmic solution	
<i>Ancylostoma caninum</i> (eosinophilic enterocolitis)	Albendazole	400 mg once	Monitor clinical course
	or Mebendazole	100 mg BID × 3 days or 500 mg once	
	or Pyrantel pamoate	11 mg/kg (max 1 g) × 3 days	
<i>Ancylostoma duodenale</i> (hookworm)	Albendazole	400 mg once	Fecal examinations 2–4 wk posttherapy
	or Mebendazole	100 mg BID × 3 days or 500 mg once	
	or Pyrantel pamoate	11 mg/kg (max 1 g) × 3 days	
<i>Angiostrongylus cantonensis</i>	Mebendazole	100 mg BID × 5 days	Monitor clinical course; may want to add corticosteroid
<i>Angiostrongylus costaricensis</i>	Drug of choice Mebendazole	200–400 mg TID × 10 days	Monitor clinical course; may want to add corticosteroid
	Alternative Thiabendazole	75 mg/kg/day in 3 doses × 3 days (max 3 g/day)	
<i>Anisakis</i> spp.	Surgical or endoscopic removal		Monitor clinical course; albendazole has also been reported to be successful

(continued)

Table 25.1 Drugs and dosages for treating parasitic infections^a (continued)

Organism or infection	Drug	Dosage ^b	Follow-up ^b and comments		
<i>Ascaris lumbricoides</i> (roundworm)	Albendazole	400 mg once	Fecal examinations 2–4 wk posttherapy		
	or Mebendazole	100 mg BID × 3 days or 500 mg once			
	or Ivermectin	150–200 µg/kg once			
<i>Babesia</i> spp.	Clindamycin	1.2 g BID i.v. parenterally or 600 mg TID p.o. × 7–10 days Children: 20–40 mg/kg/day p.o. in 3 doses × 7–10 days	Monitor clinical course; repeat blood smears if symptoms persist		
	plus Quinine	650 mg TID p.o. × 7–10 days Children: 25 mg/kg/day in 3 doses × 7–10 days			
	or Atovaquone	750 mg BID p.o. × 7–10 days Children: 20 mg/kg BID p.o. × 7–10 days	Therapeutic alternatives for persistent or relapsing infections or patients who do not tolerate clindamycin or quinine		
	plus Azithromycin	600 mg daily p.o. × 7–10 days Children: 12 mg/kg daily p.o. × 7–10 days			
	<i>Balamuthia mandrillaris</i> (leptomyxid amebae) (amebic meningoencephalitis)	Drug of choice Pentamidine isethionate		10 µg/ml	Monitor clinical response and organisms in CSF; direct wet mounts of CSF and cultures
		Alternatives			These 4 drugs used in combination
Clarithromycin (Biaxin)		500 mg TID			
Fluconazole (Diflucan)		400 mg once daily			
Sulfadiazine		1.5 g every 6 h			
	Flucytosine (Ancobon)	1.5 g every 6 h			
<i>Balantidium coli</i>	Drug of choice Tetracycline	500 mg QID × 10 days Children (≥8 yr): 40 mg/kg/day in 4 doses × 10 days (max 2 g/day)	At least 3 negative fecal examinations 1 mo after therapy; contraindicated in pregnancy and in children <8 yr		
	Alternatives Iodoquinol	650 mg TID × 20 days Children: 40 mg/kg/day in 3 doses × 20 days			
	or Metronidazole	750 mg TID × 5 days Children: 35–50 mg/kg/day in 3 doses × 5 days			

<i>Baylisascaris procyonis</i> (severe visceral and neural larva migrans) (raccoon roundworm)	Albendazole, mebendazole, thiabendazole, levamisole, ivermectin	Check with CDC Drug Service Therapy must be started as soon as possible (up to 3 days after possible infection) Albendazole 25 mg/kg/day × 20 days	Steroids may also be helpful in eye and CNS infections; laser photocoagulation therapy has been used to destroy larvae in the retina
<i>Blastocystis hominis</i> (may be comprised of multiple strains, some pathogenic and some nonpathogenic)	Clinical significance is controversial		Fecal examinations 2 wk to 1 mo after therapy (must include permanent stain); metronidazole resistance may be common; another alternative would be TMP/SMX or nitazoxanide in children
	Metronidazole	750 mg TID × 10 days Children: 35–50 mg/kg/day in 3 doses × 10 days	
	or		
	Iodoquinol	650 mg TID × 20 days Children: 30–40 mg/kg/day in 3 doses × 20 days	
<i>Brugia malayi</i>	Diethylcarbamazine (available from CDC)	Day 1: 50 mg p.c. Day 2: 50 mg TID Day 3: 100 mg TID Days 4–14: 6 mg/kg/day in 3 doses Children: Day 1: 1 mg/kg p.c. Day 2: 1 mg/kg TID Day 3: 1–2 mg/kg TID Days 4–14: 6 mg/kg/day in 3 doses	Blood smears, Knott concentration, and membrane filtration of blood for microfilariae 2–4 wk after treatment; for patients with no microfilariae in the blood, full doses can be given from day 1
	or		
	Ivermectin + albendazole	200 µg/kg once, repeat every 6–12 mo + 400 mg once	Single dose of 200 µg/kg and 400 mg once effective for treatment of microfilariae but does not kill adult worms
<i>Capillaria philippinensis</i>	Drug of choice Mebendazole	200 mg BID × 20 days	Multiple fecal examinations for eggs several months after completion of therapy
	Alternative Albendazole	400 mg BID × 10 days	
<i>Clonorchis (Opisthorchis) sinensis</i> (Chinese liver fluke)	Praziquantel	75 mg/kg/day in 3 doses × 1 day	Fecal examinations for eggs 1 and 3 mo after therapy
	or Albendazole	10 mg/kg × 7 days	
<i>Cryptosporidium</i> spp.	Nitazoxanide	500 mg BID × 3 days Children 1–3 yr: 100 mg BID × 3 days 4–11 yr: 200 mg BID × 3 days	

(continued)

Table 25.1 Drugs and dosages for treating parasitic infections^a (continued)

Organism or infection	Drug	Dosage ^b	Follow-up ^b and comments
	or Paromomycin	25–35 mg/kg/day in 2 or 4 doses	Monitor clinical response and perform stool examinations during and after experimental therapy (acid-fast stain or direct fluorescent antibody test); may be combined with azithromycin (600 mg/day)
Cutaneous larva migrans (creeping eruption, dog and cat hookworm) (<i>Ancylostoma braziliense</i> , <i>Ancylostoma caninum</i>)	Albendazole or Ivermectin or Thiabendazole	400 mg daily × 3 days 200 µg/kg daily × 1–2 days Topically with or without 25 mg/kg BID (max 3 g/day) × 2–5 days	Monitor clinical response to therapy
<i>Cyclospora cayetanensis</i>	TMP-SMX	TMP 160 mg, SMX 800 mg (1 DS tab) BID × 7–10 days Children: TMP 5 mg/kg, SMX 25 mg/kg BID × 7–10 days	Monitor clinical course and perform stool examination using modified acid-fast stains or autofluorescence
Cysticercosis (<i>Taenia solium</i>)	Albendazole	400 mg BID × 8–30 days; repeat as necessary Persons ≥60 kg: 400 mg BID with meals Children: 15 mg/kg/day (max 800 mg) in 2 doses × 8–30 days; repeat as necessary	Monitor clinical response to therapy; follow up with CT scans; corticosteroids should be given 2–3 days before and during therapy; damage may occur when treating ocular or spinal cysts, even using corticosteroids; antiseizure medication may also be required
	or Praziquantel or Surgery	50–100 mg/kg/day in 3 doses × 30 days	
<i>Dientamoeba fragilis</i>	Iodoquinol	650 mg TID × 20 days Children: 30–40 mg/kg/day (max 2 g) in 3 doses × 20 days	Fecal examinations 2–4 wk after therapy (must include permanent stained smear)
	or Paromomycin or Tetracycline	25–30 mg/kg/day in 3 doses × 7 days 500 mg QID × 10 days Children: 40 mg/kg/day in 4 doses (max 2 g) × 10 days	Contraindicated in pregnancy and in children <8 yr
	or Metronidazole	500–750 mg TID × 10 days Children: 20–40 mg/kg/day in 3 doses × 10 days	

<i>Diphyllbothrium latum</i> (broad fish tapeworm)	Drug of choice Praziquantel	5–10 mg/kg once	Fecal examinations for eggs and proglottids 1 and 3 mo after therapy
	Alternative Niclosamide	2 g once Children: 50 mg/kg once	
<i>Dipylidium caninum</i> (dog and cat tapeworm)	Drug of choice Praziquantel	5–10 mg/kg once	Fecal examinations for eggs and proglottids 1 and 3 mo after therapy
	Alternative Niclosamide	2 g once Children: 50 mg/kg once	
<i>Dracunculus medinensis</i> (guinea worm)	Metronidazole	250 mg TID × 10 days Children: 25 mg/kg/day (max 750 mg/day) in 3 doses × 10 days	Monitor clinical course; slow extraction of worm; drugs not curative, but decrease inflammation
<i>Echinococcus granulosus</i> (hydatid cyst)	Albendazole	400 mg BID × 1–6 mo Children: 15 mg/kg/day (max 800 mg) × 1–6 mo	Monitor clinical response to therapy; follow up with CT, ultrasonography, and radionuclide scans
	or Surgery		
<i>Echinococcus multilocularis</i> (alveolar hydatid cyst)	Surgery	If surgery is unsuccessful or contraindicated, albendazole may be used	Monitor clinical response to therapy; follow up with CT, ultrasonography, and radionuclide scans
	or Albendazole	400 mg BID × 1–6 mo Children: 15 mg/kg/day (max 800 mg) × 1–6 mo	
<i>Entamoeba histolytica</i> Asymptomatic cyst passer (will be unable to morphologically differentiate <i>E. histolytica</i> from <i>E. dispar</i> on the basis of the cyst)	Iodoquinol (drug of choice)	650 mg/kg TID × 20 days Children: 30–40 mg/kg/day in 3 doses × 20 days (max 2 g)	Fecal examinations 2 wk to 1 mo after therapy (must include permanent stained smear); EIAs for confirmation of true <i>E. histolytica</i> are available; trophozoites containing ingested RBCs can be identified as <i>E. histolytica</i>
	or Paromomycin Diloxanide furoate (alternative)	25–35 mg/kg/day in 3 doses × 7 days 500 mg TID × 10 days Children: 20 mg/kg/day in 3 doses × 10 days	Not available commercially

(continued)

Table 25.1 Drugs and dosages for treating parasitic infections^a (continued)

Organism or infection	Drug	Dosage ^b	Follow-up ^b and comments
Mild to moderate intestinal disease	Metronidazole	500–750 mg TID × 10 days Children: 35–50 mg/kg/day in 3 doses × 7–10 days	Fecal examinations 2 wk to 1 mo after therapy (must include permanent stained smear); EIAs for confirmation of true <i>E. histolytica</i> are available; follow up with course of iodoquinol or paromomycin used to treat asymptomatic amebiasis
	or Tinidazole	2 g/day × 3 days Children: 50 mg/kg (max 2 g) in 1 dose × 3 days	Tablets can be crushed and mixed with cherry syrup
Invasive amebiasis	Metronidazole	750 mg TID × 7–10 days Children: 35–50 mg/kg/day in 3 doses × 7–10 days	Monitor clinical response to therapy; follow up with CT, ultrasonography, and radionucleotide scans
	or Tinidazole	2 g once daily × 5 days Children: 50 mg/kg/day (max 2 g) every day × 5 days	
<i>Entamoeba polecki</i>	Metronidazole	750 mg TID × 10 days Children: 35–50 mg/kg/day in 3 doses × 10 days	Fecal examinations 2 wk to 1 mo after therapy (must include permanent stained smear)
<i>Enterobius vermicularis</i> (pinworm)	Pyrantel pamoate	11 mg/kg once (max 1 g), repeat after 2 wk	Monitor clinical response; follow up with Scotch tape check of perianal area if symptoms persist (may take 4–6 consecutive negative tapes to rule out infection)
	or Mebendazole	100 mg once, repeat after 2 wk	
	or Albendazole	400 mg once; repeat after 2 wk	
<i>Fasciola hepatica</i> (sheep liver fluke)	Triclabendazole	10 mg/kg once or twice	Fecal examinations for eggs 1 mo after therapy; problems with availability of triclabendazole
	or Bithionol	30–50 mg/kg on alternate days × 10–15 doses	
<i>Fasciolopsis buski</i> (giant intestinal fluke)	Praziquantel	75 mg/kg/day in 3 doses × 1 day	Fecal examinations for eggs 1 mo after therapy
<i>Giardia lamblia</i> (<i>G. intestinalis</i> , <i>G. duodenalis</i>)	Drug of choice Metronidazole	250 mg TID × 5 days Children: 15 mg/kg/day in 3 doses × 5 days	Fecal examinations 2 wk to 1 mo posttherapy (must include permanent stained smear or immunoassay); Entero-Test if stools are negative and patient is symptomatic; immunoassays for stool antigen available

	or Nitazoxanide	500 mg BID × 3 days Children: 1–3 yr: 100 mg q12h × 3 days 4–11 yr: 200 mg q12h × 3 days	
	or Tinidazole	2 g once Children: 50 mg/kg once (max 2 g)	Tablets can be crushed and mixed with cherry syrup
	Alternatives Paromomycin	25–35 mg/kg/day in 3 doses × 7 days	
	or Furazolidone	100 mg QID × 7–10 days Children: 6 mg/kg/day in 4 doses × 7–10 days	
	or Quinacrine	100 mg TID × 5 days Children: 2 mg/kg TID × 5 days (max 300 mg/day)	Not available commercially
<i>Gnathostoma spinigerum</i>	Surgical removal plus Albendazole	400 mg BID × 21 days	Check for additional migratory swellings
	or Ivermectin	200 µg/kg/day × 2 days	
<i>Gongylonema pulchrum</i>	Surgical removal plus Albendazole	400 mg BID × 21 days	Check buccal cavity and esophagus
<i>Heterophyes heterophyes</i> (intestinal fluke)	Praziquantel	75 mg/kg/day in 3 doses × 1 day	Fecal examinations for eggs 1 mo after therapy
<i>Hymenolepis nana</i> (dwarf tapeworm)	Praziquantel	25 mg/kg once	Fecal examinations for eggs and proglottids 2 wk and 3 mo after therapy
	or Nitazoxanide	500 mg BID × 3 days Children: 1–3 yr: 100 mg q12h × 3 days 4–11 yr: 200 mg q12h × 3 days	
<i>Isospora belli</i>	TMP-SMX	160 mg of TMP, 800 mg of SMX (1 DS tab) BID × 10 days Children: TMP 5 mg/kg, SMX 25 mg/kg BID × 10 days	Fecal examinations 1–2 wk after therapy
<i>Leishmania</i> spp.	Stibogluconate sodium (drug of choice)	20 mg of antimony/kg/day i.v. or i.m. × 28 days	For <i>L. donovani</i> , monitor clinical response to therapy; for other <i>Leishmania</i> spp., perform smear and culture of lesions 1–2 wk after therapy

(continued)

Table 25.1 Drugs and dosages for treating parasitic infections^a (continued)

Organism or infection	Drug	Dosage ^b	Follow-up ^b and comments
	or Meglumine antimonate	20 mg of antimony/kg/day × 28 days	
	or Amphotericin B	0.5–1.0 mg/kg by slow infusion daily or every 2 days for up to 8 wk	
	or Liposomal amphotericin B	3 mg/kg/day (days 1–5) and 3 mg/kg/day for days 14 and 21	
	Alternatives		
	Pentamidine isethionate	4 mg/kg daily or every 2 days i.v. or i.m. for 15–30 doses	
	or Paromomycin	Topically twice daily × 10–20 days	
<i>Loa loa</i> (African eye worm)	Diethylcarbamazine (available from CDC)	6 mg/kg in 3 doses × 14 days 300 mg once/wk recommended for preven- tion	Blood smears, Knott concentration, and mem- brane filtration of blood for microfilariae 2–4 wk after therapy; for patients with no microfilariae in the blood, full doses can be given from day one; in heavy infections albendazole preferred (slower onset of action and lower risk of enceph- alopathy), but repeated doses may be required
<i>Mansonella ozzardi</i>	Ivermectin	200 µg/kg once	As above; diethylcarbamazine ineffective
<i>Mansonella perstans</i>	Albendazole or Mebendazole	400 mg BID × 10 days 100 mg BID × 30 days	As above
<i>Mansonella streptocerca</i>	Diethylcarbamazine (available from CDC) or Ivermectin	6 mg/kg/day × 14 days 150 µg/kg once	See <i>Onchocerca volvulus</i>
<i>Metagonimus yokogawai</i> (intestinal fluke)	Praziquantel	75 mg/kg/day in 3 doses × 1 day	Fecal examinations for eggs 2–4 wk after therapy
<i>Metorchis conjunctus</i> (North American liver fluke)	Praziquantel	75 mg/kg/day in 3 doses × 1 day	Fecal examinations for eggs 2–4 wk after therapy
Microsporidia	In some genera and species, treatment not totally effective; see also nitazoxanide under <i>Giardia lamblia</i>		
Disseminated			
<i>Encephalitozoon hellem</i>	Albendazole	400 mg BID	Monitor clinical response
<i>Encephalitozoon cuniculi</i>	Albendazole	400 mg BID	Monitor clinical response
<i>Encephalitozoon (Septata) intestinalis</i>	Albendazole	400 mg BID	Monitor clinical response

<i>Pleistophora</i> sp.	Albendazole	400 mg BID	Monitor clinical response; may add itraconazole 400 mg p.o. once/day
<i>Trachipleistophora hominis</i>	Albendazole	400 mg BID	Monitor clinical response; may add itraconazole 400 mg p.o. once/day
<i>Brachiola vesicularum</i>	Albendazole	400 mg BID	Monitor clinical response; may add itraconazole 400 mg p.o. once/day
Intestinal			
<i>Enterocytozoon bieneusi</i>	Albendazole*	400 mg BID	Monitor clinical response; fecal exam for spores 2–4 wk after therapy
<i>Encephalitozoon (Septata) intestinalis</i>	Albendazole*	400 mg BID	Monitor clinical response; fecal exam for spores 2–4 wk after therapy
Ocular			
<i>Encephalitozoon hellem</i>	Albendazole plus fumagillin	400 mg BID, eye drops	Monitor clinical response
<i>Encephalitozoon cuniculi</i>	Albendazole plus fumagillin	400 mg BID, eye drops	Monitor clinical response
<i>Vittaforma corneae</i>	Albendazole plus fumagillin*	400 mg BID, eye drops	Monitor clinical response
<i>Moniliformis moniliformis</i>	Pyrantel pamoate	11 mg/kg once, repeat twice, 2 wk apart	Fecal exam for eggs 1 mo after therapy
<i>Naegleria fowleri</i> (primary amebic meningoencephalitis)	Amphotericin B	1.5 mg/kg/day i.v. in 2 doses × 3 days, then 1 mg/kg/day × 6 days	Monitor clinical response and organisms in CSF; direct wet mounts of CSF and cultures
<i>Nanophytes salmincola</i>	Praziquantel	60 mg/kg/day in 3 doses × 1 day	Fecal exam for eggs 1 mo after therapy
<i>Necator americanus</i> (hookworm)	Albendazole	400 mg once	Fecal examinations 2–4 wk posttherapy; if eggs are rare in fecal concentrations, no need to repeat therapy
	or		
	Mebendazole	100 mg BID × 3 days or 500 mg once	
	or		
	Pyrantel pamoate	11 mg/kg once (max 1 g) × 3 days	
<i>Oesophagostomum bifurcum</i>	Albendazole	400 mg once	Monitor clinical response; pyrantel pamoate may also be effective
<i>Onchocerca volvulus</i> (river blindness)	Ivermectin	150 µg/kg once, repeat every 6–12 mo until asymptomatic	Skin snips for microfilariae 3–6 mo after therapy or sooner if symptoms recur
<i>Opisthorchis viverrini</i> (Southeast Asian liver fluke)	Praziquantel	75 mg/kg/day in 3 doses × 1 day	Fecal exam for eggs 1 mo after therapy
<i>Paragonimus westermani</i> (lung fluke), <i>Paragonimus</i> spp.	Drug of choice Praziquantel	75 mg/kg/day in 3 doses × 2 days	Sputum examination for eggs 2–4 wk after therapy; fecal examinations for eggs 1–2 mo after therapy
	Alternative Bithionol	30–50 mg/kg on alternate days × 10–15 doses	
<i>Pediculus humanis</i> (body louse)	0.5% Malathion or 1% Permethrin	Topically Apply lotion to body, allow to remain for 10 min, then bathe	Examine clothing and bedding for nits and lice

(continued)

Table 25.1 Drugs and dosages for treating parasitic infections^a (continued)

Organism or infection	Drug	Dosage ^b	Follow-up ^b and comments
	Alternatives		
	Pyrethrins with piperonyl butoxide or Ivermectin	Topically with second application 1 wk later 200 µg/kg × 3, days 1, 2, and 10	
<i>Phthirus pubis</i> (pubic louse)	0.5% Malathion or 1% Permethrin	Topically Apply lotion to hair, allow to remain for 10 min, then rinse off	Examine clothing, bedding, and hair for nits and lice
	Alternatives		
	Pyrethrins with piperonylbutoxide or Ivermectin	Topically with second application 1 wk later 200 µg/kg × 3, days 1, 2, and 10	
<i>Plasmodium</i> spp. Chemoprophylaxis (prevention)			
Chloroquine-sensitive areas	Chloroquine phosphate	500 mg (300 mg of base) once/wk for 1–2 wk before travel and continuing weekly for 4–6 wk after leaving area Children: 5 mg of base/kg/wk once/wk, up to adult dose of 300 mg of base	Monitor clinical course
Chloroquine-resistant areas	Atovaquone/proguanil (drug of choice) or Mefloquine	1 adult tab/day Children: 11–20 kg: 1 peds tab/day 21–30 kg: 2 peds tabs/day 31–40 kg: 3 peds tabs/day >40 kg: 1 adult tab/day 250 mg once/wk Children: 5–10 kg: 1/8 tab once/wk 11–20 kg: 1/4 tab once/wk 21–30 kg: 1/2 tab once/wk 31–45 kg: 3/4 tab once/wk >45 kg: 1 tab once/wk	250 mg/100 mg (1 tablet) daily, beginning 1–2 days before travel, continuing during stay and for 1 wk after leaving area 250 mg p.o. once/wk for 1–2 wk before travel and continuing weekly for 4–6 wk after leaving area
	or Doxycycline	100 mg daily Children: 2 mg/kg/day, up to 100 mg/day	
	Alternatives		
	Primaquine	30 mg of base daily Children: 0.6 mg/kg of base daily	

	or		
	Chloroquine phosphate	500 mg (300 mg of base) once/wk Children: 5 mg of base/kg once/wk, up to 300 mg of base	Same as for chloroquine-sensitive areas for adults and children
	plus proguanil	200 mg once/day Children: <2 yr: 50 mg once/day 2–6 yr: 100 mg once/day 7–10 yr: 150 mg once/day >10 yr: 200 mg once/day	
Self-presumptive treatment	Atovaquone/proguanil	4 adult tabs daily × 3 days Children: <5 kg: not indicated 5–8 kg: 2 peds tabs once/day × 3 days 9–10 kg: 3 peds tabs once/day × 3 days 11–20 kg: 1 adult tab once/day × 3 days 21–30 kg: 2 adult tabs once/day × 3 days 31–40 kg: 3 adult tabs once/day × 3 days >40 kg: 4 adult tabs once/day × 3 days	A traveler can be given a course of atovaquone/proguanil, mefloquine, or quinine plus doxycycline for presumptive self-treatment of febrile illness. The drug used for self-treatment should be different from that used for prophylaxis. This approach should be used in very rare circumstances when the person cannot promptly receive medical care.
	or		
	Quinine sulfate	650 mg q8h × 3–7 days Children: 30 mg/kg/day in 3 doses × 3–7 days	
	plus		
	Doxycycline	100 mg BID × 7 days Children: 4 mg/kg/day in 2 doses × 7 days	Tetracyclines contraindicated in pregnancy and in children <8 yr old
	or		
	Mefloquine	750 mg followed 12 h later by 500 mg Children: 15 mg/kg followed 12 h later by 10 mg/kg	
Treatment			
All <i>Plasmodium</i> species except chloroquine-resistant <i>P. falciparum</i> and chloroquine-resistant <i>P. vivax</i> (oral)	Chloroquine phosphate	1 g (600 mg of base) p.o., then 500 mg (300 mg of base) 6 h later, then 500 mg (300 mg of base) at 24 and 48 h Children: 10 mg of base/kg (max 600 mg of base), then 5 mg of base/kg 6 h later, and then 5 mg of base at 24 and 48 h	Thick and thin blood smears

(continued)

Table 25.1 Drugs and dosages for treating parasitic infections^a (continued)

Organism or infection	Drug	Dosage ^b	Follow-up ^b and comments
All <i>Plasmodium</i> spp. (parenteral)	Quinidine gluconate (parenteral drug of choice)	10-mg/kg loading dose (max 600 mg) in normal saline slowly over 1–2 h followed by continuous infusion of 0.02 mg/kg/min until start of oral therapy	Continuous EKG, blood pressure, and glucose monitoring recommended; if >48 h of parenteral treatment is required, quinine or quinidine dose should be reduced by 1/3 to 1/2
	or Quinine dihydrochloride	20-mg/kg loading dose in 10 mg/kg 5% dextrose over 4 h followed by 10 mg/kg over 2–4 h q8h (max 1,800 mg/day) until start of oral therapy	Continuous EKG, blood pressure, and glucose monitoring recommended; if >48 h of parenteral treatment is required, quinine or quinidine dose should be reduced by 1/3 to 1/2
	Artemether (alternative)	3.2 mg/kg i.m., then 1.6 mg/kg/day × 5–7 days	
Chloroquine-resistant <i>P. falciparum</i>	Drugs of choice Atovaquone/proguanil	2 adult tabs BID or 4 adult tabs once/day × 3 days Children: <5 kg: not indicated 5–8 kg: 2 peds tabs once/day × 3 days 9–10 kg: 3 peds tabs once/day × 3 days 11–20 kg: 1 adult tab once/day × 3 days 21–30 kg: 2 adult tabs once/day × 3 days 31–40 kg: 3 adult tabs once/day × 3 days >40 kg: 4 adult tabs once/day × 3 days	Atovaquone/proguanil is available as a fixed-dose combination tablet: (Malarone; 250 mg of atovaquone/100 mg of proguanil) and pediatric tablets (Malarone Pediatric; 62.5 mg atovaquone/25 mg proguanil). Take with food or a milky drink. Should not be given to pregnant women or patients with severe renal impairment (creatinine clearance, <30 ml/min). A few isolated reports of <i>P. falciparum</i> resistance in Africa.
	or Quinine sulfate	650 mg q8h × 3–7 days Children: 30 mg/kg/day in 3 doses × 3–7 days	Southeast Asia: resistance has increased; treat for 7 days
	plus Doxycycline	100 mg BID × 7 days Children: 4 mg/kg/day in 2 doses × 7 days	Tetracyclines contraindicated in pregnancy and in children <8 yr
	or plus Tetracycline	250 mg QID × 7 days Children: 6.25 mg/kg QID × 7 days	Contraindicated in pregnancy and in children <8 yr
	or plus Clindamycin	20 mg/kg/day in 3 doses × 7 days	Allowed if pregnant
	Alternatives Mefloquine	750 mg followed 12 h later by 500 mg Children: 15 mg/kg followed 12 h later by 10 mg/kg	

	or Artesunate plus Mefloquine	4 mg/kg/day × 3 days 750 mg followed 12 h later by 500 mg Children: 15 mg/kg followed 12 h later by 10 mg/kg	Not available in U.S.
Chloroquine-resistant <i>P. vivax</i>	Quinine sulfate (oral drug of choice) plus Doxycycline or Mefloquine Alternatives Chloroquine plus Primaquine	650 mg q8h TID × 3–7 days Children: 25 mg/kg in 3 doses × 3–7 days 100 mg BID × 7 days Children: 2 mg/kg/day × 7 days 750 mg followed 12 h later by 500 mg Children: 15 mg/kg followed 12 h later by 10 mg/kg 25 mg of base/kg in 3 doses over 48 h 30 mg of base daily × 14 days Children: 0.6 mg of base/kg/day × 14 days	Southeast Asia: resistance increased; treat for 7 days Tetracyclines contraindicated in pregnancy and in children <8 yr
Prevention of relapses (<i>P. vivax</i> , <i>P. ovale</i> only)	Primaquine phosphate	30 mg of base/day × 14 days Children: 0.6 mg of base/kg/day × 14 days	Primaquine phosphate can cause hemolytic anemia, especially in patients whose red cells are deficient in G6PDH. This deficiency is more common in African, Asian, and Mediterranean people. Patients should be screened for G6PDH deficiency prior to treatment. Primaquine should not be used during pregnancy.
<i>Sappinia diploidea</i> (amebic meningoencephalitis)	Azithromycin plus Pentamidine (i.v.) plus Itraconazole and plus Flucytosine	250 mg/day p.o., 31 wk 300 mg/day, 6 wk 200 mg BID, 25 wk 2.75 g QID, 25 wk	Combined therapy with surgical resection of CNS lesion
<i>Sarcoptes scabiei</i> (itch mite)	Drug of choice 5% Permethrin	Topically Massage from head to soles of feet; wash off after 8–14 h	Monitor clinical course; may need mild steroid cream in sensitive individuals; may require retreatment in 10–14 days; ivermectin plus scabicide recommended for crusted scabies in immunocompromised patients

Alternatives

(continued)

Table 25.1 Drugs and dosages for treating parasitic infections^a (continued)

Organism or infection	Drug	Dosage ^b	Follow-up ^b and comments
	Ivermectin	200 µg/kg p.o. once	
	or 10% Crotamiton	Topically once/day × 2	
<i>Schistosoma haematobium</i>	Praziquantel	40 mg/kg/day in 2 doses × 1 day	Urine examinations for eggs 1 mo after therapy; bladder or rectal biopsy; treatment failure reported
<i>Schistosoma intercalatum</i>	Praziquantel	40 mg/kg/day in 2 doses × 1 day	Fecal examinations for eggs 1 mo after therapy; rectal biopsy
<i>Schistosoma japonicum</i>	Praziquantel	60 mg/kg/day in 3 doses × 1 day	Fecal examinations for eggs 1 mo after therapy; rectal biopsy
<i>Schistosoma mansoni</i>	Drug of choice Praziquantel	40 mg/kg/day in 2 doses × 1 day	Fecal examinations for eggs 1 mo after therapy; rectal biopsy
	Alternative Oxamniquine	15 mg/kg once Children: 20 mg/kg/day in 2 doses × 1 day	Contraindicated in pregnancy; East Africa, increase dose to 30 mg/kg; South Africa, increase dose to 30 mg/kg × 2 days
<i>Schistosoma mekongi</i>	Praziquantel	60 mg/kg/day in 3 doses × 1 day	Fecal examinations for eggs 1 mo after therapy; rectal biopsy
<i>Strongyloides stercoralis</i>	Drug of choice Ivermectin	200 µg/kg/day × 2 days	Fecal examinations and/or agar plate culture 1 mo after therapy
	Alternatives Albendazole	400 mg BID × 7 days	
	or Thiabendazole	50 mg/kg/day in 2 doses × 2 days (max 3 g/day)	This dosage may be toxic; might need to be reduced
<i>Taenia saginata</i> (beef tapeworm)	Drug of choice Praziquantel	5–10 mg/kg p.o. once	Fecal examinations for eggs or proglottids 1 mo after therapy
	Alternative Niclosamide	2 g once Children: 50 mg/kg once	Availability problems
<i>Taenia solium</i> (pork tapeworm)	Drug of choice Praziquantel	5–10 mg/kg p.o. once	

	Alternative Niclosamide	Same as for <i>T. saginata</i>	Same as for <i>T. saginata</i>
<i>Toxocara canis</i> , <i>T. cati</i> (visceral larva migrans)	Albendazole or Mebendazole	400 mg BID × 5 days 100–200 mg BID × 5 days	Monitor clinical course
<i>Toxoplasma gondii</i>	Pyrimethamine (drug of choice) plus Sulfadiazine Spiramycin (alternative)	25–100 mg/day × 3–4 wk Children: 2 mg/kg/day × 3 days (max 25 mg/day), then 1 mg/kg/day × 4 wk 1–1.5 g QID × 3–4 wk Children: 100–200 mg/kg/day × 3–4 wk 3–4 g/day × 3–4 weeks	Monitor clinical course and serology; use only after first trimester Can be used during first-trimester infection
<i>Trichinella spiralis</i> , other <i>Trichinella</i> spp.	Mebendazole (drug of choice) plus Corticosteroids Albendazole (alternative)	200–400 mg TID × 3 days, then 400–500 mg TID × 10 days 20–60 mg/day p.o. 400 mg p.o. BID × 8–14 days	Monitor clinical course; perform muscle biopsy in severe cases; steroids for severe symptoms Use for severe symptoms
<i>Trichomonas vaginalis</i>	Metronidazole or Tinidazole	2 g once or 500 mg BID × 7 days Children: 15 mg/kg/day p.o. in 3 doses × 7 days 2 g once Children: 50 mg/kg once (max 2 g)	Pelvic examination 1 mo after therapy; sexual partners should be treated simultaneously Take with food to minimize adverse side effects; can be used with metronidazole-resistant strains
<i>Trichostrongylus</i> spp.	Drug of choice Pyrantel pamoate Alternatives Mebendazole or Albendazole	11 mg/kg once (max 1 g) 100 mg BID × 3 days 400 mg once	Fecal examinations 2–4 wk after therapy
<i>Trichuris trichiura</i> (whipworm)	Drug of choice Mebendazole Alternative Albendazole	100 mg BID × 3 days or 500 mg once 400 mg once	Fecal examinations 2–4 wk after therapy
Tropical pulmonary eosinophilia	Diethylcarbamazine (available from CDC)	6 mg/kg/day in 3 doses × 12–21 days	Monitor clinical course; if relapse occurs, retreat

(continued)

Table 25.1 Drugs and dosages for treating parasitic infections^a (continued)

Organism or infection	Drug	Dosage ^b	Follow-up ^b and comments
<i>Trypanosoma brucei gambiense</i> (West African sleeping sickness), early stages (hemolympathic)	Drug of choice Pentamidine isethionate	4 mg/kg/day i.m. × 10 days	Thick and thin blood smears 1–2 mo after therapy
	Alternative Suramin	100–200 mg (test dose) i.v., then 1 g i.v. on days 1, 3, 7, 14, and 21 Children: 20 mg/kg on days 1, 3, 7, 14, and 21	
<i>Trypanosoma brucei rhodesiense</i> (East African sleeping sickness), early stages (hemolympathic)	Suramin	100–200 mg (test dose) i.v., then 1 g i.v. on days 1, 3, 7, 14, and 21 Children: 20 mg/kg on days 1, 3, 7, 14, and 21	
<i>T. brucei gambiense</i> and <i>T. brucei rhodesiense</i> , late stage with CNS disease	Melarsoprol	2–3.6 mg/kg/day i.v. × 3 days; after 1 wk, 3.6 mg/kg/day i.v. × 3 days; repeat again after 7 days Children: 18–25 mg/kg total over 1 mo; initial dose of 0.36 mg/kg i.v., increasing gradually to max of 3.6 mg/kg at intervals of 1–5 days for total of 9–10 doses	Cerebrospinal fluid analysis during and after therapy
	or Eflornithine	400 mg/kg/day i.v. in 4 doses × 14 days	Highly effective for <i>T. brucei gambiense</i> but variable for <i>T. brucei rhodesiense</i>
<i>Trypanosoma cruzi</i> (American trypanosomiasis, Chagas' disease)	Benznidazole	5–7 mg/kg/day in 2 divided doses × 30–90 days Children up to 12 yr: 10 mg/kg/day in 2 doses × 30–90 days	Thick and thin blood smears or xenodiagnosis 1–2 mo after therapy; monitor serology and EKG
	or Nifurtimox	8–10 mg/kg/day in 3–4 doses × 90–120 days Children: 1–10 yr: 15–20 mg/kg/day in 4 doses × 90 days 11–16 yr: 12.5–15 mg/kg/day in 4 doses × 90 days	
<i>Wuchereria bancrofti</i>	Diethylcarbamazine (available from CDC)	6 mg/kg in 3 doses × 14 days	Thick blood smears, Knott concentration, and membrane filtration of blood after 2–4 wk

^a It is **very important** to thoroughly review drug information prior to use and to review published commentary concerning availability, contraindications, and monitoring requirements. Specific information can also be obtained online by checking *The Medical Letter*, August 2004: The Medical Letter, New Rochelle, N.Y. (<http://www.medletter.com/freedocs/parasitic.pdf>).

^b QID, four times a day; BID, twice a day; TID, three times a day; max, maximum; p.o., orally; p.c., with meals; CT, computed tomography; TMP, trimethoprim; SMX, sulfamethoxazole; CSF, cerebrospinal fluid; CNS, central nervous system; i.v., intravenous; i.m., intramuscular; EIA, enzyme immunoassay; EKG, electrocardiogram. DS tab, double-strength tablet; peds, pediatric; *, see also nitazoxanide.

Table 25.2 Antiparasitic drugs^a

Drug	Manufacturer	Trade name and comments ^b
Albendazole	GlaxoSmithKline	Albenza
Aminosidine		See Paromomycin
Amphotericin B	Apothecon, others	Ambisome
Amphotericin B	Apothecon, others	Fungizone, also available generically
Artemether	Aarencos, Belgium	Artenam; not available in the United States
Artesunate	Guilin No. 1 Factory, People's Republic of China	Not available in the United States
Atovaquone	GlaxoSmithKline	Mepron
Atovaquone-proguanil	GlaxoSmithKline	Malarone
Azithromycin	Pfizer	Zithromax
Bacitracin	Many manufacturers	
Bacitracin-zinc	Apothekernes Laboratorium A.S., Oslo, Norway	Not available in the United States
Benznidazole	Roche, Brazil	Rochagan; not available in the United States
Bithionol	Tanabe, Japan	Bitin; available through CDC Drug Service
Chloroquine HCl, chloroquine phosphate	Sanofi, others	Aralen, also available generically
Clarithromycin	Abbott	Biaxin
Clindamycin	Pfizer, others	Cleocin, also available generically
Crotamiton	Westwood-Squibb	Eurax
Dapsone	Jacobus	
Diethylcarbamazine citrate USP		Hetrazan; available through CDC Drug Service
Diloxanide furoate	Boots, United Kingdom	Furamide; not available in the United States
Doxycycline	Pfizer, others	Vibramycin; also available generically
Eflornithine (difluoromethylornithine, DFMO)	Aventis	Ornidyl; available through CDC Drug Service
Fluconazole	Roerig	Diflucan
Flucytosine	ICN	Ancobon
Fumagillin	Leiter's Park Avenue Pharmacy, San Jose, CA (800-292-6773) (www.leiterrx.com)	Fumidil-B
Furazolidone	Roberts	Furoxone; not available in the United States
Iodoquinol	Glenwood, others	Yodoxin; also available generically
Itraconazole	Janssen-Ortho	Sporanox
Ivermectin	Merck	Stromectol
Ketoconazole	Janssen, others	Nizoral; also available generically
Levamisole	Janssen	Ergamisol
Malathion	Taro	Ovide
Mebendazole	McNeil	Vermox
Mefloquine	Roche	Lariam
Meglumine antimoniate	Aventis, France	Glucantime; not available in the United States
Melarsoprol	Specia	Mel-B; available through CDC Drug Service
Metronidazole	Searle, others	Flagyl; also available generically
Miltefosine	Zentaris, Germany	Impavido; not available in the United States
Niclosamide	Bayer, Germany	Yomesan; not available in the United States
Nifurtimox	Bayer, Germany	Lampit; available through CDC Drug Service
Nitazoxanide	Romark	Alinia
Ornidazole	Roche, France	Tiberal; not available in the United States
Oxamniquine	Pfizer	Vansil; not available in the United States
Paromomycin	Monarch	Humatin
Paromomycin, topical	Teva, Israel	Leshcutan; not available in the United States
Pentamidine isethionate	Fujisawa	Pentam 300, Nebupent

Permethrin	GlaxoSmithKline	Nix
Permethrin	Allergan	Elimite
Polyhexamethylene biguanide	Zeneca: Leiter's Park Avenue Pharmacy, San Jose, CA (800-292-6773) (www.leiterrx.com)	Baquacil
Praziquantel	Bayer, distributed by Schering	Biltricide; not available in the United States
Primaquine phosphate USP		
Proguanil	Wyeth-Ayerst, Canada; AstraZeneca, United Kingdom	Paludrine; not available in the United States
Proguanil-atovaquone	GlaxoSmithKline	Malarone
Propamidine isethionate	Aventis, Canada	Brolene; not available in the United States
Pyrantel pamoate	Pfizer	Antiminth; not available in the United States
Pyrethrins and piperonyl butoxide	Pfizer, others	Rid; also available generically
Pyrimethamine USP	GlaxoSmithKline	Daraprim
Quinidine gluconate	Eli Lilly	Available in the United States only from the manufacturer
Quinine dihydrochloride		Not available in the United States
Quinine sulfate	Many manufacturers	
Rifampin	Aventis, others	Rifadin; also available generically
Sodium stibogluconate	GlaxoSmithKline, United Kingdom	Pentostam; available through CDC Drug Service
Spiramycin	Aventis	Rovamycine; available in the United States only from the manufacturer
Sulfadiazine		
Suramin sodium	Bayer, Germany	Germanin; available through CDC Drug Service
Thiabendazole	Merck	Mintezol
Tinidazole	Presutti: Mission Pharmaceuticals	Tindamax
TMP/Sulfa	Roche, others	Bactrim; also available generically
Triclabendazole	Novartis	Egaten; not available in the United States
Trimetrexate	U.S. Bioscience	Neutrexin

^a Information from *The Medical Letter*, August 2004: The Medical Letter, New Rochelle, N.Y.

^b Centers for Disease Control and Prevention (CDC), Atlanta, GA 30333; Drug Service, (404) 639-3670; evenings, weekends, holidays, (404) 639-2888; drugs not available in the United States may be available through a compounding pharmacy.

Table 25.3 Information on drug resistance and susceptibility testing for selected parasites^a

Parasite and potential problems with susceptibility testing	Drug resistance and resistance genes	Susceptibility testing ^b
African trypanosomes (<i>Trypanosoma brucei gambiense</i> , <i>T. brucei rhodesiense</i>) Technically demanding tests; less relevance for field testing; potential problems with heterologous parasite populations. Lengthy time to results.	Melarsoprol, pentamidine	Cultures; assessment of viability by direct count or hydrolysis of <i>p</i> -nitrophenyl phosphate. Melarsoprol in vitro lysis assay (culture plus recording spectrophotometer for changes in absorbance of organisms over 30-min time frame). Color change assay when organisms incubated with Alamar Blue; dye added after extended incubation. Genetic markers and molecular test research ongoing.
<i>Cryptosporidium</i> spp.	Praziquantel, doxycycline, paromomycin	Cell line cultures (MDCK cells) exposed to drugs—studies ongoing.
<i>Leishmania</i> spp.	Sodium stibogluconate, meglumine antimoniate, pentamidine, amphotericin B, paromomycin, miltefosine	Promastigote cultures in standard media (Schneider's); assessment of viability by direct count, hydrolysis of <i>p</i> -nitrophenyl phosphate, conversion of MTT, reduction of Alamar Blue.

(continued)

Table 25.3 (continued)

Parasite and potential problems with susceptibility testing	Drug resistance and resistance genes	Susceptibility testing ^b
Technically demanding tests; less relevance for field testing; potential problems with heterologous parasite populations. Lengthy time to results.		Amastigotes adapted to in vitro drug testing in axenic and intracellular assays (now using firefly luciferase), cells lysed, substrate added, activity measured using luminometer. Flow cytometer also being used (isolated transfected with gene encoding GFP [fluorescent]); counting performed using flow (visceral leishmaniasis). Parasite-infected cells treated with drug, anti- <i>Leishmania</i> indirect fluorescent-antibody test used as detection system. Molecular test application research ongoing.
<i>Plasmodium</i> spp. A recent dose of antimalarial drug results in decreased test success; high parasite inocula result in overestimation of resistance; folate and pABA in culture medium result in antagonism of in vitro effect of antifolate drugs.	Chloroquine (<i>pfcr</i> , <i>pfmdr1</i>), pyrimethamine, sulfadoxine, sulfadoxine-pyrimethamine and other antifolates (<i>dhfr</i> , <i>dhps</i>), atovaquone (cytochrome <i>b</i>), quinine, mefloquine, artemisinin, atovaquone-proguanil, tetracycline, primaquine	Most in vitro tests involve <i>Plasmodium falciparum</i> (asexual RBC stages—long-term cultivation possible); well cultures are plated with living organisms and various concentrations of test drug; after incubation (24–30 h), thick films are prepared from wells and Giemsa stained, and maturation of parasites is compared with that in test wells. A one-step fluorescence assay for use in antimalarial drug screening has been developed; parasite growth is determined by using SYBR Green I, a dye with marked fluorescence enhancement upon contact with <i>Plasmodium</i> DNA. Parasites suspended in drug for longer periods (48–72 h); parasite growth and inhibition assessed by parasite counts, ELISA for HRP2 or pLDH; can be adapted to field use, and results very closely matched those obtained with a modified World Health Organization schizont maturation assay. Genetic markers for drug resistance (mutation-specific nested PCR; nested PCR followed by sequencing; RFLP; molecular beacons; real-time PCR; sequence-specific oligonucleotide probes). Drug impact on liver and sexual stages experimental.
<i>Trichomonas vaginalis</i> Potential problems with deriving axenic cultures from clinical specimens	Metronidazole, tinidazole	Testing recommended after failure of 2 standard treatment regimens; performed under both aerobic and anaerobic conditions (differences in sensitivity more pronounced when performed aerobically); well cultures are plated and examined microscopically for motile organisms (minimum lethal concentration of metronidazole: aerobic >100 µg/ml, anaerobic >3.1 µl/ml = clinical resistance). Search for metronidazole resistance genes and possible PCR assay ongoing.
Helminth testing	Multiple drugs	All studies more difficult; cultures in vitro limited; some drugs depend on components of immune system.

^a Adapted from references 2, 3, 6, 7, 11, 15, 17, 18, 20–22, and 25.^b *dhfr*, dihydrofolate reductase; *dhps*, dihydropteroate synthetase; ELISA, enzyme-linked immunosorbent assay; GFP, green fluorescent protein; HRP2, histidine-rich protein 2; MDCK, Mardin-Darby canine kidney cells; MTT, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide; pABA, *p*-aminobenzoate; pLDH, parasite lactate dehydrogenase; RBC, red blood cell; RFLP, restriction fragment length polymorphism.

fivefold on average) concentrations of albendazole sulf-oxide in plasma compared to the concentration in plasma in fasted state.

Toxicity

Side effects include headache, vomiting, diarrhea, abdominal pain, increase in serum glutamic-oxaloacetic transaminase levels, and fever; migration of *Ascaris* through the mouth and nose may be seen.

Rare fatalities associated with the use of albendazole, due to granulocytopenia or pancytopenia, have been reported. Blood counts should be monitored at the beginning of each 28-day cycle of therapy and every 2 weeks during therapy with albendazole. Albendazole therapy may be continued if the total white blood cell count and absolute neutrophil count decrease appear modest and do not progress. Albendazole should not be used in pregnant women except in clinical circumstances where no alternative management is appropriate. Patients should not become pregnant for at least 1 month following cessation of albendazole therapy. If a patient becomes pregnant while taking this drug, the therapy should be discontinued immediately; the patient should be apprised of the potential hazard to the fetus.

Patients being treated for neurocysticercosis should receive appropriate steroid and anticonvulsant therapy as required. Oral or intravenous corticosteroids should be considered to prevent cerebral hypertensive episodes during the first week of anticysticercal therapy. Cysticercosis may, in rare cases, involve the retina. Before initiation of therapy for neurocysticercosis, the patient should be examined for the presence of retinal lesions. If such lesions are visualized, the need for anticysticercal therapy should be weighed against the possibility of retinal damage caused by albendazole-induced changes to the retinal lesion.

Contraindications

Due to lack of safety information, albendazole should not be given during pregnancy or lactation. Blood counts and liver function tests should be performed at the beginning of each 28-day treatment cycle and every 2 weeks.

Amphotericin B (AmBisome) (Fujisawa)

Preparation

The drug is supplied in vials containing 50 mg of amphotericin B inserted into a liposomal membrane. The product is lyophilized, and following reconstitution with sterile water, the pH is 5.0 to 6.0. It should be stored in the refrigerator and protected from light. It may be reconstituted with the addition of 12 ml of sterile water for injection USP, without a bacteriostatic agent, to make

a 4-mg/ml solution. This may be further diluted by adding 1 ml of the 4-mg/ml solution to 40 ml of 5% glucose solution to make a final concentration of 0.1 mg of amphotericin per ml. The reconstituted product concentrate may be stored for up to 24 h under refrigeration. Injection of AmBisome should begin within 6 h of dilution with 5% dextrose injection. An existing intravenous line must be flushed with 5% dextrose injection prior to infusion of AmBisome. If this is not feasible, AmBisome should be administered through a separate line. AmBisome should never be reconstituted with saline, and saline must not be added to the reconstituted mixture. The mixture must not be mixed with any other drugs; this may cause precipitation of AmBisome.

Administration

AmBisome should be administered intravenously (i.v.), using a controlled infusion device, over a period of approximately 120 min. The infusion time may be reduced to approximately 60 min in patients in whom the treatment is well tolerated.

Toxicity

AmBisome-treated pediatric patients had a lower incidence of infusion-related fever, chills or rigors, and vomiting on day 1 than did amphotericin B deoxycholate-treated patients. The incidence of infusion-related cardiorespiratory events was also lower when AmBisome was used. In adult patients, AmBisome treatment resulted in a lower incidence of chills, hypertension, hypotension, tachycardia, hypoxia, hypokalemia, and various events related to decreased kidney function compared with amphotericin B deoxycholate.

Contraindications

AmBisome is contraindicated in patients who have demonstrated or have known hypersensitivity to amphotericin B deoxycholate or any other constituents of the product unless, in the opinion of the treating physician, the benefit of therapy outweighs the risk.

Amphotericin B (Fungizone) (Squibb)

Preparation

Fungizone is supplied in vials containing 50 mg of amphotericin B, 4 mg of sodium deoxycholate, and 20.2 mg of sodium phosphate as a buffer. It should be stored in the refrigerator and protected from light. It may be reconstituted by the addition of 10 ml of sterile water for injection USP, without a bacteriostatic agent, to make a 5-mg/ml solution. This may be further diluted by adding 1 ml of the 5-mg/ml solution to 50 ml of 5% glucose solution to

make a final concentration of 0.1 mg of amphotericin per ml. The pH of the solution should be above 4.2. Amphotericin B solutions have been diluted with cerebrospinal fluid before intrathecal administration.

Administration

Therapy is usually initiated with a test dose of 0.25 mg/kg/day and gradually increased to a maximum dose of 1.5 mg/kg/day. It must be given slowly i.v., usually over a 6-h period. Alternate-day therapy may be better tolerated. For patients with severe life-threatening infections, therapy may have to be initiated with high doses. It may be given intrathecally in the lumbar or cisternal areas. Low doses should be given if the drug is administered intraventricularly.

Toxicity

Nausea, vomiting, fever, and phlebitis are common. Some degree of renal impairment usually occurs and is dose related. Renal function (blood urea nitrogen or serum creatine) should initially be monitored daily. Other side effects include anaphylaxis, hypokalemia, hypotension, anemia, and cardiac dysrhythmias. The side effects are much milder when amphotericin B is delivered in liposomes (AmBisome). This preparation is more expensive but makes the drug more tolerable, especially in patients with known renal failure. The main side effects of liposomal preparations are hypersensitivity reactions.

Contraindications

It may be necessary to pretreat the patient with antiemetic agents or antipyretic drugs. For patients with known hypersensitivity to the drug, it should be used only in life-threatening situations. Concomitant use of other nephrotoxic drugs should be avoided. Extreme caution should be used when the patient is taking other nephrotoxic drugs such as aminoglycosides, high-dose i.v. acyclovir, ganciclovir, foscarnet, and pentamidine. Corticosteroids and adrenocorticotropic hormone may lead to hypokalemia. The drug may increase the bone marrow toxicity of ganciclovir. Probenecid may increase the levels of amphotericin B.

Artemether (Artenam) (Aarencio, Belgium), Artesunate (Sanofi-Synthélabo/Guilin)

Preparation

Artemether is oil soluble and available in tablet, capsule, or intramuscular-injection forms. Artesunate is water soluble and can be given i.v., intramuscularly, orally, or by suppository. The activity of these artemisinin derivatives decreases after 1 to 2 h. To counter this

drawback, artemisinin is given alongside lumefantrine to treat uncomplicated falciparum malaria. Lumefantrine has a half-life of about 3 to 6 days. Such a treatment is called ACT (artemisinin-based combination therapy); other examples are artemether-lumefantrine, artesunate-mefloquine, artesunate-amodiaquine, and artesunate-sulfadoxine/pyrimethamine. The artemisinin-based combinations artemether-lumefantrine and artesunate-mefloquine remain highly effective and elicit equivalent therapeutic responses in the treatment of highly drug-resistant falciparum malaria.

Administration

The drugs are given as 250-mg tablets of artemisinin and artesunate orally; they are also available as capsules containing 100 mg of artemisinin. Drugs that are available include artemether-lumefantrine (Coartem) (Novartis Pharma AG) and artesunate (Sanofi-Synthélabo/Guilin). The drugs are usually administered once a day for a minimum of 3 days.

Toxicity

The artemisinin derivatives are well tolerated, with no serious toxicity or adverse effects.

Contraindications

These drugs should be used with caution in individuals with hepatic or renal impairment. They should be avoided in pregnancy due to insufficient safety information.

Comment

Artemisia annua is a plant with a strong aroma, containing camphor and essential oils. It is a robust plant that grows in many areas of the world. However, only plants grown under special agricultural and geographic conditions contain artemisinin. The best high-yielding samples have been collected from the steep hills at altitudes over 4,500 feet around Youyang County, City of Chongqing, in Szechuan Province, China.

These drugs act mainly against the asexual erythrocytic stages of malaria. High concentrations of iron are found in red blood cells, which is also where the malaria parasites are found. When the compound enters the red blood cell, it releases free radicals, which are highly destructive to the parasites. An alternative theory suggests that artemisinins inhibit a calcium transporter in the parasite and, by specifically inhibiting this target, kill the parasites. The peroxide group in artemisinins is still crucial to activity, but the target is highly selected rather than a result of "explosion" into activity by free radicals. These drugs are also active against gametocytes by about 90% but are not effective against the intrahepatic stage of *P. vivax* and *P. ovale*.

Atovaquone (Mepron) (GlaxoSmithKline)

Preparation

Atovaquone suspension is a formulation of microfine particles of the drug. The atovaquone particles, reduced in size to facilitate absorption, are significantly smaller than those in the previously marketed tablet formulation. The suspension is for oral administration and is bright yellow with a citrus flavor, containing 150 mg of atovaquone per ml or 750 mg of atovaquone in each teaspoonful (5 ml).

Administration

The drug is given orally with meals; it is used to treat *Babesia* spp. and *Pneumocystis jiroveci* (now classified with the fungi) infections. Administering atovaquone with food enhances its absorption by approximately twofold.

Toxicity

Mepron may cause nausea, vomiting, diarrhea, and skin rashes, as well as sweating, flu syndrome, pain, sinusitis, insomnia, depression, and myalgia.

Contraindications

Mepron should not be given to anyone who has developed or has a history of life-threatening reactions to any of the components of the formulation. If it is necessary to treat patients with severe hepatic or renal impairment, caution is advised and administration should be closely monitored. This drug should be used in pregnancy only if the potential benefits outweigh the potential risks to the fetus. It should not be used during lactation.

Atovaquone-Proguanil (Malarone) (GlaxoSmithKline)

Preparation

Malarone (atovaquone and proguanil hydrochloride) is a fixed-dose combination of the antimalarial agents atovaquone and proguanil hydrochloride. Each tablet contains 250 mg of atovaquone and 100 mg of proguanil hydrochloride, and each pediatric tablet contains 62.5 mg of atovaquone and 25 mg of proguanil hydrochloride.

Administration

The drug is given orally with meals or a milky drink; atovaquone and cycloguanil (an active metabolite of proguanil) are active against the erythrocytic and exoerythrocytic stages of *Plasmodium* spp. Malarone is indicated for the prophylaxis of *P. falciparum* malaria, including in areas where chloroquine resistance has been reported. It is also indicated for the treatment of acute, uncompli-

cated *P. falciparum* malaria and is effective in regions where the drugs chloroquine, halofantrine, mefloquine, and amodiaquine may have unacceptable failure rates, presumably due to drug resistance.

Toxicity

Malarone may cause abdominal pain, nausea, vomiting, headache, diarrhea, asthenia, anorexia, and dizziness. About 5 to 10% of patients have transient asymptomatic elevations in transaminase and amylase levels.

Contraindications

Malarone should not be given to anyone who has developed or has a history of life-threatening reactions to any of the components of the formulation. Rare cases of anaphylaxis following treatment with atovaquone-proguanil have been reported. Due to the lack of safety data, the drug should be avoided during pregnancy or lactation or in patients with renal or hepatic impairment. Malarone has not been evaluated for the treatment of cerebral malaria or other severe manifestations of complicated malaria, including hyperparasitemia, pulmonary edema, or renal failure.

Comment

The drug interferes with two different pathways involved in the biosynthesis of pyrimidines required for nucleic acid replication. Atovaquone is a selective inhibitor of parasite mitochondrial electron transport, while the metabolite of proguanil hydrochloride, cycloguanil, is a dihydrofolate reductase inhibitor. Malarone is effective against asexual and sexual forms of *P. falciparum* and is used for prophylaxis and treatment. Unfortunately, resistance and drug failures are being reported for *P. falciparum*. Although the drug is also effective for treating *P. vivax* and *P. ovale*, primaquine is required to prevent relapses from the liver.

Benznidazole (Rochagan) (Roche, Brazil)

Preparation

Benznidazole is a 2-nitroimidazole derivative and is provided as 100-mg tablets. It is used to treat acute Chagas' disease but is not available in the United States.

Administration

The drug should be taken with meals, preferably after breakfast and after supper, to decrease the chance of stomach upset.

Toxicity

Side effects are seen in many individuals and include nausea, vomiting, abdominal pain, peripheral neuropathy,

thy, severe skin reactions, bone marrow suppression, and psychic disturbances.

Contraindications

Alcohol should be avoided during treatment. The drug has been noted to cause lymphoma in animal models and is mutagenic. Its use is not recommended during the first trimester of pregnancy. Benznidazole should not be used with anticoagulants or in patients who have renal or hepatic impairment. Although this side effect is rare, benznidazole can lower the number of white blood cells, increasing the patient's chance of getting an infection. It can also lower the number of platelets, which are necessary for proper blood clotting.

Comment

Benznidazole inhibits protein and RNA synthesis in *T. cruzi*; it causes increased phagocytosis, cytokine release, and production of reactive mitogen intermediates that lead to death of the parasites.

Bithionol (Bitin) (Tanabe, Japan) (CDC)

Preparation

Bitin is supplied as 500-mg capsules, which must be obtained from CDC. The drug is used to treat several trematode infections.

Administration

The capsules are taken orally with meals to minimize stomach irritation.

Toxicity

Patients may experience anorexia, nausea, vomiting, abdominal discomfort, diarrhea, dizziness, and headaches.

Contraindications

Bitin may cause leukopenia and toxic hepatitis, and photosensitization has occurred.

Comment

Bithionol, an investigational drug, is a phenolic substance structurally related to hexachlorophene. It is used as an alternative drug to praziquantel for treating *Paragonimus* infections. It can be used to treat extrapulmonary infections with *Paragonimus*, but multiple courses may be required for cure. Surgery may be needed to excise skin lesions or, rarely, brain cysts. Bithionol is also used to treat *Fasciola hepatica* infections. Its use is limited to treating either of these infections in patients who are unable to tolerate praziquantel due to previous reactions or in whom a previous course of praziquantel was ineffective.

Chloroquine Phosphate (Aralen) (Sanofi, Others)

Preparation

Aralen is supplied in 250- and 500-mg tablets of the diphosphate salt (500 mg of salt = 300 mg of base) and as a hydrochloride for parenteral injection in 5-ml vials containing 40 mg of base per ml. A liquid preparation (Nivaquine) is available outside the United States and is used as an antimalarial agent.

Administration

Aralen is given orally as per protocol for chemoprophylaxis or treatment of an acute attack. Pills can be ground up and placed in sweetened juice or fruit for administration to young children.

Toxicity

Side effects may be dose related and include gastrointestinal symptoms, skin rash, insomnia, headache, and nervousness. Rare reactions such as toxic psychosis and retinal damage, blood dyscrasias, and photophobia may occur.

Contraindications

Relative contraindications include liver, hematologic, and/or neurologic disease; psoriasis; and porphyria. It may be used in pregnant women when necessary for protection. Use of this drug is contraindicated in the presence of retinal or visual field changes either attributable to 4-aminoquinoline compounds or to any other etiology and in patients with known hypersensitivity to 4-aminoquinoline compounds. Parenteral chloroquine may cause hypotension, shock, and sudden death when given to young children.

Comment

Chloroquine is active against the erythrocytic forms of *Plasmodium vivax*, *P. malariae*, and susceptible strains of *Plasmodium falciparum* (but not the gametocytes of *P. falciparum*). It is not effective against exoerythrocytic forms of the parasite. Resistance of *P. falciparum* to chloroquine is widespread, and cases of *P. vivax* resistance have been reported.

Crotamiton (Eurax) (Westwood-Squibb)

Preparation

Eurax is supplied as a 10% cream or lotion and is used to treat scabies (*Sarcoptes scabiei*).

Administration

The cream or lotion is applied to the whole body surface below the chin after bathing and drying. A second application is advisable after 24 h. Reinfection from contaminated clothing and bed linens should be avoided.

Toxicity

The drug can cause irritation and sensitivity reactions, which may include rash or conjunctivitis.

Contraindications

The drug should not be used in the presence of acute exudative dermatitis and should not be applied near the eyes.

Dapsone (Jacobus)

Preparation

Dapsone is supplied as 25- and 100-mg scored tablets and used to treat *Plasmodium falciparum* (combination therapy) and *Pneumocystis jiroveci* (now classified with the fungi) infections.

Administration

Dapsone should be taken orally, and the dosage should be individually titrated.

Toxicity

Dapsone has been associated with frequent rashes, transient headaches, gastrointestinal irritation, anorexia, and infectious mononucleosis-like syndrome. The drug is carcinogenic in animal models. Complete blood counts should be performed frequently because the drug has been associated with death from agranulocytosis, aplastic anemia, and other blood dyscrasias.

Contraindications

The drug should not be given to patients with hypersensitivity to dapsone. Hemolysis and Heinz body formation may be exaggerated in individuals with a glucose-6-phosphate dehydrogenase (G6PDH) deficiency, or methemoglobin reductase deficiency, or hemoglobin M. This reaction is frequently dose related. Dapsone should be given with caution to these patients or to patients who have been exposed to other agents or conditions such as infection or diabetic ketosis capable of producing hemolysis.

**Diethylcarbamazine Citrate USP (Hetrazan)
(Wyeth-Ayerst) (CDC)**

Preparation

Diethylcarbamazine is a piperazine derivative and is supplied in 50-mg tablets. It is used to treat filariasis and is

effective against microfilariae; it is available from CDC. Hetrazan is effective against *Wuchereria bancrofti*, *Brugia malayi*, *B. timori*, *Onchocerca volvulus*, *Loa loa*, and *Mansonella streptocerca* but has little effect on *M. perstans* or *M. ozzardi*.

Administration

Tablets are scored to provide the appropriate dose. Medication should be taken after meals, adhering to a strict dosage schedule.

Toxicity

Reactions occur frequently and include headache, weakness, malaise, fever, joint pain, anorexia, nausea, and vomiting. These generally subside as therapy continues. Mild to severe reactions, including fever, rash, lymphadenopathy, conjunctivitis, leukocytosis, and eosinophilia, may occur in response to the parasite's death. Severe reaction may require steroid therapy and antihistamines.

Contraindications

Treatment of patients with heavy microfilaremia due to loiasis may cause allergic encephalitis, nephritis, or myocarditis. Patients with many microfilariae or onchocerciasis in ocular tissues may experience keratitis, chorioretinitis, and optic neuritis. Dose reductions are generally required in patients with renal impairment. The drug should probably be avoided in pregnancy but is not excreted in breast milk.

Comment

Diethylcarbamazine citrate, an investigational drug, is an anthelmintic agent that does not resemble other antiparasitic compounds. It is a synthetic organic compound which is highly specific for several parasites and does not contain any toxic metallic elements. It is used to treat patients with certain filarial infections, including lymphatic filariasis (*W. bancrofti*, *B. malayi*, or *B. timori*), tropical pulmonary eosinophilia, and loiasis (*Loa loa*). Treatment of lymphatic filariasis is problematic. Diethylcarbamazine kills microfilariae but only a variable proportion of adult worms. Another drug, ivermectin, rapidly reduces microfilaremia levels and may inhibit larval development in mosquitoes, but it does not kill adult worms and is not very effective against brugian filariasis.

**Diloxanide Furoate (Furamide)
(Boots, England)**

Preparation

Diloxanide furoate is supplied as scored 500-mg tablets and is used to treat amebiasis; it is not available in the United States. The drug is hydrolyzed in the bowel to

the active compound, diloxanide, which is >90% absorbed.

Administration

Furamide is given by mouth with repeated treatments as necessary.

Toxicity

The most common adverse effect is flatulence. Other side effects are seen, including vomiting, pruritus, and urticaria.

Contraindications

The use of Furamide is generally not recommended during pregnancy or lactation.

Comment

The drug helps clear the bowel of *Entamoeba histolytica* cysts; however, it is not effective for treating invasive disease in the bowel wall or liver. For this reason, it is often given with a 5-nitroimidazole.

Eflornithine (Difluoromethylornithine, Ornidyl) (Aventis) (CDC)

Preparation

The drug is available as a 200-mg/ml solution, and is used to treat African trypanosomiasis.

Administration

Ornidyl is given as a continuous i.v. infusion or orally; however, oral administration is usually followed by diarrhea. Eflornithine crosses the blood-brain barrier; thus it is beneficial for central nervous system disease associated with African trypanosomiasis.

Toxicity

Side effects occur in about 40% of patients; they include anemia, leukopenia, thrombocytopenia, diarrhea, abdominal discomfort, hearing loss, vomiting, dizziness, arthralgia, and numbness of the limbs.

Contraindications

Ornidyl should not be given with other i.v. drugs. It may worsen hemolytic disorders. Due to insufficient safety data, the drug should not be used during pregnancy or lactation.

Comment

Eflornithine inhibits ornithine decarboxylase, an enzyme required for the formation of polyamines, thus leading to inhibition of parasite growth. However, it is ineffective as monotherapy for *T. brucei rhodesiense*.

Fumagillin (Fumidil-B)

Preparation

The drug is supplied as a 10-mg/ml suspension in physiologic saline. Ocular lesions due to *Encephalitozoon hellem* have responded to fumagillin eye drops prepared from Fumidil-B used to control microsporidial infection in honeybees. For lesions due to *Vittaforma corneae*, topical therapy is generally not effective and keratoplasty may be required. The drug is available in limited supply from CDC and the World Health Organization.

Administration

Fumagillin should be applied topically once an hour until clinical improvement is demonstrated.

Toxicity

The soluble salt is toxic and should not be ingested; topical application is not toxic to the cornea.

Contraindications

No information is available.

Comment

Relapse may occur on discontinuation of fumagillin therapy.

Furazolidone (Furoxone) (Roberts)

Preparation

Furoxone is supplied as 100-mg tablets or as a flavored suspension of 50 mg/liter and is used to treat giardiasis. This drug is not available in the United States.

Administration

The drug is given orally. Apparently furazolidone is more effective by 50% than metronidazole in inhibiting in vitro cyst differentiation of *Giardia lamblia*.

Toxicity

Furoxone can cause polyneuritis, nausea, vomiting, dizziness, drowsiness, and general malaise. Skin rashes and agranulocytosis have occasionally been reported. Furazolidone is chemically similar to nitrofurantoin, which is well known to cause pulmonary hypersensitivity reactions; furazolidone may also induce pulmonary hypersensitivity reactions, and clinicians should be aware of this potentially serious adverse effect.

Contraindications

The drug should not be given to individuals hypersensitive to furazolidone or to infants younger than 1 month.

Hemolytic anemia can occur in patients with G6PDH deficiency. Alcohol should be avoided during treatment, because disulfiram-like reactions have been reported. Furazolidone is a monoamine oxidase inhibitor and should not be given concomitantly with other similar drugs.

Iodoquinol/Diiodohydroxyquin (Yodoxin) (Glenwood, Others)

Preparation

Iodoquinol/diiodohydroxyquin is supplied as 210- and 650-mg tablets and is used as an amebicide against *Entamoeba histolytica*. The drug is considered effective against the trophozoite and cyst forms.

Administration

The drug should be given with meals. For young children, a suspension may be made by mixing the pulverized tablet with cherry syrup to give a suspension containing 200 to 400 mg/5 ml. The drug is poorly absorbed.

Toxicity

There may be various forms of skin eruptions, urticaria, and pruritus. There may also be nausea, vomiting, abdominal cramps, diarrhea, and pruritus ani. Fever, chills, headache, vertigo, and enlargement of the thyroid have been reported. Optic neuritis, optic atrophy, and peripheral neuropathy have been reported in association with prolonged high-dosage 8-hydroxyquinoline therapy.

Contraindications

Iodoquinol should not be given to patients with known hypersensitivity to iodine or any 8-hydroxyquinoline compound, with renal or thyroid disease, or with severe liver disease not due to amebiasis. Iodoquinol should be used with caution in patients with thyroid disease. Protein-bound serum iodine levels may be increased during treatment with iodoquinol and may interfere with certain thyroid function tests. These effects may persist for as long as 6 months after discontinuation of therapy; this effect is unrelated to thyroid function. The drug should be withdrawn if hypersensitivity reactions occur. Severe neurologic damage, including optic neuritis, optic atrophy, and peripheral neuropathy, has occurred with prolonged high doses of this drug. The recommended doses and duration of therapy should not be exceeded. There may be persistent elevation of the protein-bound iodine level months after therapy. Because of the limited safety data available, this drug should probably be avoided during pregnancy or lactation.

Comment

The drug is thought to act by inactivating parasitic enzymes and inhibiting organism multiplication. Although it is effective for treating intestinal organisms, it is not effective for treating invasive disease in the bowel wall or liver; it is often combined with a 5-nitroimidazole. It has documented activity against *Balantidium coli*, *Dientamoeba fragilis*, *Giardia lamblia*, and *Blastocystis hominis*.

Ivermectin (Stromectol) (Merck)

Preparation

The drug is available in 6-mg tablets and is a semisynthetic macrolide used to treat nondisseminated strongyloidiasis and filariasis, particularly onchocerciasis. It is also now used for the treatment of ectoparasitic infestations such as scabies and lice, although it has no effect on the eggs (nits).

Administration

The drug is given orally with water 1 h before breakfast and is rapidly absorbed after ingestion.

Toxicity

The drug can cause fever, headache, rash, increased pruritus, joint and muscle pain, and tachycardia. A Mazzotti-type reaction has been seen in patients with onchocerciasis. Most adverse effects are a result of the host immune response to destruction of the parasites rather than effects of the drug itself.

Contraindications

Ivermectin should not be given to pregnant or lactating women, because it has been noted to cause birth defects in mice. Historical data have shown that microfilaricidal drugs, such as diethylcarbamazine citrate, might cause cutaneous and/or systemic reactions of varying severity (the Mazzotti reaction) and ophthalmologic reactions in patients with onchocerciasis. These reactions are probably due to allergic and inflammatory responses to the death of microfilariae. Patients treated with Stromectol for onchocerciasis may experience these reactions in addition to clinical adverse reactions possibly, probably, or definitely related to the drug itself.

Comment

Ivermectin is active against various life cycle stages of many but not all nematodes. It is active against the tissue microfilariae of *Onchocerca volvulus* but not against the adult form. The adult parasites reside in subcutaneous nodules which are infrequently palpable. Surgical excision of these nodules (nodulectomy) may be considered

in the management of patients with onchocerciasis, since this procedure eliminates the microfilaria-producing adult parasites.

Ivermectin may be highly effective against *Strongyloides* and produces fewer side effects than thiabendazole. Compounds of the class bind selectively and with high affinity to glutamate-gated chloride ion channels which occur in invertebrate nerve and muscle cells. This leads to an increase in the permeability of the cell membrane to chloride ions with hyperpolarization of the nerve or muscle cell, resulting in paralysis and death of the parasite.

The drug is also effective against the microfilariae of *Wuchereria bancrofti*, *Brugia malayi*, and *Loa loa*. Rarely, patients with onchocerciasis who are also heavily infected with *L. loa* develop a serious or even fatal encephalopathy either spontaneously or following treatment with an effective microfilaricide. For these patients, the following adverse experiences have also been reported: back pain, conjunctival hemorrhage, dyspnea, urinary and/or fecal incontinence, difficulty in standing and/or walking, mental status changes, confusion, lethargy, stupor, or coma. This syndrome has been seen very rarely following the use of ivermectin; a cause-and-effect relationship has not been established. For individuals who warrant treatment with ivermectin for any reason and have had significant exposure to *L. loa*-endemic areas of West or Central Africa, pretreatment assessment for loiasis and careful posttreatment follow-up should be implemented.

Malathion (Ovide) (Taro Pharmaceuticals)

Preparation

Ovide is supplied as a 0.5% aqueous emulsion and is used to treat human louse infestations, killing both lice and nits. Malathion is an organophosphate agent which acts as a pediculicide by inhibiting cholinesterase activity in vivo.

Administration

The drug is applied as a lotion to the skin or hair. It is placed on dry hair in a sufficient amount to thoroughly wet the hair. The hair is then allowed to dry naturally and shampooed after 8 to 12 h. It is then rinsed, and a fine comb is used to remove dead lice and nits. If lice are still present 7 to 9 days later, the drug should be reapplied.

Toxicity

Malathion may cause acute renal failure. Because the potential for transdermal absorption of malathion from Ovide lotion is not known at this time, strict adherence to the dosing instructions regarding its use in children, method of application, duration of exposure, and frequency of application is required.

Contraindications

The drug should not be given to individuals exposed to organophosphorous compounds or to infants or neonates. It may cause skin irritation. Because animal reproduction studies are not always predictive of human responses, this drug should be used (or handled) during pregnancy only if clearly needed. The safety and effectiveness of Ovide lotion in children younger than 6 years has not been established in well-controlled trials.

Mebendazole (Vermox) (McNeil)

Preparation

The drug is supplied as 100-mg chewable tablets; it is a benzimidazole, broad-spectrum agent used to treat nematode infections. Mebendazole is indicated for the treatment of *Enterobius vermicularis* (pinworm), *Trichuris trichiura* (whipworm), *Ascaris lumbricoides* (common roundworm), *Ancylostoma duodenale* (common hookworm), and *Necator americanus* (American hookworm) in single or mixed infections. In humans, approximately 2% of the administered drug is excreted in urine and the remainder is excreted in the feces as unchanged drug or a primary metabolite.

Administration

Tablets are chewable, but it may be necessary to pulverize them and mix them with food for administration to young children. The drug inhibits the formation of nematode microtubules and causes glucose depletion in the worms. Periodic assessment of the hematopoietic and hepatic system is advisable during prolonged therapy.

Toxicity

Abdominal pain and diarrhea occasionally occur, particularly with the expulsion of a large number of worms in children. Rash, urticaria, and angioedema have been observed on rare occasions. Very rare reports of convulsions have been documented.

Contraindications

The drug is teratogenic in rats, but the incidence of abortion and malformations in humans does not exceed the rate in the general population. The drug, however, is not recommended in pregnancy, particularly during the first trimester, unless the benefit justifies the potential risk to the fetus. It is also not recommended during lactation. In patients with severe hepatic disease, the drug should be used with caution. There is no evidence that mebendazole, even at high doses, is effective for treating hydatid disease. There have been rare reports of neutropenia and agranulocytosis when the drug was taken for prolonged periods and at dosages substantially above those recommended.

Mefloquine Hydrochloride (Lariam) (Roche)

Preparation

The drug is supplied as 250-mg tablets equivalent to 228 g of the free base; it is a synthetic 4-quinoline methanol compound structurally related to quinine. The bioavailability of the tablet formation compared with an oral solution was over 85%. The presence of food significantly enhances the rate and extent of absorption, leading to about a 40% increase in bioavailability.

Administration

Tablets should not be ingested on an empty stomach and should be taken with at least 8 oz of water.

Toxicity

The most frequent side effects include nausea, vomiting, dizziness, diarrhea, abdominal pain, and headache. Severe seizures and delirium have been reported occasionally in roughly 1 in 200 to 1 in 1,300 patients treated for acute *Plasmodium falciparum* malaria. The drug can also potentiate dysrhythmias in patients taking beta blockers. Periodic evaluation of hepatic function should be performed during prolonged prophylaxis.

Contraindications

Use of Lariam is contraindicated in patients with a known hypersensitivity to mefloquine or related compounds (e.g., quinine and quinidine). Lariam should not be prescribed for prophylaxis in patients with active depression, a recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, or other major psychiatric disorders, or in those with a history of convulsions. In patients with epilepsy, Lariam may increase the risk of convulsions. The drug should be used with caution in patients with severe hepatic or renal dysfunction. During prophylactic use, if psychiatric symptoms such as acute anxiety, depression, restlessness, or confusion occur, these may be considered prodromal to a more serious event. In these cases, the drug must be withdrawn and an alternative medication should be substituted.

In case of life-threatening, serious, or overwhelming malaria infections with P. falciparum, patients should be treated with an i.v. antimalarial drug. Following completion of i.v. treatment, Lariam may be given to complete the course of therapy.

Comment

Although its exact mechanism of action is not known, mefloquine is an antimalarial agent which acts as a blood schizonticide. The drug is thought to act by

interfering with the digestion of hemoglobin during the erythrocytic stages of the life cycle. The drug has no activity against tissue schizonts or gametocytes. Strains of *P. falciparum* with decreased susceptibility to mefloquine can be selected in vitro or in vivo. Resistance of *P. falciparum* to mefloquine has been detected in areas of multidrug resistance in Southeast Asia. Increased incidences of resistance have also been reported in other parts of the world.

Strains of *P. falciparum* resistant to mefloquine have been detected. Lariam is indicated for the treatment of mild to moderate acute malaria caused by mefloquine-susceptible strains of *P. falciparum* (both chloroquine-susceptible and -resistant strains) or by *P. vivax*. However, patients with *P. vivax* malaria are at risk of relapse since mefloquine does not eliminate the exoerythrocytic parasites in the liver. Mefloquine is also indicated for the prophylaxis of *P. falciparum* and *P. vivax* malaria infections, including those caused by chloroquine-resistant strains of *P. falciparum*.

Mefloquine should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. Women of childbearing potential who are traveling to areas where malaria is endemic should be warned against becoming pregnant. Women of childbearing potential should also be advised to practice contraception during malaria prophylaxis with mefloquine and for up to 3 months thereafter. However, in the case of unplanned pregnancy, malaria chemoprophylaxis with mefloquine is not considered an indication for pregnancy termination. Because of the potential for serious adverse reactions in nursing infants from mefloquine, a decision should be made whether to discontinue treatment, taking into account the importance of the drug to the mother.

Melarsoprol (Mel-B, Arsobal) (Aventis) (CDC)

Preparation

Melarsoprol is supplied through the CDC Parasitic Disease Drug Service as a 3.6% solution in propylene glycol. It is used to treat African trypanosomiasis. The drug should be kept refrigerated. It is to be administered only in the hospital by or under the immediate supervision of a physician.

Administration

The drug should be given in propylene glycol as a slow i.v. infusion in the hospital. Care must be taken to avoid extravasation.

Toxicity

Abdominal pain, nausea, vomiting, and diarrhea are common. Reactive encephalopathy is not uncommon and is more

likely to occur in debilitated patients and when high doses are used. The patient may also exhibit confusion, speech difficulties, restlessness, and sleep disorders. Myocardial damage, albuminuria, and hypertension have also been reported. A rare reaction is shock and subsequent death. Due to toxicity, the drug is usually reserved for the late stages of disease involving the central nervous system.

Rare side effects may include black, tarry stools; blood in urine or stools; changes in skin color of face; fainting; fast or irregular breathing; pinpoint red spots on skin; puffiness or swelling of the eyelids or around the eyes; shortness of breath; sores, ulcers, or white spots on lips or in mouth; sore throat; swollen and/or painful glands; tightness in chest; trouble in breathing; unusual bleeding or bruising; unusual tiredness or weakness; or wheezing.

Contraindications

Patients with impaired hepatic or renal function should not receive melarsoprol. Severe hemolytic reactions can occur in patients with G6PDH deficiency, and erythema nodosum may be induced in patients with leprosy. The drug should not be given during influenza epidemics. It may increase the chance of side effects in patients with fever and may increase the chance of side effects affecting the blood in patients with G6PDH deficiency.

Comment

Melarsoprol, an investigational drug, is an arsenical compound used for treating African trypanosomiasis (*Trypanosoma brucei gambiense*, *T. brucei rhodesiense*) with neurologic involvement or early African trypanosomiasis that is resistant to suramin or pentamidine. The drug apparently interferes with parasite energy generation and trophozoite multiplication.

Metronidazole (Flagyl [Searle], IVFlagyl [SCS])

Preparation

Flagyl is supplied as 375-mg tablets for oral administration and as 750-mg extended-release tablets (Flagyl ER); it is used in the treatment of amebiasis, giardiasis, trichomoniasis, and some helminth infections. It is also available in single-dose vials containing 500 mg of lyophilized powder or in 100-ml plastic containers containing a solution of 500 mg/100 ml or isotonic-buffered solution for parenteral injection. If metronidazole is being prescribed for trichomoniasis, sexual partners are often treated at the same time, even if they are asymptomatic.

Administration

Flagyl is usually given orally. When given i.v., it should be administered slowly as an intermittent or continuous infu-

sion. Other drugs should not be added to the i.v. line during the infusion. Care must be taken to follow instructions for reconstitution of the solution, because neutralization with bicarbonate is necessary to bring the pH from 0.5–2 up to the neutral range.

Toxicity

Reactions to therapy are common, especially when the drug is given in doses appropriate for treating amebiasis. The more common side effects include anorexia, nausea, vomiting, diarrhea, epigastric distress, and abdominal cramps. A metallic taste in the mouth is often reported. Headache, dizziness, and vertigo may also occur. Ataxia, paresthesias, insomnia, and irritability may also occur. A flattening of the T waves on an electrocardiogram may be evident, and rashes and urticaria have been reported. A moderate leukopenia occasionally occurs, but levels return to normal after completion of therapy. Oral and vaginal overgrowth of yeast cells may occur. In patients receiving high doses, dark urine has occurred; this finding may be due to a metabolite of the drug. Rare reactions include blood dyscrasias, dysuria, incontinence, cystitis, dyspareunia, and fever.

Contraindications

The drug should not be given to patients with a history of blood dyscrasia, active central nervous system disease, and/or known sensitivity to metronidazole. Doses should be reduced in patients with severe liver disease. The drug should not be used in pregnancy, especially in the first trimester, unless the benefits of treatment outweigh the potential hazard to the fetus. Consumption of alcohol should be avoided during the first days of treatment and for at least 3 days after the end of the treatment because severe vomiting, abdominal cramps, and flushing may occur. Other alcohol-containing preparations (for example, elixirs, cough syrups, and tonics) may also cause problems. These problems may last for at least a day after the drug has been discontinued. Leukocyte counts with differential blood counts are recommended before and after therapy. A good alternate for use during pregnancy is paromomycin.

Miltefosine (Impavido) (Zentaris, Germany)

Preparation

The drug is given orally at 30 mg/kg twice a day; it has activity against *Leishmania* spp. It is not available within the United States. In India, it has been given at 2.5 mg/kg/day for 4 weeks, with good results for visceral leishmaniasis. Good activity has also been documented against *L. viannia panamensis*, with less activity against

L. mexicana mexicana and even lower for *L. viannia braziliensis*.

Administration

The drug is given in two divided doses or a single dose orally for 28 days. It is available as 50-mg and 10-mg capsules.

Toxicity

Most patients tolerate therapy with few or no side effects. Nausea, vomiting, and diarrhea have been reported, and there have been isolated reports of dose-related motion sickness. Some patients have reversible hepatotoxicity and nephrotoxicity. Urea and creatinine levels usually return to normal by the end of the second week of therapy. Gastrointestinal symptoms could be serious in severely ill patients who are malnourished and dehydrated.

Contraindications

The drug should not be used during pregnancy or lactation.

Comment

The mechanism is not well defined, but apparently the drug interferes with cell-signaling pathways and membrane synthesis. It also induces apoptotic cell death. It is active against the extracellular promastigote and the intracellular amastigote forms of *Leishmania* spp.

Niclosamide (Yomesan, Niclocide) (Bayer, Germany)

Preparation

Niclosamide is available in 500-mg chewable tablets (chlorosalicylamide), which is effective against infections with tapeworms (*Taenia* spp., etc). The drug is no longer available in the United States. Its use is limited, and praziquantel is now more commonly used.

Administration

The drug is given orally; however, to prevent stomach upset, it is best taken after a light meal (for example, breakfast). Niclosamide tablets should be thoroughly chewed or crushed and then swallowed with a small amount of water. If this medicine is being given to a young child, the tablets should be crushed to a fine powder and mixed with a small amount of water to form a paste.

Toxicity

Most patients tolerate therapy with few or no side effects. Nausea, vomiting, and abdominal pain occur

rarely, and there have been isolated reports of fever, dizziness, urticaria, irritability, headache, and edema of the arms.

Contraindications

Niclosamide should not be given to patients shown to be hypersensitive to the drug. Insufficient data are available for an assessment of the hazards of use of this drug during pregnancy. It is not recommended for pregnant women and children younger than 2 years.

Nifurtimox (Lampit) (Bayer, Germany) (CDC)

Preparation

Nifurtimox is a nitrofurantoin and is supplied as 100-mg tablets through the CDC Parasitic Disease Drug Service; it is used in the treatment of acute Chagas' disease.

Administration

The drug is given orally. Tolerance for the drug decreases with age, and children generally can tolerate higher doses over a longer period than can adults.

Toxicity

Gastrointestinal symptoms are common and may include anorexia, weight loss, abdominal pain, nausea, and vomiting. Neuropsychiatric symptoms, including convulsions, headache, drowsiness, nervousness, vertigo, paresthesia, disorientation, and memory loss, are less common but may necessitate termination of therapy.

Contraindications

The drug should not be used in pregnant women or in children younger than 1 year. Alcohol, antibiotics, and digitalis may potentiate the side effects. It should be used with caution in elderly patients with a history of neurologic or psychiatric diseases or allergic skin reactions.

Comment

Nifurtimox, an investigational drug, is a nitrofurfurylidene derivative. Its action is apparently related to its ability to cause the production of toxic reduced products of oxygen such as superoxide, hydrogen peroxide, and hydroxyl radicals. Accumulation of these products within the parasites leads to membrane damage, enzyme inactivation, and possible inhibition of protein synthesis. Nifurtimox is used to treat acute, subacute, or early chronic Chagas' disease. Although only two cases of indigenous Chagas' disease have been reported from the United States, infections may be seen in laboratory workers, immigrants, and U.S. citizens returning from Latin America, such as Peace Corps

volunteers, military personnel, and missionaries. Drinking alcoholic beverages while taking this medicine may cause some unwanted effects. Other alcohol-containing preparations (for example, elixirs, cough syrups, and tonics) may also cause problems. Therefore, the patient should not drink alcoholic beverages or ingest other alcohol-containing preparations while taking nifurtimox.

Nitazoxanide (Alinia) (Romark)

Preparation

Nitazoxanide is a relatively new synthetic drug with good efficacy against a number of intestinal protozoa and helminths. Alinia tablets contain 500 mg of nitazoxanide, and Alinia for oral suspension, after reconstitution, contains 100 mg nitazoxanide per 5 ml. Nitazoxanide and its metabolite, tizoxanide, are active in vitro in inhibiting the growth of sporozoites and oocysts of *Cryptosporidium* spp. and trophozoites of *Giardia lamblia*. Nitazoxanide may also be effective in the treatment of intestinal microsporidiosis with *Enterocytozoon bienersi* and *Encephalitozoon intestinalis*, as well as ocular infections with *Vittaforma corneae* (see dosage information under *Giardia lamblia*).

Administration

The drug should be taken orally with food. Diabetic patients and their caregivers should be aware that the oral suspension contains 1.48 g of sucrose per 5 ml. Alinia for oral suspension should be used for pediatric patients younger than 11 years.

Toxicity

The most common adverse events reported were abdominal pain, diarrhea, headache, and nausea. Other reported side effects included weakness, fever, pain, chills, flu syndrome, dizziness, somnolence, insomnia, rash, and pruritus.

Contraindications

The pharmacokinetics of nitazoxanide in patients with compromised renal or hepatic function has not been studied. Therefore, nitazoxanide must be administered with caution to patients with hepatic and/or biliary disease, renal disease, and combined renal and hepatic disease. Nitazoxanide is highly bound to plasma protein; competition for binding sites could occur with other drugs such as warfarin. Based on limited safety data, this drug should not be used during pregnancy or lactation.

Comment

The antiprotozoal activity of nitazoxanide is thought to be due to interference with the pyruvate ferredoxin oxidoreduc-

tase (PFOR) enzyme-dependent electron transfer reaction, which is essential to anaerobic energy metabolism. Studies have shown that the PFOR enzyme from *G. lamblia* directly reduces nitazoxanide by transfer of electrons in the absence of ferredoxin. The DNA-derived PFOR protein sequence of *Cryptosporidium* spp. appears to be similar to that of *G. lamblia*. Interference with the PFOR enzyme-dependent electron transfer reaction may not be the only pathway by which nitazoxanide exhibits antiprotozoal activity.

Nitazoxanide therapy has also been given for intestinal microsporidiosis at a dose of 1,000 mg twice a day for 60 consecutive days. Three posttreatment fecal examinations, including PCR, conducted over 2 months following the end of the treatment with nitazoxanide did not reveal any microsporidial spores, and the patient continued normal bowel movements. Nitazoxanide has also been reported to be effective in cell culture against *E. intestinalis* and *V. corneae*.

Paromomycin (Humatin) (Monarch)

Preparation

Humatin is supplied as 250-mg capsules and a syrup with 125 mg per 5 ml; a broad-spectrum antibiotic, it is used to treat various intestinal protozoal infections, particularly acute and chronic intestinal amebiasis. The drug is poorly absorbed after oral administration, with almost 100% of the drug being recoverable in the stool.

Administration

The drug is given orally with a full glass of water and should be taken with food.

Toxicity

Nausea, vomiting, abdominal cramps, and diarrhea have been reported, particularly in patients taking more than 3 g/day. Dizziness has also been reported.

Contraindications

The drug should not be used in patients with impaired renal function, intestinal obstruction, or ulcerative bowel lesions. Paromomycin and other aminoglycosides should be avoided in patients with myasthenia gravis. The drug should not be used during pregnancy or lactation.

Pentamidine Isethionate (Lomidine, Pentam 300, Nebupent) (Fujisawa)

Preparation

Pentamidine isethionate is supplied as 300-mg vials for i.v. or intramuscular administration. For inhalation, the

vial contents are dissolved in sterile water and the inhalation solution is placed in a Respirgard II nebulizer. Saline solution must not be used to reconstitute the drug. Pentamidine isethionate is a toxic but highly effective drug used to treat the early stages of both types of African trypanosomiasis (*Trypanosoma brucei gambiense* and *T. brucei rhodesiense*). It does not cross the blood-brain barrier and is not effective in the treatment of the neurologic phases of the disease. It is also used to treat leishmaniasis and *Pneumocystis jiroveci* (now classified with the fungi) infection.

Administration

Vial contents should be dissolved in sterile water for intramuscular injection or in sterile water followed by sterile 5% glucose for i.v. administration. Pentamidine for inhalation should be administered for approximately 35 to 40 min at a rate of 5 to 7 liters/min.

Toxicity

Common side effects include hypotension, tachycardia, nausea, vomiting, and a metallic taste that occurs immediately after injection but subsides in 10 to 30 min. Hypoglycemia is occasionally seen from days 5 to 7 of therapy. Acute renal failure has occurred during the course of therapy; however, it is usually reversible in patients with normal renal function before therapy. Mild anemia, elevated liver transaminase levels, and leukopenia have been reported. Local pain and inflammation of the injection site are common, and sterile abscesses occasionally occur. Hypotension and profound shock have been reported after a single dose of the drug, and resuscitation equipment should always be readily available in the setting in which drug therapy is given. Occasional seizures and hallucinations have also been reported. Inhaled pentamidine can cause cough, bronchospasm, fatigue, bad taste in the mouth, shortness of breath, decreased appetite, dizziness, and rash. Pentamidine has also been associated with Stevens-Johnson syndrome.

Contraindications

Because pentamidine is generally used in life-threatening situations, there are no absolute contraindications to therapy. Careful observation of the patient is necessary because of the common side effects and severe drug reactions that may occur. Impaired renal function is frequent. Aerosol pentamidine should not be given with other drugs or given to patients with a history of anaphylactic reactions to inhaled or parenteral pentamidine. Some patients may develop a sudden, severe decrease in blood pressure after a dose of pentamidine. Pentamidine can decrease the white blood cell count, increasing the chance that the patient will contract certain infections. It can also lower the

number of platelets, which are necessary for proper blood clotting. Both low and high blood sugar levels have also been reported. Unless the benefits outweigh the potential risks, this drug should not be used during pregnancy.

Comment

Although its mode of action remains unclear, its activity may be different for different parasites. Pentamidine (Lomidine) is used only for the early phase of the disease, since it does not cross the blood-brain barrier. It is active against *T. gambiense*, but it should not be used against *T. rhodesiense*, since primary resistance to it has been found in some areas. It should also not be used in areas where pentamidine has been widely employed for chemoprophylaxis, such as in the former Belgian Congo.

Permethrin (Nix [GlaxoSmithKline], Elimate [Allergan])

Preparation

Permethrin is supplied as a 1 or 5% cream. It is used to treat scabies (a skin infestation) and lice infestations of the head, body, and pubic area ("crabs"). Permethrin does not prevent these infestations.

Administration

The drug is available as a 1% (Nix) or 5% (Elimate) cream applied directly to hair or skin to treat lice or scabies, respectively.

If using the liquid, follow these steps: shampoo the hair using regular shampoo; thoroughly rinse and towel dry hair and scalp; allow hair to air dry for a few minutes; do not stand (or sit) in a shower or bathtub; lean over a sink to apply permethrin to the hair; shake the bottle of liquid well; thoroughly wet hair and scalp with the liquid. Cover the areas behind the ears and the back of the neck; keep permethrin on the hair for 10 minutes before rinsing it off thoroughly with water; dry hair with a clean towel; comb hair with a fine-tooth comb to remove nits (lice eggs and larvae); wash hands to remove the medication.

If using the cream, follow these steps: wash entire body or take a shower; thoroughly massage the cream into the skin over the entire body, from head to toes; leave the cream on for 8 to 14 h; wash the cream off after 8 to 14 h by taking another shower; if using product for head lice, wash combs and brushes with permethrin liquid and rinse them thoroughly with water to remove the drug.

Toxicity

Side effects are rare and include occasional burning, stinging, and numbness; increased pruritus; pain; edema; erythema; and rash.

Contraindications

The cream or lotion should not be applied near the eyes or mucous membranes. The drug may cause progressive motor neuron disease.

**Polyhexamethylene Biguanide (Baqucil)
(Zeneca)**

Preparation

Baqucil is supplied as a 20% solution, which must be diluted with sterile saline to 0.02% for ophthalmic application. It is used to treat keratitis caused by *Acanthamoeba* spp.

Administration

Topical application is recommended at hourly intervals until clinical improvement is noted. Polyhexamethylene biguanide is available through Leiter's Park Avenue Pharmacy, San Jose, Calif. (800-292-6773; www.leiterrx.com).

Toxicity

No information is available.

Contraindications

No information is available.

Comment

While this therapy inactivates the trophozoites and cysts in *Acanthamoeba* keratitis in the majority of patients (approximately 90%), there have been notable failures, particularly when patients present late with deep stromal infection. Since no single drug can be assumed to be effective against all amebae, a potential complication is the risk of activation of dormant cysts which form in situ in *Acanthamoeba* and *Balamuthia* infections and which can lead to relapse following apparently effective treatment. This is particularly true for *Acanthamoeba* keratitis, a nonopportunistic infection of the cornea, which responds well to treatment with chlorhexidine gluconate and polyhexamethylene biguanide in combination with propamidine isethionate (Brolene), hexamidine (Desomodine), or neomycin. In a large series of *Acanthamoeba* keratitis patients with a positive microbiologic diagnosis at presentation, nearly 5% developed recurrent episodes of corneal and scleral inflammation with viable *Acanthamoeba* in the cornea despite prolonged treatment with biguanides and/or diamidines.

Praziquantel (Biltricide) (Bayer)

Preparation

Praziquantel is supplied as 150-, 500-, and 600-mg scored tablets; is a pyrazinoisoquinoline derivative; and

is a synthetic heterocyclic broad-spectrum anthelmintic agent effective against all schistosome species infecting humans, as well as most other trematodes and adult cestodes. However, it is not useful for treatment of nematode infections and is not effective in treating *Fasciola hepatica*.

Administration

Praziquantel is preferably taken during a meal, particularly one with a high carbohydrate content. After oral administration, over 80% of the drug is absorbed.

Toxicity

In general, the drug is well tolerated; side effects are usually mild. Reactions include malaise, headaches, dizziness, abdominal discomfort, nausea, vomiting, fever, and rarely urticaria. When it is used in high doses, as in the treatment of central nervous system cysticercosis, reactions that have been attributed to the death of the larvae can occur. These reactions include headache, peripheral neuropathy, seizures, fever, hypotension, and shock. Anaphylaxis has also been reported. Transient hyperglycemia lasting several months after therapy has also been reported. Patients are generally hospitalized during the initiation of therapy for cysticercosis because of the potential for serious reactions such as seizures and other neurologic sequelae related to an inflammatory response.

Contraindications

The drug induces drowsiness and dizziness and so should be used with caution in patients whose vocation requires mental alertness. If the drug is given to patients with ocular cysticercosis, parasite destruction may cause irreparable eye damage. Although studies involving high doses of praziquantel in pregnant animals have failed to show any harm to the fetus, there are no controlled studies of humans. The use of praziquantel in pregnant women and in children younger than 4 years has not been well studied, and both the risks and the benefits must be considered. Praziquantel does appear in human milk, and mothers should not breast-feed during treatment and for 72 h following treatment. Concomitant administration of rifampin should be avoided.

Comment

Praziquantel causes ultrastructural changes in the helminth tegument, causing increased permeability to calcium ions. It works by causing severe spasms and paralysis of the worms' muscles. Some kinds of worms are then passed in the stool. However, the patient may not notice them since they are sometimes completely destroyed in the intestine.

Primaquine Phosphate (USP)

Preparation

The drug is supplied in tablets containing 26.3 mg of primaquine phosphate, equivalent to 15 mg of salt. It is an antimalarial agent especially effective against *Plasmodium vivax* exoerythrocytic forms, terminating relapsing vivax malaria; it is usually administered with chloroquine.

Administration

Tablets have a bitter taste and may be crushed and added to a sweet liquid or fruit to make them more palatable.

Toxicity

Patients may experience abdominal pain, cramps, or epigastric distress. High doses may result in methemoglobinemia and cyanosis. Granulocytopenia and granulocytosis, hypertension, and arrhythmia are rare. Hemolysis occurs in individuals with G6PDH deficiency.

Contraindications

The drug should not be used in patients with depressed blood counts resulting from other illnesses or concurrently with drugs, such as quinacrine, that have the potential to cause hemolysis or bone marrow depression. Because primaquine phosphate can cause hemolytic anemia, patients should be screened for G6PDH deficiency, which is most common in African, Asian, and Mediterranean people. Administration of other bone marrow depressants as hemolytic agents should be avoided. The drug should not be prescribed during pregnancy.

Propamidine Isethionate (Brolene) (Aventis, Canada)

Preparation

Brolene is provided as a 0.1% solution. It is a local anti-infective agent that is used to treat keratitis caused by *Acanthamoeba* spp., but it is not available in the United States.

Administration

Brolene is administered topically each hour for the first few days and every few hours thereafter for a minimum course of 1 month.

Toxicity

The drug may cause keratopathy; this condition is reversible but may be confused with persistent or recurrent infection.

Contraindications

No information is available.

Comment

Treatment of *Acanthamoeba* keratitis is difficult due to the organism's ability to encyst. Effective medications include topical polyhexamethylene biguanide, propamidine isethionate (Brolene), chlorhexidine digluconate 0.02%, polymixin B, neomycin, and clortrimazole 1%. In one series of 10 patients, the combination of Brolene and polyhexamethylene biguanide successfully cured all cases of *Acanthamoeba* keratitis. Cautious introduction of topical steroids along with antiamebic therapy helped resolve the inflammation and provided symptomatic relief.

Pyrantel Pamoate (Antiminth) (Pfizer)

Preparation

Antiminth is supplied in 60-ml bottles containing 50 mg of pyrantel base per ml or as tablets containing 125 mg of base and is used to treat a number of different nematode infections. However, it is associated with more side effects and is being replaced with the benzimidazoles, which are more effective.

Administration

Pyrantel pamoate may be taken with food, milk, or juice.

Toxicity

Reactions are not frequently encountered, but when they do occur, they involve primarily the gastrointestinal system. They include anorexia, nausea, vomiting, abdominal pain or cramps, diarrhea and tenesmus, and transient elevations of the transaminase enzyme levels.

Contraindications

Studies of pregnant animals have failed to show any harm to the fetus, but there is no experience with pregnant humans. There are few published data on the use of the drug in children younger than 2 years. The risks and benefits of treatment in these patients should be weighed. The drug should be used with caution in patients with liver dysfunction. Its anthelmintic effect may be antagonized by piperazine.

Comment

The drug is a neuromuscular blocking agent, resulting in spastic paralysis of the adult worms. Excellent results are obtained when treating patients with ascariasis, hookworm, and pinworm infections. While there is some activity against *Trichostrongylus*, the drug is not active against *Trichuris trichiura*.

Pyrethrin with Piperonyl Butoxide (Rid) (Pfizer, Others)

Preparation

Rid is an insecticide mixture of permethrin and piperonyl butoxide, which is used as a synergist and also to treat human louse infestations.

Administration

Rid is applied topically as a shampoo to the affected area after wetting. After application, it should be left for 10 min and then rinsed thoroughly. Hair should be combed with a fine-tooth comb to remove dead lice and nits.

Toxicity

Rid may cause allergic reactions in individuals allergic to ragweed.

Contraindications

The drug should not be used near eyes or mucous membranes.

Pyrimethamine USP (Daraprim) (GlaxoSmithKline)

Preparation

Daraprim is supplied as 25-mg tablets; it is a potent folic acid antagonist used as an antimalarial agent and in treating toxoplasmosis and several other parasitic infections. Dosages for treating toxoplasmosis approach the toxic level. Daraprim should be kept away from children and infants since they are extremely susceptible to adverse effects from an overdose and deaths have been reported.

Administration

The drug may be pulverized and mixed with sweet liquid or fruit juice. Concurrent administration of folinic acid is strongly recommended for all patients. Daraprim is indicated for the treatment of toxoplasmosis when used conjointly with a sulfonamide, providing synergy with this combination approach. Although Daraprim is used to treat acute malaria, it should not be used alone for this purpose. It is also used for chemoprophylaxis of malaria; however, there is widespread resistance throughout the world.

Toxicity

Gastrointestinal complaints (anorexia, nausea, vomiting, diarrhea, and abdominal pain and tenderness) are not uncommon. Occasional elevation of the glutamic-oxaloacetic transaminase level in serum has been reported, as have skin rashes, headache, dizziness, drowsiness, and

insomnia. For patients with toxoplasmosis being treated with high doses, periodic complete blood counts, including platelet counts, are recommended. Folic acid supplementation may be necessary if the counts are depressed. Hypersensitivity reactions, occasionally severe (Stevens-Johnson syndrome, toxic epidermal necrolysis, erythema multiforme, and anaphylaxis), can occur, particularly when the drug is administered concomitantly with a sulfonamide.

Contraindications

The drug should not be used in pregnancy, and determination of human chorionic gonadotropin levels is recommended before initiation of treatment for toxoplasmosis. Caution is recommended for patients with seizure disorders and impaired hepatic or renal function. Daraprim is also contraindicated for patients with documented megaloblastic anemia due to folate deficiency.

Comment

Pyrimethamine acts against the asexual erythrocytic stage of the *Plasmodium* spp. by inhibiting the enzyme dihydrofolate reductase. The drug does not destroy gametocytes but instead arrests sporogony in the mosquito. Although the drug is active against *P. falciparum*, resistance occurs fairly rapidly and limits its use as a single agent. Therefore, the drug is often combined with a sulfonamide or sulfone, which provides sequential, synergistic inhibition of the folate biosynthesis pathway. This inhibition of folic acid biosynthesis prevents DNA replication in the parasite. Pyrimethamine is also used in combination with sulfadiazine for treating toxoplasmosis.

Quinidine Gluconate (Eli Lilly)

Preparation

Quinidine gluconate is supplied as a solution containing 80 mg/ml for injection and is used to treat severe malaria.

Administration

The drug is given i.v. in normal saline by slow infusion; 800 mg is infused in 40 ml of 5% glucose at a rate of 1 ml/min.

Toxicity

Quinidine causes gastrointestinal irritation, with nausea, vomiting, and diarrhea. Hypersensitivity may occur. Other side effects that have been reported include blurred vision, headache, belly pain, and ringing in the ears and temporary loss of hearing. Prolongation of the QT interval as indicated by an electrocardiogram, ventricular arrhythmia, hypotension, and hypoglycemia can result from the use of this drug at treatment doses.

Contraindications

The drug may induce hypotension, granulomatous hepatitis, and a lupus-like syndrome. Use should be avoided for patients with myasthenia gravis, acute infections with fever, previous hypersensitivity to quinidine, and cardiac abnormalities.

Quinine Sulfate or Quinine Dihydrochloride (Many Manufacturers)

Preparation

Quinine sulfate is supplied as 3-grain (186-mg) or 6-grain (372-mg) capsules or tablets. Quinine dihydrochloride comes in 2-ml ampoules containing 300 mg/ml (not available in the United States). It is used to treat malaria and is important in areas where i.v. quinine is not available. It is the dextrorotary optical isomer of quinine.

Administration

The oral medication is extremely bitter and may be better tolerated if mixed with sweet liquid, fruit, or cereal. For i.v. administration, medication should be diluted in normal saline at 0.5 mg/ml and administered at 1 ml/min every 8 h.

Toxicity

Mild symptoms are common and generally consist of tinnitus, headache, nausea, and disturbed vision. More severe reactions are related to inability to excrete the drug normally and to high doses. These reactions include decreased hearing, blurred vision, photophobia, diplopia, night blindness, scotomata (blind spots), mydriasis (pupil dilation), vomiting, abdominal pain, diarrhea, cutaneous flushing, sweating, rashes, facial angioedema, confusion, apprehension, excitement, delirium, and syncope.

Contraindications

Rare reactions include renal failure, acute hemolysis, hypoprothrombinemia, purpura, agranulocytosis, asthma, and ventricular tachycardia. After one dose, an idiosyncratic hypersensitivity reaction consisting of flushing, pruritus, skin rash, fever, gastric distress, dyspnea, tinnitus, and visual impairment may occur. Massive hemolysis and hemoglobinuria occasionally occur during the treatment of falciparum malaria. Quinine may aggravate the symptoms of myasthenia gravis.

Spiramycin (Rovamycine) (Aventis)

Preparation

Rovamycine is supplied as a tablet or in solution and is a macrolide antibiotic similar to leucomycin. This drug

has been tried in the treatment of cryptosporidiosis; it is available only from the manufacturer.

Administration

Spiramycin is given orally on an empty stomach or by i.v. infusion.

Toxicity

Rovamycine can cause gastrointestinal disturbances and occasional allergic reactions. More rare side effects have included bloody stools, chest pain, fever, heartburn, irregular heartbeat, nausea, recurrent fainting, stomach pain and tenderness, vomiting, and yellow eyes or skin.

Contraindications

The drug should not be given to patients with impaired liver function.

Stibogluconate Sodium (Pentostam, Solustibosan) (GlaxoSmithKline) (CDC)

Preparation

Stibogluconate sodium is available through the CDC Parasitic Disease Drug Service as a 33% solution containing 100 mg of pentavalent antimony per ml; it is used to treat leishmaniasis.

Administration

The drug is given intramuscularly or by careful, slow i.v. infusion.

Toxicity

Side effects are common and include nausea, vomiting, severe coughing, and itching. Pneumonitis, arthralgias, myalgias, bradycardia, electrocardiogram changes (T-wave depressions, increased O-T interval, and fusion of the S-T segment and T wave), abnormal liver function, headache, and mild rash also occur. Less common problems are hepatitis, hemolytic anemia, thrombocytopenia, and anaphylaxis associated with urticaria, laryngeal edema, and visceral collagens.

Contraindications

The drug should not be used in patients with myocarditis, hepatitis, liver disease, or concurrent bacterial and viral infections. Treatment should be stopped if there is progressive proteinuria, severe arthralgias, or rash. More severe reactions may include leukopenia, agranulocytosis, and electrocardiographic changes.

Comment

Pentostam (sodium stibogluconate; sodium antimony gluconate) is a pentavalent antimony compound that is

used to treat all forms of leishmaniasis (cutaneous, mucocutaneous, and visceral). This drug is a well-established antileishmanial agent that has been in use for some time. It is thought to inhibit glycolysis enzymes within the organisms.

Suramin Sodium (Germanin, Antrypol, Naphuride Sodium, Bayer 205, Moranyl, Fournau 309, Belganyl) (Bayer, Germany) (CDC)

Preparation

Suramin sodium is available through the CDC Parasitic Disease Drug Service as ampoules containing 1.0 g of powder and is a complex derivative of urea used to treat African trypanosomiasis.

Administration

A 10% solution must be prepared and used within 30 min of preparation as a slow i.v. infusion.

Toxicity

Immediate nausea, vomiting, loss of consciousness, and seizure may occur if the full i.v. dose is given to sensitive individuals. A test dose is recommended. Proteinuria is commonly seen during therapy, but it is not a parameter used to monitor therapy unless other renal function studies are abnormal. Fever is also common but is usually low grade. Rashes, localized edema, and pruritus may occur. Blepharitis, conjunctivitis, photophobia, and excessive lacrimation may occur during treatment. Kidney failure, blood dyscrasias (including pancytopenia), shock, and optic atrophy have also been reported.

Contraindications

The drug should be administered under close medical supervision and should not be used in pregnant women or in patients with hepatic or renal insufficiency. It should be used with caution in children younger than 6 years. It should not be used alone to treat African trypanosomiasis of the central nervous system.

Comment

Suramin was introduced in 1920 for the treatment of African trypanosomiasis (sleeping sickness). It is considered the drug of choice for treatment of early African trypanosomiasis with *Trypanosoma brucei rhodesiense* when the central nervous system is not involved. Pentamidine is thought to be more effective than suramin for treating early African trypanosomiasis caused by *T. brucei gambiense*. The mechanism of action of suramin is thought to be through inhibition of enzymes associated with protein synthesis and DNA metabolism.

Thiabendazole (Mintezol) (Merck)

Preparation

Mintezol is supplied as a flavored suspension containing 125 or 250 mg/5 ml, as pediatric drops containing 100 mg/ml, and as 500-mg chewable tablets. Thiabendazole is a benzimidazole that is used to treat a number of nematode infections, including strongyloidiasis, cutaneous and visceral larva migrans, trichinosis, and other intestinal roundworms.

Administration

The drug is given orally, preferably after a meal; tablets should be chewed before being swallowed.

Toxicity

Common side effects are anorexia, vomiting, and dizziness. Less frequently, diarrhea, epigastric pain, pruritus, drowsiness, lethargy, and headache occur. Side effects include Stevens-Johnson syndrome, tinnitus, visual disturbance, hypotension, perianal rash, transient rises in transaminase enzyme levels, cholestasis, parenchymal liver damage, hyperglycemia, and hematuria. Treatment may cause migration of *Ascaris* organisms to the esophagus, mouth, and nose.

Contraindications

Patients with known hypersensitivity or with renal or hepatic impairment should not use thiabendazole. The drug causes dizziness and drowsiness and should not be used by patients whose vocation requires mental alertness. It is also contraindicated as prophylaxis for pinworm infections; susceptible worm infections should be confirmed by laboratory testing prior to drug use. Due to a lack of safety data, it should be used during pregnancy and lactation only if the potential benefit justifies the potential risk to the fetus.

Comment

Thiabendazole blocks glucose uptake, depletes glucose stores, and interferes with microtubule aggregates. It also inhibits the fumarate-reductase system of helminths. However, administration of thiabendazole has been associated with side effects, and it has been replaced by other anthelmintic agents.

**Tinidazole (Tindamax)
(Mission Pharmaceuticals)**

Preparation

Tinidazole is supplied as 150-, 200-, 300-, and 500-mg and 1-g tablets or as an oral suspension of 200 mg/ml. This drug is a synthetic nitroimidazole used to treat amebiasis and giardiasis; it was formerly at Presutti Pharmaceuticals.

Tindamax oral tablets are indicated for the treatment of trichomoniasis caused by *Trichomonas vaginalis* in both female and male patients. The organism should be identified by appropriate diagnostic procedures. Because trichomoniasis is a sexually transmitted disease with potentially serious sequelae, partners of infected patients should be treated simultaneously in order to prevent reinfection. Tindamax oral tablets are indicated for the treatment of giardiasis caused by *Giardia lamblia* in both adults and pediatric patients older than 3 years. Tindamax oral tablets are indicated for the treatment of intestinal amebiasis and amebic liver abscess caused by *Entamoeba histolytica* in both adults and pediatric patients older than 3 years. It is not indicated in the treatment of asymptomatic cyst passage.

Administration

Tinidazole is given orally with or after meals. After oral administration, it is rapidly and completely absorbed. Alcoholic beverages should be avoided while taking Tindamax and for 3 days afterward.

Toxicity

Tinidazole can cause nausea, vomiting, metallic taste, and rash. Convulsive seizures and peripheral neuropathy, the latter characterized mainly by numbness or paresthesia of an extremity, have been reported to occur in patients treated with nitroimidazole drugs including tinidazole and metronidazole. The appearance of abnormal neurologic signs demands the prompt discontinuation of Tindamax therapy. Tinidazole should be administered with caution to patients with central nervous system diseases or those with evidence of or history of blood dyscrasia.

Contraindications

As with other nitroimidazole derivatives, tinidazole may enhance the effect of warfarin and other coumarin anticoagulants, resulting in a prolongation of the prothrombin time. Alcoholic beverages and preparations containing ethanol or propylene glycol should be avoided during tinidazole therapy and for 3 days afterward because abdominal cramps, nausea, vomiting, headaches, and flushing may occur. Psychotic reactions have occurred in alcoholic patients using metronidazole and disulfiram concurrently. Because animal reproduction studies are not always predictive of the human response and because there is some evidence of mutagenic potential, the use of tinidazole during pregnancy requires that the potential benefits of the drug be weighed against the possible risks to both the mother and the fetus. Tinidazole is excreted in breast milk in concentrations similar to those seen in serum. It can be detected in breast milk for up to 72 h

following administration. Interruption of breast-feeding is recommended during tinidazole therapy and for 3 days following the last dose.

Comment

The nitro group of tinidazole is reduced by cell extracts of *Trichomonas*. The free nitro radical generated as a result of this reduction may be responsible for the anti-protozoal activity. The mechanism by which tinidazole exhibits activity against *Giardia* and *Entamoeba* species is not known. Approximately 38% of *T. vaginalis* isolates with reduced susceptibility to metronidazole also show reduced susceptibility to tinidazole in vitro. The clinical significance of such an effect is not known.

Tinidazole, like metronidazole, may interfere with certain types of determinations of serum chemistry values, such as aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, triglyceride, and hexokinase glucose levels.

Triclabendazole (Egaten) (Novartis)

Preparation

Triclabendazole is used in veterinary practice and is also being used to treat human infections with liver and lung flukes. The drug is not available in the United States.

Administration

Egaten is given orally after a meal as a single or split dose of 10 mg/kg. A dose of 20 mg/kg is safe and effective for patients with acute fascioliasis when a single dose has failed to cure them.

Toxicity

Triclabendazole can cause abdominal pain; however, most studies reported no side effects. The tolerance of triclabendazole is considered excellent. Side effects include brief episodes of upper abdominal pain and slight fever and some mild and limited disturbances in liver function. These effects may be due to the paralysis and/or death of the flukes, resulting in the release of antigens or toxic products and the partial blockage of the bile ducts. Similar findings have been reported in various preliminary studies: triclabendazole has been reported to decrease parasite motility, but the exact mode of action of this drug is unknown. Some patients may require a second course of therapy.

Contraindications

Use of this drug may cause secondary cholangitis due to worm destruction. Triclabendazole has been reported to be nonmutagenic and nonteratogenic.

Shipment of diagnostic specimens, biological products, etiologic agents, or infectious substances

This chapter discusses various collection methods that are available for specimens suspected of containing parasites or parasitic elements. When a laboratory selects its collection methods, the decision should be based on a thorough understanding of the value and limitations of each. One of the most important aspects of specimen collection is that the final laboratory results based on parasite recovery and identification will depend on the initial fixation of the organisms (5, 9, 17, 31, 33). Unless the appropriate specimens are properly collected and processed, these infections may not be detected (7, 17, 31). Considering the current era of cost containment and review of clinical relevance of laboratory information generated, specimen rejection criteria have become more important within the context of all diagnostic microbiology procedures. Diagnostic laboratory results based on improperly collected specimens may require excessive expenditures of time and supplies and may also mislead the physician. As a part of any overall total quality management or continuous quality improvement program for the laboratory, the generation of test results must begin with stringent criteria for specimen acceptance or rejection.

Clinically relevant diagnostic parasitology testing also depends on receiving appropriate test orders from the physician. Depending on the patient's clinical condition and travel history, very specific diagnostic tests may be recommended. It is extremely important that physician clients are aware of the test order options available within the laboratory test menu and the pros and cons of each test when considered within the context of the patient's history and symptoms. Without the proper test orders, diagnostic test results may be misleading or actually incorrect. Appropriate and complete communication regarding test orders between the laboratory and physicians is mandatory for high-quality patient care.

Safety

All fresh specimens should be handled carefully, since each specimen represents a potential source of infectious material (bacteria, viruses, fungi, and parasites). Safety precautions should include awareness of the following: proper labeling of fixatives; specific areas designated for specimen handling (biological safety cabinets may be necessary under certain circumstances); proper containers for centrifugation; acceptable discard policies; appropriate policies for no eating,

drinking, or smoking, etc., within the working areas; and, if applicable, correct techniques for organism culture and/or animal inoculation.

Since diagnostic parasitology work is most often performed within the microbiology division of a clinical laboratory, all general guidelines for safety would also apply. Any special precautions which apply to a particular technique are discussed in the following chapters. In general, standard precautions as outlined by the Occupational Safety and Health Act must be followed when applicable, particularly when one is handling blood and other body fluids (6).

Fresh-Specimen Collection

Procedures for the recovery of intestinal parasites should always be performed before barium is used for radiological examination. Stool specimens containing barium are unacceptable for examination, and intestinal protozoa may be undetectable for 5 to 10 days after barium is given to the patient. There are also certain substances and medications that interfere with the detection of intestinal protozoa: mineral oil, bismuth, antibiotics, antimalarial agents, and nonabsorbable antidiarrheal preparations. After administration of any of these compounds, parasitic organisms may not be recovered for a week to several weeks. The two most commonly used substances are barium and antibiotics, such as tetracycline, which modify the gastrointestinal tract flora. Specimen collection should be delayed for 5 to 10 days or at least 2 weeks after barium or antibiotics, respectively, are administered (5, 9, 23, 24, 26). The use of antibacterial therapy that affects the normal gastrointestinal tract flora will diminish the numbers of protozoa, since they feed on intestinal bacteria.

Collection of the Specimen

Fecal specimens should be collected in clean, wide-mouth containers; often a 0.5-pt (ca. 0.24-liter) waxed cardboard or plastic container with a tight-fitting lid is selected for this purpose. The fit of the lid is particularly important, both from the standpoint of accidental spillage and in order to maintain moisture within the specimen. The specimens should not be contaminated with water or urine, because water may contain free-living organisms that can be mistaken for human parasites and urine may destroy motile organisms. For safety reasons, stool specimen containers should be placed in plastic bags when transported to the laboratory for testing. Fresh specimens can also be submitted in collection vials (Figure 26.1). All fresh specimens should be carefully handled since they are potential sources of infectious organisms, including

Figure 26.1 Stool collection vial; “clean vial” contains no fixatives.

bacteria, viruses, and parasites. Every specimen should be identified with the following minimal information: patient’s name and identification number, physician’s name, and the date and time the specimen was collected (if the laboratory is computerized, the date and time may reflect arrival in the laboratory, not the actual collection time). The specimen must also be accompanied by a request form indicating which laboratory procedures are to be performed. It would also be very helpful to have information concerning the presumptive diagnosis or relevant travel history; however, this information is rarely available, and under certain circumstances, the physician will have to be contacted for additional patient history [Example: Fever of unknown origin (FUO)—possible malaria].

Number of Specimens To Be Collected (Standard Recommendation)

It is recommended that a normal examination for stool parasites before therapy include three specimens, consisting of two specimens collected from normal movements and one collected after the use of a cathartic such as magnesium sulfate or Fleet’s Phospho-Soda. A cathartic with an oil base should not be used, and a stool softener (taken either orally or as a suppository) is usually inadequate for obtaining a purged specimen. The purpose of the laxative

is to stimulate some “flushing” action within the gastrointestinal tract, possibly allowing one to obtain more organisms for recovery and identification. Obviously, if the patient already has diarrhea or dysentery, the use of any laxatives would be contraindicated.

When a patient is suspected of having intestinal amebiasis, six specimens may be recommended. The examination of six specimens ensures detection of approximately 90% of amebic infections (38) (Figure 26.2). However, because of cost containment measures, the examination of six specimens is rarely requested.

Three specimens are also recommended for post-therapy examinations, and they should be collected as outlined above. However, a patient who has received treatment for a protozoan infection should be checked 3 to 4 weeks after therapy, and those treated for *Taenia* infections should be checked 5 to 6 weeks after therapy. In some cases, the physician will assume a cure for tapeworm infection unless proglottids reappear in the stool; therefore, no posttherapy specimens are submitted for examination.

Number of Specimens To Be Collected (Pros and Cons of Various Options)

During the past few years, a number of issues have surfaced regarding the collection, processing, and testing of stool specimens for diagnostic parasitology. Many of the new suggestions and options have arisen as a result of continued cost containment measures, limited reimbursement, and the elimination of mercury-based compounds for stool preservatives. The number of nonmercury

Figure 26.2 Increased detection of *Entamoeba histolytica* by using various diagnostic techniques and serial stool specimens. (Adapted by E. K. Markell, M. Voge, and D. T. John, *Medical Parasitology*, 7th ed., The W. B. Saunders Co., Philadelphia, Pa., 1992, from references 16, 22, and 29.)

preservative choices, collection systems, concentration devices, and immunoassays has increased dramatically. Many laboratories continue to review the options, and some may be having difficulties in selecting the proper approach (2–4, 11–14, 18, 25, 27, 29, 32, 36, 39, 40, 46, 50).

It is important to realize that there are many acceptable options and that many laboratories will select different approaches. These differences should not be categorized as “right or wrong” or “acceptable or unacceptable”—they are merely different! To assume that there is only one correct approach for the examination of stool specimens is neither appropriate nor realistic. There are many parameters to consider before selecting the approach for your own laboratory. In no particular order, some of the considerations include client base, physician ordering patterns, number of specimens received per month, cost, presence or absence of appropriate equipment, current and possible methodologies (including the new immunoassays such as enzyme immunoassay [EIA], fluorescent-antibody assay [FA], and cartridge devices), availability of expert microscopists, collection options, selection of preservative-stain combinations, reimbursement issues, client education, area of the world where laboratory is located, and emphasis on the most common infections (helminth or protozoa or both).

When considering available options and laboratory test menus, it is important to make sure that the pros and cons of the approaches selected are thoroughly understood and that diagnostic tests, potential results, and reporting formats are carefully explained to all clients. As an example, if the results of a stool examination are based on a concentration sediment examination only, this information must be conveyed to the physician. Many of the intestinal protozoa are missed by this diagnostic test approach, and it is important for the physician to recognize the limitations of such testing. Most physicians receive very little, if any, exposure to medical parasitology in medical school, and many newer physicians trained as generalists or family practitioners also have limited parasitology training or experience.

In most cases, it is probably realistic to assume that patients are symptomatic if they are submitting stool specimens for diagnostic parasitology testing. In an excellent article by Hiatt et al., the premise tested was that a single stool sample from a symptomatic patient would be sufficient to diagnose infections with intestinal protozoa (19). However, with additional stool examinations for symptomatic patients, the yield of intestinal protozoa increased dramatically (*Entamoeba histolytica*, 22.7% increase; *Giardia lamblia*, 11.3% increase; and *Dientamoeba fragilis*, 31.1% increase). This publication again demonstrates the problems with performing only

a single stool examination (using the ova and parasite examination). If the patient becomes asymptomatic after the first stool examination, it may be acceptable to discontinue the series of stool examinations (this should be a clinician decision).

Available options are compared to the “gold standard,” which includes a series of three stool examinations (direct, concentrate, and permanent stained smear for a fresh specimen; concentrate and permanent stained smear for a preserved specimen). The single-specimen pros and cons are discussed in the previous paragraph (symptomatic versus asymptomatic patients). A suggestion has been made to pool three specimens and to perform a single concentration and a single permanent stained smear. Depending on the number of positives and negatives, this may be a viable option, but some organisms may be missed. Another testing option for three pooled specimens might be to perform a single concentration and three separate permanent stained smears. This approach would probably increase the yield of intestinal protozoa over the previous option. Another suggestion involves placing a sample of each of three stools into a single vial of preservative. This collection approach would require only a single vial, but it is very likely that the vial would be overfilled and that mixing and the ratio of fixative to stool would be inaccurate.

One could also test patient specimens by using immunoassay reagents or kits for *Giardia lamblia*, the *Entamoeba histolytica*/*E. dispar* group, *Entamoeba histolytica*, or *Cryptosporidium* spp. However, patient history information is rarely received with the clinical specimen; fecal testing based on patient risk group or situation is impossible without sufficient information. Testing of patient specimens by immunoassay procedures should be performed on request; however, client education is critical for successful implementation of this approach. Collection and testing options and the pros and cons of each are listed in Tables 26.1 and 26.2.

The Clinical Laboratory Standards Institute (formerly the National Committee for Clinical Laboratory Standards) document *Procedures for the Recovery and Identification of Parasites from the Intestinal Tract* (Approved Guideline M28-2A) was updated in 2005. Various stool collection, processing, and testing options are also included in that publication (5).

In summary, laboratories performing diagnostic parasitology testing must decide on the appropriate test methods that are relevant for their own operations based on a number of variables mentioned above. It is unrealistic to assume or state that one approach is applicable for every laboratory; however, it is important to thoroughly understand the options within your test menu and to convey this information to your clients once your approach has

been selected for implementation. Prior discussion with clients, written educational memos, meetings, and examples of revised report formats are highly recommended prior to implementation.

Collection Times

A series of three specimens as indicated above should be submitted on separate days; if possible, the specimens should be submitted every other day; otherwise, the series of three specimens should be submitted within no more than 10 days. If a series of six specimens is requested, the specimens should also be collected on separate days or within no more than 14 days. Many organisms, particularly the intestinal protozoa, do not appear in the stool in consistent numbers on a daily basis, and the series of three specimens is considered a minimum for an adequate examination (28). It is inappropriate for multiple specimens to be submitted from the same patient on the same day. One possible exception would be stool collections from a patient who has severe, watery diarrhea such that any organisms present might be missed because of the tremendous dilution factor related to fluid loss. Even under these circumstances, acceptance of more than one specimen per patient per day should not be routine but should be done only after consultation with the physician. It is also not recommended for the three specimens to be submitted one each day for three consecutive days; however, use of this collection time frame would not be sufficient cause to reject the specimens. Adequate spacing between specimens helps to provide parasite recovery within the recommended time frames.

Although the recommended number of stool specimens is three, laboratories have been more willing to accept two specimens, primarily because of cost savings and the assumption that if the patient is symptomatic, confirmation of any organisms present is just as likely to be possible from two specimens as from three specimens. However, it is important that clients understand the pros and cons of two compared with three stools. Both collection approaches are being used by diagnostic laboratories.

Specimen Type, Specimen Stability, and Need for Preservation

Fresh specimens are mandatory for the recovery of motile trophozoites (amebae, flagellates, or ciliates). The protozoan trophozoite stage is normally found in cases of diarrhea; the gastrointestinal tract contents are moving through the system too rapidly for cyst formation to occur. Once the stool specimen is passed from the body,

Table 26.1 Fecal specimens for parasites: options for collection and processing

Option	Pros	Cons
Rejection of stools from inpatients who have been in hospital for >3 days ^a	Patients may become symptomatic with diarrhea after they have been inpatients for a few days; symptoms are usually not attributed to parasitic infections but to other causes	There is always the chance that the problem is related to a health care-associated (nosocomial) parasitic infection (rare), but <i>Cryptosporidium</i> and microsporidia are possible considerations
Examination of a single stool specimen (O&P examination); data suggest that 40–50% of organisms present will be found with only a single stool exam; two O&P exams (concentration, permanent stained smear) are acceptable but are not always as good as three specimens (this may be a relatively cost-effective approach); any patient remaining symptomatic would require additional testing	Some think that most intestinal parasitic infections can be diagnosed from examination of a single stool; if the patient becomes asymptomatic after collection of the first stool, subsequent specimens may not be necessary	Diagnosis from a single stool examination depends on experience of the microscopist, proper collection, and the parasite load in the specimen; in a series of three stool specimens, it is often the case that not all three specimens are positive and/or may be positive for different organisms
Examination of a second stool specimen only after the first is negative and the patient is still symptomatic	With additional examinations, the yield of protozoa increases (<i>Entamoeba histolytica</i> , 22.7%; <i>Giardia lamblia</i> , 11.3%; and <i>Dientamoeba fragilis</i> , 31.1%) (19)	Assumes the second (or third) stool specimen is collected within the recommended 10-day time frame for a series of stools (protozoa are shed periodically); may be inconvenient for patient
Examination of a single stool and an immunoassay (EIA, FA) (<i>Giardia</i>); this approach is a mix: one immunoassay is acceptable; one O&P exam is not the best approach (review the last option below)	If the examinations are negative and the patient's symptoms subside, probably no further testing is required	Patients may exhibit symptoms (off and on), so it may be difficult to “rule out” parasitic infections with only a single stool and one fecal immunoassay. If the patient remains symptomatic, then even if two <i>Giardia</i> immunoassays are negative, other protozoa may be missed (the <i>Entamoeba histolytica</i> /E. <i>dispar</i> group, <i>Entamoeba histolytica</i> , <i>Dientamoeba fragilis</i> , <i>Cryptosporidium</i> spp., the microsporidia). Normally, there are specific situations where fecal immunoassays or O&P exams should be ordered. It is not recommended to automatically perform both the O&P and the fecal immunoassay as a stool exam for parasites.
Pool three specimens for examination; perform one concentration and one permanent stain (billing and coding issues)	Three specimens are collected over 7–10 days and may save time and expense	Organisms present in small numbers may be missed due to the dilution factor
Pool three specimens for examination; perform a single concentration and three permanent stained smears (billing and coding issues)	Three specimens are collected over 7–10 days; would maximize the recovery of protozoa in areas of the country where these organisms are most common	Might miss light helminth infection (eggs and larvae) due to the pooling of the three specimens for the concentration; however, with a permanent stain performed on each of the three specimens, this approach would probably be the next best option after the standard approach (concentration and permanent stained smear performed on every stool)
Actually collect three stools, but put a sample of stool from all three into a single vial (patient is given a single vial only)	Pooling of the specimens would require only a single vial	This would complicate patient collection and very probably result in poorly preserved specimens, especially regarding the recommended ratio of stool to preservative and the lack of proper mixing of specimen and fixative

(continued)

Table 26.1 Fecal specimens for parasites: options for collection and processing (*continued*)

Option	Pros	Cons
Perform immunoassays on selected patients ^b by FA, EIA, or rapid cartridge methods for <i>Giardia lamblia</i> , <i>Cryptosporidium</i> spp., and/or <i>Entamoeba histolytica</i> / <i>E. dispar</i> or <i>Entamoeba histolytica</i>	Would be more cost-effective than performing immunoassay procedures on all specimens; however, the information needed to group patients is often not received with specimens; client education is critical for appropriate test orders	Labs rarely receive information that would allow them to place a patient in a particular risk group, such as children <5 yr, children from day care centers (may or may not be symptomatic), patients with immunodeficiencies, and patients from outbreaks; performance of immunoassay procedures on every stool is not cost-effective, and the positive rate will be low unless an outbreak situation is involved
Perform immunoassays and O&P examinations on request ^c for <i>Giardia lamblia</i> , <i>Cryptosporidium</i> spp., and/or <i>Entamoeba histolytica</i> / <i>E. dispar</i> or <i>Entamoeba histolytica</i> (Table 26.2)	Will limit number of stools on which immunoassay procedures are performed for parasites; immunoassay results do not have to be confirmed by any other testing (such as O&P exams or modified acid-fast stains); best approach (see also ordering options in Table 26.2)	Will require education of the physician clients regarding appropriate times and patients for whom immunoassays should be ordered; educational initiatives must also include information on the test report indicating the pathogenic parasites that will not be detected by these methods; it is critical to ensure that clients know that if patients have become asymptomatic, further testing may not be required, but that if the patient remains symptomatic, further testing (O&P exams) is required; a single O&P exam may not reveal all organisms present; present plan to physicians for approval: immunoassays or O&P exams, procedure discussion, report formats, clinical relevance, limitations on each approach

^a Two key references have addressed this issue and serve as guidelines for microbiologists in reviewing clinically relevant recommendations for specimen submission: A. J. Morris, M. L. Wilson, and L. B. Reller, Application of rejection criteria for stool ovum and parasite examinations, *J. Clin. Microbiol.* 30:3213–3216, 1992, and D. L. Siegel, P. H. Edelstein, and I. Nachamkin, Inappropriate testing for diarrheal diseases in the hospital, *JAMA* 263:979–982, 1990.

^b It is difficult to know when an early-outbreak situation is present, where screening of all specimens for either *Giardia lamblia*, *Cryptosporidium* spp., or both may be relevant. Extensive efforts are under way to encourage communication among laboratories, water companies, pharmacies, and public health officials regarding the identification of potential or actual outbreaks. If it appears that an outbreak is in the early stages, performing the immunoassays on request can be changed to performing immunoassays on all stools.

^c A number of variables will determine the approach to immunoassay testing and the ova and parasite examination (O&P exam) (geography, organisms recovered, positive rate, etc.).

trophozoites do not encyst but may disintegrate if not examined or preserved within a short time after passage. The time limit recommendations listed below are most relevant for the intestinal protozoa; most helminth eggs and larvae, coccidian oocysts, and microsporidian spores survive for extended periods. However, no one can predict which organisms will be present in the stool specimens; therefore, it is important to use the most conservative time frames for parasite recovery.

Liquid specimens should be examined within 30 min of passage, not 30 min from the time they reach the laboratory. If this general time recommendation of 30 min is not possible, the specimen should be placed in one of the available fixatives. Soft (semiformed) specimens may contain a mixture of protozoan trophozoites and cysts and should be examined within 1 h of passage; again, if this time frame is not possible, preservatives should be used. Immediate examination of formed specimens is not as critical; in fact, if the specimen is examined at any time

within 24 h after passage, the protozoan cysts should still be intact (5, 23, 24).

In review, remember that trophozoites only are usually found in liquid specimens, both protozoan trophozoites and cysts can be recovered in soft specimens, and generally cysts only are recovered in formed specimens. The time limits mentioned above are merely guidelines; however, if fresh specimens remain unpreserved for longer times before examination, many if not all organisms may disintegrate or become distorted. Fecal specimens should never be incubated or frozen prior to examination using routine microscopy. When the acceptance criteria for specimen collection are not met, the laboratory should reject the specimen and request additional specimens.

Because there is often a time lag from the time of specimen passage until receipt in the laboratory, many clinicians, clinics, and inpatient wards use a specimen collection system that includes stool preservatives (Table 26.3). A number of commercial systems are available with many

Table 26.2 Approaches to stool parasitology: test ordering

Patient and/or situation	Test ordered ^a	Follow-up test ordered
Patient with diarrhea and AIDS (or other cause of immune deficiency) Potential waterborne outbreak (municipal water supply)	<i>Cryptosporidium</i> or <i>Giardia/Cryptosporidium</i> immunoassay	If immunoassays are negative and symptoms continue, special tests for microsporidia (modified trichrome stain) and other coccidia (modified acid-fast stain) and O&P ^b exam should be performed
Patient with diarrhea (nursery school, day care center, camper, backpacker) Patient with diarrhea and potential waterborne outbreak (resort setting)	<i>Giardia</i> or <i>Giardia/Cryptosporidium</i> immunoassay	If immunoassays are negative and symptoms continue, special tests for microsporidia and other coccidia (see above) and O&P exam should be performed
Patient with diarrhea and relevant travel history Patient with diarrhea who is a past or present resident of a developing country Patient in area of United States where parasites other than <i>Giardia</i> are found	O&P exam, <i>Entamoeba histolytica/E. dispar</i> immunoassay, confirmation for <i>E. histolytica</i> ; various tests for <i>Strongyloides</i> may also be relevant (even in the absence of eosinophilia)	If exams are negative and symptoms continue, special tests for coccidia and microsporidia should be performed
Patient with unexplained eosinophilia	Although the O&P exam is recommended, the agar plate culture for <i>Strongyloides stercoralis</i> (more sensitive than the O&P exam) is also recommended	If tests are negative and symptoms continue, additional O&P exams and special tests for microsporidia and other coccidia should be performed
Patient with diarrhea (suspected food-borne outbreak)	Test for <i>Cyclospora cayetanensis</i> (modified acid-fast stain, autofluorescence)	If tests are negative and symptoms continue, special procedures for microsporidia and other coccidia and O&P exam should be performed

^a Depending on the particular immunoassay kit used, various single or multiple organisms may be included. Selection of a particular kit depends on many variables: clinical relevance, cost, ease of performance, training, personnel availability, number of test orders, training of physician clients, sensitivity, specificity, equipment, time to result, etc. Very few laboratories will handle this type of testing exactly the same. Many options are clinically relevant and acceptable for good patient care.

^b O&P exam, ova and parasite examination.

Table 26.3 Stool collection: pros and cons of fresh and preserved specimens^a

Specimen	Pros	Cons
Fresh stool	<ol style="list-style-type: none"> 1. No requirements for stool fixatives 2. Ability to see motile trophozoites 3. Lower cost (no fixative vials) 4. Can perform direct wet examination, concentration, and permanent stained smear 5. Acceptable <i>only</i> if time from stool passage to laboratory is within the time limits indicated below: in symptomatic patients, the trophozoite form of the intestinal protozoa is present and will not encyst when outside of the body but will disintegrate Time limits: liquid or watery stool, 30 min; semifformed stool, 1 h; formed stool, 24 h 	<ol style="list-style-type: none"> 1. May have excessive lag time between stool fixation or processing; trophozoites may disintegrate, thus giving a false-negative result 2. Ova and parasite examination (direct wet examination, concentration, and permanent stained smear) may be negative due to lack of organism preservation and morphology integrity
Preserved stool	<ol style="list-style-type: none"> 1. Organism morphology is preserved when lag time between stool passage and fixation is short (this can be done by allowing patients to collect and fix stool specimens at home); once the specimen is mixed with the preservative, the delivery time to the laboratory is not critical 2. Can perform concentration and permanent stain 	<ol style="list-style-type: none"> 1. Cost of collection vials may represent a cost increase; however, overall expense may be lower because of much more accurate result (patient outcome) 2. Disposal of vials may be a problem if the laboratory is using preservatives containing mercuric chloride

^a Most products used for specimen collection are available from any major medical supply house. FA, fluorescent antibody. Adapted from reference 9.

preservative choices; the use of such systems has become routine for many institutions, and some request a custom collection kit that may contain several types of preservatives for stool specimens, depending on the tests normally ordered by the clinicians that they service. Specific information concerning collection kit components is provided in appendix 1.

KEY POINTS

Stool Specimen Collection

1. Occupational Safety and Health Act regulations (including standard precautions) should be used for handling all specimens.
2. Interfering substances (oil-based laxatives, barium, antibiotics) should be avoided when stool specimens are collected.
3. Contamination with urine or water should be avoided.
4. Recommendation for collection: three specimens collected, one every other day or within a 10-day time frame.

Note There are some exceptions; see Table 26.1.

5. Liquid stool: examine or preserve within 30 min of passage (trophozoites). Soft stool: examine or preserve within 1 h of passage (trophozoites and cysts). Formed stool: examine or preserve within 24 h of passage. Note that *Dientamoeba fragilis* trophozoites (no known cyst forms) can be found in formed stool specimens as well as liquid specimens.

Preservation of Specimens

Preservatives

There are a number of reasons why a lag time may occur from the time of specimen passage until examination in the laboratory (e.g., the workload in the laboratory or the transit distance or time for the specimen to reach the facility). To preserve protozoan morphology and to prevent the continued development of some helminth eggs and larvae, the stool specimens can be placed in preservative immediately after passage (by the patient using a collection kit) or once the specimen is received by the laboratory. There are several fixatives available; the more common ones, including formalin, Merthiolate (thimerosal)-iodine-formalin (MIF), sodium acetate-acetic acid-formalin (SAF), Schaudinn's fluid, polyvinyl alcohol (PVA), and the single-vial systems are discussed in detail (Table 26.4). Regardless of the fixative selected, adequate mixing of the specimen and preservative is mandatory. A flow diagram for preservation and processing is shown in Figure 26.3.

Note When selecting an appropriate fixative, keep in mind that a permanent stained smear is mandatory for a complete examination for parasites (5, 7, 9, 10, 33, 35). It is also important to remember that disposal regulations for compounds containing mercury are becoming more restrictive; each laboratory will have to check applicable state and federal regulations to help determine fixative options.

Formalin

Formalin has been used for many years as an all-purpose fixative that is appropriate for helminth eggs and larvae and for protozoan cysts, oocysts, and spores. Two concentrations are commonly used: 5%, which is recommended for preservation of protozoan cysts, and 10%, which is recommended for helminth eggs and larvae. Although 5% is often recommended for all-purpose use, most commercial manufacturers provide 10%, which is more likely to kill all helminth eggs (Figure 26.4). To help maintain organism morphology, the formalin can be buffered with sodium phosphate buffers, i.e., neutral formalin. Selection of specific formalin formulations is at the user's discretion. *Aqueous formalin will permit the examination of the specimen as a wet mount only, a technique much less accurate than a permanent stained smear for the identification of intestinal protozoa. However, the fecal immunoassays for Giardia lamblia and Cryptosporidium spp. can be performed from the aqueous formalin vial. Fecal immunoassays for the Entamoeba histolytica/E. dispar group and Entamoeba histolytica are limited to fresh or frozen fecal specimens.* After centrifugation, special stains for the coccidia (modified acid-fast stains) and the microsporidia (modified trichrome stains) can be performed from the concentrate sediment obtained from formalin-preserved stool material. The most common formalin preparation is 10% formalin, prepared as follows:

Formaldehyde (USP)	100 ml (or 50 ml for 5%)
Saline solution, 0.85% NaCl.....	900 ml (or 950 ml for 5%)

Dilute 100 ml of formaldehyde with 900 ml of 0.85% NaCl solution. (Distilled water may be used instead of saline solution.)

Note Formaldehyde is normally purchased as a 37 to 40% HCHO solution; however, for dilution, it should be considered to be 100%.

If you want to use buffered formalin, the recommended approach (5, 31) is to mix thoroughly 6.10 g of Na_2HPO_4 and 0.15 g of NaH_2PO_4 and store the dry mixture in a tightly closed bottle. Prepare 1 liter of either 10 or 5% formalin, and add 0.8 g of the buffer salt mixture.

Table 26.4 Preservatives used in diagnostic parasitology (stool specimens)

Preservative	Concentration	Permanent stained smear	Immunoassays (<i>Giardia lamblia</i> , <i>Cryptosporidium</i> spp.)	Comments
5% or 10% formalin	Yes	No	Yes	EIA, FA, cartridge
5% or 10% buffered formalin	Yes	No	Yes	EIA, FA, cartridge
MIF	Yes	Polychrome IV stain	ND	No published data
SAF	Yes	Iron hematoxylin	Yes	EIA, FA, cartridge
PVA ^a	Yes, but rarely used	Trichrome or iron hematoxylin	No	PVA interferes with immunoassays
Modified PVA ^b	Yes, but rarely used	Trichrome or iron hematoxylin	No	PVA interferes with immunoassays
Modified PVA ^c	Yes	Trichrome or iron hematoxylin	Some, but not all	PVA interferes with immunoassays
Single-vial systems ^d	Yes	Trichrome or iron hematoxylin	Some, but not all	Check with the manufacturer
Schaudinn's fluid (without PVA) ^a	Yes, but rarely used	Trichrome or iron hematoxylin	No	Mercury interferes with immunoassays

^a These two fixatives use the mercuric chloride base in the Schaudinn's fluid; this formulation is still considered to be the "gold standard" against which all other fixatives are evaluated (organism morphology after permanent staining). Additional fixatives prepared with non-mercuric-chloride-based compounds are continuing to be developed and tested.

^b This modification uses a copper sulfate base rather than mercuric chloride.

^c This modification uses a zinc base rather than mercuric chloride and works well with both trichrome and iron-hematoxylin stains.

^d These modifications use a combination of ingredients (including zinc) but are prepared from proprietary formulas. The aim is to provide a fixative that can be used for the fecal concentration, permanent stained smear, and available immunoassays (EIA, FA) for *Giardia lamblia*, *Cryptosporidium* spp., and *Entamoeba histolytica* (or the *Entamoeba histolytica*/E. *dispar* group).

Protozoan cysts (not trophozoites), coccidian oocysts, microsporidian spores, helminth eggs, and larvae are well preserved for long periods in 10% aqueous formalin. Hot (60°C) formalin can be used for specimens containing helminth eggs, since in cold formalin, some thick-shelled eggs (e.g., *Ascaris lumbricoides*) continue to develop, become infective, and remain viable for long periods. Several grams of fecal material should be thoroughly mixed in 5 or 10% formalin.

To collect large numbers of cysts, eggs, or larvae relatively free from other debris, the whole stool specimen is mixed in water and then strained through several layers of gauze. The suspension is allowed to sediment in a cone-shaped glass or flask for 1 h or more, and the supernatant fluid is discarded. The specimen may be washed several times in this manner before the sediment is finally fixed in hot 10% formalin, as mentioned above. When working with watery diarrhea specimens from patients with suspected cases of coccidiosis or microsporidiosis, the specimen should not be strained through gauze (oocysts and small bits of mucus may cling to the gauze); centrifugation (500 × g for 10 min) is necessary to sediment the oocysts and/or spores.

Formalin: summary

Advantages	Disadvantages
Good overall fixative for stool concentration	Does not preserve trophozoites well
Easy to prepare, long shelf life	Does not adequately preserve organism morphology for a good permanent stained smear
Formalinized stool can be used with some of the immunoassay detection kits (<i>Giardia lamblia</i> , <i>Cryptosporidium</i> spp.)	

MIF

MIF (37) is a good stain preservative for most kinds and stages of parasites found in feces; it is especially useful for field surveys. It is used with all common types of stools and aspirates; protozoa, eggs, and larvae can be diagnosed without further staining in temporary wet mounts, either made immediately after fixation or prepared several weeks later. Although some laboratories maintain that a permanent stained smear can be prepared from specimens preserved in MIF, most laboratories using such a fixative examine the material only as a wet preparation (direct smear and/or concentration sediment). For a good discussion of this technique, see reference 8.

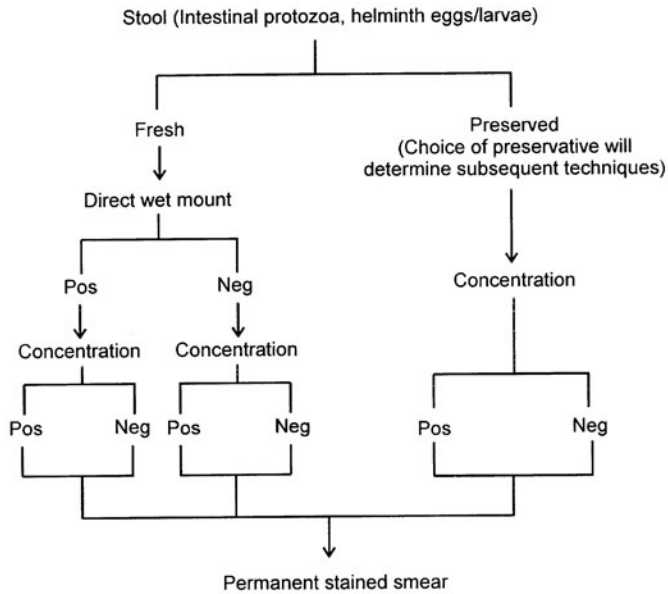

Figure 26.3 Flow diagram for preservation and processing of stool specimens. As mentioned in the text, the examination of fecal specimens using the ova and parasite examination is not considered complete unless a concentration and a permanent stained smear are examined for every specimen submitted to the laboratory. For a fresh specimen, a direct wet mount should be performed if the specimen is very soft to liquid; the complete ova and parasite examination would include the direct wet mount, the concentration, and the permanent stained smear. If the specimen is submitted in preservative, the direct wet mount should be eliminated (no motility is possible); the complete ova and parasite examination would include the concentration and the permanent stained smear (5, 9).

Figure 26.4 Stool collection vial containing 10% formalin; note the “FILL LINE” and the poison signs at each side of the label. When the stool specimen is added to the vial, the final ratio of stool to preservative is about 1:3.

The MIF preservative is prepared in two stock solutions, stored separately and mixed immediately before use.

Solution I (stored in a brown bottle)

- Distilled water..... 50 ml
- Formaldehyde (USP)..... 5 ml
- Thimerosal (tincture of Merthiolate, 1:1,000)..... 40 ml
- Glycerin..... 1 ml

Solution II (Lugol’s Solution) (good for several weeks in a tightly stoppered brown bottle)

- Distilled water..... 100 ml
- Potassium iodide crystals (KI) 10 g
- Iodine crystals (add after KI dissolves) 5 g

Combine 9.4 ml of solution I with 0.6 ml of solution II just before use.

1. Add about one-quarter teaspoon (1 g) of fresh feces to the solution, and mix with an applicator.

Fecal material should be formed or soft if egg counts are to be made later; liquid stool does not work very well for worm burden estimates.

2. Within 24 h, if undisturbed, the specimen forms three well-defined layers. The top layer, a clear orange fluid, consists mainly of formalin, Merthiolate, and water; it does not trap eggs or protozoa. The interface is a thick, pale orange or creamy yellow layer, usually 1 to 2 mm thick; this layer may trap some protozoa and helminth eggs. The bottom layer consists of deeper-staining particulate matter; eggs and protozoa are found throughout this layer.
3. With a glass pipette, MIF direct smears can be made from both the interface and bottom layers. Best results are obtained by making smears from both layers.
4. It has been suggested by some workers that a concentration technique applied to the MIF method (referred to as the MIFC or TFC method) gives

satisfactory results. This contention is debatable, and Dunn (8) suggests that it is not nearly as reliable as the MIF direct smear method.

MIF: summary

Advantages	Disadvantages
Components both fix and provide stain color	Contains mercury compounds (thimerosal)
Easy to prepare, long shelf life	Morphology of organisms on permanent stained smears generally not as good as that seen with Schaudinn's fluid or PVA (mercuric chloride base)
Very useful for field surveys	

SAF

SAF lends itself to the concentration technique, the permanent stained smear, and fecal immunoassays for *Giardia* and *Cryptosporidium* and has the advantage of not containing mercuric chloride, as is found in Schaudinn's fluid and some of the PVA fixatives (39, 49). It is a liquid fixative, much like the 10% formalin described above (Figure 26.5). The sediment is used to prepare the permanent smear, and it is frequently recommended that the stool

Figure 26.5 Stool collection vials, one containing SAF fixative and the other containing Z-PVA, one of the non-mercury-based fixatives. This combination of collection vials is an excellent option; concentrations and fecal immunoassays can be performed from the SAF vial, while the permanent stained smear can be performed from the Z-PVA vial. If the laboratory is going to use the iron-hematoxylin permanent stain, the permanent smear for staining could also be prepared from the SAF vial.

material be placed on an albumin-coated slide to improve adherence to the glass (Figure 26.6).

SAF is considered to be a “softer” fixative than mercuric chloride. The organism morphology is not quite as sharp after permanent staining as that of organisms originally fixed in solutions containing mercuric chloride. *The pairing of SAF-fixed material with iron hematoxylin staining provides better organism morphology than does staining SAF-fixed material with trichrome (personal observation).* Although SAF has a long shelf life and is easy to prepare, the smear preparation technique may be a bit more difficult for less experienced laboratory personnel who are not familiar with fecal specimen techniques. Laboratories that have considered using only a single preservative have selected this option (concentration, permanent stain, fecal immunoassays for *Giardia* and *Cryptosporidium*). Helminth eggs and larvae, protozoan trophozoites and cysts, and coccidian oocysts and microsporidian spores are preserved by this method. After centrifugation, special stains for the coccidia (modified acid-fast stains) and the microsporidia (modified trichrome stains) can be used with the concentrate sediment obtained from SAF-preserved stool material.

SAF fixative is prepared as follows:

- Sodium acetate..... 1.5 g
- Acetic acid, glacial..... 2.0 ml
- Formaldehyde, 37 to 40% solution..... 4.0 ml
- Distilled water..... 92.0 ml

To make Mayer's albumin, mix equal parts of egg white and glycerin. Place 1 drop on a microscope slide, and add 1 drop of SAF-preserved fecal sediment (from the

Figure 26.6 Albumin used to precoat the slide prior to the application of SAF-fixed stool concentration sediment. Once the smear is dry, it is ready for permanent staining.

concentration procedure). After mixing, allow the smear to dry at room temperature for 30 min prior to staining.

SAF: summary

Advantages	Disadvantages
Can be used for concentration and permanent stained smears	Poor adhesive properties, albumin-coated slides recommended
Contains no mercury compounds	Protozoan morphology better if iron hematoxylin stains used for permanent stained smears (trichrome fair)
Easy to prepare, long shelf life	May be a bit more difficult to use; however, this does not seem to be a limiting factor
SAF-preserved stool can be used with the new immunoassay methods (<i>Giardia</i> and <i>Cryptosporidium</i>)	

Schaudinn's Fluid

Schaudinn's fluid is designed to be used with fresh stool specimens or samples from the intestinal mucosal surface. Many laboratories that receive specimens from in-house patients (no problem with delivery times) often select this approach. Permanent stained smears are then prepared from fixed material. A concentration technique for Schaudinn's fluid-preserved material is also available but is not widely used.

Mercuric Chloride, Saturated Aqueous Solution

- Mercuric chloride (HgCl₂)..... 110 g
- Distilled water..... 1,000 ml

Use a beaker as a water bath; boil (use a hood if available) until the mercuric chloride is dissolved; let stand for several hours until crystals form.

Schaudinn's Fixative (Stock Solution)

- Mercuric chloride, saturated aqueous solution..... 600 ml
- Ethyl alcohol, 95% 300 ml

Immediately before use, add 5 ml of glacial acetic acid per 100 ml of stock solution.

Schaudinn's fluid: summary

Advantages	Disadvantages
Fixative for smears prepared from fresh fecal specimens or samples from the intestinal mucosal surfaces	Not generally recommended for use in concentration procedures
Provides excellent preservation of protozoan trophozoites and cysts	Contains mercuric chloride—disposal problem
	Poor adhesive qualities with liquid or mucoid specimens

PVA

PVA is a plastic resin that is normally incorporated into Schaudinn's fixative (1). The PVA powder is *not* a

fixative but serves as an adhesive for the stool material; i.e., when the stool-PVA-fixative mixture is spread onto the glass slide, it adheres because of the PVA component. Fixation is still accomplished by the Schaudinn's fluid itself. Perhaps the greatest advantage of the use of PVA is the fact that a permanent stained smear can be prepared. Although some laboratories may perform a fecal concentration from a PVA-preserved specimen, some parasites do not concentrate well, nor do some exhibit the typical morphology that would be seen in concentration sediment from a formalin-based fixative. PVA fixative solution is highly recommended as a means of preserving cysts and trophozoites for later examination. The use of PVA fixative also permits specimens to be shipped (by regular mail service) from any location in the world to a laboratory for subsequent examination. PVA fixative is particularly useful for liquid specimens and should be used in the ratio of 3 parts PVA to 1 part fecal specimen. The formula is as follows:

- PVA..... 10.0 g
- Ethyl alcohol, 95% 62.5 ml
- Mercuric chloride, saturated aqueous 125.0 ml
- Acetic acid, glacial..... 10.0 ml
- Glycerin..... 3.0 ml

Mix the liquid ingredients in a 500-ml beaker. Add the PVA powder (stirring is not recommended). Cover the beaker with a large petri dish, heavy wax paper, or foil, and allow the PVA to soak overnight. Heat the solution slowly to 75°C. When this temperature is reached, remove the beaker and swirl the mixture for 30 s until a homogeneous, slightly milky solution is obtained.

PVA: summary

Advantages	Disadvantages
Can be used to prepare permanent stained smears and perform concentration techniques (see also Disadvantages)	<i>Trichuris trichiura</i> eggs and <i>Giardia lamblia</i> cysts are not concentrated as easily as from formalin-based fixatives;
Provides excellent preservation of protozoan trophozoites and cysts	<i>Strongyloides stercoralis</i> larval morphology is poor (better to use formalin-based preservation); <i>Isospora belli</i> oocysts may not be visible in PVA fixative-preserved material (better to use formalin-fixed specimens)
Long shelf life (months to years) in tightly sealed containers at room temperature	Contains mercury compounds (Schaudinn's fluid)
Allows specimens to be shipped to any laboratory for subsequent examination	May turn white and gelatinous when it begins to dehydrate or when refrigerated
Specimens preserved in PVA cannot be used with the fecal immunoassay kits	Difficult to prepare in the laboratory

Modified PVA

Although there has been a great deal of interest in developing preservatives without the use of mercury compounds, substitute compounds have not provided the quality of preservation necessary for comparable protozoan morphology on the permanent stained smear. Copper sulfate has been tried (15, 20) but does not provide results equal to those seen with mercuric chloride (15). However, zinc sulfate has proven to be a good mercury substitute and is used with trichrome stain (Figure 26.5) (16). Although zinc substitutes have become widely available, each manufacturer has a proprietary formula for the fixative.

Copper Sulfate Solution

- CuSO₄ · 5H₂O..... 20.0 g
- Distilled water 1,000 ml

Add the CuSO₄ · 5H₂O to 1,000 ml of distilled water heated to 100°C. Mix until dissolved.

Modified PVA Fixative (Stock Solution)

- Copper sulfate solution 600 ml
- Ethyl alcohol, 95% 300 ml

Immediately before use, add 5 ml of glacial acetic acid per 100 ml of stock solution.

Modified PVA: summary

Advantages	Disadvantages
Can prepare permanent stained smears and perform concentration techniques	Overall protozoan morphology of trophozoites and cysts is poor when preserved in the copper sulfate-based fixative, particularly compared with organisms preserved with mercuric chloride-based fixatives
Many workers prefer the zinc substitutes over those prepared with copper sulfate	Zinc-based fixatives are a better alternative
Does not contain mercury compounds	Staining characteristics of protozoa not consistent—some good, some poor; organism identification may be more difficult, particularly with small protozoan cysts

Single-Vial Collection Systems (Other than SAF)

Several manufacturers now have available single-vial stool collection systems, similar to SAF or modified PVA methods (12). From the single vial, both the concentration and permanent stained smear can be prepared (Figures 26.7 through 26.9). It is also possible to perform fecal immunoassay procedures from some of these vials. Make sure to ask the manufacturer about all three capabilities (concentration, permanent

Figure 26.7 ECOFIX is an example of a fixative that represents the single-vial collection system. This fixative has been coupled with its own stain, the ECOSTAIN (12). Remember to inquire about the compatibility of all single-vial systems with the immunoassay procedures; not all single-vial preservatives are compatible with all fecal immunoassays.

Single-vial systems: summary

Advantages	Disadvantages
Can be used to prepare permanent stained smears and perform concentration techniques	Overall protozoan morphology of trophozoites and cysts is not as good as that for organisms preserved with mercuric chloride-based fixatives; morphology similar to modified PVA options
Can be used in fecal immunoassay procedures (some exceptions)	Staining characteristics of protozoa not consistent—some good, some poor; identification of <i>Endolimax nana</i> cysts may be difficult
Do not contain mercury compounds	

stained smear, fecal immunoassay procedures) and for specific information indicating that there are no formula components that would interfere with any of the three methods. Like the zinc substitutes, these formulas are proprietary.

Figure 26.8 ProtoFix is a single-vial collection option. It is always important to review peer-reviewed literature regarding the results of new products compared with those previously in use.

Use of Fixatives

Quality Control for Stool Fixatives

Fixatives for fecal specimens are checked for quality control by the manufacturer before sale, generally with the use of living protozoa. If you prepare your own fixatives, the following approach can be used for quality control. The specimen used for quality control presented below is designed to be used with fixatives from which permanent stained smears will be prepared (Schaudinn's fluid, PVA fixative, modified PVA fixative, SAF, or MIF). However, the same quality control specimen can also be used in a concentration; the white blood cells (WBCs) can be seen in the concentrate sediment (sedimentation concentration) or in the surface film (flotation concentration).

1. Obtain a fresh, anticoagulated blood specimen, centrifuge, and obtain a buffy coat sample (try and find a specimen with a high WBC count).
2. Mix approximately 2 g of soft, fresh fecal specimen (normal stool, containing no parasites) with several drops of the buffy coat cells.

Figure 26.9 UNIFIX is a single-vial collection system; information on this product can be found at the company website (www.med-chem.com). This fixative works well with trichrome stain.

3. Prepare several fecal smears, and fix immediately in Schaudinn's fluid to be quality controlled.
4. Mix the remaining feces-buffy coat mixture in 10 ml of PVA fixative, modified PVA fixative, SAF, or MIF preservative to be quality controlled.
5. Allow 30 min for fixation, and then prepare several fecal smears. Allow to dry thoroughly (60 min at room temperature or 30 to 60 min in an incubator [approximately 35°C]). Do not use a heat block.
6. Stain the slides by the normal staining procedure (trichrome, iron-hematoxylin).
7. After staining, if the WBCs appear well fixed and display typical morphology and color, one can assume that any intestinal protozoa placed in the same lot number of preservative would also be well fixed, provided that the fecal sample was fresh and fixed within the recommended time limits.
8. The bulk quality control specimen can be concentrated as for a normal patient specimen. If the fixative is performing correctly, the WBCs will be

visible in the concentration sediment or surface film (depending on the method used).

9. Record all quality control results. If the WBC morphology does not confirm good fixation, describe the results and indicate what corrective actions were used (repeated the test, prepared new fixative).

A. Schaudinn's or PVA fixative with trichrome or iron-hematoxylin stain

B. SAF fixative with iron-hematoxylin stain

Procedure Notes for Use of Preservatives

1. Most of the commercially available kits have a "fill to" line on the vial label to indicate how much fecal material should be added to ensure adequate preservation of the fecal material (ratio of one part stool to three parts fixative). *However, patients often overfill the vials; remember to open the vials with the vials turned away from your face. There may be excess gas in the vials that may create aerosols once the vial lids are opened.*
2. Although the two-vial system (one vial of 5 or 10% buffered formalin [concentration] and one vial of PVA fixative [permanent stained smear]) has always been the "gold standard," laboratories are beginning to use other options, including the single-vial collection systems. Changes in the selection of fixatives are based on the following considerations:
 - A. Problems with disposal of mercury-based fixatives (availability of high-temperature incineration facilities and cost) and lack of multilaboratory contracts for disposal of such products
 - B. The cost of a two-vial system compared with the cost of a single collection vial
 - C. Selection of specific stains (trichrome, iron hematoxylin) to use with specific fixatives
 - D. Whether the newer fecal immunoassay kits can be used with stool specimens preserved in that particular fixative

Procedure Limitations for Use of Preservatives

1. Adequate fixation still depends on the following parameters:
 - A. Meeting recommended time limits for lag time between passage of the specimen and fixation
 - B. Use of the correct ratio of specimen to fixative (1:3)
 - C. Thorough mixing of the fixative and specimen (once the specimen is received in the laboratory, any additional mixing at that time will not counteract the earlier lack of fixative-specimen mixing and contact)
2. Unless the appropriate stain is used with each fixative, the final permanent stained smear may be difficult to examine (organisms hard to see and/or identify). Examples of appropriate combinations are as follows:

Shipment of Diagnostic Specimens, Biological Products, Etiologic Agents, or Infectious Substances

Biological materials shipped domestically or internationally must be packaged in compliance with hazardous-materials transport regulations. The United States has incorporated the United Nations Recommendations on the Transport of Dangerous Goods into law, making the U.S. regulations consistent with foreign shipment regulations. The U.S. regulations for packing diagnostic specimens and infectious agents for shipment were modified in 2006. The Public Health Service, Department of Transportation, and Postal Service specify requirements for packaging and shipping of biological materials. These regulations, plus those for packaging and shipping of materials via air, are similar; most carriers elect to follow the international shipping regulations within the International Air Transport Association (IATA) *Dangerous Goods Regulations* (Table 26.5).

Anyone packaging diagnostic specimens or infectious agents for shipment must receive training and be tested every 2 years. Those who complete the training and test will receive a certificate. The regulations are designed to protect all personnel who may come in contact with the package; compliance with these rules is the responsibility of the sender. Definitions of relevant terms can be found in Tables 26.5 and 26.6.

Double mailing containers should be used in shipping any parasitologic specimens other than microscope slides. The inner container is an aluminum screw-cap mailing tube that fits into an outer cardboard screw-cap mailing container. The specimen vials or tubes in the inner aluminum cylinder should be packed in cotton to absorb any moisture or material that might result from leakage or breakage. Instruction sheets, patient information sheets, etc., may be wrapped around the metal cylinder before it is placed in the outer cardboard mailer. For all packages containing infectious substances, an itemized list of contents must be enclosed between the secondary packaging and the outer packaging (21, 22, 30, 34, 41–45, 47, 48). Specific packing instructions can be found in Table 26.7, and significant changes in IATA requirements effective 2 June 2006 can be found in Table 26.8. An excellent review can be found through the *Sentinel Laboratory Guidelines for Suspected Agents of Bioterrorism, Packing and Shipping Diagnostic and Clinical Specimens, Infectious Substances, and Biological Agents*, published by the American Society for Microbiology in 2005. Training and training mate-

Table 26.5 Agencies governing transportation of dangerous goods

Governing authority	Agency ^a	Regulations
United Nations	ICAO	<i>Technical Instructions for the Safe Transport of Dangerous Goods by Air</i>
Commercial airline industry	IATA	<i>Dangerous Goods Regulations</i>
United States	DOT	<i>United States Hazardous Materials Uniform Safety Act</i>
United States	USPS	<i>Domestic Mail Manual. CO23 Hazardous Materials</i>
Canada	Transport Canada	<i>Transportation of Dangerous Goods Regulations</i>
Other nations		Individual national regulations

^a ICAO, International Civil Aviation Organization; IATA, International Air Transport Association; DOT, Department of Transportation; USPS, U.S. Postal Service.

rial for the transportation of dangerous goods and infectious substances is available at the American Society for Microbiology (www.asm.org) and IATA (training manuals) (www.iata.com). Many of the packaging suppliers of shipping containers also have relevant training materials (SafTPak, CARGOPak).

Prepared slides, such as stained fecal smears or blood films, do not require double mailers for shipment. They may be packed in boxes, cardboard slide holders, or any other suitable container that will prevent damage or breakage. Slides should be individually wrapped in toilet tissue or facial tissue. If a number of slides are to be mailed, they can be wrapped in toilet paper as follows: place a slide on the tissue, wrap the slide several times, place the next slide on top of the first, and continue to wrap the slide several times. The series of slides will be padded and can be easily unwrapped on arrival. When you place slides in the flat cardboard containers, they need additional protection; some slides will arrive broken if this thin cardboard container is merely placed in an envelope for mailing. A plastic slide container with a snap top is an excellent option for shipping microscope slides.

Note If the slides are mounted with Permout or other mounting media, they should be completely dry before being packed.

All packages prepared for mailing should contain a complete information sheet about the specimen. An address label should be enclosed inside the package, as well as being on the outside container. All labels should be checked to ensure proper delivery. Also, remember that if you use an overnight carrier, the address must also contain a street address, not just a P.O. box or general

address such as department and institution. Guidelines for packaging are provided in Table 26.7.

Documentation

The Shipper's Declaration for Dangerous Goods is a legal document that serves as a contract between the shipper and carrier; it must be accurate and legible and have no spelling errors. However, if minor discrepancies in typing or punctuation are present, they are no longer considered errors if they do not compromise safety. The document must be either handwritten by one person or typed. Two copies of the Shipper's Declaration must be completed and signed for each shipment. One copy is retained by the shipper, and the other is forwarded with the package; one copy can be a carbon copy. This document is required for shipping infectious substances and toxic substances; it is not required for shipping diagnostic specimens or biological products. If there are no dangerous goods in a shipment with dry ice, the Shipper's Declaration is not required. It is important for personnel within the laboratory to thoroughly understand these regulations and to have sample copies of appropriate documentation for referral. A checklist used by carriers to decide to accept or reject a package is widely used; a copy of this document should also be on file within the laboratory.

The current editions of the Codes of Federal Regulations can be obtained from the Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402. Inquiries about Postal Service publications may be directed to U.S. Postal Service, 475 L'Enfant Plaza, Washington, D.C. 20260-5365. Dangerous Goods Regulations can be obtained from Publications Assistant, International Air Transport Association, 2000 Peel Street, Montreal, Quebec, Canada, H3A 2R4.

Table 26.6 Definitions of relevant terms for packing and shipping^a

Term	Definition
Biological product	A substance which originated from living organisms (including humans and other mammals) and has been manufactured and distributed in accordance with compliance and licensing requirements set forth by the federal government; can be classified as an infectious substance or a diagnostic (or clinical) specimen if such is appropriate. Biological products can be finished or unfinished; are intended for use in the prevention, treatment, or diagnosis of disease in humans or animals; and can be used for investigational, experimental, or development purposes. Biological products include such common items as clinical microbiology reagents and kits, serologic reagents, diagnostic reagents, and vaccines. In certain parts of the world, some licensed biological products are regarded as biohazardous and either are subject to compliance criteria specified for infectious substances or must adhere to other restrictions imposed by the government of that country.
Biological substance, category B	Any infectious substance that does not meet the criteria for a category A substance. See “Diagnostic or clinical specimen” below.
Category A substance	An infectious substance or microorganism that is transported <i>in a form</i> which, when exposure to it occurs, is capable of causing permanent disability or is life-threatening.
Category B substance	An infectious substance which does not meet category A criteria; an infectious substance <i>not</i> in a form capable of causing disability, life-threatening illness, or a fatal disease. Category B substances generally are considered to be (i) patient or clinical specimens reasonably expected to contain, or being cultured or otherwise tested for, a non-category A pathogen and (ii) cultures of microorganisms not specifically listed in category A.
Code of Federal Regulation (CFR)	U.S. laws published in the <i>Federal Register</i> and available online at http://www.gpoaccess.gov/cfr/index.html .
Culture	The result of a process by which pathogens are intentionally propagated. This definition refers to typical laboratory cultures of microorganisms grown in broth or on solid media. Typical clinical cultures may be classified as either category A or category B, depending on the organism concerned and the professional judgment of the shipper (49).
Dangerous goods	Materials which, when not properly handled and contained, can pose a risk to the health, safety, property, or environment and which are shown on the list of dangerous goods in the IATA <i>Dangerous Goods Regulations</i> .
Diagnostic or clinical specimen	A category B infectious substance; an infectious substance which does not meet the criteria for category A; generally considered to be clinical specimens such as swabs, tissue, and body fluids commonly encountered in a clinical laboratory and being cultured or otherwise tested for a pathogen.
Infectious substance	A substance which is known or reasonably expected to contain pathogens (microorganisms which can cause disease in humans and animals); material known to contain or reasonably suspected of containing a category A or B pathogen or substance; can be a class (class 6), a division (division 6.2), or a category (category A or B) of dangerous goods as defined by IATA.
Packaging	All of the materials used to contain a shipped substance and to prepare the substance for shipping; the container (receptacle) and its associated components (e.g., tubes, containers, absorbent material, boxes, and labels) used to contain and pack a substance and to ensure compliance with packing requirements.
Packing instructions	IATA-defined directions that shippers must follow to select, assemble, mark, label, and document the packing process for shipping dangerous goods, including diagnostic specimens and infectious substances; include manufacturing, testing, and performance specifications for packaging materials.
Pathogen	A microorganism (bacterium, mycobacterium, fungus, parasite, virus, plasmid, genetic element, proteinaceous infectious particle [prion], or genetically modified organism) that is known to cause or is reasonably expected to be able to cause disease in humans or animals.
Patient specimen	Material collected from humans or animals, including but not limited to excreta, secretions, blood and its components, tissue, body fluids, body organs and parts, and swabs of human material, being transported for purposes such as research, diagnosis, investigational activities, and disease treatment and prevention.
Primary specimen container	The innermost packaging containing a diagnostic specimen or infectious substance; composed of glass, metal, or plastic; must be leakproof; must be positively sealed if it contains an infectious substance.

(continued)

Table 26.6 Definitions of relevant terms for packing and shipping^a (continued)

Term	Definition
Secondary specimen container	The container that contains the primary specimen container.
Shipper	Anyone who ships goods by a commercial carrier (usually an employee of a company or health care facility [e.g., laboratory staff member]); anyone who offers goods for transport to a member of IATA; anyone who completes and signs the Shipper's Declaration. The person who signs the Shipper's Declaration is the person who accepts responsibility for the accuracy of the information on the document.
Shipper's Declaration for Dangerous Goods	Shipper's Declaration: an IATA-defined and -mandated form which must accompany each shipment of dangerous goods; contains information that describes the dangerous goods; is helpful to persons who handle the shipment; must be completed by the shipper.

^aAdapted from *Sentinel Laboratory Guidelines for Suspected Agents of Bioterrorism, Packing and Shipping Diagnostic and Clinical Specimens, Infectious Substances, and Biological Agents*, American Society for Microbiology, 2005.

Table 26.7 Comparison of packing directions for exempt human specimens and IATA packing instructions 650 and 602^a

Requirement	Exempt human specimens ^a	650 ^b	602 ^c
Leakproof primary (1°) and secondary (2°) containers	Yes	Yes	Yes
Pressure-resistant 1° or 2° container	— ^d	Yes	Yes
Absorbent between 1° and 2° containers ^e	Yes	Yes	Yes
List of contents between 2° and outer package	—	Yes	Yes
Rigid outer packaging	—	Yes	Yes
Positively sealed 1° container	—	No	Yes
Name, address, and phone no. of responsible person on outer package or air waybill	—	Yes	Yes
Shipper's Declaration for Dangerous Goods	—	No	Yes
Outer packaging			
Markings and labels	—	Less	More
Strict manufacturing specifications	No	No	Yes
Quantity limits for passenger and cargo aircraft			
Maximum for each 1° container	—	1 liter (1 kg)	50 ml (50 g)
Total maximum for outer package	—	4 liters (4 kg)	50 ml (50 g)
Cost of labor and materials to pack substance	Least	More	Most

^a Includes substances with minimal likelihood of causing disease in humans and animals and substances not likely to contain pathogens; adapted from *Sentinel Laboratory Guidelines for Suspected Agents of Bioterrorism, Packing and Shipping Diagnostic and Clinical Specimens, Infectious Substances, and Biological Agents*, American Society for Microbiology, 2005.

^b Packing instructions for biological substances, Category B.

^c Packing instructions for category A infectious substances.

^d —, requirement not specified by IATA or DOT.

^e Not required for solid substances such as tissue and solid agar media cultures or slants.

Table 26.8 Changes in IATA requirements effective 2 June 2006 (relevant for parasitology)^a

1. *Culture* and *patient specimen* have been defined, and the definitions are user-friendly. The term *laboratory culture* is no longer used.
2. Packing instructions for patient specimens have been provided.
3. Classification of infectious substances according to risk groups has been replaced by classification of substances into either category A substance, category B substance, exempt human or animal specimen, exempt substance, and patient specimen.
4. Packing directions for exempt human or animal specimen have been provided.
5. The technical name of a substance packed according to PI 602 is no longer required after the proper shipping name marking on the outer package. For example, a package labeled “Infectious Substance, Affecting Humans (Hepatitis C Virus)” is now labeled “Infectious Substance, Affecting Humans.” The technical name is still required on Shipper’s Declarations.
6. Packing Instruction 650: The proper shipping name of category B substances may now be designated Diagnostic Specimen, Clinical Specimen, or Biological Substance, Category B. Beginning 1 January 2007, only Biological Substance, Category B, will be acceptable.
7. Packing Instruction 650: Quantity limits have been revised to allow up to 1 liter of liquid per primary container.
8. Packing Instruction 650: now mandates use of rigid outer containers.
9. Packing Instruction 650: Packages must be marked with a diamond symbol which contains “UN3373,” and a “Diagnostic Specimen” marking adjacent to the diamond.
10. Packing Instruction 650: If an air waybill is used, the “Nature and Quantity of Goods” box must indicate the text “Diagnostic Specimen,” “Clinical Specimen,” or “Biological Substance, Category B,” and the indication “UN 3373.”
11. The “Prior arrangements as required...” statement in the Additional Handling Information section of the Shipper’s Declaration is no longer required.
12. The requirement for an “air eligibility” label or marking (airplane symbol inside of a circle) has been replaced by the following certification statement on the Shipper’s Declaration: “I declare that all of the applicable air transport requirements have been met.”
13. Overpacks must now be labeled “Overpack” instead of “Inner Packages Comply...”
14. “Biological Substance, Category B” has been added to the IATA list of proper shipping names. Beginning 1 January 2007, this proper shipping name will replace “Clinical Specimen” and “Diagnostic Specimen.”
15. Some hazardous materials (e.g. 10% formalin) used as a preservative are exempt from regulations if the quantity is ≤30 ml per primary container.
16. Persons who pack and ship select agents and toxins and category A agents should receive security training commensurate with their responsibilities.

Macroscopic and Microscopic Examination of Fecal Specimens

Macroscopic examination

Microscopic examination (ova and parasite examination)

Direct wet smear

Concentration (sedimentation and flotation)

- Formalin-ethyl acetate sedimentation concentration
- Iodine-trichrome stain for sediment
- Zinc sulfate flotation concentration
- Commercial fecal concentration devices
- Automated workstation for the microscopic analysis of fecal concentrates

Permanent stained smear

- Preparation of material for staining
- Trichrome stain
- Iron hematoxylin stain
- Modified iron hematoxylin stain (incorporating the carbol fuchsin step)
- Polychrome IV stain
- Chlorazol black E stain

Specialized stains for coccidia (*Cryptosporidium*, *Iso spor a*, and *Cyclo spor a* species) and the microsporidia

Modified Kinyoun's acid-fast stain (cold method)

Modified Ziehl-Neelsen acid-fast stain (hot method)

Carbol fuchsin negative stain for *Cryptosporidium* (from W. L. Current)

Rapid safranin method for *Cryptosporidium*

Rapid safranin method for *Cyclo spor a*, using a microwave oven

Auramine O stain for coccidia (from Thomas Hänscheid)

Modified trichrome stain for the microsporidia (Weber—green)

Modified trichrome stain for the microsporidia (Ryan—blue)

Modified trichrome stain for the microsporidia (Kokoskin—hot method)

Acid-fast trichrome stain for *Cryptosporidium* and the microsporidia

Macroscopic Examination

If the consistency of a stool specimen can be determined (formed, soft, or liquid), this information may give an indication of the organism stages that might be present. Trophozoites (potentially motile forms) of the intestinal protozoa are usually found in liquid specimens; both trophozoites and cysts might be found in a soft specimen; and the cyst forms are usually found in formed specimens. However, there are always exceptions to these general statements. Coccidian oocysts and microsporidian spores can be found in any type of fecal specimen; in the case of *Cryptosporidium* spp., the more liquid the stool, the more oocysts that are found in the specimen. Helminth eggs may be found in any type of specimen, although the chances of finding eggs in a liquid stool are reduced by the dilution factor. Tapeworm proglottids may be found on or beneath the stool on the bottom of the collection container. Adult pinworms and *Ascaris lumbricoides* are occasionally found on the surface or in the stool.

The presence of blood in or on the specimen may indicate several things and should always be reported. Dark stools may indicate bleeding high in the gastrointestinal tract, and fresh (bright red) blood most often is the result of bleeding at a lower level. In certain parasitic infections, blood and mucus may be present. Soft or liquid stool accompanied by blood is more suggestive of an amebic infection; these areas of blood and mucus should be carefully examined for the presence of trophic amebae. *Occult blood in the stool may or may not be related to a parasitic infection and could result from a number of different conditions.* Ingestion of various compounds may give a distinctive color to the stool (iron, black; barium, light tan to white).

Many laboratories prefer that stool specimens be submitted in some type of preservative. Rapid fixation of the specimen immediately after passage (by the patient) provides an advantage in terms of recovery and identification of intestinal protozoa. This advantage (preservation of organisms before distortion or disintegration) is thought to outweigh the limited motility information that might be gained by examining fresh specimens as direct wet mounts. Other laboratories still request a collection system that includes both a preserved specimen and the remainder of the fresh stool. Certainly cost is a factor, because several vials in the collection system cost more than a single vial containing preservative. Each laboratory will have to decide for itself, often basing the decision on the types of procedures ordered by the physicians who use the

laboratory service, the test method selected (traditional methods, new immunoassay detection kits, or both), and the lag time between specimen collection and submission to the laboratory.

With increased emphasis on continuous quality improvement, managed-care contracts, cost containment, and the clinical relevance of diagnostic test results generated, compliance with specimen acceptance or rejection criteria has become more important and a necessary part of overall quality performance. *The generation of patient data begins with the quality of the specimen; anything that is done to compromise that quality should not be acceptable within the laboratory setting.*

If the specimen has not been preserved immediately after passage, it is important to know the age of the specimen when it reaches the laboratory. Freshly passed specimens are necessary for the detection of trophic amebae, flagellates, and ciliates. Liquid specimens must be examined within 30 min of passage (not 30 min from the time the specimen reaches the laboratory or is clocked in by the computer). Soft specimens should be examined within 1 h of passage. Immediate examination of a formed specimen is not as critical; however, if the stool cannot be examined on the day of collection, portions of the specimen should be preserved. In a routine laboratory setting, these time frames are often neither practical nor possible. Thus, the routine use of stool preservatives for diagnostic parasitology is highly recommended.

Microscopic Examination (Ova and Parasite Examination)

The microscopic examination of the stool specimen, normally called the ova and parasite examination, consists of three separate techniques: the direct wet smear, the concentration, and the permanent stained smear. Each of these methods is designed for a particular purpose and forms an integral part of the total examination (2, 3, 5, 8, 10, 14, 15, 22, 23, 25, 26, 30–32, 34, 37, 39–43, 46; J. Palmer, Letter, *Clin. Microbiol. Newsl.* 13:39–40, 1991). With increased emphasis on proper specimen collection and cost containment, the approach to the ova and parasite examination has changed somewhat during the last few years. Many laboratories are requesting that all fecal specimens be collected in preservatives prior to delivery to the laboratory to decrease the lag time between specimen passage and fixation, thus providing better organism morphology and subsequent identification.

Because preserved organisms do not exhibit motility, the direct wet smear is no longer considered a mandatory part of the routine ova and parasite examination. However, if fresh fecal specimens are delivered to the laboratory, the direct wet smear, particularly on liquid or very soft stools, should be performed.

In addition to normal specimen debris, the microscopic examination of fecal material may reveal the following:

1. Trophozoites and cysts of intestinal protozoa
2. Oocysts of coccidia and spores of microsporidia
3. Helminth eggs and larvae
4. Red blood cells (RBCs), which may indicate ulceration or other hemorrhagic problems
5. White blood cells (WBCs), specifically polymorphonuclear leukocytes (PMNs), which may indicate inflammation
6. Eosinophils, which usually indicate the presence of an immune response (which may or may not be related to a parasitic infection)
7. Macrophages, which may be present in bacterial or parasitic infections
8. Charcot-Leyden crystals, which may be found when disintegrating eosinophils are present (and may or may not be related to a parasitic infection)
9. Fungi (*Candida* spp.) and other yeasts and yeast-like fungi
10. Plant cells, pollen grains, or fungal spores, which may simulate some helminth eggs, protozoan cysts, coccidian oocysts, or microsporidial spores
11. Plant fibers or root or animal hairs, which may simulate helminth larvae

Direct Wet Smear

Normal mixing in the intestinal tract usually ensures an even distribution of organisms. However, depending on the level of infection, examination of the fecal material as a direct smear may or may not reveal organisms. The direct wet smear is prepared by mixing a small amount of stool (about 2 mg) with a drop of 0.85% NaCl; this mixture provides a uniform suspension under a 22- by 22-mm coverslip. Some workers prefer a 1.5- by 3-in. (1 in. = 2.54 cm) slide for the wet preparations rather than the standard 1- by 3-in. slide, which is routinely used for the permanent stained smear. A 2-mg sample of stool forms a low cone on the end of a wooden applicator stick. If more material is used for the direct mount, the suspension is usually too thick for an accurate examination; any sample of less than 2 mg results in the examination of too thin a suspension, thus decreasing the chances of finding organisms. If present, blood or mucus should always be examined as a direct mount. The entire 22- by 22-mm coverslip should be systematically examined with the low-power objective (10 \times) and low light intensity (Figure

27.1); any suspicious objects may then be examined with the high dry objective (40×). Use of an oil immersion objective (100×) on mounts of this kind is not routinely recommended unless the coverslip is sealed to the slide (a no. 1 thickness coverslip is recommended for oil immersion). For a temporary seal, a cotton-tipped applicator stick dipped in equal parts of heated paraffin and petroleum jelly should be used. Nail polish can also be used to seal the coverslip. *Many workers think that the use of the oil immersion objective on this type of preparation is impractical, especially since morphological detail is more readily seen by oil immersion examination of the permanent stained smear.* This is particularly true in a busy clinical laboratory situation.

The direct wet mount is used primarily to detect motile protozoan trophozoites. These organisms are very pale and transparent, two characteristics that require the use of low light intensity. Protozoan organisms in a saline preparation usually appear as refractile objects. If suspicious objects are seen on high dry power, at least 15 s should be allowed to detect motility of slowly moving protozoa. Application of heat by placing a hot penny on the edge of a slide may enhance the motility of trophic protozoa. Tapping on the coverslip can also stimulate the fluid to move; objects will roll over, thus providing a better view of the parasite or artifact. Helminth eggs and/or larvae, protozoan cysts, and coccidian oocysts may also be seen on the wet film, although these forms are more likely to be detected after fecal concentration procedures (Figure 27.2).

After the wet preparation has been thoroughly checked for trophic amebae, a drop of iodine can be placed at the edge of the coverslip or a new wet mount can be prepared with iodine alone (Figure 27.3). A weak iodine solution is recommended; too strong a solution may obscure the organisms. Several types of iodine are available; Lugol's and D'Antoni's are discussed here. Gram's iodine, used in bacterial work, is not recommended for staining parasitic organisms.

Figure 27.1 Method of scanning direct wet film preparation with a 10× objective. Note that the entire coverslip preparation should be examined before indicating the examination is negative. (Illustration by Nobuko Kitamura.)

If preserved specimens are submitted to the laboratory, it is more cost-effective and clinically relevant to omit the direct smear and begin the stool examination with the concentration procedure, particularly since motile protozoa are not viable because of the prior addition of preservative. Even if parasites are seen on a direct mount of preserved stool, they would almost certainly be seen on the concentration examination as well as on the permanent stained smear (protozoa in particular). With few exceptions, intestinal protozoa should never be identified on the basis of a wet mount alone; permanent stained smears should be examined to confirm the specific identification of suspected organisms.

Saline (0.85% NaCl)

NaCl.....	0.85 g
Distilled water	100.0 ml

1. Dissolve the NaCl in distilled water in a flask or bottle, using a magnetic stirrer.
2. Distribute 10 ml into each of 10 screw-cap tubes.
3. Label as 0.85% NaCl with an expiration date of 1 year.
4. Sterilize by autoclaving at 121°C for 15 min.
5. When cool, store at 4°C.

D'Antoni's Iodine

Potassium iodide.....	1.0 g
Powdered iodine crystals.	1.5 g
Distilled water	100.0 ml

1. Dissolve the potassium iodide and iodine crystals in distilled water in a flask or bottle, using a magnetic stirrer.
2. The potassium iodide solution should be saturated with iodine, with some excess crystals left on the bottom of the bottle.
3. Store in a brown, glass-stoppered bottle at room temperature and in the dark.
4. This stock solution is ready for immediate use. Label as D'Antoni's iodine with an expiration date of 1 year (the stock solution remains good as long as an excess of iodine crystals remains on the bottom of the bottle).
5. Aliquot some of the iodine into a brown dropper bottle. The working solution should have a strong-tea color and should be discarded when the color lightens (usually within 10 to 14 days).

Note The stock and working solution formulas are identical, but the stock solution is held in the dark and will retain the strong-tea color while the working solution will fade and have to be periodically replaced (Figure 27.4).

Lugol's Iodine

Potassium iodide..... 10.0 g
 Powdered iodine crystals 5 g
 Distilled water 100.0 ml

1. Follow the directions listed above for D'Antoni's iodine, including the expiration date of 1 year.
2. Dilute a portion 1:5 with distilled water for routine use (working solution).
3. Place this working solution into a brown dropper bottle. The working solution should have a strong-tea color and should be discarded when the color lightens (usually within 10 to 14 days).

Nair's Buffered Methylene Blue Stain for Trophozoites (Direct Smear)

Although not commonly used, Nair's buffered methylene blue stain is effective in showing nuclear detail in the trophozoite stages when used at a low pH; a pH range of 3.6 to 4.8 allows more active penetration of dye into the organism (35). After 5 to 10 min, the cytoplasm is stained a pale blue, with the nuclei being a darker blue; the slide should be examined within 30 min. Methylene blue (0.06% in an acetate buffer at pH 3.6) usually gives satisfactory results.

Acetate Buffer Solution Stock Solution A (0.2 M)

Acetic acid (CH₃COOH)..... 11.55 ml
 Distilled water..... 1,000.0 ml

Acetate Buffer Solution Stock Solution B (0.2 M)

Sodium acetate (NaC₂H₃O₂) ... 16.4 g
 or
 Sodium acetate
 (NaC₂H₃O₂ · 3H₂O) 27.2 g
 Distilled water..... 1,000.0 ml

Mix the quantity of stock solutions A and B shown in the table on the following page and dilute with distilled water to a total of 100 ml.

Figure 27.2 Direct wet smear with saline. (Top row) *Giardia lamblia* trophozoite (left), *G. lamblia* cyst (right); (second row) *Entamoeba* sp. (probably *E. coli*) (left), *Blastocystis hominis* central body form (right); (third row) *Entamoeba hartmanni* trophozoite (left), *E. hartmanni* cyst (right); (fourth row) *Isospora belli* immature oocyst (left), *Iodamoeba bütschlii* cyst (right); (bottom row) *Balantidium coli* cyst (left), *Chilomastix mesnili* cyst (right).

Desired pH	Stock solution A (ml)	Stock solution B (ml)
3.6	46.3	3.7
3.8	44.0	6.0
4.0	41.0	9.0
4.2	36.8	13.2
4.4	30.5	19.5
4.6	25.5	24.5

Figure 27.3 Direct wet smear with saline and iodine. (Top) *Entamoeba coli* cyst with iodine; (middle) *E. coli* cyst with saline (left), *E. coli* cyst with iodine added (right); (bottom) *Iodamoeba bütschlii* cysts with iodine. Note that more detail can be seen once the iodine is added to the wet mount. Also, when iodine is used, the glycogen vacuole stains dark (brownish gold to brown) in the *Iodamoeba* cysts and is clearly visible.

Figure 27.4 Commercially prepared D'Antoni's iodine; most commercial suppliers can provide this iodine solution.

Quality Control for Direct Smear

1. Check the working iodine solution each time it is used or periodically (once a week). The iodine and Nair's methylene blue solutions should be free of any signs of bacterial or fungal contamination.
2. The iodine should be the color of strong tea (discard if it is too light).
3. Protozoan cysts stained with iodine should contain yellow-gold cytoplasm, brown glycogen material, and paler refractile nuclei. The chromatoidal bodies may not be as clearly visible as they are in a saline mount. Human white blood cells (buffy coat cells) mixed with negative stool can be used as a quality control (QC) specimen. These human cells, when mixed with negative stool, mimic protozoan parasites. The human cells stain with the same color as that seen in the protozoa.
4. Protozoan trophozoite cytoplasm should stain pale blue and the nuclei should stain a darker blue with the methylene blue stain. Human WBCs mixed with negative stool should stain the same colors as seen with the protozoa.

- The microscope should be calibrated (within the last 12 months), and the original optics used for the calibration should be in place on the microscope when objects are measured. Some microbiologists feel that calibration is not required on a yearly basis; however, if the microscope receives heavy use, is in a position where it can be bumped, or does not receive routine maintenance, yearly calibration is recommended. The calibration factors for all objectives should be posted on the microscope or close by for easy access.
- All QC results should be appropriately recorded; the laboratory should also have an action plan for “out-of-control” results.

Procedure for Direct Wet Smear

- Place 1 drop of 0.85% NaCl on the left side of the slide and 1 drop of iodine (working solution) on the right side of the slide. If preferred, two slides can be used instead of one. One drop of Nair’s methylene blue can also be placed on a separate slide, although this technique is less common.
 - Take a small amount of fecal specimen (the amount picked up on the end of an applicator stick when introduced into the specimen), and thoroughly emulsify the stool in the saline and iodine preparations (use separate sticks for each).
 - Place a 22-mm coverslip (no. 1) on each suspension.
 - Systematically scan both suspensions with the 10× objective. The entire coverslip area should be examined under low power (total magnification, ×100).
 - If something suspicious is seen, the 40× objective can be used for more detailed study. At least one-third of the coverslip should be examined under high dry power (total magnification, ×400), even if nothing suspicious has been seen.
 - Another approach is to prepare and examine the saline mount and then add iodine at the side of the coverslip. The iodine will diffuse into the stool-saline mixture, providing some stain for a second examination. Remember, the iodine will kill any organisms present; thus, no motility will be seen after the iodine is added to the preparation.
- oocysts are often confirmed using autofluorescence or the modified acid-fast stain. Spores of the microsporidia are too small, and the shape resembles other debris within the stool; therefore, they are not readily visible in a direct smear.
- Motile trophozoites and protozoan cysts may or may not be identified to the species level (depending on the clarity of the morphology) and should be confirmed using the permanent stained smear.
Examples: *Giardia lamblia* trophozoites
Entamoeba coli cysts
 - Helminth eggs and/or larvae may be identified.
Examples: *Ascaris lumbricoides* eggs
Strongyloides stercoralis larvae
 - Isospora belli* oocysts may be identified; however, *Cyclospora* and *Cryptosporidium* oocysts are generally too small to be recognized or identified without subsequent immunoassays or modified acid-fast staining.
Example: *Isospora belli* oocysts
 - Artifacts and/or other structures may also be seen and reported as follows.
Note These crystals and cells are quantitated; however, the quantity is usually assessed when the permanent stained smear is examined under oil immersion.
Examples: Moderate Charcot-Leyden crystals
Few RBCs
Moderate PMNs

Procedure Notes for Direct Wet Smear

Results and Patient Reports from Direct Wet Smear

Protozoan trophozoites and/or cysts and helminth eggs and larvae may be seen and identified. In a heavy infection with *Cryptosporidium* spp., *Cyclospora cayetanensis*, or *Isospora belli*, oocysts may be seen in a direct smear; however, some type of modified acid-fast stain or fecal immunoassay is normally used to detect *Cryptosporidium* spp., particularly when few oocysts are present. *Cyclospora*

- In preserved specimens, the formalin replaces the saline and can be used as a direct smear; however, no organism motility will be visible (organisms are killed by 5 or 10% formalin). Consequently, the direct wet smear is usually not performed when the specimen (already preserved) arrives in the laboratory. *The technical time is better spent performing the concentration and permanent stained smear. This approach is recommended for specimens submitted to the laboratory in preservative (3).*
- As mentioned above, some workers prefer to make the saline and iodine mounts on separate slides and on 2- by 3-in. slides. Often, there is less chance of getting fluids on the microscope stage if separate slides (less total fluid on the slide and under the coverslip) or larger slides are used. Selection of slide size depends on the personal preference of laboratory personnel.
- The microscope light should be reduced for low-power observations, since most organisms are overlooked with bright light due to limited contrast

of the internal morphology. This is particularly true when the preparation is being examined without the use of iodine. Illumination should be regulated so that some of the cellular elements in the feces show refraction. Most protozoan cysts and some coccidian oocysts are refractile under these light conditions.

Procedure Limitations for Direct Wet Smear

1. As mentioned above, because motility is lost when specimens are placed in preservatives, many laboratories are no longer performing the direct wet smear (the primary purpose is to see motility) but are proceeding directly to the concentration and permanent stained smear procedures as a better, more cost-effective use of personnel time, as well as a more clinically relevant approach.
2. Most of the time, results obtained from wet smear examinations should be confirmed by permanent stained smears. Some protozoa are very small and difficult to identify to the species level using just the direct wet smear technique. Confirmation is particularly important for *Entamoeba histolytica*/*E. dispar* versus *Entamoeba coli*. Findings from the direct wet smear examination can be reported as “preliminary, based on the direct wet mount examination only,” and the final report can be submitted after the concentration and permanent stain procedures are completed. However, if the labora-

tory turnaround time is less than 24 h, there is no need to send out a preliminary report; the final report can be submitted once the complete ova and parasite examination has been performed.

Concentration (Sedimentation and Flotation)

Fecal concentration has become a routine procedure as a part of the complete ova and parasite examination for parasites; it allows the detection of small numbers of organisms that may be missed by using only a direct wet smear (26, 43). There are two types of concentration procedures, sedimentation and flotation, both of which are designed to separate protozoan organisms and helminth eggs and larvae from fecal debris by centrifugation and/or differences in specific gravity (Figure 27.5) (3, 8).

Sedimentation methods (by centrifugation) lead to the recovery of all protozoa, oocysts, eggs, and larvae present; however, the concentration sediment that will be examined contains more debris. Although some workers recommend using both flotation and sedimentation procedures for every stool specimen submitted for examination, this approach is impractical for most laboratories. If one technique is selected for routine use, the sedimentation procedure is recommended as being the easiest to perform and the least subject to technical error (Figure 27.6).

A flotation procedure permits the separation of protozoan cysts, coccidian oocysts, and certain helminth eggs and larvae through the use of a liquid with a high specific

REVIEW Direct Smear	
Topic	Comments
Principle	To assess worm burden of patient, to provide quick diagnosis of heavily infected specimen, to check organism motility, and to diagnose organisms that might not be seen from concentration or permanent stain methods.
Specimen	Any fresh stool specimen that has not been refrigerated (liquid or soft stool).
Reagents	0.85% NaCl; Lugol's or D'Antoni's iodine; Nair's methylene blue can be used for trophozoites (not common).
Examination	Low-power examination ($\times 100$) of entire 22- by 22-mm coverslip preparation (both saline and iodine); high dry power examination ($\times 400$) of at least one-third of the coverslip area (both saline and iodine).
Results and Laboratory Reports	Results from the direct smear examination should often be considered presumptive; however, some organisms could be definitively identified (<i>Giardia lamblia</i> cysts and <i>Entamoeba coli</i> cysts, helminth eggs and larvae, <i>Isospora belli</i> oocysts). These reports should be categorized as “preliminary,” while the final report would be available after the results of the concentration and permanent stained smear were available. However, if the testing turnaround time is <24 h, it is best to report the test results after the ova and parasite examination (fresh specimen, direct wet smear; concentration, permanent stained smear) is complete.
Procedure Notes and Limitations	Once iodine is added to the preparation, the organisms are killed and motility is lost. Specimens that arrive in the laboratory already preserved do not require a direct smear examination; the concentration and permanent stained smear should be performed instead. Direct smears are normally examined at low ($\times 100$) and high dry ($\times 400$) power; oil immersion examination ($\times 1,000$) is not recommended (organism morphology not that clear).

Figure 27.5 Fecal concentration procedures: various layers seen in tubes after centrifugation. (A) Formalin-ether (or ethyl acetate). The sediment should be well mixed, and a drop of sediment should be examined using the 10 \times low-power objective and the 40 \times high dry power objective. (B) Zinc sulfate (the surface film should be within 2 to 3 mm of the tube rim). Material from both the surface film and the sediment must be examined before the specimen is indicated as negative. Heavy or operculated helminth eggs do not float. (Illustration by Nobuko Kitamura.)

gravity. The parasitic elements are recovered in the surface film, and the debris remains in the bottom of the tube. This technique yields a cleaner preparation than does the sedimentation procedure; however, some helminth eggs (operculated eggs and/or very dense eggs such as unfertilized *Ascaris* eggs) do not concentrate well in the flotation method (Figure 27.7). The specific gravity may be increased, although this may produce more distortion in the eggs and protozoa. Laboratories that use only flotation procedures may fail to recover all of the parasites present; to ensure detection of all organisms in the sample, both the surface film and the sediment should be carefully

Figure 27.6 Sedimentation concentration. (Left) Unfertilized *Ascaris lumbricoides* egg. (Right) *Hymenolepis diminuta* egg.

examined. Directions for any flotation technique must be followed exactly to produce reliable results.

Formalin-Ethyl Acetate Sedimentation Concentration

By centrifugation, the formalin-ethyl acetate sedimentation concentration procedure leads to the recovery of all protozoa, eggs, and larvae present; however, the preparation contains more debris than is found in the flotation procedure. Ethyl acetate is used as an extractor of debris and fat from the feces and leaves the parasites at the bottom of the suspension in the sediment. The formalin-ethyl acetate sedimentation concentration procedure is recommended as being the easiest to perform, allowing recovery of the broadest range of organisms, and being the least subject to technical error.

Figure 27.7 Flotation concentration. (Upper) *Fasciolopsis buski* egg (left), *Diphyllobothrium latum* egg (right). Note that both of these eggs in the top row are operculated and do not float in the zinc sulfate flotation concentration method; the opercula pop open, and the eggs fill with fluid and sink to the bottom of the tube. (Lower) Hookworm egg (left), *Trichuris trichiura* egg (right). These eggs concentrate using the flotation method and can be seen in the surface film. However, remember that both the surface film and the sediment must be examined by this method before reporting the final ova and parasite examination results.

The specimen must be fresh or formalinized stool (5 or 10% buffered or nonbuffered formalin or sodium acetate-acetic acid-formalin [SAF]). Many of the single-vial preservative systems are also acceptable; however, the formulas are proprietary (e.g., UNIFIX; Medical Chemical Corp., Torrance, Calif.). Polyvinyl alcohol (PVA)-preserved specimens can also be used. However, PVA preservative formulations are rarely used for concentration methods in most laboratories but are highly recommended for the preparation of permanent stained smears.

5 or 10% Formalin

Formaldehyde (USP)

..... 100 ml (for 10%) or

..... 50 ml (for 5%)

Saline solution..... 900 ml (for 10%) or

0.85% NaCl 950 ml (for 5%)

Note Formaldehyde is normally purchased as a 37 to 40% HCHO solution; however, for dilution, it should be considered to be 100%.

Dilute 100 ml of formaldehyde with 900 ml of 0.85% NaCl solution. (Distilled water may be used instead of saline solution.)

Quality Control for Sedimentation Concentration

1. Check the liquid reagents each time they are used; the formalin and saline should appear clear, without any visible contamination.
2. The microscope should be calibrated (within the last 12 months), and the objectives and oculars used for the calibration procedure should be in place on the microscope when objects are measured. The calibration factors for all objectives should be posted on the microscope or close by for easy access. Some researchers feel that a microscope does not require calibration every 12 months; however, if the microscope is moved periodically, can be easily bumped, or does not receive adequate maintenance, it should be rechecked yearly for calibration accuracy.
3. Known positive specimens should be concentrated and organism recovery should be verified at least quarterly and particularly after the centrifuge has been recalibrated. Human WBCs (buffy coat cells) mixed with negative stool can be used as a QC specimen. These human cells, when mixed with negative stool, can mimic protozoan parasites. The human cells concentrate just like human parasites such as protozoa and helminth eggs and larvae.
4. All QC results should be appropriately recorded; the laboratory should also have an action plan for "out-of-control" results.

Procedure for Sedimentation Concentration

1. Transfer 1/2 teaspoon (about 4 g) of fresh stool into 10 ml of 5 or 10% formalin in a shell vial, unwaxed paper cup, or round-bottom tube (the container may be modified to suit individual laboratory preferences). Mix the stool and formalin thoroughly, and let the mixture stand for a minimum of 30 min for fixation. If the specimen is already in 5 or 10% formalin (or SAF or other non-PVA single-vial preservatives), stir the stool-preservative mixture.
2. Depending on the amount and viscosity of the specimen, strain a sufficient quantity through wet gauze (no more than two layers of gauze or one layer if the new "pressed" gauze [e.g., Johnson & Johnson nonsterile three-ply gauze, product 7636] is used) into a conical 15-ml centrifuge tube to give the desired amount of sediment (0.5 to 1 ml) for step 3 below. Usually, 8 ml of the stool-formalin mixture prepared in step 1 is sufficient. If the specimen is received in a vial of preservative (5 or 10% formalin, SAF, or other single-vial preservatives), approximately 3 to 4 ml of the preservative-stool mixture is sufficient for testing. If the vial contains very little specimen, then the entire amount may be used in the procedure. *If the specimen contains a lot of mucus, do not strain through gauze but immediately fix in 5 or 10% formalin for 30 min and centrifuge for 10 min at 500 × g. Proceed directly to step 10.*
3. Add 0.85% NaCl or 5 or 10% formalin (some workers prefer to use formalin for all rinses) almost to the top of the tube, and centrifuge for 10 min at 500 × g. The amount of sediment obtained should be approximately 0.5 to 1 ml.
4. Decant and discard the supernatant fluid, and resuspend the sediment in saline or formalin; add saline or formalin almost to the top of the tube, and centrifuge again for 10 min at 500 × g. This second wash may be eliminated if the supernatant fluid after the first wash is light tan or clear. Some prefer to limit the washing to one step (regardless of the clarity or color of the supernatant fluid after centrifugation) to eliminate additional manipulation of the specimen prior to centrifugation. The more the specimen is manipulated and/or rinsed, the more likely it is that some organisms will be lost and accidentally discarded prior to examination.
5. Decant and discard the supernatant fluid, and resuspend the sediment on the bottom of the tube in 5 or 10% formalin. Fill the tube half full only. If the amount of sediment left in the bottom of

the tube is very small or the original specimen contained a lot of mucus, do not add ethyl acetate in step 6; merely add the formalin, spin, decant, and examine the remaining sediment.

6. Add 4 to 5 ml of ethyl acetate. Stopper the tube, and shake it vigorously for at least 30 s. Hold the tube so that the stopper is directed away from your face.
7. After a 15- to 30-s wait, carefully remove the stopper.
8. Centrifuge for 10 min at $500 \times g$. Four layers should result: a small amount of sediment (containing the parasites) in the bottom of the tube; a layer of formalin; a plug of fecal debris on top of the formalin layer; and a layer of ethyl acetate at the top.
9. Free the plug of debris by ringing the plug with an applicator stick; decant and discard all of the supernatant fluid. After proper decanting, a drop or two of fluid remaining on the side of the tube may run down into the sediment. Mix this fluid with the sediment.
10. If the sediment is still somewhat solid, add 1 or 2 drops of saline or formalin to the sediment, mix, add a small amount of material to a slide, add a coverslip (22 by 22 mm, no. 1), and examine.
11. Systematically scan with the $10\times$ objective. The entire coverslip area should be examined under low power (total magnification, $\times 100$).
12. If something suspicious is seen, the $40\times$ objective can be used for more detailed study. At least one-third of the coverslip should be examined under high dry power (total magnification, $\times 400$), even if nothing suspicious has been seen. As in the direct wet smear, iodine can be added to enhance morphological detail, and the coverslip can be tapped to see objects move and turn over.

Results and Patient Reports from Sedimentation Concentration

Protozoan trophozoites and/or cysts and helminth eggs and larvae may be seen and identified. Protozoan trophozoites are less likely to be seen. In a heavy infection with *Cryptosporidium* spp. or *C. cayetanensis*, oocysts may be seen in the concentrate sediment; oocysts of *I. belli* can also be seen. Spores of the microsporidia are too small, and the shape resembles that of other debris within the stool; therefore, they are not readily visible in the concentration sediment.

1. Protozoan cysts may or may not be identified to the species level (depending on the clarity of the morphology).

Examples: *Entamoeba coli* cysts
Giardia lamblia cysts

2. Helminth eggs and/or larvae may be identified.

Examples: *Ascaris lumbricoides* eggs
Hookworm larvae

3. *I. belli* oocysts may be identified; however, *Cyclospora* and *Cryptosporidium* oocysts are generally too small to be recognized or identified by subsequent immunoassays or modified acid-fast staining.

Example: *Isospora belli* oocysts

4. Artifacts and/or other structures may also be seen and reported as follows.

Note These crystals and cells are quantitated; however, the quantity is usually assessed when the permanent stained smear is examined under oil immersion).

Examples: Moderate Charcot-Leyden crystals
Few RBCs
Moderate PMNs

Procedure Notes for Sedimentation Concentration

1. The gauze should never be more than one (pressed gauze) or two (woven gauze) layers thick; more gauze may trap mucus (containing *Cryptosporidium* oocysts and/or microsporidial spores).
2. Tap water may be substituted for 0.85% NaCl throughout this procedure, although the addition of water to fresh stool causes *Blastocystis hominis* cyst (central body) forms to rupture and is not recommended. In addition to the original 5 or 10% formalin fixation, some workers prefer to use 5 or 10% formalin for all rinses throughout the procedure.
3. Ethyl acetate is widely recommended as a substitute for ether (37). It can be used in the same way in the procedure and is much safer. Hemo-De can also be used and is thought to be safer than ethyl acetate (35).
 - A. After the plug of debris is rimmed and excess fluid is decanted, *the sides of the tube can be swabbed with a cotton-tipped applicator stick while the tube is still upside down to remove excess ethyl acetate. This is particularly important if you are working with plastic centrifuge tubes or the plastic commercial concentrators.* If the sediment is too dry after the tube has been swabbed, add several drops of saline before preparing the wet smear for examination.

- B. If there is excess ethyl acetate in the smear of the sediment prepared for examination, bubbles will be present, which will obscure the material of interest.
4. If specimens are received in SAF, begin the procedure at step 2.
 5. *If specimens are received in PVA, the first two steps of the procedure should be modified as follows.*
 - A. Immediately after stirring the stool-PVA mixture with applicator sticks, pour approximately half of the mixture into a tube (container optional) and add 0.85% NaCl (or 5 or 10% formalin) almost to the top of the tube.
 - B. Filter the stool-PVA-saline (or formalin) mixture through wet gauze into a 15-ml centrifuge tube. Follow the standard procedure from here to completion, beginning with step 3.
 6. Too much or too little sediment will result in an ineffective concentration sediment examination.
 7. The centrifuge should reach the recommended speed before the centrifugation time is monitored. *However, since most laboratories have their centrifuges on automatic timers, the centrifugation time in this protocol takes into account the fact that some time will be spent coming up to speed prior to full-speed centrifugation. If the centrifugation time at the proper speed (10 min at 500 × g) is reduced, some of the organisms (Cryptosporidium and Cyclospora oocysts or microsporidian spores) may not be recovered in the sediment.*

Procedure Limitations for Sedimentation Concentration

1. Results obtained with wet smears (direct wet smears or concentration sediment wet smears) should usually be confirmed by permanent stained smears. Some protozoa are very small and difficult to identify as to species with just the direct wet smears. Also, special stains are sometimes necessary for organism identification.
 2. Confirmation is particularly important for *E. histolytica*/*E. dispar* versus *E. coli*.
 3. Certain organisms (*G. lamblia*, hookworm eggs, and occasionally *Trichuris* eggs) may not concentrate as well from PVA-preserved specimens as they do from those preserved in formalin. However, if enough *G. lamblia* organisms are present to concentrate from formalin, PVA should contain enough for detection on the permanent stained smear. In clinically important infections, the number of helminth eggs present would ensure detection regardless of the type of preservative used. Also, the morphology of *Strongyloides stercoralis* larvae is not as clear from specimens in PVA as from specimens fixed in formalin.
4. For unknown reasons, *I. belli* oocysts are routinely missed in the concentrate sediment when concentrated from PVA-preserved specimens. The oocysts would be found if the same specimen were preserved in formalin rather than PVA.
 5. In past publications, recommended centrifugation times have not taken into account potential problems with the recovery of *Cryptosporidium* oocysts. **There is anecdotal evidence strongly indicating that *Cryptosporidium* oocysts may be missed unless the centrifugation speed is 500 × g for a minimum of 10 min.**
 6. Adequate centrifugation time and speed have become very important for recovery of microsporidial spores. In some of the earlier publications, use of uncentrifuged material was recommended. **However, we have found that centrifugation for 10 min at 500 × g definitely increases the number of microsporidial spores available for staining and subsequent examination.**

Iodine-Trichrome Stain for Sediment

A combination of Lugol's iodine solution and trichrome stain can be used to stain fecal sediment from the concentration procedure (18). Coloring the eggs and cysts yellow-brown (iodine) and the debris green (trichrome) provides contrast which facilitates the detection of parasites. The use of such an approach usually depends on personal preferences and the results of parallel trials of the current method and new methods being considered. This wet examination can be used as an adjunct procedure *but does not take the place of the unstained wet examination of the sediment.*

Quality Control for Iodine-Trichrome Stain for Sediment

1. Check the working iodine solution each time it is used or periodically (once a week). The iodine and trichrome stain solutions should be free of any signs of bacterial or fungal contamination.
2. The iodine should be the color of strong tea (discard if it is too light).
3. Protozoan cysts stained with iodine should contain yellow-gold cytoplasm, brown glycogen material, and paler refractile nuclei. The chromatoidal bodies may not be as clearly visible as in a saline mount. Human WBCs (buffy coat cells) mixed

with negative stool can be used as a QC specimen. The human cells stain with the same color as that seen in the protozoa. The background debris stains green from the components of the trichrome stain.

- If appropriate due to extensive use and/or lack of routine maintenance, the microscope should be calibrated (within the last 12 months), and the original optics used for the calibration should be in place on the microscope when objects are being measured. The calibration factors for all objectives should be posted on the microscope or close by for easy access.
- All QC results should be appropriately recorded; the laboratory should also have an action plan for “out-of-control” results.

Procedure for Iodine-Trichrome Stain for Sediment

- Place 4 drops of Lugol’s iodine solution into a test tube.
- Place 4 drops of fecal concentrate into the test tube. Mix well.
- Place 2 drops of the Lugol’s iodine solution-fecal concentrate mixture from step 2 on a glass slide.
- Add 1 drop of trichrome stain. Mix with a wooden applicator, and cover with a coverslip (22 by 22 mm, no. 1).
- Microscopically examine the entire preparation under low power ($\times 100$) and at least one-third of the area under high dry power ($\times 400$).

Results and Patient Reports from Iodine-Trichrome Stain for Sediment

Protozoan trophozoites and/or cysts and some helminth eggs and larvae may be seen and identified. Lugol’s iodine stains *A. lumbricoides* and *Taenia* eggs quite dark; these eggs are difficult to recognize and may be mistaken for debris, hence the need for the unstained sediment examination. In a heavy infection with *Cryptosporidium* spp., oocysts may be seen in a direct smear; however, some type of modified acid-fast stain or fecal immunoassay is normally used to detect these organisms, particularly when few oocysts are present. Oocysts of *I. belli* can also be seen in a direct smear. *Cyclospora* oocysts may not be recognized because they resemble debris. Spores of the microsporidia are too small, and the shape resembles that of other debris within the stool; therefore, they are not readily visible in a direct smear.

- Protozoan cysts may or may not be identified to the species level (depending on the clarity of the morphology).
Example: *Iodamoeba bütschlii* cysts

- Helminth eggs and/or larvae may be identified.
Example: *Hymenolepis nana* eggs
- I. belli* oocysts may be identified; however, *Cyclospora* and *Cryptosporidium* oocysts are generally too small to be recognized or identified by subsequent immunoassays or modified acid-fast staining.
Example: *Isospora belli* oocysts
- Artifacts and/or other structures may also be seen and reported as follows.

Note These cells are quantitated; however, the quantity is usually assessed when the permanent stained smear is examined under oil immersion.

Example: Moderate PMNs

Procedure Notes for Iodine-Trichrome Stain for Sediment

- As mentioned above, some workers prefer to make the wet mounts on larger slides. Often, there is less chance of getting fluids on the microscope stage if larger slides are used.
- This stain is darker than the traditional iodine stain. The microscope light should be increased over that used for the unstained wet smear examination.

Procedure Limitations for Iodine-Trichrome Stain for Sediment

- Because this is a darker stain than routine iodine stains, it is important to also examine a saline wet smear. This is particularly important because *A. lumbricoides* and *Taenia* eggs stain too dark with the iodine and may not be recognized as helminth eggs.
- Results obtained with wet smears should usually be confirmed by permanent stained smears. Some protozoa are very small and difficult to identify to the species level with just the direct wet smears. Confirmation is particularly important for *E. histolytica*/*E. dispar* versus *E. coli*. These findings can be reported as “preliminary report, based on direct wet smear examination only,” and the final report can be submitted after the concentration and permanent stain procedures are completed. However, if the examination turnaround time is approximately 24 h or less, there is no need for a preliminary report; the final report can be submitted after completion of the concentration and permanent stained smear examinations.

Zinc Sulfate Flotation Concentration

The flotation procedure permits the separation of protozoan cysts and eggs of certain helminths from excess debris through the use of a liquid (zinc sulfate) with a high specific gravity. The parasitic elements are recovered in the surface film, and the debris and some heavy parasitic elements remain in the bottom of the tube. This technique yields a cleaner preparation than does the sedimentation procedure; however, some helminth eggs (operculated and/or very dense eggs, such as unfertilized *Ascaris* eggs) do not concentrate well in the flotation method; a sedimentation technique is recommended to detect these infections.

When the zinc sulfate solution is prepared, the specific gravity should be 1.18 for fresh stool specimens; it must be checked with a hydrometer. This procedure may be used on formalin-preserved specimens if the specific gravity of the zinc sulfate is increased to 1.20; however, this usually causes more distortion in the organisms present and is not recommended for routine clinical use. **To ensure detection of all possible organisms, both the surface film and the sediment must be examined.** For most laboratories, this is not a practical approach.

The specimen must be fresh or formalinized stool (5 or 10% buffered or nonbuffered formalin, SAF, or other non-PVA single-vial preservatives). PVA-preserved specimens can also be used; however, this approach is not commonly used or recommended.

Zinc Sulfate (33% Aqueous Solution)

Zinc sulfate 330 g
Distilled water 670 ml

1. Dissolve the zinc sulfate in distilled water in an appropriate flask or beaker, using a magnetic stirrer.
2. Adjust the specific gravity to 1.20 by the addition of more zinc sulfate or distilled water. Use a specific gravity of 1.18 with fresh stool (nonformalinized).
3. Store in a glass-stoppered bottle with an expiration date of 24 months.

Quality Control for Flotation Concentration

1. Check the reagents each time they are used. The formalin, saline, and zinc sulfate should appear clear, without any visible contamination.
2. The microscope should be calibrated (within the last 12 months), and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. The calibration factors for all objectives should be posted on the microscope or close by for easy access. As

mentioned above, some workers feel that recalibration of the microscope is not necessary each year; however, this would depend on the use and maintenance of that particular piece of equipment.

3. Known positive specimens should be concentrated and organism recovery should be verified at least quarterly, particularly after the centrifuge has been recalibrated. Human WBCs (buffy coat cells) mixed with negative stool can be used as a QC specimen. These human cells, when mixed with negative stool, mimic human parasites. The human cells concentrate just like human parasites such as protozoa and helminth eggs and larvae.
4. All QC results should be appropriately recorded; the laboratory should also have an action plan for “out-of-control” results.

Procedure for Flotation Concentration

1. Transfer 1/2 teaspoon (about 4 g) of fresh stool into 10 ml of 5 or 10% formalin in a shell vial, unwaxed paper cup, or round-bottom tube (the container may be modified to suit individual laboratory preferences). Mix the stool and formalin thoroughly. Let the mixture stand for a minimum of 30 min for fixation. If the specimen is already in 5 or 10% formalin (or SAF), stir the stool-formalin (or SAF) mixture.
2. Depending on the size and density of the specimen, strain a sufficient quantity through wet gauze (no more than two layers of gauze or one layer if the new “pressed” gauze [e.g., Johnson & Johnson nonsterile three-ply gauze, product 7636] is used) into a conical 15-ml centrifuge tube to give the desired amount of sediment (0.5 to 1 ml) in step 3 below. Usually, 8 ml of the stool-formalin mixture prepared in step 1 is sufficient. If the specimen is received in vials of preservative (5 or 10% formalin, SAF, or other single-vial preservatives), approximately 3 to 4 ml of the mixture is sufficient unless the specimen has very little stool in the vial. *If the specimen contains a lot of mucus, do not strain through gauze but immediately fix in 5 or 10% formalin for 30 min and centrifuge for 10 min at 500 × g. Proceed directly to step 5.*
3. Add 0.85% NaCl almost to the top of the tube, and centrifuge for 10 min at 500 × g. Approximately 0.5 to 1 ml of sediment should be obtained. Too much or too little sediment results in an ineffective concentration examination.
4. Decant and discard the supernatant fluid, resuspend the sediment in 0.85% NaCl almost to the top of the tube, and centrifuge for 10 min at 500

$\times g$. This second wash may be eliminated if the supernatant fluid after the first wash is light tan or clear. Some prefer to limit the washing to one step (regardless of the color and clarity of the supernatant fluid) to eliminate additional manipulation of the specimen prior to centrifugation. The more the specimen is manipulated and/or rinsed, the more likely it is for parasitic elements to be lost.

5. Decant and discard the supernatant fluid, and resuspend the sediment on the bottom of the tube in 1 to 2 ml of zinc sulfate. Fill the tube within 2 to 3 mm of the rim with additional zinc sulfate.
6. Centrifuge for 2 min at $500 \times g$. Allow the centrifuge to come to a stop without interference or vibration. Two layers should result: a small amount of sediment in the bottom of the tube, and a layer of zinc sulfate. The protozoan cysts and some helminth eggs are found in the surface film; some operculated and/or heavy eggs are found in the sediment.
7. Without removing the tube from the centrifuge, remove 1 or 2 drops of the surface film with a Pasteur pipette or a freshly flamed (and allowed to cool) wire loop and place them on a slide. Do not use the loop as a “dipper”; simply touch the surface (bend the loop portion of the wire 90° so that the loop is parallel with the surface of the fluid). Make sure the pipette tip or wire loop is not below the surface film (Figure 27.8).
8. Add a coverslip (22 by 22 mm, no. 1) to the preparation. Iodine may be added to the preparation.
9. Systematically scan with the $10\times$ objective. The entire coverslip area should be examined under low power (total magnification, $\times 100$).
10. If something suspicious is seen, the $40\times$ objective can be used for more detailed study. At least one-third of the coverslip should be examined with high dry power (total magnification, $\times 400$), even if nothing suspicious has been seen. As in the direct wet smear, iodine can be added to enhance

morphological detail, and the coverslip can be gently tapped to observe objects moving and turning over.

Results and Patient Reports from Flotation Concentration

Protozoan trophozoites and/or cysts and some helminth eggs and larvae may be seen and identified. Heavy helminth eggs and operculated eggs do not float in zinc sulfate; they are seen in the sediment within the tube. The high specific gravity of the zinc sulfate causes the opercula to pop open; the eggs fill with fluid and sink to the bottom. Protozoan trophozoites are less likely to be seen. In a heavy infection with *Cryptosporidium* spp. or *C. cayetanensis*, oocysts may be seen in the concentrate sediment; oocysts of *I. belli* can also be seen. Spores of the microsporidia are too small, and the shape resembles other debris within the stool; therefore, they are not readily visible in the concentration sediment.

1. Protozoan cysts may or may not be identified to the species level (depending on the clarity of the morphology).
Example: *Giardia lamblia* cysts
2. Helminth eggs and/or larvae may be identified.
Example: Hookworm eggs
3. *I. belli* oocysts may be identified; however, *Cyclospora* and *Cryptosporidium* oocysts are generally too small to be recognized or identified by subsequent immunoassays or modified acid-fast staining.
Example: *Isospora belli* oocysts
4. Artifacts and/or other structures may also be seen and reported as follows.

Note These cells are quantitated; however, the quantity is usually assessed when the permanent stained smear is examined.

Examples: Few macrophages
Moderate PMNs

Figure 27.8 Method used to remove the surface film in the zinc sulfate flotation concentration procedure. (A) A wire loop is gently placed on (not under) the surface film. (B) The loop is then placed on a glass slide. (Illustration by Nobuko Kitamura.)

Procedure Notes for Flotation Concentration

1. The gauze should never be more than one or two layers thick; more gauze may trap mucus (containing *Cryptosporidium* oocysts, *Cyclospora* oocysts, and/or microsporidial spores). A round-bottom tube is recommended rather than a centrifuge tube.
2. Tap water may be substituted for 0.85% NaCl throughout this procedure, although the addition of water to fresh stool causes *B. hominis* cyst (central body) forms to rupture and is not recommended. In addition to the original 5 or 10% formalin fixation, some workers prefer to use 5 or 10% formalin for all rinses throughout the procedure.
3. If fresh stool is used (nonformalin preservatives), the zinc sulfate should be prepared with a specific gravity of 1.18. If formalinized specimens are to be concentrated, the zinc sulfate should have a specific gravity of 1.20.
4. If specimens are received in SAF or other single-vial preservatives, begin the procedure at step 2.
5. If fresh specimens are received, the standard procedure requires the stool to be rinsed in distilled water prior to the addition of zinc sulfate in step 4. *However, the addition of fresh stool to distilled water will destroy any B. hominis cysts present and is not a recommended approach.*
6. Some workers prefer to remove the tubes from the centrifuge prior to sampling the surface film. This is acceptable; however, there is more chance that the surface film will be disturbed prior to sampling.
7. Some workers prefer to add a small amount of zinc sulfate to the tube so that the fluid forms a slightly convex meniscus. A coverslip is then placed on top of the tube so that the undersurface touches the meniscus. It is left undisturbed for 5 min. The coverslip is then carefully removed and placed on a slide for examination. This approach tends to be somewhat messy, particularly if too much zinc sulfate has been added.
8. When using the hydrometer (solution at room temperature), mix the solution well. Float the hydrometer in the solution, giving it a slight twist to ensure that it is completely free from the sides of the container. Read the bottom meniscus and correct the figure for temperature, if necessary. Most hydrometers are calibrated at 20°C. A difference of 3°C between the solution temperature (room temperature) and the hydrometer calibration temperature requires a correction of 0.001, to be added if above and subtracted if below 20°C.

Procedure Limitations for Flotation Concentration

1. Results obtained with wet smears (direct wet smears or concentrated specimen wet smears) should usually be confirmed by permanent stained smears. Some protozoa are very small and difficult to identify to the species level with just the direct wet smears. Also, special stains are sometimes necessary for organism identification.
2. Confirmation is particularly important for *E. histolytica/E. dispar* versus *E. coli*.
3. Protozoan cysts and thin-shelled helminth eggs are subject to collapse and distortion when left for more than a few minutes in contact with the high-specific-gravity zinc sulfate. The surface film should be removed for examination within 5 min of the time the centrifuge comes to a stop. The longer the organisms are in contact with the zinc sulfate, the more distortion will be seen on microscopic examination of the surface film.
4. *Since most laboratories have their centrifuges on automatic timers, the centrifugation time in this protocol takes into account the fact that some time will be spent coming up to speed prior to full-speed centrifugation.*
5. **If zinc sulfate is the only concentration method used, both the surface film and the sediment should be examined to ensure detection of all possible organisms.**

Commercial Fecal Concentration Devices

There are a number of commercially available fecal concentration devices which may help a laboratory to standardize the concentration technique. Standardization is particularly important when personnel rotate throughout the laboratory and may not be familiar with parasitology techniques. These devices help ensure consistency, thus leading to improved parasite recovery and subsequent identification. Some of the systems are enclosed and provide a clean, odor-free approach to stool processing, features that may be important to nonmicrobiology personnel processing such specimens. Both 15- and 50-ml systems are available. It is important to remember that a maximum of 0.5 to 1.0 ml of sediment is needed in the bottom of the tube. Often, when the 50-ml systems are used, there is too much sediment in the bottom of the tube. This problem can be solved by adding less of the fecal specimen to the concentration system prior to centrifugation. Since the sediment is normally mixed thoroughly and 1 drop is taken to a coverslip for examination, good mixing may not occur if too much sediment is used. There also appears to be layering in the bottom of the tubes; again, adding less material to the concentrator at

the beginning should help eliminate this problem (Figures 27.9 through 27.12).

Automated Workstation for the Microscopic Analysis of Fecal Concentrates

The FE-2 (DiaSys Corp., Waterbury, Conn.) is a countertop workstation that automates the microscopic analysis of fecal concentrates (Figure 27.13). The system automates the aspiration, resuspension, staining or diluting (based on user preference), transfer, presentation, and disposal of fecal concentrates. When the sample button is pressed, within 5 s two samples of fecal concentrate are automatically and simultaneously aspirated from the concentrate tube and transported to the glass dual-flow-cells of the Optical Slide Assembly (Figure 27.14). Based on user preference, the FE-2 also simultaneously stains or dilutes one of the two samples to be examined. After the microscopic examination of the fecal suspension within the glass viewing chambers, the flow chambers can be purged and cleaned and are ready for the next specimen. The dual-flow-cell Optical Slide Assembly is designed to fit within the stage clips of any standard upright microscope. The Optical Slide Assembly accommodates bright-field, phase-contrast, polarized-light, and other common forms of microscopy. The system can be moved from one microscope to another or can be set up as

a semipermanent station for fecal concentrate microscopy. Removal to another microscope just involves removing the Optical Slide Assembly from the microscope stage.

Permanent Stained Smear

The detection and correct identification of many intestinal protozoa frequently depend on the examination of the permanent stained smear with the oil immersion lens (100 \times objective). These slides not only provide the microscopist with a permanent record of protozoan organisms identified but also may be used for consultations with specialists when unusual morphologic characteristics are found. Considering the morphologic variations that are possible, organisms that are very difficult to identify and do not fit the pattern for any one species may be found. A routine work flow diagram including the permanent stained smear is shown in Figure 27.15.

Although an experienced microscopist can occasionally identify certain organisms on a wet preparation, most identifications should be considered tentative until confirmed by the permanent stained slide. The smaller protozoan organisms are frequently seen on the stained smear when they are easily missed with only the direct smear and concentration methods. *For these reasons, the*

REVIEW Concentration	
Topic	Comments
Principle	To concentrate the parasites present, either through sedimentation or by flotation. The concentration is specifically designed to allow recovery of protozoan cysts, coccidian oocysts, microsporidian spores, and helminth eggs and larvae.
Specimen	Any stool specimen that is fresh or preserved in formalin, PVA (mercury- or non-mercury based), SAF, MIF, or the newer single-vial-system fixatives.
Reagents	5% or 10% formalin, ethyl acetate, zinc sulfate (specific gravity, 1.18 for fresh stool and 1.20 for preserved stool); 0.85% NaCl; Lugol's or D'Antoni's iodine.
Examination	Low-power examination ($\times 100$) of entire 22- by 22-mm coverslip preparation (iodine recommended but optional); high dry power examination ($\times 400$) of at least one-third of the coverslip area (both saline and iodine).
Results and Laboratory Reports	Often, results from the concentration examination should be considered presumptive; however, some organisms could be definitively identified (<i>Giardia lamblia</i> cysts and <i>Entamoeba coli</i> cysts, helminth eggs and larvae, <i>Isospora belli</i> oocysts). These reports should be categorized as "preliminary," while the final report would be available after the results of the concentration and permanent stained smear were available. However, if the testing turnaround time is <24 h, it is best to report the test results after the ova and parasite examination (fresh specimen, direct wet smear; concentration, permanent stained smear) is complete.
Procedure Notes and Limitations	Formalin-ethyl acetate sedimentation concentration is the most commonly used. Zinc sulfate flotation does not detect operculated or heavy eggs; both the surface film and sediment must be examined before a negative result is reported. Smears prepared from concentrated stool are normally examined at low ($\times 100$) and high dry ($\times 400$) power; oil immersion examination ($\times 1,000$) is not recommended (organism morphology is not that clear). The addition of too much iodine may obscure helminth eggs (will mimic debris).

Figure 27.9 (Upper) FPC JUMBO large concentration tubes and connector system (Evergreen Scientific). (Lower) Small concentration tubes and FPC HYBRID connector system (Evergreen Scientific).

permanent stain is recommended for every stool sample submitted for a routine parasite examination. It is also important to remember that the fecal immunoassays for specific organisms have proven to be more sensitive than the routine or specialized stains for *Giardia lamblia* or *Cryptosporidium* spp. (16, 33).

There are a number of staining techniques available; selection of a particular method may depend on the degree of difficulty of the procedure and the amount of time necessary to complete the stain. The older classical method is the long Heidenhain iron hematoxylin method; however, for routine diagnostic work, most laboratories select one of the shorter procedures, such as the trichrome method or one of the modified methods involving iron hematoxylin. Other procedures are available (7, 8, 11, 13–15, 18, 20, 22, 31, 39, 42, 47; J. Palmer, Letter, *Clin. Microbiol. Newsl.* 13:39–40, 1991), and some of them are presented here.

Figure 27.10 Stool collection vial and funnel used in fecal concentration (Hardy Diagnostics).

Most problems encountered in the staining of protozoan trophozoites and cysts in fecal smears occur because the specimen is too old, the smears are too dense, the smears are allowed to dry before fixation, or fixation is inadequate. There is variability in fixation in that immature cysts fix more easily than mature cysts, and *E. coli* cysts require a longer fixation time than do those of other species. It is critical that adequate mixing occur between the fecal specimen and preservative (7, 11, 13, 21, 36, 47).

Preparation of Material for Staining

Fresh Material

1. When the specimen arrives, prepare two slides with applicator sticks or brushes and *immediately* (without drying) place them in Schaudinn's fixative. Allow the slides to fix for a minimum of 30 min; overnight fixation is acceptable. The amount of fecal material smeared on the slide should be thin enough that newsprint can be read through the smear. Smears preserved in liquid Schaudinn's fixative should be placed in 70% alcohol to remove the excess fixative prior to placement in

- iodine-alcohol (used for mercury-based fixatives).
- If the fresh specimen is liquid, place 3 or 4 drops of PVA fixative (Schaudinn's fixative to which has been added a plastic powder [PVA], which serves as an adhesive to "glue" the fecal material onto the slide) on the slide, mix several drops of fecal material with the PVA fixative, spread the mixture, and allow it to dry for several hours in a 37°C incubator or overnight at room temperature.
 - Proceed with the trichrome staining procedure by placing the slides in iodine-alcohol.

PVA-Preserved Material

- Stool specimens that are preserved in PVA fixative (mercuric chloride, copper sulfate, or zinc sulfate bases) should be allowed to fix for at least 30 min. Thoroughly mix the contents of the vial or bottle (PVA fixative/stool specimen) with two applicator sticks.
- Pour some of the well-mixed PVA fixative-stool mixture onto a paper towel, and allow it to stand for 3 min to absorb out the excess PVA fixative. *Do not eliminate this step.*
- With an applicator stick (or brush), apply some of the stool material from the paper towel to two slides and allow them to dry for several hours in a 37°C incubator or overnight at room temperature.

Note The PVA fixative-stool mixture should be spread to the edges of the glass slide; this will cause the film to adhere to the slide during staining. It is also important to thoroughly dry the slides in order to prevent the material from washing off during staining.

- The dry slides may then be placed into iodine-alcohol. There is no need to give them a 70% alcohol rinse before placing them in the iodine-alcohol, because the PVA smears are already dry (unlike the wet smears coming out of Schaudinn's fixative). The iodine-alcohol is used to remove the mercuric chloride from the slides before they are stained. When reviewing the trichrome staining procedure, you will note that this step is not required if the stool specimen is preserved in a copper sulfate- or zinc sulfate-based preservative.

Figure 27.11 (Top) PARA-SED concentration system with both small and large tubes (Medical Chemical Corp.). (Middle) SED-CONNECT system with collection vials and various reagents (Medical Chemical Corp.). (Bottom) Filter attachment system (Medical Chemical Corp.). Note the screen, which is a substitute for the gauze in the traditional gauze/filter concentration method. See also MICRO-SED.

California State Department of Health Modification (2) for PVA-Preserved Material

1. Thoroughly mix the PVA-stool mixture, and strain it through damp (with tap water) gauze into 15-ml centrifuge tubes.
2. After centrifugation (2 min at $500 \times g$), decant and discard the PVA fixative and swab the sides of the tubes to remove any excess PVA. Although stains for *Cryptosporidium* spp. are not recommended from PVA-preserved material, the centrifuge speed indicated here is probably not sufficient to recover the oocysts or microsporidian spores for special staining, fecal immunoassays using fluorescence, or other diagnostic procedures.
3. Use the remaining sediment to prepare coverslip smears (not 3- by 1-in. slides), which are immediately (without drying) stained, beginning with the iodine-alcohol step of the trichrome staining procedure (for removal of mercuric chloride).
4. The staining times can be reduced to 2 to 4 min, and dehydration steps can be reduced to 1 min each.

Note This procedure will work quite well for most stool specimens preserved in PVA fixative. However, for very liquid specimens or those containing large amounts of mucus, drying the smears before staining will be advantageous.

SAF-Preserved Material (47)

1. Thoroughly mix the SAF-stool mixture, and strain it through gauze into a 15-ml centrifuge tube.
2. After centrifugation (1 min at $500 \times g$), decant and discard the supernatant fluid. Although stains for coccidian oocysts and microsporidian spores are not recommended from PVA-preserved material, the centrifuge speed indicated here is probably not sufficient to recover the oocysts or spores. Centrifugation time and speed are recommended as 10 min at $500 \times g$. The final amount of sediment should be about 0.5 to 1.0 ml. If necessary, adjust by repeating step 1 or by resuspending the sediment in saline (0.85% NaCl) and removing part of the suspension.
3. Prepare a smear from the sediment for later staining by placing 1 drop of Mayer's albumin on the slide and adding 1 drop of SAF-preserved fecal sediment.

Figure 27.12 (Upper left) MACRO-CON concentration system (Meridian Bioscience). (Upper right) SPINCON concentration system (Meridian Bioscience). (Lower) Funnel used in fecal concentration (Meridian Bioscience).

Figure 27.13 Countertop workstation that automates the microscopic analysis of fecal concentrates (DiaSys Corp.).

Allow the smear to air dry at room temperature for 30 min prior to staining. The SAF stool smear can also be postfixated in Schaudinn's fixative prior to staining (begin the trichrome stain protocol with the 70% alcohol rinse prior to iodine-alcohol).

- After being dried, the smear can be placed directly into 70% alcohol (step 4) of the staining procedure (the iodine-alcohol step can be eliminated).

Merthiolate-Iodine-Formalin (MIF)-Preserved Material

- Prepare a Mayer's albumin-coated slide and allow it to air dry at room temperature for 30 min.
- From the MIF vial (material allowed to settle in the vial for at least 1 h undisturbed), remove a portion of sediment and place this material onto

Figure 27.14 Dual-flow-cell Optical Slide Assembly (DiaSys Corp.) that fits into the stage clips of any standard upright microscope.

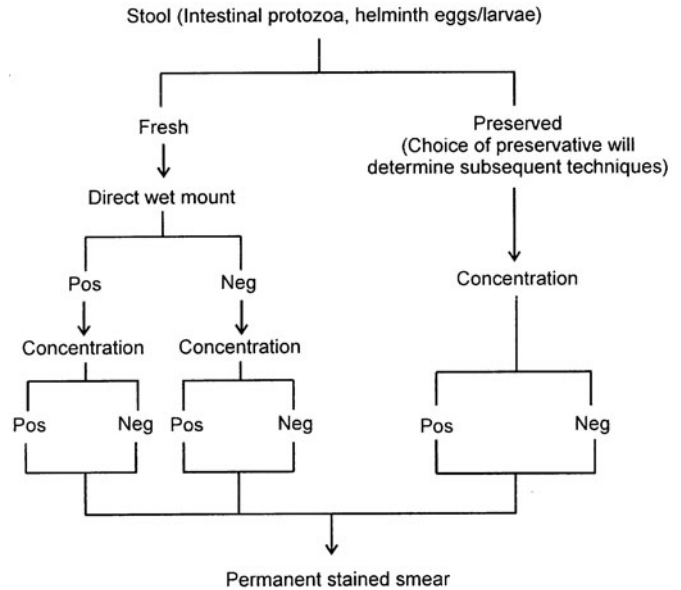

Figure 27.15 Work flow diagram for fecal specimens. The total examination includes the direct mount, concentrate, and permanent stained smear (fresh specimen) or the concentrate and permanent stained smear (preserved specimens).

the albumin-coated slide. Allow the slide to remain flat for 5 min; if there is still fluid left on the slide after this time, stand it up and allow the excess fluid to run off onto a paper towel.

- After all excess fluid is removed, the slides are ready for staining in polychrome IV stain.

As seen in the previous chapter, some of the single-vial fecal preservative systems are satisfactory but some do not provide morphology of sufficient quality to allow organism identification after permanent staining (21). In this particular study, when the single-vial fixatives were compared with mercuric chloride-based PVA, it was found that ECOFIX (Meridian Diagnostics, Inc., Cincinnati, Ohio) and ProtoFix (Alpha-Tec Systems, Inc., Vancouver, Wash.) were environmentally acceptable substitutes for PVA. PARASAFE (Scientific Device Laboratory, Inc., Des Plaines, Ill.) was not acceptable. Another acceptable substitute is UNIFIX (Medical Chemical Corp., Torrance, Calif.), which was equal to Z-PVA and other non-mercuric-chloride-based PVA formulations (13; "hands on" unpublished data). It is also important to remember that some manufacturers have their own stain that can be used with their particular fixative; an example would be ECOSTAIN coupled with ECOFIX (Meridian Diagnostics, Inc.) (11).

As discussed in the previous chapter, various examination options are available for very specific

areas within the United States. Kellogg and Elder (22) reported that in their area (York, Pa.), examination of a single trichrome-stained smear of a concentrated stool specimen from PVA-preserved stool appeared to be a cost-effective alternative to routine analysis of both concentrated and unconcentrated specimens for parasites. It would appear from this information that in that part of the country, they tend to see mainly protozoan parasites and very few helminth infections (22).

Trichrome Stain

The trichrome technique of Wheatley (46) for fecal specimens is a modification of Gomori's original staining procedure for tissue (15). It is a rapid, simple procedure which produces uniformly well stained smears of the intestinal protozoa, human cells, yeast cells, and artifact material in about 45 min or less.

The specimen usually consists of fresh stool smeared on a microscope slide, which is immediately fixed in liquid Schaudinn's fixative, or PVA-preserved stool smeared on a slide and allowed to air dry. Although SAF- and MIF-preserved specimens can be stained with trichrome, there are other stains which are recommended for better overall results. Trichrome stains also work well with some of the single-vial preservatives such as UNIFIX (Medical Chemical Corp., Torrance, Calif.).

Trichrome Stain

Chromotrope 2R.....	0.6 g
Light green SF.....	0.3 g
Phosphotungstic acid.....	0.7 g
Acetic acid (glacial).....	1.0 ml
Distilled water.....	100 ml

1. Prepare the stain by adding 1.0 ml of acetic acid to the dry components. Allow the mixture to stand (ripen) for 15 to 30 min at room temperature.
2. Add 100 ml of distilled water. Properly prepared stain is purple.
3. Store in a glass or plastic bottle at room temperature. The shelf life is 24 months.

70% Ethanol plus Iodine

1. Prepare a stock solution by adding iodine crystals to 70% alcohol until a dark solution is obtained (1 to 2 g/100 ml).
2. To use, dilute the stock solution with 70% alcohol until a dark reddish brown (port wine) or strong-tea color is obtained. As long as the color

is acceptable, working solution does not have to be replaced. Replacement time depends on the number of smears stained and the size of the container (1 week to several weeks).

90% Ethanol, Acidified

90% ethanol.....	99.5 ml
Acetic acid (glacial).....	0.5 ml

Prepare by combining.

70% Isopropyl or Ethyl Alcohol

100% Ethyl Alcohol (Recommended)
or 95% Ethyl Alcohol (Second Choice)
Xylene or Xylene Substitute

Quality Control for Trichrome Stain

1. Stool samples used for quality control can be fixed stool specimens known to contain protozoa or PVA-preserved negative stools to which buffy coat cells (PMNs or macrophages) have been added. A QC smear prepared from a positive PVA sample or a PVA sample containing buffy coat cells should be used when new stain is prepared or at least once each week. Cultured protozoa can also be used.
2. A QC slide should be included with a run of stained slides at least monthly; more frequent QC is recommended for those who may be unfamiliar with the method (32).
3. If the xylene becomes cloudy or there is an accumulation of water in the bottom of the staining dish containing xylene, discard the old reagents, clean the dishes, dry thoroughly, and replace with fresh 100% ethanol and xylene.
4. All staining dishes should be covered to prevent evaporation of reagents (screw-cap Coplin jars or glass lids).
5. Depending on the volume of slides stained, staining solutions will have to be changed on an as-needed basis.
6. When the smear is thoroughly fixed and the staining procedure is performed correctly, the cytoplasm of protozoan trophozoites is blue-green, sometimes with a tinge of purple. Cysts tend to be slightly more purple. Nuclei and inclusions (chromatoidal bars, RBCs, bacteria, and Charcot-Leyden crystals) are red, sometimes tinged with purple. The background material usually stains green, providing a nice color contrast with the protozoa. This contrast is more distinct than that obtained with the hematoxylin stain, which

tends to stain everything in shades of gray-blue to black.

7. If appropriate, the microscope should be calibrated (within the last 12 months), and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. The calibration factors for all objectives should be posted on the microscope for easy access (multiplication factors can be pasted on the body of the microscope).
8. Known positive microscope slides, Kodachrome 2 × 2 projection slides, and photographs (reference books) should be available at the workstation.
9. Record all QC results; the laboratory should also have an action plan for “out-of-control” results.

Procedure for Trichrome Stain with Mercury-Based Fixatives (Figure 27.16)

Note In all staining procedures for fecal and gastrointestinal tract specimens, the term “xylene” is used in the generic sense. Xylene substitutes are recommended for the safety of all personnel performing these procedures.

1. Prepare the slide for staining as described above.
2. Remove the slide from liquid Schaudinn’s fixative, and place it in 70% ethanol for 5 min.
3. Place the slide in 70% ethanol plus iodine for 1 min for fresh specimens or 5 to 10 min for PVA air-dried smears. The exposure to iodine will remove the mercuric chloride from the smear prior to staining with the actual trichrome dyes (substitution of iodine for mercury).
4. Place the slide in 70% ethanol for 5 min.* This and the next step in 70% ethanol will remove the iodine from the smear.
5. Place it in a second container of 70% ethanol for 3 min.*
6. Place it in trichrome stain for 10 min. The fecal smear no longer contains either mercuric chloride or iodine and is now ready for staining.
7. Place it in 90% ethanol plus acetic acid for 1 to 3 s. Immediately drain the rack (see Procedure Notes), and proceed to the next step. Do not allow slides to remain in this solution. This is the destaining step.
8. Dip the slide several times in 100% ethanol. Use this step as a rinse.
9. Place it in two changes of 100% ethanol for 3 min each.* This is a dehydration step.
10. Place it in xylene for 5 to 10 min.* This is a dehydration step.
11. Place it in a second container of xylene for 5 to 10

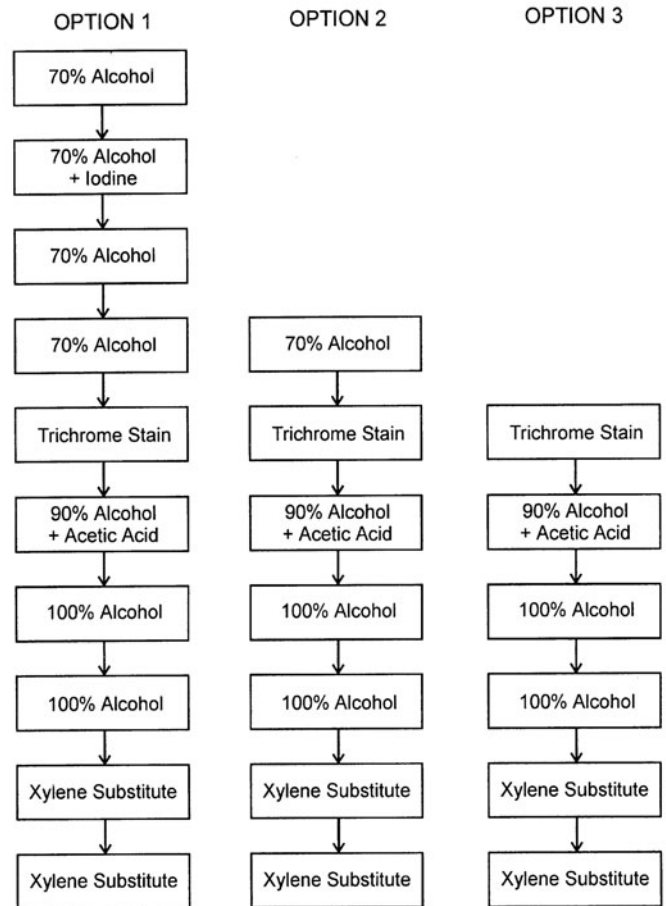

Figure 27.16 Trichrome staining. Option 1, for use with smears prepared from fixatives containing mercuric chloride. The iodine is used to remove the mercuric chloride, and the subsequent two alcohol rinse steps remove the iodine. Thus, prior to staining, both the mercuric chloride and iodine have been removed from the smear. Options 2 and 3, for use with smears prepared from fixatives containing no mercuric chloride (the user can select option 2 or 3; there is minimal to no difference).

min.* This step completes the dehydration process (removal of all water on the smear).

12. Mount the slide with a coverslip (no. 1 thickness), using mounting medium (e.g., Permount).
13. Allow the smear to dry overnight or after 1 h at 37°C.
14. Examine the smear microscopically with the 100× objective. Examine at least 200 to 300 oil immersion fields before reporting a negative result (Figure 27.17).

*Slides may be held for up to 24 h in these solutions without harming the quality of the smear or stainability of organisms.

Procedure for Trichrome Stain with Non-Mercury-Based Fixatives (Iodine-Alcohol Step and Alcohol Rinse Not Required) (Figure 27.16)

1. Prepare the slide for staining as described above.
2. Place the slide in 70% ethanol for 5 min.*
3. Place it in the trichrome stain for 10 min. Some people prefer to place the dry smear directly into the stain and eliminate step 2 from the protocol.
4. Place it in 90% ethanol plus acetic acid for 1 to 3 s. Immediately drain the rack (see Procedure Notes), and proceed to the next step. Do not allow slides to remain in this solution.
5. Dip the slide several times in 100% ethanol. Use this step as a rinse.
6. Place it in two changes of 100% ethanol for 3 min each.*
7. Place it in xylene for 5 to 10 min.*
8. Place it in a second container of xylene for 5 to 10 min.*
9. Mount with a coverslip (no. 1 thickness), using mounting medium (e.g., Permount).
10. Allow the smear to dry overnight or after 1 h at 37°C.
11. Examine the smear microscopically with the 100× objective. Examine at least 200 to 300 oil immersion fields before reporting a negative result.

*Slides may be held for up to 24 h in these solutions without harming the quality of the smear or stainability of organisms.

Note An alternative method to using mounting medium is as follows (3).

- A. Remove the slide from the last container of xylene, place it on a paper towel (flat position), and allow it to air dry. Remember that some of the xylene substitutes may take a bit longer to dry than xylene itself does.
- B. Approximately 5 to 10 min before you want to examine the slide, place a drop of immersion oil on the dry fecal film. Allow the oil to sink into the film for a minimum of 10 to 15 min. If the smear appears to be very refractile on examination, you have not waited long enough for the oil to sink into the film or you need to add a bit more oil to the film.
- C. Once you are ready to examine the slide, place a no. 1 (22- by 22-mm) coverslip onto the oiled smear, add another drop of immersion oil onto the top of the coverslip (as you would normally do for any slide with a coverslip), and examine with the oil immersion lens (100× objective).
- D. *Do not eliminate adding the coverslip*; the dry

Figure 27.17 Guess the identity of these intestinal protozoa! See p. 830 for the answers.

fecal material on the slide often becomes very brittle after dehydration. Without the addition of the protective coverslip, you might scratch the surface of the oil immersion lens. Coverslips are much cheaper than oil immersion objectives!

Results and Patient Reports from the Trichrome Staining Method

Protozoan trophozoites and cysts are readily seen, although helminth eggs and larvae may not be easily identified because of excess stain retention (wet smears from the concentration procedure[s] are recommended for detection of these organisms) (Figure 27.18). Yeasts (single and budding cells and pseudohyphae) and human cells (macrophages, PMNs, and RBCs) can be identified. The following quantitation chart can be used for examination of permanent stained smears with the oil immersion lens (100× objective; total magnification, ×1,000).

Quantitation of Parasites, Cells, Yeasts, and Artifacts

Quantity	No. per 10 oil immersion fields ($\times 1,000$)
Few	≤ 2
Moderate	3–9
Many	≥ 10

1. Report the organism and stage (do not use abbreviations).
Examples: *Entamoeba histolytica*/E. *dispar* trophozoites
Giardia lamblia trophozoites
2. Quantitate the number of *B. hominis* organisms seen (rare, few, moderate, many). Do not quantitate other protozoa.
Example: Moderate *Blastocystis hominis*
3. Note and quantitate the presence of human cells.
Example: Moderate WBCs, many RBCs, few macrophages, rare Charcot-Leyden crystals
4. Report and quantitate yeast cells.
Example: Moderate budding yeast cells and few pseudohyphae
5. Save positive slides for future reference. Label prior to storage (name, patient number, organisms present). Most laboratories discard their negative permanent stained smears after several weeks (rotate storage boxes and discard when full).

Procedure Notes for the Trichrome Staining Method

1. The single most important step in the preparation of a well-stained fecal smear is good fixation. If this has not been done, the protozoa may be distorted or shrunk, may not be stained, or may exhibit an overall pink or red color with poor internal morphology.
2. Slides should always be drained between solutions. Touch the end of the slide to a paper towel for 2 s

Figure 27.18 Intestinal protozoa in the genus *Entamoeba* (stained with trichrome stain). Rows, from top to bottom, show *Entamoeba histolytica* trophozoites (note ingested RBCs), *Entamoeba histolytica*/E. *dispar* trophozoites (the morphology does not allow differentiation between pathogenic *E. histolytica* and nonpathogenic *E. dispar*), *Entamoeba histolytica*/E. *dispar* cysts, *Entamoeba coli* trophozoites (note uneven nuclear chromatin), and *Entamoeba coli* cysts (note the rough ends of chromatoidal bars and nuclear characteristics).

to remove excess fluid before proceeding to the next step. This will maintain the staining solutions for a longer period. The slide can also be touched against the staining dish to drain off excess fluid before moving on to the next dish.

3. Incomplete removal of mercuric chloride (Schaudinn's fixative and PVA fixative with a mercuric chloride base) may cause the smear to contain highly refractive crystals or granules, which may prevent finding or identifying any organisms present. Since the 70% ethanol-iodine solution removes the mercury complex, it should be changed at least weekly to maintain the strong-tea color. A few minutes are usually sufficient to keep the slides in the iodine-alcohol; too long a time in this solution may also adversely affect the staining of the organisms.
4. When using non-mercury-based fixatives, the iodine-alcohol step (used for the removal of mercury) and the subsequent alcohol rinse (removal of the iodine) can be eliminated from the procedure. The smears for staining can be prerinsed with 70% alcohol and then placed in the trichrome stain, or they can be placed directly into the trichrome stain as the first step in the staining protocol (Figure 27.16).
5. Smears that are predominantly green may be due to the inadequate removal of iodine by the 70% ethanol (steps 4 and 5). Lengthening the time of these steps or more frequent changing of the 70% ethanol will help.
6. To restore weakened trichrome stain, remove the cap and allow the ethanol to evaporate (ethanol carried over on the staining rack from a previous dish). After a few hours, fresh stock stain may be added to restore lost volume. Older, more concentrated stain produces more intense colors and may require slightly longer destaining times (an extradip). PVA smears usually require a slightly longer staining time due to the presence of the plastic PVA powder.
7. Although the trichrome stain is used essentially as a "progressive" stain (that is, no destaining is necessary), best results are obtained by using the stain "regressively" (destaining the smears briefly in acidified alcohol after the initial overstaining). Good differentiation is obtained by destaining for a very short time (two dips only, approximately 2 to 3 s); prolonged destaining results in poor differentiation.
8. It is essential to rinse the smears free of acid to prevent continued destaining. Since 90% alcohol will continue to leach trichrome stain from the smears, it is recommended that after the acid-alcohol is used, the slides be quickly rinsed in 100% alcohol and then dehydrated through two additional changes of 100% alcohol.
9. In the final stages of dehydration (steps 9 to 11), the 100% ethanol and the xylenes (or xylene substitute) should be kept as free from water as possible. Coplin jars must have tight-fitting caps to prevent both evaporation of reagents and absorption of moisture. If the xylene becomes cloudy after addition of slides from the 100% ethanol, return the slides to fresh 100% ethanol and replace the xylene with fresh stock.
10. If the smears peel or flake off, the specimen might have been inadequately dried on the slide (in the case of PVA-fixed specimens), the smear may have been too thick, or the slide may have been greasy (fingerprints). However, slides generally do not have to be cleaned with alcohol prior to use.
11. On examination, if the stain appears unsatisfactory and it is not possible to obtain another slide to stain, the slide may be restained. Place the slide in xylene to remove the coverslip, and reverse the dehydration steps, adding 50% ethanol as the last step. Destain the slide in 10% acetic acid for several hours, and then wash it thoroughly first in water and then in 50 and 70% ethanol. Place the slide in the trichrome stain for 8 min, and complete the staining procedure (5).

Procedure Limitations for the Trichrome Staining Method

1. The permanent stained smear is not recommended for staining helminth eggs or larvae; they are often too dark (excess stain retention) or distorted. However, they are occasionally recognized and identified. The wet smear preparation from the concentrate is the recommended approach for identification of helminth eggs and larvae.
2. The smear should be examined with the oil immersion lens (100×) for the identification of protozoa, human cells, Charcot-Leyden crystals, yeast cells, and artifact material. Quantitation of these cells and other structures is normally done from the examination of the permanent stained smear, not the wet smear preparations (direct wet smear or concentration wet smear).
3. This high-magnification (oil immersion; total magnification, ×1,000) examination is recommended for protozoa, particularly for confirming species identification.
4. With low magnification (10× objective), one might see eggs or larvae; however, this is not recommended as a routine approach.
5. In addition to helminth eggs and larvae, *I. belli* oocysts are best seen in wet preparations

(concentration wet smears prepared from formalin-preserved, not PVA-preserved, material).

6. *Cryptosporidium* and *Cyclospora* oocysts are generally not recognized on a trichrome-stained smear (acid-fast stains or the immunoassay reagent kits are recommended). Microsporidial spores do not stain sufficiently for recognition by the regular trichrome method; modified trichrome stains are required.

Iron Hematoxylin Stain

The iron hematoxylin stain is one of a number of stains that allow one to make a permanent stained slide for detecting and quantitating parasitic organisms. Iron hematoxylin was the stain used for most of the original morphologic descriptions of intestinal protozoa found in humans (5) (Figure 27.19). On oil immersion power ($\times 1,000$), one can examine the diagnostic features used to identify the protozoan parasites. Although there are many modifications of iron hematoxylin techniques, only two methods are outlined below: the Spencer-Monroe (41) and Tompkins-Miller (42) procedures. Both methods can be used with either fresh, SAF-preserved, PVA-preserved, or single-vial system-preserved specimens.

The specimen usually consists of fresh stool smeared on a microscope slide, which is immediately fixed in Schaudinn's fixative, PVA-preserved stool smeared on a slide and allowed to air dry, SAF-preserved stool smeared on an albumin-coated slide and allowed to air dry, or single-vial-preserved stool smeared on an albumin-coated slide and allowed to air dry. In some cases, the albumin is not absolutely necessary as an adhesive.

Iron Hematoxylin Stain (Spencer-Monroe Method) (41)

Solution 1

Hematoxylin (crystal or powder) 10 g
Ethanol (absolute) 1,000 ml

Place solution in a stoppered clear flask or bottle, and allow it to ripen in a lighted room for at least 1 week at room temperature.

Solution 2

Ferrous ammonium sulfate
[Fe(NH₄)₂(SO₄)₂ · 6H₂O] 10 g
Ferric ammonium sulfate
[FeNH₄(SO₄)₂ · 12H₂O] 10 g
Hydrochloric acid (concentrated) 10 ml
Distilled water 1,000 ml

Figure 27.19 Intestinal protozoa (stained with iron hematoxylin stain). (Upper) *Dientamoeba fragilis* trophozoites (note the fragmented nuclei). (Lower left) *Iodamoeba bütschlii* trophozoite (note the large karyosome). (Lower right) *Iodamoeba bütschlii* cyst (note the large glycogen vacuole and “basket” nucleus).

Working solution

Mix equal volumes of solutions 1 and 2. The working solution should be made fresh every week.

70% ethanol plus iodine

1. Prepare a stock solution by adding iodine crystals to 70% alcohol until a dark solution is obtained (1 to 2 g/100 ml).
2. To use, dilute the stock solution with 70% alcohol until a dark reddish brown strong-tea color is obtained. As long as the color is acceptable, new working solution does not have to be made. The replacement time will depend on the number of smears stained and the size of the container (1 week to several weeks).

90% ethanol, acidified

90% ethanol 99.5 ml
Acetic acid (glacial) 0.5 ml

Prepare by combining.

70% Isopropyl or Ethyl Alcohol
100% Ethyl Alcohol (Recommended)
or 95% Ethyl Alcohol (Second Choice)
Xylene or Xylene Substitute

Quality Control for Iron Hematoxylin Stain

1. Stool samples used for quality control can be fixed stool specimens known to contain protozoa or PVA-preserved negative stools to which buffy coat cells (PMNs or macrophages) have been added. A QC smear prepared from a positive PVA sample or a PVA sample containing buffy coat cells should be used when new stain is prepared or at least once each week. Cultured protozoa can also be used.
2. A QC slide should be included with a run of stained slides at least monthly; more frequent QC is recommended for those who may be unfamiliar with the method.
3. If the xylene becomes cloudy or there is an accumulation of water in the bottom of the staining dish, discard the old reagents, clean the dishes, dry them thoroughly, and replace with fresh 100% ethanol and xylene.
4. All staining dishes should be covered to prevent evaporation of reagents (screw-cap Coplin jars or glass lids).
5. Depending on the volume of slides stained, staining solutions should to be changed on an as-needed basis.
6. When the smear is thoroughly fixed and the stain is performed correctly, the cytoplasm of protozoan trophozoites will be blue-gray, sometimes with a tinge of black. Cysts tend to be slightly darker. Nuclei and inclusions (chromatoidal bars, RBCs, bacteria, and Charcot-Leyden crystals) are dark gray-blue, sometimes almost black. The background material usually stains pale gray or blue, providing some color intensity contrast with the protozoa. This contrast is less distinct than that obtained with the trichrome stain, which tends to stain everything with multiple colors (pink, red, purple, green, blue).
7. The microscope should be calibrated (within the last 12 months) (recommended but not always required, depending on the use and care of the microscope), and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. The calibration factors for all objectives should be posted on the microscope for easy access (multiplication factors can be pasted on the body of the microscope).
8. Known positive microscope slides, Kodachrome 2 × 2 projection slides, and photographs (reference books) should be available at the workstation.
9. Record all QC results; the laboratory should also have an action plan for “out-of-control” results.

Procedure for Iron Hematoxylin Stain with Mercury-Based Fixatives

Note In all staining procedures for fecal and gastrointestinal tract specimens, the term “xylene” is used in the generic sense. Xylene substitutes are recommended for the safety of all personnel performing these procedures.

1. Prepare the slide for staining as previously described (for SAF smears or smears prepared from other non-mercury single-vial preservatives, proceed to step 4).
2. Place the slide in 70% ethanol for 5 min.
3. Place the slide in the iodine–70% ethanol (70% alcohol to which is added enough D’Antoni’s iodine to obtain a strong-tea color) solution for 2 to 5 min. The iodine is designed to remove the mercury from the smear.
4. Place it in 70% ethanol for 5 min (this rinse step removes the iodine). Begin the procedure for SAF-fixed slides at this point.*
5. Wash the slide in running tap water (constant stream of water into the container) for 10 min.
6. Place the slide in iron hematoxylin working solution for 4 to 5 min.
7. Wash the slide in running tap water (constant stream of water into the container) for 10 min.
8. Place the slide in 70% ethanol for 5 min.*
9. Place the slide in 95% ethanol for 5 min.*
10. Place the slide in two changes of 100% ethanol for 5 min each.*
11. Place the slide in two changes of xylene for 5 min each.*
12. Add Permount to the stained area of the slide, and cover with a coverslip.

Note An alternative method to using mounting medium is given on p. 804.

13. Examine the smear microscopically with the 100× objective. Examine at least 200 to 300 oil immersion fields before reporting a negative result.

*Slides may be held for up to 24 h in these solutions without harming the quality of the smear or stainability of organisms.

Procedure for Iron Hematoxylin Stain with Non-Mercury-Based Fixatives

1. Prepare the slide for staining as described above.
2. Place it in 70% ethanol for 5 min.*
3. Wash the slide in running tap water (constant stream of water into the container) for 10 min.
4. Place the slide in iron hematoxylin working solution for 4 to 5 min.
5. Wash the slide in running tap water (constant stream of water into the container) for 10 min.

6. Place the slide in 70% ethanol for 5 min.*
7. Place the slide in 95% ethanol for 5 min.*
8. Place the slide in two changes of 100% ethanol for 5 min each.*
9. Place the slide in two changes of xylene for 5 min each.*
10. Add Permount to the stained area of the slide and cover it with a coverslip.
Note An alternative method to using mounting medium is given on p. 804.
11. Examine the smear microscopically with the 100× objective. Examine at least 200 to 300 oil immersion fields before reporting a negative result.

*Slides may be held for up to 24 h in these solutions without harming the quality of the smear or stainability of organisms.

Results and Patient Reports from the Iron Hematoxylin Staining Method

Protozoan trophozoites and cysts are readily visible, although helminth eggs and larvae may not be easily identified because of excess stain retention (wet smears from the concentration procedure[s] are recommended for detection of these organisms). Yeasts (single and budding cells and pseudohyphae) and human cells (macrophages, PMNs, and RBCs) can be identified. The following quantitation chart can be used for examination of permanent stained smears with the oil immersion lens (100× objective; total magnification, ×1,000).

1. Report the organism and stage (do not use abbreviations).
 Examples: *Entamoeba coli* trophozoites
Dientamoeba fragilis trophozoites
2. Quantitate the number of *B. hominis* organisms seen (rare, few, moderate, many). Do not quantitate other protozoa.
 Example: Many *Blastocystis hominis*
3. Note and quantitate the presence of human cells.
 Example: Moderate WBCs, few macrophages,

few RBCs, rare Charcot-Leyden crystals

4. Report and quantitate yeast cells.
 Example: Many budding yeast cells and few pseudohyphae
5. Save positive slides for future reference. Label prior to storage (name, patient number, organisms present). Most laboratories hold their negative smears for several weeks and then discard them; slide boxes that are rotated can be used to batch, store, and discard negative smears.

Procedure Notes for the Iron Hematoxylin Staining Method

1. The single most important step in the preparation of a well-stained fecal smear is good fixation. If this has not been done, the protozoa may be distorted or shrunk, may not be stained, or may exhibit an overall gray or blue-gray color with poor internal morphology.
2. Slides should always be drained between solutions. Touch the end of the slide to a paper towel for 2 s to remove excess fluid before proceeding to the next step. This will maintain the staining solutions for a longer period. The slides can also be drained against the edge of each container before being moved to the next container.
3. Incomplete removal of mercuric chloride (Schaudinn’s fixative and PVA fixative prepared with a mercuric chloride base) may cause the smear to contain highly refractive crystals or granules, which may prevent finding or identifying any organisms present. Since the 70% ethanol-iodine solution removes the mercury complex, it should be changed at least weekly to maintain the strong-tea color. A few minutes are usually sufficient to keep the slides in the iodine-alcohol; too long a time in this solution may also adversely affect the staining of the organisms.
4. When using non-mercury-based fixatives, the iodine-alcohol step (used for the removal of mercury) and the subsequent alcohol rinse (used for the removal of iodine) can be eliminated from the procedure. The smears for staining can be pre-rinsed with 70% alcohol and then placed in the water step prior to the hematoxylin stain as the first step in the staining protocol.
5. For staining large numbers of slides, the working hematoxylin solution may be diluted and affect the quality of the stain. If dilution occurs, discard the working solution and prepare a fresh working solution.

Quantitation of Parasites, Cells, Yeasts, and Artifacts

Quantity	No. per 10 oil immersion fields (×1,000)
Few	≤2
Moderate	3–9
Many	≥10

6. The shelf life of the stock hematoxylin solutions may be extended by keeping the solutions in the refrigerator at 4°C. Because of crystal formation in the working solutions, it may be necessary to filter them before preparing a new working solution.
7. In the final stages of dehydration (steps 9 to 11), the 100% ethanol and the xylenes should be kept as free from water as possible. Coplin jars must have tight-fitting caps to prevent both evaporation of reagents and absorption of moisture. If the xylene becomes cloudy after addition of slides from the 100% ethanol, return the slides to fresh 100% ethanol and replace the xylene with fresh stock.
8. If the smears peel or flake off, the specimen might have been inadequately dried on the slide (in the case of PVA-fixed specimens), the smear may have been too thick, or the slide may have been greasy (fingerprints). However, slides generally do not have to be cleaned with alcohol prior to use.
9. On examination, if the stain appears unsatisfactory and it is not possible to obtain another slide to stain, the slide may be restained. Place the slide in xylene to remove the coverslip, and reverse the dehydration steps, adding 50% ethanol as the last step. Destain the slide in 10% acetic acid for several hours, and then wash it thoroughly first in water and then in 50 and 70% ethanol. Place the slide in the iron hematoxylin stain for 8 min, and complete the staining procedure (3, 5).
4. With low magnification (10× objective), one might see eggs or larvae; however, this is not recommended as a routine approach.
5. In addition to helminth eggs and larvae, *I. belli* oocysts are best seen in wet preparations (concentration wet smears prepared from formalin-preserved, not PVA-preserved, material).
6. *Cryptosporidium* and *Cyclospora* oocysts are generally not recognized on an iron hematoxylin-stained smear (modified acid-fast stains or the fecal immunoassay for *Cryptosporidium* spp. is recommended).

Iron Hematoxylin Stain (Tompkins-Miller Method) (42)

A longer iron hematoxylin method was described by Tompkins and Miller (42). Since differentiation of overstained slides is critical in most iron hematoxylin staining procedures, Tompkins and Miller have described a method that employs phosphotungstic acid to destain the protozoa and that gives excellent results, even in unskilled hands.

1. Prepare the slide for staining as described above (for SAF or non-mercury-based smears, proceed to step 4).
2. Place the slide in 70% ethanol for 5 min.
3. Place the slide in the iodine-70% ethanol (70% alcohol to which is added enough D'Antoni's iodine to obtain a strong-tea color) solution for 2 to 5 min.
4. Place it in 50% ethanol for 5 min. Begin the procedure for SAF- or non-mercury-fixed slides at this point.*
5. Wash the slide in running tap water (constant stream of water into the container) for 3 min.
6. Place the slide in 4% ferric ammonium sulfate mordant for 5 min.
7. Wash the slide in running tap water (constant stream of water into the container) for 1 min.
8. Place the slide in 0.5% aqueous hematoxylin for 2 min.
9. Wash the slide in tap water for 1 min.
10. Place the slide in 2% phosphotungstic acid for 2 to 5 min.
11. Wash the slide in running tap water for 10 min.
12. Place the slide in 70% ethanol (plus a few drops of saturated aqueous lithium carbonate) for 3 min.
13. Place the slide in 95% ethanol for 5 min.*
14. Place the slide in two changes of 100% ethanol for 5 min each.*
15. Place the slide in two changes of xylene for 5 min each.*

Procedure Limitations for the Iron Hematoxylin Staining Method

1. The permanent stained smear is not recommended for staining helminth eggs or larvae; these structures are often too dark (excess stain retention) or distorted. However, they are occasionally recognized and identified. The wet smear preparation from the concentrate is the recommended approach for identification of helminth eggs and larvae.
2. The smear should be examined with the oil immersion lens (100×) for the identification of protozoa, human cells, Charcot-Leyden crystals, yeast cells, and artifact material. Quantitation of these cells and other structures is normally done from the examination of the permanent stained smear, not the wet smear preparations (direct wet smear, concentration wet smear).
3. This high-magnification (oil immersion; total magnification, ×1,000) examination is recommended for protozoa, particularly for confirming species identification.

16. Add Permout to the stained area of the slide, and cover it with a coverslip.

Note An alternative method to using mounting medium is as follows.

- A. Remove the slide from the last container of xylene, place it on a paper towel (flat position), and allow it to air dry. Remember that some of the xylene substitutes may take a bit longer to dry.
- B. Approximately 5 to 10 min before you want to examine the slide, place a drop of immersion oil on the dry fecal film. Allow the oil to sink into the film for a minimum of 10 to 15 min. If the smear appears to be very refractile on examination, you have not waited long enough for the oil to sink into the film or you need to add a bit more oil onto the film.
- C. Once you are ready to examine the slide, place a no. 1 (22- by 22-mm) coverslip onto the oiled smear, add another drop of immersion oil to the top of the coverslip (as you would normally do for any slide with a coverslip), and examine with the oil immersion lens (100× objective).
- D. *Do not eliminate adding the coverslip*; the dry fecal material on the slide often becomes very brittle after dehydration. Without the addition of the protective coverslip, you might scratch the surface of your oil immersion lens. Coverslips are much cheaper than oil immersion objectives!

17. Examine the smear microscopically with the 100× objective. Examine at least 200 to 300 oil immersion fields before reporting a negative result.

*Slides may be held for up to 24 h in these solutions without harming the quality of the smear or stainability of organisms.

Modified Iron Hematoxylin Stain (Incorporating the Carbol Fuchsin Step)

The following combination staining method for SAF-preserved fecal specimens was developed to allow the microscopist to screen for acid-fast organisms in addition to other intestinal parasites (Figure 27.20). For laboratories using iron hematoxylin stains in combination with SAF-fixed material and modified acid-fast stains for *Cryptosporidium*, *Cyclospora*, and *Isospora*, this modification represents an improved approach to current staining methods (J. Palmer, Letter, *Clin. Microbiol. Newsl.* 13:39–40, 1991). This combination stain provides a saving in both time and personnel use.

Any fecal specimen submitted in SAF or other non-mercury single-vial-system preservatives can be used. Fresh fecal specimens after fixation in SAF for 30 min can also be used. This combination stain approach is not recommended for specimens preserved in Schaudinn's fixative or PVA using a mercuric chloride base.

Mayer's Albumin

Add an equal quantity of glycerin to a fresh egg white. Mix gently and thoroughly. Store at 4°C, and indicate an expiration date of 3 months. Mayer's albumin from commercial suppliers can normally be stored at 25°C for 1 year [e.g., product 756, E. M. Diagnostic Systems Inc., 480 Democrat Road, Gibbstown, NJ 08027; (800) 443-3637].

Stock Solution of Hematoxylin Stain

Hematoxylin powder 10 g
Ethanol (95% or 100%) 1,000 ml

1. Mix well until dissolved.
2. Store in a clear-glass bottle in a light area. Allow to ripen for 14 days before use.
3. Store at room temperature with an expiration date of 1 year.

Mordant

Ferrous ammonium sulfate
[Fe(NH₄)₂(SO₄)₂ · 6H₂O]..... 10 g
Ferric ammonium sulfate
[FeNH₄(SO₄)₂ · 12H₂O]..... 10 g
Hydrochloric acid (concentrated).... 10 ml
Distilled water to..... 1,000 ml

Working Solution of Hematoxylin Stain

1. Mix equal quantities of stock solution of stain and mordant.

Figure 27.20 Iron hematoxylin stain incorporating the carbol fuchsin step. Note the modified acid-fast *Cryptosporidium* oocysts and the *Giardia lamblia* cyst.

2. Allow the mixture to cool thoroughly before use (prepare at least 2 h prior to use). The working solution should be made fresh every week.

Picric Acid

Mix equal quantities of distilled water and an aqueous saturated solution of picric acid to make a 50% saturated solution.

Acid-Alcohol Decolorizer

Hydrochloric acid (concentrated).... 30 ml
Alcohol to 1,000 ml

70% Alcohol and Ammonia

70% alcohol..... 50 ml
Ammonia 0.5–1.0 ml

Add enough ammonia to bring the pH to approximately 8.0.

Carbol Fuchsin

1. To make basic fuchsin (solution A), dissolve 0.3 g of basic fuchsin in 10 ml of 95% ethanol.
2. To make phenol (solution B), dissolve 5 g of phenol crystals in 100 ml of distilled water. (Gentle heat may be needed.)
3. Mix solution A with solution B.
4. Store at room temperature. The solution is stable for 1 year.

Procedure for Modified Iron Hematoxylin Stain (Carbol Fuchsin Step)

1. Prepare slide.
 - A. Place 1 drop of Mayer's albumin on a labeled slide.
 - B. Thoroughly mix the sediment from the fecal concentration with an applicator stick.
 - C. Add approximately 1 drop of the fecal concentrate to the albumin, and spread the mixture over the slide.
2. Allow the slide to air dry at room temperature (the smear appears opaque when dry).
3. Place the slide in 70% alcohol for 5 min.
4. Wash the slide in a container of tap water (not under running water) for 2 min.
5. Place the slide in Kinyoun's stain for 5 min.
6. Wash the slide in running tap water (constant stream of water into container) for 1 min.
7. Place the slide in acid-alcohol decolorizer for 4 min.*
8. Wash the slide in running tap water (constant stream of water into container) for 1 min.
9. Place the slide in iron hematoxylin working solution for 8 min.

10. Wash the slide in distilled water (in container) for 1 min.
11. Place the slide in picric acid solution for 3 to 5 min.
12. Wash the slide in running tap water (constant stream of water into container) for 10 min.
13. Place the slide in 70% alcohol plus ammonia for 3 min.
14. Place the slide in 95% alcohol for 5 min.
15. Place the slide in 100% alcohol for 5 min.
16. Place the slide in two changes of xylene for 5 min.

*This step can also be performed as follows.

- A. Place the slide in acid-alcohol decolorizer for 2 min.
- B. Wash the slide in running tap water (constant stream of water into container) for 1 min.
- C. Place the slide in acid-alcohol decolorizer for 2 min.
- D. Wash the slide in running tap water (constant stream of water into container) for 1 min.
- E. Continue the staining sequence with step 9 (iron hematoxylin working solution).

Procedure Notes for Modified Iron Hematoxylin Stain (Carbol Fuchsin Step)

1. The first 70% alcohol step acts with the Mayer's albumin to "glue" the specimen to the glass slide. The specimen may wash off if insufficient albumin is used or if the slides are too thick and are not completely dry before being stained.
2. The working hematoxylin stain should be checked each day of use by adding a drop of stain to alkaline tap water. If a blue color does not develop, prepare a fresh working stain solution.
3. The picric acid differentiates the hematoxylin stain by removing more stain from fecal debris than from the protozoa and removing more stain from the organism cytoplasm than from the nucleus. When properly stained, the background should be various shades of gray-blue and the protozoa, with medium blue cytoplasm and dark blue-black nuclei, should be easily seen.

Polychrome IV Stain

Polychrome IV stain can be used in place of trichrome for staining fecal smears by the MIF, PVA, or SAF fixative method. Both the stain and staining directions are available commercially (Devetec, Inc., P.O. Box 10275, Bradenton, FL 34282). Another source for the stain is Scientific Device Laboratory, Inc., P.O. Box 88, Glenview, IL 60025. Polychrome IV stain has been used primarily to stain permanent smears prepared from MIF-preserved fecal specimens.

REVIEW Permanent Stained Smears	
Topic	Comments
Principle	To provide contrasting colors for the background debris and parasites present; designed to allow examination and recognition of detailed organism morphology under oil immersion examination (100× objective for a total magnification of ×1,000). Designed primarily to allow recovery and identification of the intestinal protozoa.
Specimen	Any stool specimen that is fresh or is preserved in PVA (mercury- or non-mercury based), SAF, MIF, or the newer single-vial-system fixatives.
Reagents	Trichrome, iron hematoxylin, modified iron hematoxylin, polychrome IV, or chlorazol black E stains and their associated solutions; dehydrating solutions (alcohols and xylenes); mounting fluid optional.
Examination	Oil immersion examination of at least 300 fields; additional fields may be required if suspect organisms have been seen in the wet preparations from the concentrated specimen.
Results and Laboratory Reports	The majority of the suspect protozoa and/or human cells could be confirmed by the permanent stained smear. These reports should be categorized as “final” and would be signed out as such (the direct wet smear and concentration examination would provide “preliminary” results). However, if the testing turnaround time is <24 h, it is best to report the test results after the ova and parasite examination (fresh specimen, direct wet smear; concentration, permanent stained smear) is complete. Therefore, the reports would not be identified as “preliminary” or “final.”
Procedure Notes and Limitations	The most commonly used stains include trichrome and iron hematoxylin. Unfortunately, helminth eggs and larvae take up too much stain and usually cannot be identified from the permanent stained smear. Also, coccidian oocysts and microsporidian spores usually require other special staining methods for identification. Permanent stained smears are normally examined under oil immersion examination (×1,000), and low or high dry power is not recommended. Confirmation of the intestinal protozoa (both trophozoites and cysts) is the primary purpose of this technique.

Chlorazol Black E Stain

Chlorazol black E staining, developed by Kohn (23), is a method in which both fixation and staining occur in a single solution. This approach is used for fresh specimens, but it is not recommended for PVA-fixed material (14) because it does not include an iodine-alcohol step, which is used to remove the mercuric chloride compound found in both Schaudinn's fixative and PVA fixative prepared with mercuric chloride. The optimal staining time must be determined for each batch of fixative-stain. The length of time for which the fixative-stain can be used depends on the number of slides run through the solution within a 30-day period. If the slides appear visibly red, the solution must be changed. Although this stain is not widely used, it is another option to consider.

Specialized Stains for Coccidia (*Cryptosporidium*, *Isospora*, and *Cyclospora* Species) and the Microsporidia

Modified Kinyoun's Acid-Fast Stain (Cold Method)

Cryptosporidium spp. and *I. belli* have been recognized as causes of severe diarrhea in immunocompromised hosts but can also cause diarrhea in immunocompetent

hosts (6). Oocysts in clinical specimens may be difficult to detect without special staining (29). Modified acid-fast stains are recommended to demonstrate these organisms. Unlike the Ziehl-Neelsen modified acid-fast stain, the modified Kinyoun's stain does not require the heating of reagents for staining (17). With additional reports of diarrheal outbreaks due to *Cyclospora* spp., it is also important to remember that these organisms are modified acid-fast variable and can be identified by this staining approach. Although the microsporidian spores are also acid fast, their size (1 to 2 μm) makes identification very difficult without special modified trichrome stains or the use of immunoassay reagents (1, 9, 24, 38, 44, 45).

Concentrated (500 × g for 10 min) sediment of fresh, formalin-preserved, or other single-vial fixative-preserved stool may be used. Other types of clinical specimens such as duodenal fluid, bile, and pulmonary specimens (induced sputum, bronchial washings, or biopsy specimens) may also be stained (Figure 27.21).

50% Ethanol

1. Add 50 ml of absolute ethanol to 50 ml of distilled water.
2. Store at room temperature. The solution is stable for 1 year. Note the expiration date on the label.

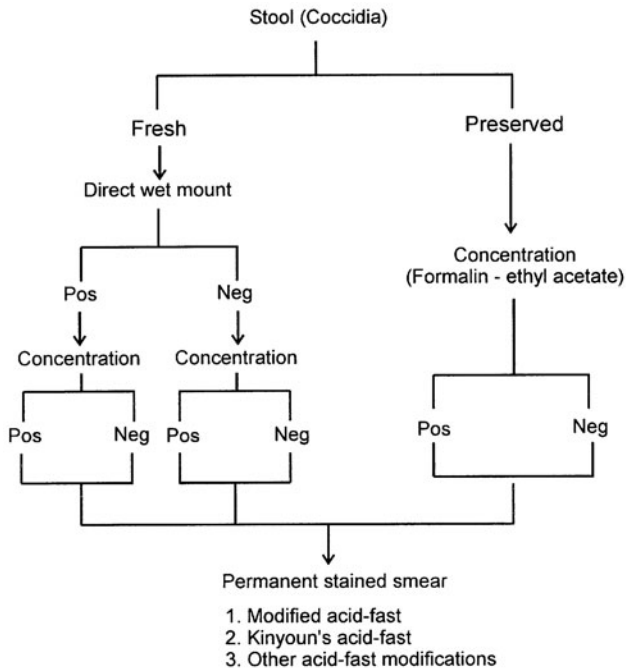

Figure 27.21 Work flow diagram for fecal specimens (cocciidia). The most important part of the procedure would be the concentrate (*Isospora* sp.) and the permanent stained smear, using one of the modified acid-fast techniques (*Cryptosporidium* and *Cyclospora* spp.).

Kinyoun's Carbol Fuchsin

1. Dissolve 4 g of basic fuchsin in 20 ml of 95% ethanol (solution A).
2. Dissolve 8 g of phenol crystals in 100 ml of distilled water (solution B).
3. Mix solutions A and B.
4. Store at room temperature. The solution is stable for 1 year. Note the expiration date on the label.

1% Sulfuric Acid

1. Add 1 ml of concentrated sulfuric acid to 99 ml of distilled water.
2. Store at room temperature. The solution is stable for 1 year. Note the expiration date on the label.

Loeffler Alkaline Methylene Blue

1. Dissolve 0.3 g of methylene blue in 30 ml of 95% ethanol.
2. Add 100 ml of dilute (0.01%) potassium hydroxide.
3. Store at room temperature. The solution is stable for 1 year. Note the expiration date on the label.

Quality Control for Kinyoun's Acid-Fast Stain

1. A control slide of *Cryptosporidium* from a 10% formalin-preserved specimen is included with each

staining batch run. If the *Cryptosporidium* slide stains well, any *Isospora* or *Cyclospora* oocysts present will also take up the stain, although *Cyclospora* oocysts tend to be acid-fast variable (Figure 27.22).

2. *Cryptosporidium* spp. stain pink-red. Oocysts measure 4 to 6 μm , and four sporozoites may be visible within some oocysts. The background should stain uniformly blue.
3. The specimen is also checked for adherence to the slide (macroscopically).
4. The microscope should be calibrated (within the last 12 months), and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. The calibration factors for all objectives should be posted on the microscope for easy access (multiplication factors can be pasted on the body of the microscope). If the microscopes receive adequate maintenance and are not moved frequently, yearly recalibration may not be necessary.
5. Known positive microscope slides, Kodachrome 2 \times 2 projection slides, and photographs (reference books) should be available at the workstation.
6. Record all QC results; the laboratory should also have an action plan for "out-of-control" results.

Procedure for Kinyoun's Acid-Fast Stain

1. Smear 1 to 2 drops of concentrated specimen sediment on the slide, and allow it to air dry. Do not make the smears too thick (you should be able to see through the wet material before it dries). Prepare two smears.
2. Fix with absolute methanol for 1 min.
3. Flood the slide with Kinyoun's carbol fuchsin and stain for 5 min.
4. Rinse the slide briefly (3 to 5 s) with 50% ethanol.
5. Rinse the slide thoroughly with water.
6. Decolorize with 1% sulfuric acid for 2 min or until no more color runs from the slide.
7. Rinse the slide with water. Drain.
8. Counterstain with methylene blue for 1 min.
9. Rinse the slide with water. Air dry.
10. Examine the slide with the low or high dry objective. To see the internal morphology, use an oil objective (100 \times).

Results and Patient Reports from Kinyoun's Acid-Fast Staining Method

The oocysts of *Cryptosporidium*, *Cyclospora*, and *Isospora* spp. stain pink to red to deep purple. Some of the four sporozoites may be visible in the *Cryptosporidium* oocysts. Some of the *Isospora* immature oocysts (entire oo-

Figure 27.22 Quality control slides for performing modified acid-fast stains (*Cryptosporidium* and *Cyclospora* spp.) (Medical Chemical Corp.).

cyst) will stain, while those that are mature usually appear with the two sporocysts within the oocyst wall stained pink to purple and a clear area between the stained sporocysts and the oocyst wall. The background stains blue. If *Cyclospora* oocysts are present (uncommon unless in an outbreak situation), they tend to be approximately 8 to 10 μm , they resemble *Cryptosporidium* spp. but are larger, and they have no definite internal morphology; the acid-fast staining tends to be more variable than that seen with *Cryptosporidium* or *Isospora* spp. (Figures 27.23 and 27.24). Some of the *Cyclospora* oocysts tend to look like “wrinkled cellophane,” with tremendous variation in color intensity ranging from clear to pink to red to deep purple to almost black. The stain intensity also depends on the thickness of the smear, the percentage of acid in the decolorizer (1% sulfuric acid recommended), and the length of time the smear is in contact with the decolorizer. If the patient has a heavy infection with microsporidia (immunocompromised patient), small (1- to 2- μm) spores may be seen but may not be recognized as anything other than bacteria or small yeast cells.

There is usually a range of color intensity in the organisms present; not every oocyst appears deep pink to

purple. The greatest staining variation will be seen with *Cyclospora* oocysts; do not decolorize too long.

1. Report the organism and stage (oocyst). Do not use abbreviations.
Examples: *Cryptosporidium* spp. oocysts
Isospora belli oocysts
2. Call the physician when these organisms are identified.
3. Save positive slides for future reference. Label prior to storage (name, patient number, organisms present).

Procedure Notes for Kinyoun's Acid-Fast Staining Method

1. Routine stool examination stains (trichrome and iron hematoxylin) are not recommended; however, sedimentation concentration (500 \times g for 10 min) is recommended for the recovery and identification of the coccidia after the concentration sediment has been stained with one of the modified acid-fast stains. The routine concentration (formalin-ethyl acetate) can be used to recover *Isospora* oocysts (wet sediment examination and/or modified acid-fast stains), but routine permanent stains (trichrome and iron hematoxylin) are not reliable for this purpose.
2. PVA-preserved specimens are not acceptable for staining with the modified acid-fast stain. However, specimens preserved in SAF or other non-mercury single-vial-system fixatives are perfectly acceptable.

Figure 27.23 *Cyclospora cayetanensis* stained with modified acid-fast stain. Note the range of color intensity; some oocysts resemble “wrinkled cellophane.”

Figure 27.24 *Cyclospora* (8 to 10 μm), *Cryptosporidium* (4 to 6 μm), and artifact ($\sim 2 \mu\text{m}$) stained with modified acid-fast stain. Note that the *Cyclospora* oocyst did not stain (modified acid-fast variable) and has the “wrinkled-cellophane” appearance, while both the *Cryptosporidium* oocyst and the artifact did stain modified acid-fast positive. These artifacts are frequently seen; it is very important to measure objects seen in the modified acid-fast smears to confirm that they are actual parasites and not artifacts.

3. Avoid the use of wet-gauze filtration (an old, standardized method of filtering stool prior to centrifugation) with too many layers of gauze that may trap organisms and not allow them to flow into the fluid to be concentrated. It is recommended that no more than two layers of gauze be used; another option is to use the commercially available concentrators that use plastic or metal screens instead of gauze.
4. Other organisms that stain positive include acid-fast bacteria, *Nocardia* spp., and the microsporidia (which are very difficult to find and identify even when they appear to be acid fast).
5. It is very important that smears not be too thick. Thicker smears may not adequately destain.
6. Concentration of the specimen is essential to demonstrate organisms. The number of organisms seen in the specimen may vary from many to very few; therefore, the organisms are concentrated in the sediment, which is used to prepare the smears for subsequent staining.
7. Some specimens require treatment with 10% KOH because of their mucoid consistency. Add 10 drops of 10% KOH to the sediment, and vortex until homogeneous. Rinse with 10% formalin, and centrifuge ($500 \times g$ for 10 min). Without decanting the supernatant, take

1 drop of the sediment and smear it thinly on a slide.

8. Commercial concentrators and reagents are available. (See Appendix 1.)
9. Concentrations of sulfuric acid of 1.0 to 3.0% are normally used. Higher concentrations remove too much stain. The use of acid-alcohol (routinely used in the Ziehl-Neelsen acid-fast staining method for the mycobacteria) decolorizes all organisms; therefore, one must use the modified decolorizer (1 to 3% H_2SO_4) for good results. In general, 1% acid is recommended; this approach will provide excellent staining results for all the coccidia.
10. There is some debate whether organisms lose their ability to take up the acid-fast stain after long-term storage in 10% formalin. Some laboratories have reported this diminished staining.
11. Specimens should be centrifuged in capped tubes, and gloves should be worn during all phases of specimen processing.

Procedure Limitations for Kinyoun’s Acid-Fast Staining Method

1. Light infections with *Cryptosporidium* spp. may be missed (small number of oocysts). The fecal immunoassay methods are more sensitive.
2. Multiple specimens must be examined, since the numbers of oocysts present in the stool vary from day to day. A series of three specimens submitted on alternate days is recommended.
3. *Cyclospora* may be suspected if the organisms appear to be *Cryptosporidium* but are about twice the size (about 10 μm) (Figure 27.24). The microsporidial spores are extremely small (1 to 2 μm) and will probably not be recognized unless they are very numerous and appear to have a somewhat different morphology from the bacteria in the preparation.

Modified Ziehl-Neelsen Acid-Fast Stain (Hot Method)

Cryptosporidium and *Isospora* have been recognized as causes of severe diarrhea in immunocompromised hosts but can also cause diarrhea in immunocompetent hosts. Oocysts in clinical specimens may be difficult to detect without special staining. Modified acid-fast stains are recommended to demonstrate these organisms. Application of heat to the carbol fuchsin assists in the staining, and the use of a milder decolorizer allows the organisms to retain their pink-red color (9). With continued reports of diarrheal outbreaks due to *Cyclospora*, it is also impor-

tant to remember that these organisms are acid fast and can be identified by using this staining approach (27, 28). Although the microsporidial spores are also acid fast, their size (1 to 2 μm) makes identification very difficult without special stains or the use of monoclonal antibody reagents.

Concentrated sediment of fresh, formalin-, or other non-mercury single-vial fixative-preserved stool may be used. Other types of clinical specimens such as duodenal fluid, bile, and pulmonary specimens (induced sputum, bronchial washings, or biopsy specimens) may also be stained.

Carbol Fuchsin

1. To make basic fuchsin (solution A), dissolve 0.3 g of basic fuchsin in 10 ml of 95% ethanol.
2. To make phenol (solution B), dissolve 5 g of phenol crystals in 100 ml of distilled water. (Gentle heat may be needed.)
3. Mix solution A with solution B.
4. Store at room temperature. The solution is stable for 1 year. Note the expiration date on the label.

5% Sulfuric Acid

1. Add 5 ml of concentrated sulfuric acid to 95 ml of distilled water.
2. Store at room temperature. The solution is stable for 1 year. Note the expiration date on the label.

Methylene Blue

1. Dissolve 0.3 g of methylene blue chloride in 100 ml of distilled water.
2. Store at room temperature. The solution is stable for 1 year. Note the expiration date on the label.

Quality Control for the Modified Ziehl-Neelsen Acid-Fast Staining Method

QC guidelines are the same as those for the Kinyoun's acid-fast stain and are given on p. 814.

Procedure for the Modified Ziehl-Neelsen Staining Method

1. Smear 1 to 2 drops of specimen on the slide, and allow it to air dry. Do not make the smears too thick (you should be able to see through the wet material before it dries). Prepare two smears.
2. Dry on a heating block (70°C) for 5 min.
3. Place the slide on a staining rack, and flood it with carbol fuchsin.
4. With an alcohol lamp or Bunsen burner, gently heat the slide to steaming by passing a flame under the slide. Discontinue heating once the stain begins to steam. Do not boil.

5. Allow the specimen to stain for 5 min. If the slide dries, add more stain without additional heating.
6. Rinse thoroughly with water. Drain.
7. Decolorize with 5% sulfuric acid for 30 s. (Thicker slides may require a longer destain.)
8. Rinse the slide with water. Drain.
9. Flood the slide with methylene blue for 1 min.
10. Rinse the slide with water, drain, and air dry.
11. Examine with low or high dry objective. To see internal morphology, use the oil objective (100 \times).

Results and Patient Reports from the Modified Ziehl-Neelsen Acid-Fast Staining Method

The oocysts of *Cryptosporidium* and *Isospora* spp. stain pink to red to deep purple. Some of the four sporozoites may be visible in the *Cryptosporidium* oocysts. Some of the *Isospora* immature oocysts (entire oocyst) stain, while those that are mature usually appear with the two sporocysts within the oocyst wall stained a pink to purple color and a clear area between the stained sporocysts and the oocyst wall (Figure 27.25). The background stains blue. If *Cyclospora* oocysts are present (uncommon), they tend to be approximately 8 to 10 μm , they resemble *Cryptosporidium* oocysts but are larger, and they have no definite internal morphology; the acid-fast staining tends to be more variable than that seen with *Cryptosporidium* or *Isospora* spp. If the patient has a heavy infection with microsporidia (immunocompromised patient), small (1- to 2- μm) spores may be seen but may not be recognized as anything other than bacteria or small yeast cells.

There is usually a range of color intensity in the organisms present; not every oocyst appears deep pink to purple. The greatest staining variation would be seen with *Cyclospora* organisms.

1. Report the organism and stage (oocyst). Do not use abbreviations.
Examples: *Cryptosporidium* spp. oocysts
Isospora belli oocysts
Cyclospora cayetanensis oocysts
2. Call the physician when these organisms are identified.
3. Save positive slides for future reference. Label prior to storage (name, patient number, organisms present).

Procedure Notes for the Modified Ziehl-Neelsen Acid-Fast Staining Method

1. Routine stool examination stains (trichrome and iron hematoxylin) are not recommended; however, sedimentation concentration (500 \times g for 10 min) is acceptable for the recovery and identification of

the coccidia, particularly after the concentration sediment has been stained with one of the modified acid-fast stains. The routine concentration (formalin-ethyl acetate) can be used to recover *Isospora* oocysts (wet sediment examination and/or modified acid-fast stains), but routine permanent stains (trichrome and iron hematoxylin) are not reliable for this purpose.

2. PVA-preserved specimens are not acceptable for staining with the modified acid-fast stain. However, specimens preserved in SAF or other single-vial preservatives are perfectly acceptable.
3. Avoid the use of wet-gauze filtration (an old, standardized method of filtering stool prior to centrifugation) with too many layers of gauze that may trap organisms and not allow them to flow into the fluid to be concentrated. It is recommended that no more than two layers of gauze be used. Another option is to use the commercially available concentration systems in which metal or plastic screens are used for filtration.
4. Other organisms that stain positive include acid-fast bacteria, *Nocardia* spp., and the microsporidia (which are very difficult to find and identify even when they appear to be acid fast).
5. It is very important that smears not be too thick. Thicker smears may not adequately destain.
6. Concentration of the specimen is essential to demonstrate organisms. The number of organisms

seen in the specimen may vary from numerous to very few. Therefore, the sensitivity of the method is enhanced if the stains are performed on concentrated sediment.

7. Some specimens require treatment with 10% KOH because of their mucoid consistency. Add 10 drops of 10% KOH to the sediment, and vortex until homogeneous. Rinse with 10% formalin, and centrifuge ($500 \times g$ for 10 min). Without decanting the supernatant, take 1 drop of the sediment and smear it thinly on a slide.
8. Commercial concentrators and reagents are available.
9. Do not boil the stain. Gently heat until steam rises from the slide. Do not allow the stain to dry on the slide.
10. Various concentrations of sulfuric acid (0.25 to 10%) may be used; the destaining time varies according to the concentration used. Generally, a 1 or 5% solution is used. The use of acid-alcohol (routinely used in the Ziehl-Neelsen acid-fast staining method for the mycobacteria) decolorizes all organisms; therefore, the modified decolorizer must be used for good results.
11. There is some debate whether organisms lose their ability to take up the acid-fast stain after long-term storage in 10% formalin. Some laboratories have reported this diminished staining.
12. Specimens should be centrifuged in capped tubes, and gloves should be worn during all phases of specimen processing.

Figure 27.25 (Upper) Immature *Isospora belli* oocyst stained with modified acid-fast stain; (lower) *I. belli* immature oocyst (left) (note that the entire oocyst retains the stain) and *I. belli* mature oocyst containing two sporocysts (right).

Procedure Limitations for the Modified Ziehl-Neelsen Acid-Fast Staining Method

1. Light infections with *Cryptosporidium* or *Cyclospora* may be missed (small number of oocysts). When available, fecal immunoassay methods for *Cryptosporidium* are more sensitive.
2. Multiple specimens must be examined, since the numbers of oocysts present in the stool vary from day to day. A series of three specimens submitted on alternate days is recommended.
3. The identification of both *Cyclospora* organisms and microsporidia may be difficult. *Cyclospora* may be suspected if the organisms appear to be *Cryptosporidium* but are about twice the size (about 8 to 10 μm). The microsporidial spores are extremely small (1 to 2 μm) and will probably not be recognized unless they are very numerous and appear to have a somewhat different morphology from the other bacteria in the preparation.
4. Often, artifact material may be seen in these stained smears (Figure 27.24). The artifacts may resemble

the oocysts of *Cryptosporidium* or *Cyclospora*; therefore, it is very important that any “parasites” seen in the stained smears be measured for confirmation.

There are three other stains that can be used for the coccidia, although they may not be as common as the Kinyoun or hot acid-fast method. They are the carbol fuchsin negative stain, the safranin stain, and the auramine O stain.

Carbol Fuchsin Negative Stain for *Cryptosporidium* (from W. L. Current)

1. Mix thoroughly an equal volume (3 to 10 μ l) of fresh or formalin-fixed stool and Kinyoun’s carbol fuchsin on a slide.
2. Spread out as a thin film, and allow to air dry at room temperature.
3. Add immersion oil directly to the stained smear, and then cover with a coverslip.
4. Observe under bright-field microscopy ($\times 400$). Everything but the oocysts stains darkly. The oocysts are bright and refractile because they contain water and everything else is oil soluble.

Rapid Safranin Method for *Cryptosporidium* (1)

1. Smear fresh or formalin-fixed feces on a slide, and allow the film to air dry at room temperature.
2. Fix briefly with one pass through the Bunsen burner flame.
3. Fix for 3 to 5 min with 3% HCl in methanol.
4. Wash with tap water (brief rinse).
5. Stain with 1% aqueous safranin for 1 min (heat until steam appears) (the authors indicate by personal communication that boiling may be beneficial).
6. Rinse in tap water.
7. Counterstain with 1% methylene blue for 30 s (0.1% aqueous crystal violet was almost as good, but malachite green was unsatisfactory).

Rapid Safranin Method for *Cyclospora*, Using a Microwave Oven (4, 44)

Another rapid safranin method uniformly stains *Cyclospora* oocysts a brilliant reddish orange. However, the fecal smears must be heated in a microwave oven before being stained. This stain is fast, reliable, and easy to perform (44).

1. Using a 10- μ l aliquot of concentrated stool, prepare the smear by spreading the material thinly across the slide.
2. Allow the smear to dry on a 60°C slide warmer.
3. Cool the slide to room temperature before staining.
4. Place the slide in a Coplin jar containing acidic alcohol (3% [vol/vol] HCl in methanol), and let it stand for 5 min.
5. Wash off excess acidic alcohol with cold tap water.
6. Place the slide(s) into the Coplin jar containing the safranin solution in acidified water (pH 6.5), and microwave at full power (650 W) for 1 min. (Place the staining jar in another container to catch the overflow of stain because of boiling.)
7. Wash off excess stain with cold tap water.
8. Place the slide(s) for 1 min in a Coplin jar containing 1% methylene blue.
9. Rinse gently with cold tap water.
10. Air dry.
11. Add a coverslip to the slide by using Cytoseal 60 or other mounting medium; the immersion oil mounting method can also be used.
12. Examine the smear with low-power or high dry power objectives. To see additional morphology, use the oil immersion objective (100 \times).

Auramine O Stain for Coccidia (from Thomas Hänscheid)

Coccidia are acid-fast organisms and also stain well with auramine O (phenolized auramine O). The size and typical appearance of *Cryptosporidium*, *Cyclospora*, and *Isospora* oocysts enables auramine O-stained slides to be examined at low power using the 10 \times objective. The entire sample area can usually be examined in less than 30 s. The low cost of the reagents, the simple staining protocol, and the rapid microscopic examination also make this staining method suitable for screening unconcentrated fecal specimens.

Concentrated sediment from fresh or non-PVA-preserved stool may be used. Other stool samples may also be used, such as unconcentrated stool submitted for culture in a bacteriology transport medium. However, to increase the sensitivity of the test, small numbers of oocysts are more easily detected using concentrated stools.

Auramine O Stain

Solution 1

Auramine O	0.1 g
95% ethanol	10 ml

Solution 2

Phenol crystals	3.0 g
Distilled water	87 ml

Combine solutions 1 and 2. Store in a dark bottle at room temperature for up to 3 months.

Destaining agent (0.5% acid-alcohol)

Concentrated HCl	0.5 ml
70% ethanol	100 ml

Store at room temperature for up to 3 months.

Counterstain (0.5% potassium permanganate)

Potassium permanganate	0.5 g
Distilled water	100 ml

Quality Control for the Auramine O Stain for Coccidia

QC guidelines are the same as those for the Kinyoun's acid-fast stain and are given on p. 814.

Procedure for the Auramine O Stain for Coccidia

- Using a 10- to 20- μ l aliquot of concentrated stool, prepare the smear by spreading the material across the slide.
- Heat fix the slides either on a 65 to 75°C heat block for at least 2 h or with the flame of a Bunsen burner. However, do not overheat. Another fixation option would be to fix the slide in absolute methanol for 1 min, air dry, and then proceed with staining.
- Cool the slide to room temperature before staining.
- Flood the slide with the phenolized auramine O solution.
- Allow the smear to stain for ca. 15 min. *Do not heat.*
- Rinse the slide in water. Drain excess water from the slide.
- Flood the slide with the destaining solution (0.5% acid-alcohol).
- Allow to decolorize for 2 min.
- Flood with counterstain (potassium permanganate) solution.
- Stain for 2 min. *The timing of this step is critical.*
- Rinse the slide in water. Drain excess water from the slide.
- Allow the smear to air dry. Do not blot.
- Examine the smear with a fluorescence microscope with a 10 \times objective and fluorescein isothiocyanate optical filters (auramine O: excitation max., ~435 nm in water; emission max.,

~510 nm). Screen the whole sample area for the presence of fluorescent oocysts. Suspicious objects can be reexamined using a 20 \times or 100 \times objective.

- Smears can be restained by any of the carbol fuchsin (modified acid-fast) staining procedures to allow examination with light microscopy.

Results and Patient Reports from the Auramine O Staining Method

Cryptosporidium and *Cyclospora* oocysts fluoresce brightly and have a regular round appearance ("starry sky" appearance with the 10 \times objective). In contrast to the large majority of fluorescent artifacts, the oocysts do not stain homogeneously. Thus, the fluorescence is heterogeneously distributed in the interior of the oocyst (Figure 27.26). *Isospora* oocysts fluoresce brightly with three patterns: (i) a more or less brightly but heterogeneously stained interior of the whole oocyst, (ii) one brightly staining sporocyst, or (iii) two brightly staining sporocysts within the oocyst wall.

- Report the organism and stage (oocyst). Do not use abbreviations.
Examples: *Cryptosporidium* spp. oocysts
Isospora belli oocysts
Cyclospora cayetanensis oocysts
- Call the physician when these organisms are identified.
- Save positive slides for future reference. Label prior to storage (name, patient number, organisms present). These slides can be kept at room temperature in the dark, and the fluorescence remains stable for up to 3 to 4 weeks.

Procedure Notes for the Auramine O Staining Method

- It is mandatory that positive control smears be stained and examined each time patient specimens are stained and examined.
- For best results, examine the auramine O solution for deposits and remove them by filtration or centrifugation. This problem can also be avoided by preparing smaller volumes more frequently.
- Slides should be observed as soon as possible after staining. However, they can be kept at room temperature in the dark, and fluorescence remains stable for up to 3 to 4 weeks.

Procedure Limitations for the Auramine O Staining Method

- Light infections might be missed, particularly if

unconcentrated stool is used; it is always recommended that concentrated stool sediment be used for staining.

2. Use of the 40× high dry objective often causes a blurred image (fluorescent “halo” around the image, hazy contours), which appears to be the effect of interfering fluorescence from the auramine O stain located outside the plane of focus (Figure

27.26). The 100× oil immersion objective gives better-quality images. Immersion oils used for light microscopy may be autofluorescent, and special low-fluorescence immersion oil should be used.

3. If the fluorescence is not clear or definitive, a suspicious slide can be restained with a modified acid-fast stain and reexamined using light microscopy and the 100× oil immersion objective.
4. If protected from sunlight, auramine O slides can be kept on the bench at room temperature for up to 2 to 3 weeks, with only minor loss of fluorescence (photo bleaching).

(Middle) *Isoospora belli* stained with auramine O fluorescent stain (courtesy of Thomas Hänscheid). (Bottom) *Cryptosporidium* spp. stained with auramine O fluorescent stain (left, 40× objective; right, 100× oil immersion objective) (courtesy of Thomas Hänscheid).

Modified Trichrome Stain for the Microsporidia (Weber—Green) (45)

The diagnosis of intestinal microsporidiosis (*Enterocytozoon bieneusi*, *Encephalitozoon intestinalis*) has depended on the use of invasive procedures and subsequent examination of biopsy specimens, often by electron microscopy. However, the need for a practical method for the routine clinical laboratory has stimulated some work in the development of additional methods. Slides prepared from fresh or formalin-fixed stool specimens can be stained by a chromotrope-based technique and can be examined under light microscopy. This staining method is based on the fact that stain penetration of the microsporidial spore is very difficult; therefore, the dye content in the chromotrope 2R is greater than that routinely used to prepare Wheatley’s modification of Gomori’s trichrome method, and the staining time is much longer (90 min) (Figures 27.27 and 27.28) (38, 45, 46). At least several of these stains are available commercially from a number of suppliers.

The specimen can be fresh stool or stool that has been preserved in 5 or 10% formalin, SAF, or the newer single-val-system fixatives. Actually, any specimen other than tissue thought to contain microsporidia could be stained by this method.

Trichrome Stain (Modified for Microsporidia) (Weber—Green) (45)

Chromotrope 2R.....	6.0 g*
Fast green.....	0.15 g
Phosphotungstic acid.....	0.7 g
Acetic acid (glacial)	3.0 ml
Distilled water.....	100.0 ml

* (10 times the normal trichrome stain formula)

1. Prepare the stain by adding 3.0 ml of acetic acid to the dry ingredients. Allow the mixture to stand (ripen) for 30 min at room temperature.
2. Add 100 ml of distilled water. Properly prepared stain is dark purple.

REVIEW Modified Acid-Fast Smears	
Topic	Comments
Principle	To provide contrasting colors for both the background debris and parasites present; designed to allow examination and recognition of acid-fast characteristic of the organisms under high dry examination (40× objective for a total magnification of ×400). Designed primarily to allow recovery and identification of intestinal coccidian oocysts. Internal morphology (sporozoites) is seen in some <i>Cryptosporidium</i> oocysts under oil immersion (×1,000 magnification).
Specimen	Any stool specimen that is fresh or preserved in formalin, SAF, or the newer single-vial-system fixatives.
Reagents	Kinyoun's acid-fast stain, modified Ziehl-Neelsen stain, and their associated solutions; dehydrating solutions (alcohols and xylenes); mounting fluid optional; the decolorizing agents are less intense than the routine acid-alcohol used in routine acid-fast staining (this fact is what makes these procedures "modified" acid-fast procedures).
Examination	High dry examination of at least 300 fields; additional fields may be required if suspect organisms have been seen but are not clearly acid fast.
Results and Laboratory Reports	The identification of <i>Cryptosporidium</i> and <i>Isoospora</i> oocysts should be possible; <i>Cyclospora</i> oocysts, which are twice the size of <i>Cryptosporidium</i> oocysts, should be visible but tend to be more acid-fast variable. The stain intensity depends on the thickness of the smear, the percentage of acid in the decolorizer, and the length of time the smear is in contact with the decolorizer. Although microsporidia are acid fast, their small size makes their recognition very difficult. Final laboratory results would depend heavily on the appearance of the QC slides and comparison with patient specimens.
Procedure Notes and Limitations	Both the cold and hot modified acid-fast methods are excellent for the staining of coccidian oocysts. There is some feeling that the hot method may result in better stain penetration, but the differences are probably minimal. Procedure limitations are related to specimen handling (proper centrifugation speeds and time, use of no more than two layers of wet gauze for filtration, and complete understanding of the difficulties in recognizing microsporidial spores). There is also some controversy concerning whether the organisms lose the ability to take up acid-fast stains after long-term storage in 10% formalin. The organisms are more difficult to find in specimens from patients who do not have the typical, watery diarrhea (more formed stool contains more artifact material).

3. Store in a glass or plastic bottle at room temperature. The shelf life is at least 24 months.

Acid-Alcohol

90% ethyl alcohol..... 995.5 ml
Acetic acid (glacial) 4.5 ml

Prepare by combining the two solutions.

Quality Control for the Modified Trichrome Staining Method (Weber—Green)

1. Unfortunately, the only way to perform acceptable QC procedures for the modified trichrome staining method is to use actual microsporidial spores as the control organisms. Obtaining these positive controls may be somewhat difficult. It is particularly important to use the actual organisms, because the spores are difficult to stain and they are very small (1 to 2.5 μm).
2. A QC slide should be included with each run of stained slides, particularly if the staining setup is used infrequently.
3. All staining dishes should be covered to prevent evaporation of reagents (screw-cap Coplin jars or glass lids).
4. Depending on the volume of slides stained, staining solutions must be changed on an as-needed basis.
5. When the smear is thoroughly fixed and the stain is performed correctly, the spores are ovoid and refractile, with the spore wall being bright pinkish red. Occasionally, the polar tube can be seen either as a stripe or as a diagonal line across the spore. The majority of the bacteria and other debris tend to stain green. However, some bacteria and debris still stain red.
6. The specimen is also checked for adherence to the slide (macroscopically).
7. The microscope should be calibrated (within the last 12 months), and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. The calibration factors for all objectives should be posted on the microscope for easy access (multiplication factors can be pasted on the body of the microscope).

Figure 27.27 (Upper) Microsporidian spores in a stool specimen concentrate sediment stained with a modified trichrome stain. The spores range from about 1.5 to 2.0 μm in diameter. Note the horizontal lines, indicating the presence of a polar tubule. (Lower) Microsporidian spores from a nasopharyngeal aspirate stained with a modified trichrome stain. Note the presence of the polar tubule within several of the spores.

Although recalibration every 12 months may not be necessary, this will vary from laboratory to laboratory, depending on equipment care and use.

8. Known positive microscope slides, Kodachrome 2 \times 2 projection slides, and photographs (reference books) should be available at the workstation.
9. Record all QC results; the laboratory should also have an action plan for “out-of-control” results.

Procedure for Modified Trichrome Staining Method (Weber—Green)

1. Using a 10- μl aliquot of unconcentrated (concentrated recommended), preserved liquid stool (5 or 10% formalin or SAF or one of the non-PVA single-vial preservatives), prepare the smear by spreading the material over an area 45 by 25 mm.

Figure 27.28 Microsporidian spores in a urine sediment, stained with a modified trichrome stain. Note that some of the spores are intracellular. A urine specimen tends to be “cleaner” than stool; therefore the spores may be easier to see and identify in urine or any specimen that contains less artifact material than stool.

2. Allow the smear to air dry.
3. Place the smear in absolute methanol for 5 min.
4. Allow the smear to air dry.
5. Place in trichrome stain for 90 min.
6. Rinse in acid-alcohol for no more than 10 s.
7. Dip slides several times in 95% alcohol. Use this step as a rinse.
8. Place in 95% alcohol for 5 min.
9. Place in 100% alcohol for 10 min.
10. Place in xylene substitute for 10 min.
11. Mount with a coverslip (no. 1 thickness), using mounting medium.
12. Examine smears under oil immersion ($\times 1,000$), and read at least 300 fields; the examination time will probably be at least 10 min per slide.

Modified Trichrome Stain for the Microsporidia (Ryan—Blue) (38)

A number of variations to the modified trichrome stain (Weber—green) have been tried in an attempt to improve the contrast between the color of the spores and the background staining. Optimal staining was achieved by modifying the composition of the trichrome solution. This stain is also available commercially from a number of suppliers.

The specimen can be fresh stool or stool that has been preserved in 5 or 10% formalin, SAF, or the newer single-vial-system fixatives. Actually, any specimen other than

tissue thought to contain microsporidia could be stained by this method.

**Trichrome Stain (Modified for Microsporidia)
(Ryan—Blue)**

Chromotrope 2R.....	6.0 g*
Aniline blue.....	0.5 g
Phosphotungstic acid.....	0.25 g
Acetic acid (glacial).....	3.0 ml
Distilled water.....	100.0 ml

*(10 times the normal trichrome stain formula)

1. Prepare the stain by adding 3.0 ml of acetic acid to the dry ingredients. Allow the mixture to stand (ripen) for 30 min at room temperature.
2. Add 100 ml of distilled water, and adjust the pH to 2.5 with 1.0 M HCl. Properly prepared stain is dark purple. The staining solution should be protected from light.
3. Store in a glass or plastic bottle at room temperature. The shelf life is at least 24 months.

Acid-Alcohol

90% ethyl alcohol.....	995.5 ml
Acetic acid (glacial).....	4.5 ml

Prepare by combining the two solutions.

Quality Control for the Modified Trichrome Staining Method (Ryan—Blue)

1. Unfortunately, the only way to perform acceptable QC procedures for this method is to use actual microsporidial spores as the control organisms. Obtaining these positive controls may be somewhat difficult. It is particularly important to use the actual organisms, because the spores are difficult to stain and are very small (1 to 2.5 μm).
2. A QC slide should be included with each run of stained slides, particularly if the staining setup is used infrequently.
3. All staining dishes should be covered to prevent evaporation of reagents (screw-cap Coplin jars or glass lids).
4. Depending on the volume of slides stained, staining solutions must be changed on an as-needed basis.
5. When the smear is thoroughly fixed and the stain is performed correctly, the spores are ovoid and refractile, with the spore wall being bright pinkish red. Occasionally, the polar tube can be seen either as a stripe or as a diagonal line across the spore. The majority of the bacteria and other debris tend to stain blue. However, some bacteria and debris still stain red.

6. The specimen is also checked for adherence to the slide (macroscopically).
7. The microscope should be calibrated (within the last 12 months), and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. The calibration factors for all objectives should be posted on the microscope for easy access (multiplication factors can be pasted on the body of the microscope). Although recalibration every 12 months may not be necessary, this will vary from laboratory to laboratory, depending on equipment care and use.
8. Known positive microscope slides, Kodachrome 2 \times 2 projection slides, and photographs (reference books) should be available at the workstation.
9. Record all QC results; the laboratory should also have an action plan for “out-of-control” results.

Procedure for the Modified Trichrome Staining Method (Ryan—Blue)

1. Using a 10- μl aliquot of concentrated (10 min at 500 \times g), preserved liquid stool (5 or 10% formalin, SAF, or one of the non-PVA single-vial preservatives, zinc based), prepare the smear by spreading the material over an area 45 by 25 mm.
2. Allow the smear to air dry.
3. Place the smear in absolute methanol for 5 or 10 min.
4. Allow the smear to air dry.
5. Place in trichrome stain for 90 min.
6. Rinse in acid-alcohol for no more than 10 s.
7. Dip the slides several times in 95% alcohol. Use this step as a rinse (no more than 10 s).
8. Place in 95% alcohol for 5 min.
9. Place in 95% alcohol for 5 min.
10. Place in 100% alcohol for 10 min.
11. Place in xylene substitute for 10 min.
12. Mount with a coverslip (no. 1 thickness), using mounting medium.
13. Examine smears under oil immersion (\times 1,000), and read at least 300 fields; the examination time will probably be at least 10 min per slide.

Results and Patient Reports from Modified Trichrome Staining Methods (Weber or Ryan)

The microsporidial spore wall should stain pinkish to red, with the interior of the spore being clear or perhaps showing a horizontal or diagonal stripe which represents the polar tube. The background appears green or blue, depending on the method. Other bacteria, some yeast cells, and some debris stains pink to red; the shapes and sizes of the various components may be helpful in dif-

ferentiating the spores from other structures. The results of this staining procedure should be reported only if the positive control smears are acceptable. The production of immunoassay reagents should provide a more specific and sensitive approach to the identification of the microsporidia in fecal specimens.

1. Report the organism.

Examples: Microsporidial spores present. The following information can be added to the report to assist the physician in treating and following the patient:

The organisms are most probably *Enterocytozoon bienersi* or *Encephalitozoon intestinalis* (if from fecal specimen or urine).

The organisms are most probably *Encephalitozoon intestinalis* (identification to species highly likely) (generally the organism involved in disseminated cases from the gastrointestinal tract to other body sites).

Procedure Notes for Modified Trichrome Staining Methods (Weber or Ryan)

1. It is mandatory that positive control smears be stained and examined each time patient specimens are stained and examined.
2. Because of the difficulty in getting the stain to penetrate the spore wall, prepare thin smears and do not reduce the staining time in trichrome. Also, make sure the slides are not left too long in the decolorizing agent (acid-alcohol). If the control organisms are too light, leave them in the trichrome longer and shorten the time to two dips in the acid-alcohol solution. Also, remember that the 95% alcohol rinse after the acid-alcohol should be performed quickly to prevent additional destaining from the acid-alcohol reagent.
3. When you purchase the chromotrope 2R, obtain the highest dye content available. Two sources are Harleco, Gibbstown, N.J., and Sigma Chemical Co., St. Louis, Mo. (dye content among the highest [85%]). Fast green and aniline blue can be obtained from Allied Chemical and Dye, New York, N.Y. See also appendix 5.
4. In the final stages of dehydration, the 100% ethanol and the xylenes (or xylene substitutes) should be kept as free from water as possible. Coplin jars must have tight-fitting caps to prevent both evaporation of reagents and absorption of moisture. If the xylene becomes cloudy after addition of slides from 100% alcohol, return the slides to

fresh 100% alcohol and also replace the xylene with fresh stock.

Procedure Limitations for Modified Trichrome Staining Methods (Weber or Ryan)

1. Although this staining method stains the microsporidia, the range of stain intensity and the small size of the spores causes some difficulty in identifying these organisms. Since this procedure results in many other organisms or objects staining in stool specimens, differentiation of the microsporidia from surrounding material is still very difficult. There also tends to be some slight size variation among the spores.
2. If the patient has severe watery diarrhea, there is less artifact material in the stool to confuse with the microsporidial spores; however, if the stool is semi-formed or formed, the amount of artifact material is much greater and the spores are much harder to detect and identify. Also, the number of spores varies according to the stool consistency (generally, the more liquid the stool, the more spores will be present). However, remember that there is also a dilution factor if the stool is very liquid.
3. The workers who developed some of these procedures think that concentration procedures result in an actual loss of microsporidial spores; therefore, there is a recommendation to use unconcentrated, formalinized stool. However, there are no data indicating which centrifugation speeds, etc., were used in the study.
4. In the UCLA Clinical Microbiology Laboratory, we have generated data (unpublished) to indicate that **centrifugation at $500 \times g$ for 10 min dramatically increases the number of microsporidial spores available for staining (from the concentrate sediment)**. This is the same method we use for centrifugation of all stool specimens, regardless of the suspected organism.
5. Avoid the use of wet-gauze filtration (an old, standardized method of filtering stool prior to centrifugation) with too many layers of gauze that may trap organisms and not allow them to flow into the fluid to be concentrated. It is recommended that no more than two layers of gauze be used. Another option is to use the commercially available concentration systems in which metal or plastic screens are used for filtration.

Modified Trichrome Stain for the Microsporidia (Kokoskin—Hot Method) (24)

Changes in temperature from room temperature to 50°C and in the staining time from 90 to 10 min have been rec-

ommended as improvements for the modified trichrome staining methods. The procedure is as follows.

1. Using a 10- μ l aliquot of concentrated, preserved stool (5 or 10% formalin or SAF), prepare the smear by spreading the material over an area 45 by 25 mm.
2. Allow the smear to air dry.
3. Place the smear in absolute methanol for 5 min.
4. Allow the smear to air dry.
5. Place in trichrome stain for 10 min at 50°C.
6. Rinse in acid-alcohol for no more than 10 s.
7. Dip the slide several times in 95% alcohol. Use this step as a rinse (no more than 10 s).
8. Place in 95% alcohol for 5 min.
9. Place in 100% alcohol for 10 min.
10. Place in xylene substitute for 10 min.
11. Mount with a coverslip (no. 1 thickness), using mounting medium.
12. Examine the smear under oil immersion ($\times 1,000$) and read at least 300 fields; the examination time will probably be at least 10 min per slide.

Acid-Fast Trichrome Stain for *Cryptosporidium* and the Microsporidia

The detection of *Cryptosporidium* spp. and the microsporidia from stool specimens has depended on two separate stains. However, a method is now available that stains both organisms, an important improvement since dual infections have been demonstrated in AIDS patients (12). This acid-fast trichrome stain yields results comparable to those obtained by the Kinyoun and modified trichrome methods and considerably reduces the time necessary for microscopic examination (19, 20) (Figure 27.29). Also, it appears that modified trichrome stains and staining with fluorochromes are equally useful in the diagnosis of microsporidiosis; however, a combination of the two methods may be more sensitive in cases where the number of spores is very small (19).

The specimen can be fresh stool or stool that has been preserved in 5 or 10% formalin, SAF, or some of the newer single-vial-system fixatives. Actually, any specimen other than tissue thought to contain microsporidia could be stained by this method.

Trichrome Stain (Modified for Microsporidia) (4)

Chromotrope 2R.....	6.0 g*
Aniline blue.....	0.5 g
Phosphotungstic acid.....	0.7 g
Acetic acid (glacial).....	3.0 ml
Distilled water.....	100.0 ml

*(10 times the normal trichrome stain formula)

Figure 27.29 *Cryptosporidium* spp. and microsporidian spores in an acid-fast trichrome stain. Note the size differential.

1. Prepare the stain by adding 3.0 ml of acetic acid to the dry ingredients. Allow the mixture to stand (ripen) for 30 min at room temperature.
2. Add 100 ml of distilled water, and adjust the pH to 2.5 with 2.0 N HCl. Properly prepared stain is dark purple. The staining solution should be protected from light.
3. Store in a glass or plastic bottle at room temperature. The shelf life is at least 24 months.

Carbol Fuchsin Solution

Phenol solution

Phenol.....	25.0 g
Distilled water.....	500.0 ml

Saturated alcoholic fuchsin solution

Basic fuchsin.....	2.0 g
96% ethanol.....	25.0 ml

Add the mixture of phenol and water to 25.0 ml of the saturated alcoholic fuchsin solution.

Acid-Alcohol

90% ethyl alcohol.....	995.5 ml
Acetic acid (glacial).....	4.5 ml

Prepare by combining the two solutions.

Quality Control for the Acid-Fast Trichrome Staining Method

1. Unfortunately, the only way to perform acceptable QC procedures for this method is to use actual microsporidian spores as the control organisms.

Obtaining these positive controls may be somewhat difficult. It is particularly important to use the actual organisms because the spores are difficult to stain and are very small (1 to 2.5 μm).

2. A QC slide should be included with each run of stained slides, particularly if the staining setup is used infrequently.
3. All staining dishes should be covered to prevent evaporation of reagents (screw-cap Coplin jars or glass lids).
4. Depending on the volume of slides stained, staining solutions must be changed on an as-needed basis.
5. When the smear is thoroughly fixed and the stain is performed correctly, the spores are ovoid and refractile, with the spore wall being bright pinkish red. Occasionally, the polar tube can be seen either as a stripe or as a diagonal line across the spore. The majority of the bacteria and other debris tend to stain blue; however, some bacteria and debris stain red.
6. The specimen is also checked for adherence to the slide (macroscopically).
7. The microscope should be calibrated (within the last 12 months if it has received heavy use), and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. The calibration factors for all objectives should be posted on the microscope for easy access (multiplication factors can be pasted on the body of the microscope). Although recalibration every 12 months may not be necessary, this varies from laboratory to laboratory, depending on equipment care and use.
8. Known positive microscope slides, Kodachrome 2 \times 2 projection slides, and photographs (reference books) should be available at the workstation.
9. Record all QC results; the laboratory should also have an action plan for "out-of-control" results.

Procedure for the Acid-Fast Trichrome Staining Method

1. Using a 10- μl aliquot of concentrated (10 min at 500 \times g), preserved liquid stool (5 or 10% formalin, SAF, or one of the single-vial preservatives, zinc based), prepare the smear by spreading the material over an area 45 by 25 mm.
2. Allow the smear to air dry.
3. Place the smear in absolute methanol for 5 or 10 min.
4. Allow the smear to air dry.
5. Place in carbol fuchsin solution for 10 min (no heat required).
6. Rinse briefly with tap water.
7. Decolorize with 0.5% acid-alcohol.

8. Briefly rinse with tap water.
9. Place in trichrome stain for 30 min at 37°C.
10. Rinse in acid-alcohol for no more than 10 s.
11. Dip the slide several times in 95% alcohol. Use this step as a rinse (no more than 10 s).
12. Place in 95% alcohol for 30 s.
13. Allow the slide to air dry.
14. Examine the smear under oil immersion (\times 1,000) and read at least 300 fields; the examination time will probably be at least 10 min per slide.

Results and Patient Reports from the Acid-Fast Trichrome Staining Method

The microsporidial spore wall should stain pink, with the interior of the spore being clear or perhaps showing a horizontal or diagonal stripe that represents the polar tube; a vacuole may also be visible in some spores. The *Cryptosporidium* oocysts stain bright pink or violet. The results of this staining procedure should be reported only if the positive control smears are acceptable. The production of immunoassay reagents should provide a more specific and sensitive approach to the identification of the microsporidia in fecal specimens.

1. Report the organism.

Examples: Microsporidial spores present. The following information can also be added to the report to assist the physician in treating and following the patient:

The organisms are probably *Enterocytozoon bieneusi* or *Encephalitozoon intestinalis* (if from fecal specimens or urine).

The organisms are probably *Encephalitozoon intestinalis* (identification to species highly likely) (generally the organism involved in disseminated cases from the gastrointestinal tract to kidneys; organisms are recovered in urine).

Procedure Notes for the Acid-Fast Trichrome Staining Method

1. It is mandatory that positive control smears be stained and examined each time patient specimens are stained and examined.
2. Because of the difficulty in achieving stain penetration through the spore wall, prepare thin smears and do not reduce the staining time in trichrome. Also, make sure the slides are not left too long in the decolorizing agent (acid-alcohol). If the control organisms are too light, leave them in the trichrome longer and shorten the time to two dips

in the acid-alcohol solution. Also, remember that the 95% alcohol rinse after the acid-alcohol step should be performed quickly to prevent additional destaining from the acid-alcohol reagent.

- When you purchase the chromotrope 2R, obtain the highest dye content available. Two sources are Harleco, Gibbstown, N.J., and Sigma Chemical Co., St. Louis, Mo. (the dye content is among the highest [85%]). Fast green and aniline blue can be obtained from Allied Chemical and Dye, New York, N.Y. See also appendix 5.
- In the final stages of dehydration, the 95% ethanol should be kept as free from water as possible. Coplin jars must have tight-fitting caps to prevent both evaporation of reagents and absorption of moisture.

Procedure Limitations for the Acid-Fast Trichrome Staining Method

- Although this staining method stains the microsporidia, the range of stain intensity and the small size of the spores may still cause some difficulty in identifying these organisms. Since this procedure

results in many other organisms or objects staining in stool specimens, differentiation of the microsporidia from surrounding material is still very difficult. There also tends to be some slight size variation among the spores.

- If the patient has severe watery diarrhea, there is less artifact material in the stool to confuse with the microsporidial spores; however, if the stool is semiformed or formed, the amount of artifact material is much greater and so the spores are much harder to detect and identify. Also, the number of spores may vary according to the stool consistency (generally, the more liquid the stool, the more spores are present).
- The workers who developed some of these procedures think that concentration procedures result in an actual loss of microsporidial spores; therefore there is a recommendation to use unconcentrated, formalinized stool. However, there are no data indicating which centrifugation speeds, etc., were used in the study.
- In the UCLA Clinical Microbiology Laboratory, we have generated data (unpublished) to indicate that **centrifugation at $500 \times g$ for 10 min** dra-

REVIEW Modified Trichrome–Stained Smears	
Topic	Comments
Principle	To provide contrasting colors for the background debris and parasites present; designed to allow examination and recognition of organism morphology under oil immersion (100× objective for a total magnification of ×1,000). Designed primarily to allow recovery and identification of microsporidial spores. Internal morphology (horizontal or diagonal “stripes” may be seen in some spores under oil immersion [×1,000 magnification]).
Specimen	Any stool specimen that is fresh or is preserved in formalin, SAF, or one of the single-vial-system fixatives.
Reagents	Modified trichrome stain (using high-dye-content chromotrope 2R) and associated solutions; dehydrating solutions (alcohols and xylenes); mounting fluid optional.
Examination	Oil immersion examination of at least 300 fields; additional fields may be required if suspect organisms have been seen but are not clearly identified.
Results and Laboratory Reports	The identification of microsporidial spores may be possible; however, their small size will make recognition very difficult. Final laboratory results would depend heavily on the appearance of the QC slides and comparison with patient specimens. Although extruded polar tubes have been seen in clinical samples such as sputum, cerebrospinal fluid, urine, intestinal biopsy specimens, conjunctival swab specimens, and duodenal fluid, they are rarely seen in fecal specimens.
Procedure Notes and Limitations	Because of the difficulty in getting dye to penetrate the spore wall, this staining approach can be very helpful. Procedure limitations are related to specimen handling (proper centrifugation speeds and time, use of no more than two layers of wet gauze for filtration, and complete understanding of the difficulties in recognizing microsporidial spores owing to their small size [1 to 2.0 μm]).
Important Questions for Commercial Suppliers	Make sure to ask about specific fixatives and whether the fecal material can be stained with the modified trichrome stains and modified acid-fast stains. Also, ask if the fixatives prevent the use of any of the newer immunoassay methods now available for several of the intestinal amebae, flagellates, coccidia, and microsporidia (under development).

matically increases the number of microsporidial spores available for staining (from the concentrate sediment). We use the same protocol for centrifugation of all stool specimens, regardless of the suspected organism. The acid-fast trichrome procedure presented here also recommended the use of centrifuged fecal specimens.

- Avoid the use of wet-gauze filtration (an old, standardized method of filtering stool prior to centrifugation) with too many layers of gauze that may trap organisms and not allow them to flow into the fluid to be concentrated. It is recommended that no more than two layers of gauze be used. Another option is to use the commercially available concentration systems that use metal or plastic screens for filtration.

Baermann technique

Agar plate culture for *Strongyloides stercoralis*

Egg studies

Estimation of worm burdens

Hatching of schistosome eggs

Search for tapeworm scolex

Qualitative test for fecal fat

Quantitation of reducing substances (Clinitest)

Among the diagnostic techniques used with stool specimens, the routine ova and parasite examination is the best known. This technique has three components: the direct wet mount, the examination of material from a stool concentrate, and the permanent stained smear. This is an excellent procedure and is recommended for most intestinal parasites. However, several other diagnostic techniques are available for the recovery and identification of parasitic organisms. Most laboratories do not routinely offer all of these techniques, but many are relatively simple and inexpensive to perform (7, 13, 14). The clinician should be aware of the possibilities and the clinical relevance of information obtained from using such techniques. Occasionally, it is necessary to examine stool specimens for the presence of scolices and proglottids of cestodes and adult nematodes and trematodes to confirm the diagnosis and/or for species identification. A method for the recovery of these stages is also described in this chapter. Although not routinely performed, tests for fecal fat and reducing substances are also included.

Culture of Larval-Stage Nematodes

Nematode infections giving rise to larval stages that hatch in soil or in tissues may be diagnosed by using certain fecal culture methods to concentrate the larvae. *Strongyloides stercoralis* larvae are generally the most common larvae found in stool specimens. However, depending on the fecal transit time through the intestine and the patient's condition, rhabditiform and, rarely, filariform larvae may be present. Also, if there is a delay in examination of the stool, embryonated ova as well as larvae of hookworm may be present. Culture of feces for larvae is useful to (i) reveal their presence when they are too scanty to be detected by concentration methods; (ii) distinguish whether the infection is due to *S. stercoralis* or hookworm on the basis of rhabditiform larval morphology by allowing hookworm egg hatching to occur, releasing first-stage larvae; and (iii) allow the development of larvae into the filariform stage for further differentiation.

The use of certain fecal culture methods (sometimes referred to as coproculture) is especially helpful for detection of light infections with hookworm, *S. stercoralis*, and *Trichostrongylus* spp. and for specific identification of parasites. The rearing of infective-stage nematode larvae also helps in the specific

diagnosis of hookworm and trichostrongyle infections because the eggs of many of these species are identical and specific identifications are based on larval morphology. Additionally, such techniques are useful for obtaining a large number of infective-stage larvae for research purposes. Four culture techniques and one “enhanced-recovery” method are described in this chapter.

Harada-Mori Filter Paper Strip Culture

To detect light infections with hookworm, *S. stercoralis*, and *Trichostrongylus* spp., as well as to facilitate specific identification, the Harada-Mori filter paper strip culture technique is very useful (Figure 28.1). This filter paper test tube culture technique was initially introduced by Harada and Mori in 1955 (10) and was later modified by others (12, 23).

In a study looking at the prevalence of *S. stercoralis* in three areas of Brazil, the diagnostic efficacy of the agar plate culture method (discussed later in this chapter) was as high as 93.9% compared to only 28.5 and 26.5% by the Harada-Mori filter paper culture and fecal concentration methods, respectively, when fecal specimens were processed using all three methods (17). Among the 49 positive samples, about 60% were confirmed as positive by using the agar plate method alone. These results indicate that the agar plate approach is probably a much more sensitive diagnostic method than the other two and is recommended for the diagnosis of strongyloidiasis.

The technique requires filter paper to which fresh fecal material is added and a test tube into which the filter paper is inserted. Moisture is provided by adding water

Figure 28.1 Culture methods for the recovery of larval-stage nematodes: Harada-Mori tube method and petri dish culture method. Viable larvae are present if the specimen contains *S. stercoralis* or other nematodes. Wear gloves when handling the culture devices. (Illustration by Nobuko Kitamura.)

to the tube, which continuously soaks the filter paper by capillary action. Incubation under suitable conditions favors hatching of ova and/or development of larvae. Fecal specimens to be cultured should not be refrigerated, since some parasites (especially *Necator americanus*) are susceptible to cold and may fail to develop after refrigeration. Also, caution must be exercised in handling the filter paper strip itself, since infective *Strongyloides* larvae may migrate upward as well as downward on the paper strip. Always observe standard precautions and wear gloves when performing these procedures.

Quality Control for Harada-Mori Filter Paper Strip Culture

1. Follow routine procedures for optimal collection and handling of fresh fecal specimens for parasitologic examination.
2. Examine known positive and negative samples of stools (from laboratory animals), if available, to gain some experience in using the procedure.
3. Review larval diagrams and descriptions for confirmation of larval identification.
4. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. If the microscope undergoes hard use or is moved around within the laboratory, it is strongly recommended that recalibration be performed every 12 months. However, if the microscope remains in the same location and receives normal use, such frequent recalibration may not be required. The calibration factors for all objectives should be posted on the microscope for easy access (multiplication factors can be pasted on the body of the microscope).
5. Record all quality control (QC) results.

Procedure for Harada-Mori Filter Paper Strip Culture

1. Smear 0.5 to 1 g of fresh feces in the center of a narrow strip of filter paper (3/8 by 5 in. [1 in. = 2.54 cm], slightly tapered at one end).
2. Add 3 to 4 ml of distilled water to a 15-ml conical centrifuge tube; identify the specimen on the tube.
3. Insert the filter paper strip into the tube so that the tapered end is near the bottom of the tube. The water level should be approximately 1/2 in. below the fecal spot. It is not necessary to cap the tube. However, a cork stopper or a cotton plug may be used.
4. Maintain the tube upright in a rack at 25 to 28°C. Add distilled water to maintain the original level

(usually evaporation takes place over the first 2 days, and then the culture becomes stabilized).

5. Keep the tube for 10 days, and check it daily by withdrawing a small amount of fluid from the bottom of the tube. Prepare a smear on a glass slide, cover the slide with a coverslip, and examine the smear with the 10× objective.
6. Examine the larvae for motility and typical morphological features to reveal whether hookworm, *Strongyloides*, or *Trichostrongylus* larvae are present.

Results and Patient Reports from Harada-Mori Filter Paper Strip Culture

Larval nematodes of hookworm, *S. stercoralis*, or *Trichostrongylus* spp. may be recovered. If *Strongyloides* organisms are present, free-living stages and larvae may be found after several days in culture.

1. Report “No larvae detected” if no larvae could be detected at the end of the incubation.
2. Report larvae detected by fecal culture.
Example: *Strongyloides stercoralis* larvae detected by fecal culture

Procedure Notes for Harada-Mori Filter Paper Strip Culture

1. If the larvae are too active to observe under the microscope and morphologic details are difficult to see, the larvae can be heat killed within the tube or after removal to the slide; iodine can also be used to kill larvae.
2. Infective larvae may be found any time after the fourth day or even on the first day in a heavy infection. Since infective larvae may migrate upward as well as downward on the filter paper strip, *caution must be exercised in handling the fluid and the paper strip itself to prevent infection. Handle the filter paper with forceps. Wear gloves when handling the cultures.*
3. It is important to maintain the original water level to keep optimum humidity.
4. Fresh stool is required for this procedure; preserved fecal specimens or specimens obtained after a barium meal are not suitable.

Procedure Limitations for Harada-Mori Filter Paper Strip Culture

1. The Harada-Mori technique allows both parasitic and free-living forms of nematodes to develop. If specimens have been contaminated with soil or water containing these forms, it

may be necessary to distinguish parasitic from free-living forms. This distinction is possible since parasitic forms are more resistant to slight acidity than are free-living forms. Proceed as follows (22, 24).

Add 0.3 ml of concentrated hydrochloric acid per 10 ml of water containing the larvae (adjust the volume accordingly to achieve a 1:30 dilution of acid). Free-living nematodes are killed, while parasitic species live for about 24 h.

2. Specimens that have been refrigerated or preserved are not suitable for culture. Larvae of certain species are susceptible to cold environments.

Filter Paper/Slant Culture Technique (Petri Dish)

An alternative technique for culturing *Strongyloides* larvae is a filter paper/slant culture on a microscope slide placed in a glass or plastic petri dish (Figure 28.1), which was originally described by Little (19). As with previous techniques, sufficient moisture is provided by continuous soaking of the filter paper in water. Fresh stool material is placed on the filter paper, which is cut to fit the dimensions of a standard (1- by 3-in.) microscope slide. The filter paper is then placed on a slanted glass slide in a glass or plastic petri dish containing water. This technique allows direct examination of the culture system with a dissecting microscope to look for nematode larvae and free-living stages of *S. stercoralis* in the fecal mass or the surrounding water without having to sample the preparation. *Always wear gloves when performing these procedures.*

Quality Control for the Filter Paper/Slant Culture Technique (Petri Dish)

1. Follow routine procedures for optimal collection and handling of fresh fecal specimens for parasitologic examination.
2. Examine known positive and negative samples of stools (from laboratory animals), if available, to make sure that the procedure is precise.
3. Review larval diagrams and descriptions for confirmation of larval identification.
4. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. The calibration factors for all objectives should be posted on the microscope for easy access (multiplication factors can be pasted on the body of the microscope).
5. Record all QC results.

Procedure for the Filter Paper/Slant Culture Technique (Petri Dish)

1. Cut a filter paper strip (1 by 3 in.), and smear a film of 1 to 2 g of fresh fecal material in the center of the strip.
2. Place the strip on a glass slide (1 by 3 in.). Place the slide inclined at one end of the petri dish by resting the slide on a piece of glass rod or glass tubing; identify the specimen on the dish (Figure 28.1).
3. Add water to the petri dish so that at least the bottom one-fourth of the slide is immersed in water. The stool will be kept moist by capillary action. Cover the dish, and maintain it at 25 to 28°C. As needed, add water to maintain the original level.
4. Keep the dish for 10 days. Examine daily, either with the dissecting microscope or by withdrawing a small amount of fluid and placing it on a microscope slide. Cover with a coverslip, and examine microscopically with the 10× and 40× objectives.
5. Examine any larvae recovered for typical morphologic features.

Results and Patient Reports from the Filter Paper/Slant Culture Technique (Petri Dish)

Larval nematodes of hookworm, *S. stercoralis*, or *Trichostrongylus* spp. may be recovered. If *Strongyloides* organisms are present, free-living stages and larvae may be found after several days in culture.

1. Report “No larvae detected” if no larvae could be detected at the end of incubation.
2. Report larvae detected by fecal culture.
Example: *Strongyloides stercoralis* larvae detected by fecal culture

Procedure Notes for the Filter Paper/Slant Culture Technique (Petri Dish)

1. It is often difficult to observe details in rapidly moving larvae; a drop of iodine or formalin or slight heating can be used to kill the larvae.
2. Infective larvae may be found any time after the fourth day and occasionally after the first day in heavy infections. Since infective larvae may migrate anywhere on the filter paper strip, *caution must be exercised in handling the fluid and the paper strip itself to prevent infection. Wear gloves when handling the cultures.*
3. There may be infective larvae in the moisture that accumulates under the petri dish lid, so be careful not to allow the water to touch the skin when raising the lid.

4. It is important to maintain the original water level to keep optimum humidity.
5. Preserved fecal specimens or specimens obtained after a barium meal are not suitable; fresh stool specimens must be used.

Procedure Limitations for the Filter Paper/Slant Culture Technique (Petri Dish)

1. The filter paper/slant culture technique allows both parasitic and free-living forms of nematodes to develop. If specimens have been contaminated with soil or water containing these forms, it may be necessary to distinguish parasitic from free-living forms. This distinction is possible since parasitic forms are more resistant to slight acidity than are free-living forms. Proceed as follows (22, 24).
Add 0.3 ml of concentrated hydrochloric acid per 10 ml of water containing the larvae (adjust the volume accordingly to achieve a 1:30 dilution of acid). Free-living nematodes are killed, while parasitic species live for about 24 h.
2. Specimens that have been refrigerated or preserved are not suitable for culture. Larvae of certain species are susceptible to cold environments.

Charcoal Culture

Another way to culture hookworm, *Strongyloides*, and trichostrongyle larvae is by using a granulated charcoal culture. The conditions of this culture provide an environment for larval development that mimics conditions in nature. It provides an efficient way to harvest large numbers of infective-stage larvae for use in experimental infections.

Quality Control for Charcoal Culture

1. Follow routine procedures for optimal collection and handling of fresh fecal specimens for parasitologic examination.
2. Examine known positive and negative samples of stools (from laboratory animals), if available, to make sure that the procedure is precise.
3. Review larval diagrams and descriptions for confirmation of larval identification.
4. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. The calibration factors for all objectives should be posted on the microscope for easy access (multiplication factors can be pasted on the body of the microscope).
5. Record all QC results.

Procedure for Charcoal Culture

1. Mix 20 to 40 g of fresh fecal material in tap water until a thick suspension is obtained.
2. Add this suspension to a storage dish (4 by 3 in.) that is slightly more than half filled with no. 10 granulated hardwood charcoal. Mix thoroughly with a wooden tongue depressor until the fecal suspension is evenly distributed throughout the moistened charcoal. Water can be added to ensure that there is adequate moisture, but do not add so much water than it forms a layer on the bottom of the dish. The surface of the charcoal should glisten.
3. Cover the dish, and place it in the dark (in a drawer or cabinet).
4. Check the dish the next day to make sure that there is still sufficient moisture (i.e., that the charcoal still glistens); if water is needed, sprinkle it on the surface without further mixing.
5. Check the dish each day for moisture content. *Caution must be used because moisture will accumulate on the underface of the lid, and it may contain infective-stage larvae.*
6. Approximately 5 or 6 days after the culture has been prepared, hookworm and *Strongyloides* larvae will have reached the infective stage. This can occur earlier if the patient has a heavy infection with numerous larvae in the stool.
7. To harvest the larvae, prepare a round gauze pad of 10- to 12-layer thickness stapled at the edges and cut to fit the dish. Moisten the pad (not dripping wet), and apply it carefully with forceps so that it snugly covers the surface of the charcoal. *Do not allow your hands to touch the charcoal—the larvae will be infective!*
8. Expose the dish, with lid off, to a light source such as a gooseneck lamp. The lamp should be 6 to 8 in. from the surface of the charcoal. Make sure the lamp is not too close; the larvae can be killed by the heat.
9. After approximately 1 h, the pad can be carefully removed with forceps and inverted onto the surface of water in a pilsner glass filled with water. The gauze pad will remain at the top, and the larvae will now make their way through the pad, enter the water, and fall to the bottom of the glass, where they can be harvested with a pipette after another 30 to 60 min. With care, there will be no charcoal at the bottom of the glass, and the larvae will form a clean sediment.

Results and Patient Reports from Charcoal Culture

Larval nematodes of hookworm, *S. stercoralis*, or *Trichostrongylus* spp. may be recovered. If *Strongyloides*

organisms are present, free-living stages and larvae may be found after several days in culture.

1. Report “No larvae detected” if no larvae could be detected at the end of incubation.
2. Report larvae detected by fecal culture.
Example: *Strongyloides stercoralis* larvae detected by fecal culture

Procedure Notes for Charcoal Culture

1. It is often difficult to observe details in rapidly moving larvae; a drop of iodine or formalin or slight heating can be used to kill the larvae.
2. Infective larvae may be found any time after the fourth day and occasionally after the first day in heavy infections. Since infective larvae may be present, *use caution when handling the fluid, gauze pad, and charcoal to prevent infection. Wear gloves when handling the cultures.*
3. It is important to maintain the moisture on the charcoal to keep optimum humidity (the charcoal should glisten).
4. Preserved fecal specimens or specimens obtained after a barium meal are not suitable; fresh stool specimens must be obtained.

Procedure Limitations for Charcoal Culture

1. This technique allows both parasitic and free-living forms of nematodes to develop. If specimens have been contaminated with soil or water containing these forms, it may be necessary to distinguish parasitic from free-living forms. This distinction is possible since parasitic forms are more resistant to slight acidity than are free-living forms. Proceed as follows (22, 24).
Add 0.3 ml of concentrated hydrochloric acid per 10 ml of water containing the larvae (adjust the volume accordingly to achieve a 1:30 dilution of acid). Free-living nematodes are killed, while parasitic species live for about 24 h.
2. Specimens that have been refrigerated or preserved are not suitable for culture. Larvae of certain species are susceptible to cold environments.

Baermann Technique

Another method of examining a stool specimen suspected of containing small numbers of *Strongyloides* larvae is the use of a modified Baermann apparatus (Figure 28.2). The Baermann technique, in which a funnel apparatus is used, relies on the principle that active larvae will migrate from

a fresh fecal specimen that has been placed on a wire mesh with several layers of gauze which are in contact with tap water (2, 7, 28). Larvae migrate through the gauze into the water and settle to the bottom of the funnel, where they can be collected and examined. The main difference between this method and the Harada-Mori and petri dish methods is the greater amount of fresh stool used, possibly providing a better chance of larval recovery in a light infection. Besides being used for patient fecal specimens, this technique can be used to examine soil specimens for the presence of larvae.

Quality Control for the Baermann Technique

1. Follow routine procedures for optimal collection and handling of fresh specimens for parasitologic examination.
2. Examine known positive and negative samples of stools (from laboratory animals), if available, to make sure that the procedure is precise.
3. Review larval diagrams for confirmation of larval identification.
4. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. The calibration factors for all objectives should be posted on the microscope for easy access (multiplication factors can be pasted on the body of the microscope).
5. Record all QC results.

Procedure for the Baermann Technique

1. If possible, use a fresh fecal specimen that has been obtained after administration of a mild saline cathartic, not a stool softener. Soft stool is recommended; however, any fresh fecal specimen is acceptable.
2. Set up a clamp supporting a 6-in. glass funnel. Attach rubber tubing and a pinch clamp to the bottom of the funnel. Place a collection beaker underneath (Figure 28.2).
3. Place a wire gauze or nylon filter over the top of the funnel, followed by a pad consisting of two layers of gauze.
4. Close the pinch clamp at the bottom of the tubing, and fill the funnel with tap water until it just soaks the gauze padding.
5. Spread a large amount of fecal material on the gauze padding so that it is covered with water. If the fecal material is very firm, first emulsify it in water.
6. Allow the apparatus to stand for 2 h or longer; then draw off 10 ml of fluid into the beaker by releasing the pinch clamp, centrifuge the fluid for

Figure 28.2 (Upper) Baermann apparatus. (Illustration by Nobuko Kitamura.) (Lower) Baermann apparatus set up in the laboratory.

2 min at $500 \times g$, and examine the sediment under the microscope (magnification, $\times 100$ and $\times 400$) for the presence of motile larvae. *Make sure that the end of the tubing is well inside the beaker before slowly releasing the pinch clamp. Infective larvae may be present; wear gloves when performing this procedure.*

Results and Patient Reports from the Baermann Technique

Larval nematodes (hookworm, *S. stercoralis*, or *Trichostrongylus* spp.) may be recovered. Both infective and noninfective *Strongyloides* larvae may be recovered, particularly in a heavy infection.

1. Report “No larvae detected” if no larvae could be detected at the end of incubation.
2. Report larvae detected by fecal culture.
Example: *Strongyloides stercoralis* larvae detected by fecal culture

Procedure Notes for the Baermann Technique

1. It may be difficult to observe morphologic details in rapidly moving larvae; a drop of iodine or formalin or slight heating can be used to kill the larvae.
2. Infective larvae may be found any time after the fourth day and occasionally after the first day in heavy infections. *Caution must be exercised in handling the fluid, gauze pad, and beaker to prevent infection. Wear gloves when using this technique.*
3. Remember to make sure that the pinch clamp is tight until you want to release some of the water.
4. Preserved fecal specimens or specimens obtained after a barium meal are not suitable for processing by this method; fresh stool specimens must be obtained.

Procedure Limitations for the Baermann Technique

1. The Baermann technique allows both parasitic and free-living forms of nematodes to develop. If specimens have been contaminated with soil or water containing these forms, it may be necessary to distinguish parasitic from free-living forms. This distinction is possible since parasitic forms are more resistant to slight acidity than are free-living forms. Proceed as follows (22, 24).
Add 0.3 ml of concentrated hydrochloric acid per 10 ml of water containing the larvae (adjust the volume accordingly to achieve a 1:30 dilution of acid). Free-living nematodes are killed, while parasitic species live for about 24 h.
2. Specimens that have been refrigerated or preserved are not suitable for culture. Larvae of certain species are susceptible to cold environments.
3. *Gloves should be worn when this procedure is performed.*
4. Release the pinch clamp slowly to prevent splashing; have the end of the tubing close to the bottom of the beaker for the same reason.

Modification of the Baermann Method

A simple modification of the Baermann method for diagnosis of strongyloidiasis has been developed (11). For this modification, the funnel used in the original version is replaced by a test tube with a rubber stopper, perforated to allow insertion of a plastic pipette tip (Figure 28.3). The tube containing the fecal suspension is inverted over another tube containing 6 ml of saline solution and incubated at 37°C for at least 2 h. The saline solution from the second tube is centrifuged, and the pellet is observed microscopically as a wet mount. Larvae of *S. stercoralis* can be found in the pellet. Although the method is almost identical to the original Baermann method, the amount of stool used in the modified method is smaller.

Agar Plate Culture for *Strongyloides stercoralis*

Agar plate cultures are also recommended for the recovery of *S. stercoralis* larvae and tend to be more sensitive than some of the other diagnostic methods (1, 8, 15, 16, 18, 20, 25, 29). It is important to remember that more than half of *S. stercoralis*-infected individuals tend to have low-level infections (27). The agar plate method continues to

Figure 28.3 Baermann apparatus modification. (Adapted from reference 11.)

be documented as a more sensitive method than the usual direct smear or fecal concentration methods (15, 16, 20, 25). Daily search for furrows on agar plates for up to six consecutive days results in increased sensitivity for diagnosis of both *S. stercoralis* and hookworm infections. Also, a careful search for *S. stercoralis* should be performed for all patients with comparable clinical findings before a diagnosis of idiopathic eosinophilic colitis is made, because the consequent steroid treatment may have a fatal outcome by inducing widespread dissemination of the parasite (6). Human T-cell leukemia virus type 1 (HTLV-1) infection is endemic in a number of Latin American countries. HTLV-1-associated myelopathy/tropical spastic paraparesis and adult T-cell leukemia-lymphoma are emerging diseases in the region. *S. stercoralis* hyperinfection syndrome and therapeutic failure in apparently healthy patients with nondisseminated strongyloidiasis may be markers of HTLV-1 infection (9).

Stool is placed onto agar plates, and the plates are sealed to prevent accidental infections and held for 2 days at room temperature. As the larvae crawl over the agar, they carry bacteria with them, thus creating visible tracks over the agar (Figure 28.4). The plates are examined under the microscope for confirmation of the presence of larvae, the surface of the agar is then washed with 10% formalin, and final confirmation of larval identification is made via wet examination of the sediment from the formalin washings (Figure 28.5).

Occasionally, finding nematode larvae in sputum or bronchoalveolar lavage fluid specimens may be very suggestive of a potential infection with *S. stercoralis*. In Figure 28.6, larvae can be seen stained with Giemsa stain or a Gram stain. Once larvae are seen in respiratory specimens, fecal specimens can be collected for agar plate cultures to confirm strongyloidiasis.

Agar

- 1.5% agar
- 0.5% meat extract
- 1.0% peptone
- 0.5% NaCl

Note Positive tracking on agar plates has been seen on a number of different types of agar. However, the most appropriate agar formula is that listed above.

Quality Control for Agar Plate Culture for *Strongyloides stercoralis*

1. Follow routine procedures for optimal collection and handling of fresh fecal specimens for parasitologic examination.
2. Examine agar plates to ensure that there is no cracking and the agar pour is sufficient to prevent drying. Also, make sure that there is no excess water on the surface of the plates.

Figure 28.4 Agar plate culture method for *Strongyloides stercoralis*. (Upper) Agar plate showing bacterial growth after being distributed over the plate by the movement of the larval worms. (Lower) More random pattern of bacterial growth from the inoculation of bacteria over the agar from the movement of the larval worms.

3. Review larval diagrams and descriptions for confirmation of larval identification.
4. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. The calibration factors for all objectives should be posted on the microscope for easy access (multiplication factors can be pasted on the body of the microscope).
5. Record all QC results (condition of agar plates).

Procedure for Agar Plate Culture for *Strongyloides stercoralis*

1. Place approximately 2 g of fresh stool in the center of the agar plate (area approximately 1 in. in diameter).

Figure 28.5 Agar culture method for *Strongyloides stercoralis*. (1) Agar plates are prepared. (2) Agar is dried for 4 to 5 days on the bench top. (3) Plates are stored in plastic bags. (4) Fresh stool is submitted to the laboratory. (5) Approximately 2 g of stool is placed onto an agar plate. (6) The plate is sealed with tape. (7) The culture plate is incubated at 26 to 33°C for 2 days. (8) The plate is examined microscopically for the presence of tracks (bacteria carried over agar by migrating larvae). (9) 10% formalin is placed onto agar through a hole made in the plastic with hot forceps. (10) Material from the agar plate is centrifuged. (11) The material is examined as a wet preparation for rhabditiform or filariform larvae (high dry power; magnification, $\times 400$). (Illustration by Sharon Belkin.)

2. Replace the lid, and seal the plate with cellulose tape.
3. Maintain the agar plate (right side up) at room temperature for 2 days.
4. After 2 days, examine the sealed plates through the plastic lid under the microscope for microscopic colonies that develop as random tracks on the agar

and evidence of larvae at the ends of the tracks away from the stool.

Note It has been documented that daily search for tracks on agar plates for up to six consecutive days results in increased sensitivity for diagnosis of both *S. stercoralis* and hookworm infections (18). When

Figure 28.6 *Strongyloides stercoralis* larvae. (Upper) Giemsa-stained larvae in a specimen of bronchoalveolar lavage fluid. (Lower) Gram-stained larva in a respiratory specimen (sputum).

trying to rule out strongyloidiasis in immunocompromised patients or in those who may receive immunosuppressive drugs, it is recommended that two plates be set up, one that can be examined after 2 days and one that can be examined after the full 6 days.

5. With the ends of hot forceps, make a hole in the top of the plastic petri dish.
6. Gently add 10 ml of 10% formalin through the hole onto the agar surface, and swirl to cover the surface and rinse the agar plate. Allow to stand for 30 min.
7. Remove the tape and lid of the agar plate. Pour the 10% formalin through a funnel into a centrifuge tube. Do not try and pour the formalin off directly into the centrifuge tube—the tube opening is too small, and formalin will be spilled onto the counter.
8. Centrifuge the formalin rinse fluid 5 min at $500 \times g$.
9. Prepare a wet smear preparation from the sediment and examine with a $10\times$ objective (low power) for presence of larvae. If larvae are found, confirm the identification with a $40\times$ objective (high dry power).

Results and Patient Reports from Agar Plate Culture for *Strongyloides stercoralis*

Larval nematodes of hookworm, *S. stercoralis*, or *Trichostrongylus* spp. may be recovered. If *Strongyloides* organisms are present, free-living stages and larvae may be found after several days on the agar plates.

1. Report “No larvae detected” if no larvae could be detected at the end of incubation and rinse procedure.
2. Report larvae detected by agar plate culture.
Example: *Strongyloides stercoralis* larvae detected by agar plate culture.

Procedure Notes for Agar Plate Culture for *Strongyloides stercoralis*

1. If the larvae are too difficult to observe under the microscope and morphologic details are difficult to see, the larvae can be formalin killed within the plate and examined in the formalin-concentrated sediment.
2. Infective larvae may be found any time after the first or second day or even on the first day in a heavy infection. Since infective larvae may be present on the agar, *caution must be exercised in handling the plates once the cellulose tape is removed. Wear gloves when handling the cultures.*
3. It is important to maintain the plates upright at room temperature. Do not incubate or refrigerate them at any time; this also applies to the fresh stool specimen.
4. Fresh stool is required for this procedure; preserved fecal specimens or specimens obtained after a barium meal are not suitable.

Procedure Limitations for Agar Plate Culture for *Strongyloides stercoralis*

1. The agar plate culture technique is successful if any larvae present are viable. If the fresh stool specimen is too old, larvae may not survive and a negative result will be reported.
2. Specimens that have been refrigerated or preserved are not suitable for culture. Larvae of certain species are susceptible to cold environments.

Egg Studies

Estimation of Worm Burdens

The only human parasites for which it is reasonably possible to correlate egg production with adult worm burdens are *Ascaris lumbricoides*, *Trichuris trichiura*, and

REVIEW Culture of Larval-Stage Nematodes	
Topic	Comments
Principle	Culture of feces for larvae is useful to (i) reveal their presence when they are too scanty to be detected by concentration methods; (ii) distinguish whether the infection is due to <i>S. stercoralis</i> or hookworm on the basis of rhabditiform larval morphology by allowing hookworm egg hatching to occur, releasing first-stage larvae; and (iii) allow development of larvae into the filariform stage for further differentiation.
Specimen	Any stool specimen that is fresh and has not been refrigerated can be used.
Examination	Daily checking of the fluid for the presence of larvae; hold the cultures for 10 days before submitting the final report. Agar plate cultures can be held for 6 days. When trying to rule out strongyloidiasis in immunocompromised patients or in those who may receive immunosuppressive drugs, it is recommended that two plates be set up, one that can be examined after 2 days and one that can be examined after the full 6 days.
Results and Laboratory Reports	The failure to recover larvae does not completely rule out the possibility of infection; however, the probability of infection is very low when results are negative.
Procedure Notes and Limitations	There is always the prospect of recovering infective larvae; <i>gloves must be worn at all times when performing these procedures and carrying out fluid examinations</i> . Make sure that the culture systems are kept hydrated; a certain amount of water will evaporate and be lost as a result of culture equilibration, particularly during the first couple of days.

the hookworms (*Necator americanus* and *Ancylostoma duodenale*). The specific instances in which information on approximate worm burdens is useful are when one is determining the intensity of infection, deciding on possible chemotherapy, and evaluating the efficacy of the drugs administered. With current therapy, the need for monitoring therapy through egg counts is no longer as relevant. However, several methods that can be used if necessary are discussed below. Remember that egg counts are estimates; you will obtain count variations regardless of how carefully you follow the procedure. If two or more fecal specimens are being compared, it is best to have the same individual perform the technique on both samples and to do multiple counts.

Direct-Smear Method of Beaver

The direct-smear method of Beaver is the easiest to use and is reasonably accurate when performed by an experienced technologist. In the original method, Beaver (3) used a calibrated photoelectric cell to prepare a direct smear of exactly 2 mg. For routine purposes, this is impractical, and the procedure has subsequently been modified (4) such that a direct smear of 2 mg (enough fresh fecal material to form a low cone on the end of a wooden applicator stick) of stool is prepared. Egg counts on the direct smear are reported as eggs per smear, and

the appropriate calculations can be made to determine the number of eggs per gram of stool.

Dilution Egg Count

The Stoll count (26) is probably the most widely used dilution egg-counting procedure for the purpose of estimating worm burdens. However, because of cost containment and clinical relevance (therapy is often initiated with no egg count data), most laboratories do not offer this procedure.

Stoll displacement flasks for use in this procedure are available commercially. These flasks have a long neck with etched lines at 56 and 60 ml to facilitate proper filling with sodium hydroxide and fecal material. If commercial Stoll flasks are unavailable, any flask that can hold the sodium hydroxide solution, a weighed amount of 4 g of stool, and a few small glass beads can be used for a container.

1. In a calibrated Stoll flask, add 0.1 N sodium hydroxide to the 56-ml mark.
2. Add fresh fecal material to the flask so that the level of fluid rises to the 60-ml mark. This amount of feces is equivalent to 4 g of feces.
3. Add a few glass beads, and shake vigorously to make a uniform suspension. If the specimen is hard, the mixture may be placed in a refrigerator overnight before shaking to aid in mixing.

4. With a calibrated pipette, quickly remove 0.15 ml of suspension and transfer it to a slide.
5. Do not use a coverslip; place the slide on a mechanical stage, and count all of the eggs.
6. Multiply the egg count by 100 to obtain the number of eggs per gram of stool.
7. The estimate (eggs per gram) obtained will vary according to the consistency of the stool. The following correction factors should be used to convert the estimate to a formed-stool basis:

mushy formed	×1.5
mushy	×2
mushy diarrheic.....	×3

Egg counts on liquid specimens are generally unreliable; the most accurate counts are obtained with use of formed or semiformed specimens.

Modified Stoll Dilution Method

1. Fill a 15-ml centrifuge tube to the 14-ml mark with 0.1 N sodium hydroxide.
2. Add stool to bring the liquid contents up to the 15-ml mark.
3. Mix thoroughly with a wooden applicator stick.
4. If the stool is hard, allow the mixture to stand for several hours.
5. Shake to thoroughly mix, and quickly withdraw exactly 0.15 ml from the middle of the suspension.
6. Transfer the material to a slide, cover (it may be easier to count without a coverslip, since occasionally the eggs flow to the outside of the coverslip), and count the eggs in the entire preparation.
7. Multiply the egg count per preparation by 100 to give an uncorrected count of eggs per milliliter. Corrections may be made as in the Stoll dilution method for original stool consistency.

Correlation with Treatment

The following numbers have been compiled to indicate the correlation between egg counts and the need for treatment. The two helminths listed below are generally the only ones for which the egg count will determine whether the patient is treated for the initial infection. As mentioned above, with the current therapeutic agents available, this information has become less clinically relevant, at least in many parts of the world. However, it has been recognized that egg counts do not always correlate with or accurately predict the worm burden of the host.

1. For *T. trichiura*, about 30,000 eggs/g indicates the presence of several hundred worms, which may cause definite symptoms.
2. For hookworm, about 2,500 to 5,000 eggs/g usually indicates a clinically significant infection.

The effectiveness of therapy for any helminth infection may be evaluated by doing repeated egg counts after treatment. Low egg counts for *T. trichiura* and hookworm are generally reflected by a lack of clinical signs and symptoms in individuals harboring these parasites. However, the presence of even one *Ascaris* worm is potentially dangerous because of the active migrating habits of this parasite, which may result in serious clinical manifestations.

Hatching of Schistosome Eggs

When schistosome eggs (Figure 28.7) are recovered from either urine or stool, they should be carefully examined to determine viability. The presence of living miracidia within the eggs indicates an active infection that may require therapy. The viability of the miracidia can be determined in two ways: (i) the cilia of the flame cells (primitive excretory cells) may be seen on a wet smear by using high dry power and are usually actively moving, and (ii) the miracidia may be released from the eggs by a hatching procedure (Figure 28.8) (5, 7, 21, 22). The eggs usually hatch within several hours when placed in 10 volumes of dechlorinated or spring water (hatching may begin soon after contact with the water). The eggs that are recovered in the urine (24-h specimen collected with no preservatives) are easily obtained from the sediment and can be examined under the microscope to determine viability. McMullen and Beaver (21) recommended the use of a sidearm flask, but an Erlenmeyer flask is an acceptable substitute.

Figure 28.7 *Schistosoma mansoni* egg showing flame cells. (Illustration by Nobuko Kitamura; modified from E. C. Faust et al., *Craig and Faust's Clinical Parasitology*, 8th ed., Lea & Febiger, Philadelphia, Pa., 1970.)

Figure 28.8 (Upper) Sidearm hatching flask used to recover miracidia from viable schistosome eggs. (Illustration by Nobuko Kitamura.) (Lower) Miracidium larva released from egg during hatching procedure. (Armed Forces Institute of Pathology photograph.)

Quality Control for Hatching of Schistosome Eggs

1. Make sure that the water used is chlorine free; chlorine kills the miracidia. You can use bottled water or leave tap water in an open pan overnight before use.
2. Check the saline solution (used to prepare the stool concentration) for the presence of any free-living organisms (flagellates or ciliates). This is normally not a problem.
3. Since it is neither realistic nor practical for the majority of laboratories to perform parallel positive-control procedures, review drawings and size measurements of schistosome eggs and/or miracidia.
4. The microscope should be calibrated, and the objectives and oculars used for the calibration procedure should be used for all measurements on the microscope. The calibration factors for all objectives should be posted on the microscope for easy access (multiplication factors can be pasted on the body of the microscope).
5. Record all QC results.

Procedure for Hatching Schistosome Eggs

1. Thoroughly homogenize a fresh stool specimen (40 to 50 g) in 50 to 100 ml of 0.85% NaCl.
2. Strain through two layers of gauze placed on a funnel. Collect material in a small beaker or 50-ml centrifuge tube.
3. Allow the suspension to settle for 1 h. Pour off and discard the supernatant fluid, and repeat this rinse process at least twice.
4. Decant the saline solution, resuspend the sediment in a small quantity of chlorine-free (spring) water (10 to 20 ml), and pour the suspension into a 500-ml sidearm flask or an Erlenmeyer flask.
5. Add chlorine-free water to the flask so that the fluid level rises to 2 to 3 cm in the side arm or to the top 2 cm of the Erlenmeyer flask. Cover the flask with aluminum foil or black paper, leaving the side arm of the flask exposed to light; if an Erlenmeyer flask is used, cover to 1 cm below the level of fluid in the neck of the flask.
6. Allow the flask to stand at room temperature for several hours or overnight in subdued light.
7. Place a bright light at the side of the flask opposite the surface of exposed water. Do not place the light against the glass, to avoid generation of excess heat. As the eggs hatch, the liberated miracidia will swim to the upper layers and collect in the side arm (or neck region of an Erlenmeyer flask). Make sure that the exposed part of the flask or side arm of the hatching flask does not get too warm.
8. Examine the illuminated area with a magnifying lens (hand lens) to look for minute white organisms swimming rapidly in a straight line (placing dark cardboard or black paper behind the flask will facilitate observation of the white miracidia against a black background).

Results and Patient Reports from Hatching Schistosome Eggs

Living miracidia may be seen; however, failure to see these larvae does not rule out schistosomiasis.

1. Report as “Miracidia of schistosomes detected, indicating the presence of viable eggs.”
2. Report as “No miracidia of schistosomes detected; presence of eggs is not ruled out by this procedure.”

Procedure Notes for Hatching Schistosome Eggs

1. Both urine and stool specimens must be collected without preservatives and should not be refrigerated before being processed.

REVIEW Egg Studies	
Topic	Comments
Principle	The specific instances in which information on approximate worm burdens is useful are when one is determining the intensity of infection, deciding on possible chemotherapy, and evaluating the efficacy of the drugs administered. With current therapy, the need for monitoring therapy through egg counts is no longer as relevant. The hatching of schistosome eggs can provide very important information for the physician; if the eggs are viable, treatment is recommended. If nothing but dead eggshells is seen, it is less critical for the patient to receive therapy.
Specimen	Any stool specimen that is fresh and has not been refrigerated can be used. For the hatching test or microscopic review for miracidium viability, it is critical that the stool specimen be processed (rinsed, centrifuged) with 0.85% NaCl rather than water, which would stimulate the eggs to hatch prematurely.
Examination	Multiple egg counts should be performed on the same specimen; it is also recommended that clinical decisions be based on a series of egg counts over time, particularly when one is monitoring therapy. All schistosome eggs recovered (but not hatched) should be examined under the microscope for moving cilia (flame cells) within the miracidium larvae.
Results and Laboratory Reports	The failure to recover nematode eggs does not completely rule out the possibility of infection; however, the probability of infection is very low when results are negative, particularly with helminths such as <i>T. trichiura</i> , <i>A. lumbricoides</i> , and hookworm. When schistosome eggs are reported, the viability of the eggs (miracidium larva within the eggshell) must be indicated. If dead eggshells are seen, the “nonviability” of these eggs also needs to be indicated.
Procedure Notes and Limitations	Egg counts are always subject to error; multiple counts are recommended. When performing egg counts, remember to use the stool consistency factors when calculating the total number of eggs. The failure to find schistosome eggs or to see evidence of egg viability does not rule out the possibility of schistosomiasis, particularly when a long-standing infection is suspected.

- Hatching does not occur until the saline is removed and nonchlorinated water is added. If a stool concentration is performed, use saline throughout the procedure to prevent premature hatching.
- Make sure that the light is not too close to the side arm or top layer of water in the Erlenmeyer flask. Excess heat kills the miracidia.

Procedure Limitations for Hatching Schistosome Eggs

- The absence of live miracidia does not rule out the presence of schistosome eggs. Nonviable eggs or eggs that failed to hatch are not detected by this method. Microscopic examination of direct or concentrated specimens should be used to demonstrate the presence or absence of eggs.
- Egg viability can be determined by placing some stool or urine sediment (same material as used for the hatching flask) on a microscope slide. Low-power magnification ($\times 100$) can be used to locate

the eggs. Individual eggs can be examined under high dry magnification ($\times 400$); the detection of moving cilia on the flame cells (primitive excretory system) confirms egg viability.

- Free-living ciliates may be present in soil-contaminated water. Therefore, it may be necessary to perform the following steps to differentiate those forms from the parasitic miracidia (3).
 - Transfer a few drops of the suspension containing the organisms to a 3- by 2-in. slide, and examine under the microscope.
 - Add a drop of weak iodine solution (weak-tea color) or dilute methylene blue (pale blue).
 - Parasitic miracidia will stop moving, while free-living forms continue to move.

Search for Tapeworm Scolex

Since the medication used for treatment of tapeworms is usually very effective, a search for tapeworm scolices is rarely requested and no longer clinically relevant.

However, stool specimens may have to be examined for the presence of scolices and gravid proglottids of cestodes for proper species identification. This procedure requires mixing a small amount of feces with water and straining the mixture through a series of wire screens (graduated from coarse to fine mesh) to look for scolices and proglottids. *Remember to use standard precautions and wear gloves when performing this procedure.* The appearance of scolices after therapy is an indication of successful treatment. If the scolex has not been passed, it may still be attached to the mucosa; the parasite is capable of producing more segments from the neck region of the scolex, and the infection continues. If this occurs, the patient can be retreated when proglottids begin to reappear in the stool.

After treatment for tapeworm removal, the patient should be instructed to take a saline cathartic and to collect all stool material passed for the next 24 h. The stool material should be immediately placed in 10% formalin, thoroughly broken up, and mixed with the preservative (1-gal [3.8-liter] plastic jars, half full of 10% formalin, are recommended).

For additional information, see chapter 33.

Quality Control for the Tapeworm Scolex Search

1. Follow routine procedures for optimal collection and handling of fresh fecal specimens for parasitologic examination.
2. Review diagrams and sizes of proglottids and scolices of tapeworms.

Procedure for the Tapeworm Scolex Search

1. Mix a 24-h stool specimen (fresh or preserved in 10% formalin) with water, and thoroughly break up the specimen to make a watery suspension.
2. Strain the suspension (or the purged stool) through a double layer of screen wire or a sieve (a coarse-mesh screen placed over a fine-mesh screen).
3. Wash off the sediment remaining from each portion by running a slow flow of tap water over it.
4. Examine the cleansed debris with a hand lens to look for scolices and proglottids (the *Taenia* scolex is 0.5 to 1 cm long and 1 to 2 mm wide).
5. Repeat steps 3 and 4 for each portion of the suspension strained.
6. Collect the strained sediment in a glass petri dish, and place the dish over a black surface to increase the contrast of organisms against the background.
7. Observe with a magnifying hand lens, and pick pieces of worms with an applicator stick.
8. Rinse gravid proglottids and/or scolices with tap water, blot them dry on paper towels, and place them between two microscope slides separated at the edges by thin pieces of cardboard.

9. Fasten the preparation by placing rubber bands at each end of the slides so that the segments become somewhat flattened.
10. Observe under the low power of a dissecting microscope for the number of uterine branches and genital pores in the segments and the presence or absence of a rostellum of hooks on the scolex. Quite often, the scolex is broken off from the rest of the strobila (chain of proglottids) and is ~1 cm long.

Results and Patient Report from the Tapeworm Scolex Search

Tapeworm proglottids may be recovered (either singly or several attached together), and a scolex may or may not be seen.

1. Report as “A search for adult worms reveals the presence/absence of ... (finding).”
Example: *Taenia saginata* scolex present

Procedure Notes for the Tapeworm Scolex Search

1. Remember that *Taenia solium* eggs are infective (cysticercosis), as are the eggs of *Hymenolepis nana*.
2. *Wear gloves when performing this procedure.*
3. Specimens preserved in 10% formalin are recommended.
4. If the patient has received niclosamide or praziquantel, a purged specimen is required, which should be immediately preserved in 10% formalin.
5. Wood’s lamp may be used to reveal the scolices if the patient has been given quinacrine dyes; the worms will have absorbed the dye, and they fluoresce at a wavelength of 360 nm. Also, after the use of quinacrine, tapeworm proglottids appear yellow.

Procedure Limitations for the Tapeworm Scolex Search

1. Niclosamide or praziquantel therapy leads to dissolution of the tapeworm. Therefore, the scolex and other proglottids may be difficult to recover unless the patient receives a saline purge soon after taking the medication.
2. It is often difficult to identify proglottids without staining. Identification may be achieved by staining with India ink.

Qualitative Test for Fecal Fat

The microscopic examination of stool with the addition of Sudan III is a very simple, quick, and widely used technique to screen the specimen for fat. Fresh, unpreserved fecal ma-

REVIEW Search for Tapeworm Scolex	
Topic	Comments
Principle	The procedure requires mixing feces (from a 24-h stool specimen preserved with 10% formalin) with water and straining the mixture through a series of wire screens, graduated from coarse to fine mesh, to look for scolices and proglottids. The same procedure may be used to look for small adult nematodes and trematodes. Appearance of scolices after therapy is an indication of successful treatment.
Specimen	Any posttherapy 24-h stool specimen submitted in 10% formalin, preferably collected after the patient has taken a saline cathartic, can be used. Single stools in 10% formalin can be submitted, but the chance of finding the scolex is minimal.
Examination	A hand lens may be necessary during the search for the scolex. Also, remember to place the material in the screen over something black to provide more contrast between the dark background and the pale yellow to white scolex. The entire specimen must be strained and examined before negative results are reported.
Results and Laboratory Reports	If the scolex or proglottids are recovered, they should be identified to species level if possible, particularly if the tapeworm is <i>Taenia solium</i> .
Procedure Notes and Limitations	Remember that the eggs of <i>Taenia solium</i> (pork tapeworm) are infectious for humans (cysticercosis); <i>all stools should be handled carefully, and gloves should be worn at all times</i> . <i>T. solium</i> eggs within the uterine branches of a gravid proglottid may not be preserved, even in 10% formalin. Failure to find the tapeworm scolex does not rule out the possibility of cure, particularly when a saline cathartic has not been used.

terial is required. If there is a time delay prior to testing, the specimen should be refrigerated. Specimens collected more than 48 h earlier or specimens that are dried out should be discarded, and fresh specimens should be collected. Although this technique is quite old and the original paper may be difficult to obtain, it was published in 1961 (6b).

Sudan Black IV Stain, also known as scarlet red, was introduced by Michaelis in 1901 as a fat stain. It is a dimethyl derivative of Sudan III, which makes it a deeper and more intense stain, but it has similar physical properties and is fat soluble. This stain has been widely used as a screening method because it is easy to use and correlates well with quantitative methods.

Sudan Black IV Stain is used as a qualitative method to detect the presence of fecal fat. Normally the stool does not contain more than 20 g of fat daily. In patients with steatorrhea, fat malabsorption occurs, and greater quantities of fat are detected in the stool. This procedure, when performed carefully and consistently, is a simple method of detecting this condition in the patient (18a).

Sudan Stain

95% ethanol
 Glacial acetic acid (36% [vol/vol])
 Sudan III stain
 or
 Sudan Black IV, certified 3.0 mg
 (Hardy Diagnostics, Santa Maria, Calif.)

95% ethanol 740 ml
 Deionized water 260 ml

Quality Control for the Qualitative Test for Fecal Fat

1. Follow routine procedures for optimal collection and handling of fresh fecal specimens for parasitology.
2. Run a QC sample with each batch of patient tests as in procedure below.
3. As a positive control, mayonnaise is used; red-stained fat globules should be observed microscopically.
4. As a negative control, water is used; no fat globules are observed.
5. Record all QC results. If the QC results are unacceptable, the test must be repeated and documented on the corrective action sheet.

Procedure for the Qualitative Test for Fecal Fat (Sudan III)

1. Mix a small amount of stool with an equal amount of 95% ethanol in a test tube. Mix well.
2. Add 2 drops of Sudan III stain to the stool-ethanol mixture. Mix well, and let stand for a few minutes.
3. Using a pipette, remove a drop from the test tube and place it on a slide. Cover with a coverslip.

4. Using the microscope, examine the slide for globules of fat stained red (neutral fat) and needle-like crystals (fatty acid).
5. Add several drops of glacial acetic acid to the test tube. Remove a drop from the test tube and place it on a slide. Cover with a coverslip.
 - A. Gently heat the slide over a flame. (Do not boil.)
 - B. Observe again on the microscope for globules of fat stained red.

Results and Patient Reports for the Qualitative Test for Fecal Fat (Sudan III)

Red-stained fat globules or fatty acid crystals are seen microscopically. Report the specimen as “fat not increased” or “fat increased” depending on the number of globules seen.

1. If fewer than 100 globules/high-power field (hpf) are seen before or after heating, report as “fat not increased.”
2. If more than 100 globules/hpf of fat are seen before or after heating, report as “fat increased.”
3. If fatty acid crystals have been seen before heating and globules appear after heating, report as “fatty acids increased.”

Procedure for the Qualitative Test for Fecal Fat (Sudan Black IV)

1. Place a small aliquot of stool suspension on a clean glass slide.
2. Mix 2 drops of 95% ethanol with the suspension on the slide.
3. Add 2 drops of Sudan Black IV Stain to the suspension on the slide, and mix well.
4. Cover the suspension with a coverslip, and examine microscopically for the presence of large orange or red droplets.

Results and Patient Reports for the Qualitative Test for Fecal Fat (Sudan Black IV)

1. Fatty acids are present as lightly staining flakes or needle-like crystals that do not stain.
2. Soaps appear as nonstaining formless flakes, coarse crystals, or rounded masses.
3. Neutral fats appear as large orange or red droplets. If 60 or more stained droplets (neutral fats) are seen per 400× (high-power) field, it is a presumptive finding that the patient has steatorrhea.

Procedure Limitations for the Qualitative Test for Fecal Fat

1. The formation of large needle-like crystals as the preparation cools after heating does not necessarily mean that the original globules were fatty acid.

Sudan III forms very short needle-like crystals in bunches as it dries.

2. Very few, if any, neutral fat globules are seen in a normal stool specimen. The presence of large amounts of neutral fat should raise suspicion that the patient has ingested mineral oil or castor oil, thus causing a false-positive result.
3. Do not count the fat that is present in vegetable cells.

Quantitation of Reducing Substances (Clinitest)

Clinitest is a reagent tablet test based on the classic Benedict's copper sulfate reduction reaction, combining ingredients with an integral heat-generating system. Clinitest provides clinically useful information about carbohydrate metabolism by determining the amount of reducing substance in urine or stool. Reducing substances convert the cupric (Cu^{2+}) to cuprous (Cu^+) oxide and cause a change in solution color ranging from green to orange. Unpreserved stool is required; the specimen should be placed in the refrigerator if there is a delay in testing. Specimens collected more than 48 h earlier or specimens that are dried out should be discarded, as fresh specimens should be collected. Although this is a relatively old method, there are references in the literature (6a).

Clinitest Tablets

Clinitest reagent tablets (store tablets at room temperature in a plastic bag)
Deionized water
Chek-Stix positive control

Quality Control for Quantitation of Reducing Substances (Clinitest)

1. Follow routine procedures for optimal collection and handling of fresh fecal specimens for parasitology.
2. Run a QC sample with each batch of patient tests as in procedure below.
3. As a positive control, Chek-Stix is used; the development of a green, yellow, or orange color with a yellow or red precipitate is considered a positive result.
4. As a negative control, 0.5 ml of deionized water is used; blue color is considered a negative result.
5. Record all QC results. If the QC results are unacceptable, the test must be repeated and documented on the corrective action sheet.

Procedure for Quantitation of Reducing Substances (Clinitest)

1. All testing on clinical specimens should be performed in a biological safety cabinet by personnel wearing gloves and a lab coat.

2. Add 1 volume of stool to 2 volumes of deionized water, and mix thoroughly.
3. Using a disposable transfer pipette, transfer 15 drops of this suspension into a clean test tube.
4. Drop one Clinitest tablet reagent into the test tube.
5. Observe the reaction. Do not shake the tube while the chemical reaction is occurring.
6. Wait 15 s after the reaction stops, and gently shake contents to mix.
7. Compare the color of the liquid to the color chart in the package insert of the Clinitest tablet reagent.
8. Discard supplies in appropriate biohazard containers.

Results and Patient Reports for Quantitation of Reducing Substances (Clinitest)

1. Negative: clear to cloudy blue color
2. Positive: compare the liquid color to the color chart, and grade the degree of color development to the color chart (trace, 1+, 2+, 3+, or 4+). These results equate to the grams of the reducing substance present per deciliter of sample.
3. Positive: report as trace (0.25 g/dl), 1+ (0.5 g/dl), 2+ (0.75 g/dl), 3+ (1.0 g/dl), or 4+ (≥ 2 g/dl)
Example: 1+ (0.5 g/dl)
4. Negative
Example: Negative

Procedure Limitations for Quantitation of Reducing Substances (Clinitest)

1. Clinitest is not specific for glucose and reacts with any reducing substance in stool, including lactose, fructose, galactose, and pentoses.
2. Interfering substances may affect the results. These include salicylates, penicillin, large quantities of ascorbic acid, nalidixic acid, and cephalosporins.
3. Failure to observe the reaction at all times may lead to erroneously low results if reducing substances are present in large amounts. If more than 2% sugar is present, a rapid color change may occur during boiling, causing the color to pass rapidly through bright orange to a dark brown or greenish brown.

Examination for Pinworm

A roundworm parasite that has worldwide distribution and is commonly found in children is *Enterobius vermicularis*, known as the pinworm or seatworm. The adult female worm migrates out of the anus, usually at night, and deposits her eggs on the perianal area. The adult female (8 to 13 mm long) is occasionally found on the surface of a stool specimen or on the perianal skin. Since the eggs are usually deposited around the anus, they are not commonly found in feces and must be detected by other diagnostic techniques. Diagnosis of pinworm infection is usually based on the recovery of typical eggs, which are described as thick-shelled, football-shaped eggs with one slightly flattened side. Each egg often contains a fully developed embryo and will be infective within a few hours after being deposited.

The most striking symptom of this infection is pruritus, which is caused by the migration of the female worms from the anus onto the perianal skin before egg deposition. The sometimes intense itching results in scratching and occasional scarification. In most infected people, this may be the only symptom, and many individuals remain asymptomatic. Eosinophilia may or may not be present.

Infections tend to be more common in children and occur more often in females than in males. In heavily infected females, there may be a mucoid vaginal discharge, with subsequent migration of the worms into the vagina, uterus, fallopian tubes, or other body sites including the urinary tract, where they become encapsulated (1–3, 12, 22). Although tissue invasion has been attributed to the pinworm, these cases are not numerous. Symptoms that have been attributed to the pinworm infection, particularly in children, include nervousness, insomnia, nightmares, and even convulsions. In some cases, perianal granulomas may result (3).

In one report, a homosexual man presented with severe abdominal pain and hemorrhagic colitis, eosinophilic inflammation of the ileum and colon, and numerous unidentifiable larval nematodes in the stool. Using morphologic characteristics and molecular cloning of nematode rRNA genes, the parasites were identified as larvae of *E. vermicularis*; these larvae are rarely seen and are not

thought to cause disease. The authors stated that occult enterobiasis is widely prevalent and may be a cause of unexplained eosinophilic enterocolitis (18).

Cellulose Tape Preparations

The most widely used diagnostic procedure for pinworm infection is the cellulose tape (adhesive cellophane tape) method (10, 14, 15) (Figures 29.1 to 29.3). Several commercial collection procedures are also available. Specimens should be obtained in the morning before the patient bathes or goes to the bathroom. At least four to six consecutive negative slides should be observed before the patient is considered free of infection. Occasionally adult female pinworms are seen on the tapes or swabs.

Collection of the Specimen

1. Place a strip of cellulose tape on a microscope slide, starting 1/2 in. (1 in. = 2.54 cm) from one end and running toward the same end, continuing around this end lengthwise; tear off the strip flush with the other end of the slide. Place a strip of paper, 1/2 by 1 in., between the slide and the tape at the end where the tape is torn flush.
2. To obtain the sample from the perianal area, peel back the tape by gripping the label, and with the tape looped (adhesive side outward) over a wooden tongue depressor held against the slide and extended about 1 in. beyond it, press the tape firmly against the right and left perianal folds.
3. Spread the tape back on the slide, adhesive side down.
4. Write the name and date on the label.

Figure 29.1 Collection of *Enterobius vermicularis* eggs by the cellulose tape method. (Illustration by Nobuko Kitamura.)

Figure 29.2 Diagram of a commercial kit (Evergreen Scientific) for use in sampling the perianal area for the presence of pinworm (*E. vermicularis*) eggs. On the left is the vial containing the sampler, which has sticky tape around the end. Once this is applied to the perianal area and eggs are picked up on the tape, the label area is placed at one end of the slide. The sticky tape is rolled down the slide and attaches to the glass. This device is easy to use and provides an area sufficient for adequate sampling. A minimum of four to six consecutive negative tapes are required to rule out a pinworm infection; most laboratories are accepting four rather than requesting the full six.

Note Do *not* use Magic transparent tape; use regular clear cellulose tape. If Magic tape is submitted, a drop of immersion oil can be placed on top of the tape to facilitate clearing.

Examination

Lift one side of the tape, apply 1 small drop of toluene or xylene, and press the tape down on the glass slide. The preparation will then be cleared, and the eggs will be visible. Examine the slide with low power and low illumination.

Anal Swabs

The anal swab technique (21) is also available for the detection of pinworm infections; however, most laboratories use the cellulose tape method because it eliminates the necessity for preparing and storing swabs. At least four

Figure 29.3 (Top) *Enterobius vermicularis* (pinworm) eggs seen in a Scotch tape preparation; note the football-shaped eggs with one side a bit more flat than the other. In some preparations, eggs are seen that contain fully developed larvae; such eggs are infective. (Middle) Adult female pinworm found on a collection device. Note the large, round esophageal bulb. (Bottom) Adult female pinworm, enlarged anterior end. Note the cephalic expansions around the end of the head, as well as the large, round esophageal bulb.

consecutive negative swabs should be obtained before the patient is considered free of infection.

Collection of the Specimen

Specimens should be obtained in the morning before the patient bathes or goes to the bathroom.

1. Prepare a mixture of 4 parts petrolatum to 1 part paraffin, and heat until liquid (just melted).
2. Dip the end of the cotton swab into the mixture,

remove the swab, and allow it to cool. If the cotton is not thoroughly coated, dip it again.

3. Store the coated swab in a 100- by 13-mm tube, and plug the end of the tube with cotton. These tubes may be stored for long periods, preferably under refrigeration.
4. Rub the swab gently over the perianal surface and into the folds. Insert the swab into the anal opening about 1/4 in., and then replace it in the tube.

Examination

1. Fill the tube containing the swab half full of xylene or xylene substitute, and let it stand for 3 to 5 min.
2. Remove the swab, and centrifuge the tube at $500 \times g$ for 1 min.
3. Remove the supernatant fluid with a pipette (do not pour it off).
4. Place the sediment on a slide, and examine the material for eggs. The fluid can be examined under a coverslip, in a depression slide, or in a wax pencil circle drawn on the slide (to prevent the fluid from spreading).

Sigmoidoscopy Material

Material obtained from sigmoidoscopy can be helpful in the diagnosis of amebiasis that has not been detected by routine fecal examinations; however, a series of at least three routine stool examinations for parasites should be performed on each patient before sigmoidoscopy examination is done. Another option would be to use the immunoassay kits that are designed to detect either the *Entamoeba histolytica*/*E. dispar* group or specifically pathogenic *E. histolytica*; fresh or frozen stools are required for these kits.

Material from the mucosal surface should be aspirated or scraped and should not be obtained with cotton-tipped swabs. If swabs are the only method available, a small amount of cotton should be used on the end of the stick and should be wound tightly to prevent absorption of the sigmoidoscopy material into the cotton. At least six representative areas of the mucosa should be sampled and examined (six samples, six slides).

The specimen should be processed immediately. Usually, the amount of material is limited and should be handled properly to ensure the best examination possible. Various methods of examination are available (direct mount, several options for permanent stains). All are recommended; however, depending on the availability of trained personnel, proper fixation fluids, or the amount of specimen obtained, one or two procedures may be used. If the amount of material limits the examination to one

procedure, the use of polyvinyl alcohol (PVA) fixative is highly recommended.

If the material is to be examined by any of the new immunoassay detection kits (for *Cryptosporidium* spp. or *Giardia lamblia*), 5 or 10% formalin or sodium acetate-acetic acid-formalin (SAF) fixative is recommended. However, as mentioned above, if immunoassay kits are to be used for detection of the *E. histolytica*/*E. dispar* group or specifically pathogenic *E. histolytica*, fresh or frozen stools are required. Many physicians performing sigmoidoscopy procedures do not realize the importance of selecting the proper fixative for material to be examined for parasites. For this reason, it is recommended that a parasitology specimen tray (containing Schaudinn's liquid fixative, PVA fixative, and 5 or 10% formalin) be provided or that a trained technologist be available at the time of sigmoidoscopy to prepare the slides. Even the most thorough examination will be meaningless if the specimen has been improperly prepared.

Direct Saline Mount

If there is no lag time after collection and a microscope is available in the immediate vicinity, some of the material should be examined as a direct saline mount for the presence of motile trophozoites. A drop of material is mixed with a drop of 0.85% sodium chloride and examined under low light intensity for the characteristic movement of amebae. It may take time for the organisms to become acclimated to this type of preparation; therefore, motility may not be obvious for several minutes. There will be epithelial cells, macrophages, and possibly polymorphonuclear leukocytes and red blood cells (RBCs), which will require a careful examination to reveal amebae (Figure 29.4).

Note Since specific identification of protozoan organisms can be difficult when only the direct saline mount is used, this technique should be used only when sufficient material is left to prepare permanent stained smears.

Morphologic differentiation between the *E. histolytica*/*E. dispar* group and *Entamoeba coli* can be difficult, in addition to the problem of differentiating human cells from protozoa. Also, unless trophozoites containing ingested RBCs are seen, it is impossible to differentiate organisms in the *E. histolytica*/*E. dispar* group from the actual pathogen, *E. histolytica*.

Permanent Stained Slide

Schaudinn's Fixative

Most of the material obtained at sigmoidoscopy can be smeared (gently) onto a slide and immediately immersed in Schaudinn's fixative. These slides can then be stained

with trichrome stain and examined for specific cell morphology, either protozoan or otherwise. The procedure and staining times are identical to those for routine fecal smears.

PVA Fixative

If the material is bloody, contains a lot of mucus, or is a "wet" specimen, a few (no more than 2 or 3) drops of PVA fixative can be mixed with 1 or 2 drops of specimen directly on the slide, which is allowed to air dry (a 37°C incubator can be used) for at least 2 h before being stained. If time permits, the PVA smears should be allowed to dry overnight; they can be routinely stained with trichrome stain and examined as a permanent mount.

SAF Fixative

Material obtained at sigmoidoscopy can be placed in small amounts of SAF. After fixation for 30 min, the specimen can be centrifuged for 10 min at 500 × g, and smears from the small amount of sediment can be prepared for permanent staining with iron hematoxylin (trichrome stain would be the second choice). One of the organisms most strongly suspected when sigmoidoscopy is performed is *E. histolytica*, whose morphology is normally seen from the permanent stained smear; however, this identification assumes that RBCs are seen within the cytoplasm of the trophozoites (Figure 29.4). If RBCs are not seen in the trophozoite cytoplasm, the report should indicate that organisms in the *E. histolytica*/*E. dispar* group have been seen and identified. However, if SAF is used, both the permanent stained smear and a fecal immunoassay kit can be used. If enough material for only a single procedure is available, the permanent stained smear is recommended, particularly if the iron hematoxylin stain (incorporating the carbol fuchsin step) is used (J. Palmer, Letter, *Clin. Microbiol. Newsl.* 13:39–40, 1991).

Figure 29.4 *Entamoeba histolytica* trophozoites. (Left) Trophozoite in wet-mount preparation. (Right) Trophozoite in permanent stained smear. Note that the nuclear and cytoplasmic characteristics are more easily seen after staining (trichrome or iron hematoxylin).

Duodenal Contents

Duodenal Drainage

In infections with *G. lamblia*, *Strongyloides stercoralis*, or *Cryptosporidium* spp., routine stool examinations may not reveal the organisms. Duodenal drainage material can be submitted for examination as direct or concentration wet mounts or permanent stained smears, techniques that may reveal the parasites (Figure 29.5). *Use standard precautions and wear gloves when handling the specimen.*

The specimen should be submitted to the laboratory in a tube containing no preservative; the amount may vary from <0.5 ml to several milliliters of fluid. The specimen may be centrifuged (10 min at 500 × g) and should be examined immediately as a wet mount for motile organisms (iodine may be added later to facilitate the identification of any organisms present). If the specimen cannot be completely examined within 2 h after it is taken, any remaining material should be preserved in 5 to 10% formalin. However, it is not possible to prepare a permanent stain from the formalin-preserved material. Schaudinn's fluid, PVA, modified PVA, SAF, or one of the single-vial-system preservatives is recommended for that purpose. The "falling-leaf" motility often described for *Giardia* trophozoites is rarely seen in fresh, unpreserved preparations. The organisms may be caught in mucus strands, and the movement of the flagella on the *Giardia* trophozoites may be the only subtle motility seen for these flagellates. *Strongyloides* larvae are usually very motile. Remember to keep the light intensity low.

The duodenal fluid may contain mucus; this is where the organisms, particularly *Giardia*, tend to be found. Therefore, centrifugation of the specimen is important, and the sedimented mucus should be examined. Immunoassay detection kits (*Cryptosporidium* or *Giardia*) can also be used with fresh or formalinized material.

If a presumptive diagnosis of giardiasis is made on the basis of the wet-preparation examination of the fresh specimen, the coverslip can be removed and the specimen can be fixed with either Schaudinn's fluid or PVA for subsequent staining with either trichrome or iron hematoxylin. If the amount of duodenal material submitted is very small, permanent stains can be prepared rather than using any part of the specimen for a wet-smear examination. Some investigators think that this approach provides a more permanent record, and the potential visual problems with unstained organisms, very minimal motility, and a lower-power examination can be avoided by using oil immersion examination of the stained specimen at ×1,000 magnification.

Duodenal Capsule Technique (Entero-Test)

A simple and convenient method of sampling duodenal contents that eliminates the need for intestinal intubation has been devised (5). The device consists of a length of

Figure 29.5 Duodenal aspirate specimens. (Top) *Giardia lamblia* in mucus from a duodenal aspirate stained with trichrome stain. Note the teardrop trophozoites (from the front view) and the darker-staining trophozoites that resemble the curved part of a spoon (side view). Also notice the number of organisms contained within the mucus. (Middle) A *Strongyloides stercoralis* rhabditiform larva in a wet mount. The genital primordium packet of cells is visible about halfway down the larva on the right side. (Bottom) *Cryptosporidium* spp. oocysts in duodenal aspirate material stained with a modified acid-fast stain.

nylon yarn coiled inside a gelatin capsule (Figure 29.6). The yarn protrudes through one end of the capsule; this end of the line is taped to the side of the patient's face. The capsule is then swallowed, the gelatin dissolves in the stomach, and the weighted string is carried by peristalsis into the duodenum. The yarn is attached to the weight by a slipping mechanism; the weight is released and passes

Figure 29.6 Entero-Test capsule for sampling duodenal contents. The device consists of a length of nylon yarn coiled inside a gelatin capsule. The yarn protrudes through one end of the capsule; this end of the line is taped to the side of the patient's face. The capsule is then swallowed, the gelatin dissolves in the stomach, and the weighted string is carried by peristalsis into the duodenum. (Illustration by Nobuko Kitamura.)

out in the stool when the line is retrieved after a period of 4 h. Bile-stained mucus clinging to the yarn is then scraped off (mucus can also be removed by pulling the yarn between thumb and finger) and collected in a small petri dish; *disposable gloves should be worn*. Usually 4 or 5 drops of material are obtained.

The specimen should be examined immediately as a wet mount for motile organisms (iodine may be added later to facilitate the identification of any organisms present). If the specimen cannot be completely examined within an hour after the yarn has been removed, the material should be preserved in 5 to 10% formalin or PVA-preserved mucus smears should be prepared. Organism motility is like that described above for duodenal drainage.

Note The pH of the terminal end of the yarn should be checked to ensure adequate passage into the duodenum (a very low pH means that it never left the stomach). The terminal end of the yarn should be a yellow-green color, indicating that it was in the duodenum (the bile duct drains into the intestine at this point).

Urogenital Specimens

Trichomoniasis

The identification of *Trichomonas vaginalis* (Figure 29.7) is usually based on the examination of a wet preparation of vaginal and urethral discharges and prostatic secretions or urine sediment. Multiple specimens may have to be examined before the organisms are detected. These specimens are diluted with a drop of saline and examined under low power and reduced illumination for the presence of actively motile organisms; as the jerky motility begins to diminish, it may be possible to observe the undulating membrane, particularly under high dry power. Recent data indicate that microscopic examination of a spun urine specimen performed in conjunction with microscopic examination of a vaginal fluid specimen improves the detection rate of *T. vaginalis*. While 73% of infections were detected by examination of vaginal fluid specimens and 64% were detected by examination of spun urine, the combined percentage using both methods was 85% (7). It is also important to remember that

Figure 29.7 (Upper) *Trichomonas vaginalis* trophozoite. (Illustration by Sharon Belkin.) (Lower) *T. vaginalis* trophozoites seen in a wet mount preparation.

in older men with nongonococcal urethritis, diagnostic evaluation, empirical treatment, and partner management should include the possibility of infection with *T. vaginalis* (17).

Stained smears are usually not necessary for the identification of this organism. The large number of false-positive and false-negative results reported on the basis of stained smears strongly suggests the value of confirmation by observation of motile organisms from the direct mount, from appropriate culture media (4, 8, 9, 24), or from direct detection with monoclonal antibodies (11). The ability of Amies gel agar transport medium to maintain the viability of *T. vaginalis* was examined by comparison with specimens immediately inoculated into culture medium. The immediate-inoculation method detected infections in 64 (94.1%) of 68 patients, while the transport method detected infections in 62 (91.2%) of 68 patients (6). However, the data depend on the type of medium used, the time taken for transport, and the temperature at which transport was carried out. Additional information on culture options can be found in chapter 32.

T. vaginalis infection is the most prevalent sexually transmitted disease in the world. To improve diagnostic results, PCR is now being used for the detection of this infection. In a comparison of the results of PCR with those of the InPouch TV culture system in a study of 23 women who were positive, PCR detected 22 (96%) of the 23 while the wet-preparation examination detected only 12 (52%) (19). Of the 17 discrepant results, 10 were PCR positive and 7 were determined to be false positives. The sensitivity of this PCR examination was 97%, with a specificity of 98%. Other studies also report excellent results using PCR (16, 23, 26).

Filariasis

Examination of urinary sediment is indicated in certain filarial infections. The occurrence of microfilariae in urine has been reported with increasing frequency in *Onchocerca volvulus* infections in Africa. The triple-concentration technique is recommended for the recovery of microfilariae (14) (see chapter 31).

Urine is collected into a bottle, the volume is recorded, and thimerosal (1 ml/100 ml of urine) is added. The specimen is placed in a funnel fitted with tubing and a clamp; this preparation is allowed to settle overnight. The following day, 10 to 20 ml of urine is withdrawn and centrifuged. The supernatant fluid is discarded, and the sediment is resuspended in 0.85% NaCl. This preparation is again centrifuged, and 0.5 to 1.0 ml of the sediment is examined under the microscope for the presence of non-motile microfilariae. The membrane filtration technique

used with blood (see chapter 31) can also be used with urine for the recovery of microfilariae. Administration of the drug diethylcarbamazine (Hetrazan) has been reported to enhance the recovery of microfilariae from the urine (20).

Schistosomiasis

A membrane filter technique for the recovery of *Schistosoma haematobium* eggs is also useful (25) (Figures 29.8 and 29.9).

Membrane Filter Technique

1. Collect a urine sample in a container (urine should be well mixed before step 2).
2. With a syringe, draw up 1 ml of urine into the syringe barrel.
3. Fill the rest of the barrel volume with air.
4. Attach the filter holder containing an 8- μ m-pore-size Nuclepore membrane filter to the syringe.
5. Express the urine through the filter.

Figure 29.8 Membrane filtration system. (Upper) Membrane holder, which can be attached to a syringe for filtration of various types of specimens, particularly urine. (Lower) Package of membranes; different sizes with various mesh sizes are available, depending on the clinical specimen and suspected organism size.

Figure 29.9 *Schistosoma haematobium* eggs from a urine filtration. Note the terminal spines on the eggs. Since the specimens were not preserved prior to filtration, determination of the viability of the eggs is possible. The viability information should be conveyed to the physician as a part of the report.

6. Remove the filter, and place it on a microscope slide face down.
7. Moisten the filter with 0.85% NaCl.
8. Examine the filter under 100× power for the presence of eggs.

The efficiency of the polycarbonate membrane filtration technique for detecting *S. haematobium* eggs in urine is increased by using a pore size of 14 μm and the suction of a water jet pump. Egg concentrations of 1 egg in >1,000 ml of urine can be detected. Viability can be assessed after filtration by staining with trypan blue. This technique is highly recommended in light infections with small numbers of eggs in which previous diagnostic methods have not confirmed the infection (13).

Cutaneous ulcer

Biopsy material

Skin

Lymph nodes

Muscle

Rectum and bladder

Since *Pneumocystis jiroveci* (previously *P. carinii*) has been reclassified with the fungi, this organism is no longer included in the book or discussed in terms of organism, disease, pathogenesis, and diagnosis. However, other organisms such as the microsporidia can be stained using silver stains, so these methods and references have been kept in this chapter and will periodically refer to *Pneumocystis jiroveci*.

Expectorated Sputum

Although it is not one of the more common specimens, expectorated sputum may be submitted for examination for parasites. Organisms in sputum that may be detected and may cause pneumonia, pneumonitis, or Loeffler's syndrome include the migrating larval stages of *Ascaris lumbricoides*, *Strongyloides stercoralis*, and hookworm; the eggs of *Paragonimus* spp.; *Echinococcus granulosus* hooklets; and *P. jiroveci* (now classified with the fungi), *Entamoeba histolytica*, *Entamoeba gingivalis*, *Trichomonas tenax*, *Cryptosporidium* spp., and possibly the microsporidia (41). In a *Paragonimus* infection, the sputum may be viscous and tinged with brownish flecks, which are clusters of eggs ("iron filings"), and may be streaked with blood (Figure 30.1).

Collection and Examination of the Specimen

Sputum is usually examined as a wet mount (saline or iodine), using low and high dry power ($\times 100$ and $\times 400$). The specimen is not concentrated before preparation of the wet mount. If the sputum is thick, an equal amount of 3% sodium hydroxide (or undiluted chlorine bleach) can be added; the specimen is thoroughly mixed and then centrifuged. NaOH should not be used if *Entamoeba* spp. or *T. tenax* is being sought. After centrifugation, the supernatant fluid is discarded and the sediment can be examined as a wet mount with saline or iodine. If examination has to be delayed for any reason, the sputum should be fixed in 5 or 10% formalin to preserve helminth eggs or larvae or in polyvinyl alcohol fixative to be stained later for protozoa. Usually, sputum is not a recommended specimen for the diagnosis of *P. jiroveci*; however, if such a specimen is accepted by the laboratory, other stains such as silver methenamine, Giemsa, or immunoassay reagents are used. If *Cryptosporidium* is suspected (rare), acid-fast or immunoassay techniques normally used for stool specimens can be used

Figure 30.1 *Paragonimus* spp. eggs. (Left) Operculated eggs in a sputum specimen. (Right) Eggs photographed at a higher magnification.

(see chapters 4 and 27) (9, 15, 16, 43). Trichrome stains of material may aid in differentiating *E. histolytica* from *E. gingivalis*, and Giemsa stain may better define larvae and juvenile worms.

A sputum specimen should be collected properly so the laboratory receives a “deep sputum” sample for examination rather than a specimen that is primarily saliva from the mouth rather than from the lower respiratory passages. If the sputum is not induced, the patient can be instructed as follows.

1. Expecterated sputum specimens are collected after the patient is instructed in the appropriate measures to ensure high-quality specimens, including prior mouth washing with hydrogen peroxide and exclusion of saliva from specimens. Try to obtain the specimen early in the morning, when the chances of obtaining a deep sputum specimen are increased.
2. Transport the specimen to the laboratory in clean, closed containers as quickly as possible. Select any blood-tinged, viscous areas for sampling.
3. If the specimen is uniformly mucoid:
 - A. *Wear gloves when handling specimens.*
 - B. Remove a 1.0-ml portion to a 15-ml conical tube.
 - C. Add 1.0 ml of mucolytic agent such as Sputalysin (Sputalysin Stat-Pack dithiothreitol solution [Behring Diagnostics, Inc.]) which has been prepared as specified by the manufacturer. This reagent can be stored unopened at room temperature until the expiration date. Date and store working solution at 4°C (include the expiration date). Discard working solution after 48 h. Prepare working solution by removing 1.0 ml from the 10-ml bottle and diluting with 9.0 ml of sterile water.

- D. Incubate at room temperature for 15 min.
- E. Add 2.0 ml of phosphate buffer (pH 6.8; M/15 [0.067 M]).
- F. Centrifuge the material at $500 \times g$ for 5 min.
- G. Decant supernatant fluid, and use sediment to prepare wet mounts and smears.
- H. Quality control measures should include the following.
 - a. Ensure that the saline and mucolytic agent are free of contamination (particulate matter) as determined by a clear appearance. If cloudy, discard and make new working solution.
 - b. Control the trichrome stain for each new set of reagents with a specimen containing blood to ensure that white cells stain with purple nuclei and blue-green cytoplasm. If cells do not stain appropriately, change reagents.
 - c. With each new lot of Giemsa stain or new buffer, check the stain with a specimen containing blood to ensure that red cells stain grayish, white cell nuclei stain red-purple, and cytoplasm stains bluish. If cells do not stain appropriately, check the stock stain and buffer to find cause.
 - d. Yeast-containing material may be used as a positive control for silver staining.
 - e. Both *P. jiroveci*-positive and *P. jiroveci*-negative and yeast-positive material should be used for immune-specific staining (check with suppliers).
 - f. Stains cannot be evaluated if controls do not stain appropriately. A stain is not within acceptable results when:
 - (i) *P. jiroveci* does not stain or stains black without delineation of “parentheses.”
 - (ii) Other fungi and actinomycetes do not stain.
 - g. Store stock stain solutions in area away from light; discard any reagent (prior to the expiration date) that is cloudy or appears contaminated.
 - h. Evaluate the fluorescence microscope for correct light wavelength, using commercially available quality control slides.
 - i. Record all quality control results.

Procedure for Examination of Sputum

1. *Wear gloves when performing these procedures.*
2. For expecterated sputum (no addition of mucolytic agent):
 - A. Using a Pasteur pipette, place 1 or 2 drops (50 μ l) on one side of a 2- by 3-in. (1 in. = 2.54

- cm) glass slide, and cover with a 22- by 22-mm (no. 1) coverslip.
- B. Place a second drop on the slide, add 1 drop of saline, and cover with a coverslip.
 3. Expecterated sputum (treated with a mucolytic agent) can be resuspended in 100 μ l of saline; place 1 drop on a 2- by 3-in. slide, and cover with a coverslip.
 4. Save the untreated specimen and remaining treated specimen for permanent smear preparation if stains are required.
 5. Examine the entire 22- by 22-mm coverslip wet preparation under low light with the 10 \times objective to detect eggs, larvae, oocysts, or amebic trophozoites.
 6. If results are inconclusive, prepare smears for permanent staining.
 - A. Place 1 drop of sediment in the center of each of three 1- by 3-in. glass slides, and spread the material with the tip of the pipette.
 - B. Place one slide in Schaudinn's fixative while wet; air dry the other two thoroughly.
 - C. Trichrome stain the slide fixed in Schaudinn's fixative.
 - D. Fix the air-dried smears in methanol; stain one with Giemsa and the other with a modified acid-fast stain. The modified trichrome stain may have to be used if infection with microsporidia is suspected (52).
 - E. Put immersion oil on stained smears; examine the Giemsa-stained smear with the 10 \times objective and the trichrome-stained smear with the 50 \times oil objective if available; otherwise, use the 100 \times oil objective. Read at least 300 oil immersion fields (total magnification, \times 1,000) before reporting the specimen as negative.
 - F. The methenamine silver stain can be used; however, expecterated sputum is generally not recommended as an acceptable specimen for the recovery and identification of *P. jiroveci*.
 7. Report any organisms found as follows.
 - A. Give genus and species, if necessary, after confirmation with permanent stain.
 - B. "No parasites found" in expecterated sputum is considered a normal/negative report; therefore, call the physician if any organisms are found.

Note Care should be taken not to confuse *E. gingivalis*, which may be found in the mouth and saliva, with *E. histolytica*, which could result in an incorrect suspicion of pulmonary abscess. *E. gingivalis* usually contains ingested polymorphonuclear leukocytes, while *E. histolytica* may contain ingested red blood cells but

not polymorphonuclear leukocytes (Figure 30.2). *T. tenax* would also be found in saliva from the mouth and thus would be an incidental finding and normally not an indication of pulmonary problems (Figure 30.3).

Induced Sputum

Concentrated stained preparations of induced sputum specimens are commonly used to detect *P. jiroveci* and differentiate trophozoite and cyst forms from other possible causes of pneumonia, particularly in AIDS patients (23, 29, 39, 47, 55). Organisms must be differentiated from other fungi such as *Candida* spp. and *Histoplasma capsulatum*. Although induced sputum specimens have been used successfully in the diagnosis of *P. jiroveci* in some institutions, they have not been useful in others (40). This difference may be due in part to careful adherence to specimen rejection criteria. If the clinical evaluation of a patient suggests *P. jiroveci* pneumonia and the induced sputum specimen is negative, a bronchoalveolar lavage fluid specimen should be evaluated with the stains presented in this protocol (2, 19, 36, 55).

Collection and Examination of the Specimen

Induced sputum specimens are collected by pulmonary or respiratory therapy staff after patients have used appropriate cleansing procedures to reduce oral contamination. Nebulizing procedures are generally determined by the respiratory therapy staff collecting the specimens. The induction protocol is critical for the success of the procedure, and it is mandatory for well-trained individuals to be involved in the recovery of organisms. Patients with *Pneumocystis* pneumonia usually have dry, nonproductive coughs. Organisms are rarely detected in expecterated sputum, which is not accepted by many laboratories as a clinically relevant specimen. In cooperation with the

Figure 30.2 (Left) *Entamoeba gingivalis* containing ingested polymorphonuclear leukocytes within large vacuoles. (Right) *Entamoeba histolytica* containing ingested red blood cells.

Figure 30.3 (Left) *Trichomonas tenax* from the mouth (stained with Giemsa stain). (Right) *Trichomonas vaginalis* from a genital specimen (stained with Giemsa stain). Note the large nucleus in *T. tenax* and the fact that this flagellate is somewhat smaller than *T. vaginalis*.

pulmonary staff, the laboratory processing the specimens must establish a protocol for this diagnostic procedure. Induced sputum specimens are most useful for detection of *P. jiroveci* in human immunodeficiency virus-infected individuals, because others have fewer, less readily detected organisms. Stains that can be used for organism detection include the rapid methenamine silver stain, the rapid Giemsa stain (Diff-Quik or Giemsa Plus), the Giemsa stain, and immune-specific staining (2, 5, 6, 18, 25, 27, 28, 32, 34, 35, 37, 42, 44, 51, 55).

Preparation of the Specimen Prior to Staining

1. Wear gloves when handling specimens.
2. Specimens which contain mucus should be treated with a mucolytic agent by adding the agent in a 1:1 ratio with the specimen, usually 2 or 3 ml, and incubating the specimen at room temperature for 15 min. Large-volume specimens usually are watery. These specimens (up to 20 to 25 ml) should be concentrated by centrifugation prior to the addition of a mucolytic agent.
3. Centrifuge the specimen at $500 \times g$ for 5 min in capped centrifuge tubes and closed carriers.
4. Decant supernatant fluids into a disinfectant solution (1:10 dilution of bleach).
5. If the sediment contains a significant amount of blood, treat a portion (one-half to one-third) with a red-cell lytic agent such as saponin or Lyse in one-half to one-third of the volume of the sediment, leave at room temperature for 5 min, and recentrifuge.
6. Decant supernatant fluid from treated specimens.
7. Use Pasteur pipettes to resuspend remaining sediment.

8. Using 1- by 3-in. glass slides, place drops of sediment in the center of each slide. For specimens treated to lyse red cells, prepare two smears, one from material before lytic treatment and one from the treated specimen.
9. Spread the drops with the pipette so that they are thin and even.
10. Air dry slides, and dip them in methanol prior to Giemsa or silver staining. Fix slides for immune-specific staining as specified in the package insert directions.

Reagents Used in Staining Procedures

1. Mucolytic agent: Sputalysin Stat-Pack dithiothreitol solution (Behring Diagnostics, Inc.). Redcell lytic agent: saponin (Aldrich, Milwaukee, Wis.; ICN Biochemicals, Costa Mesa, Calif.), Lyse (Curtin Matheson Scientific, Inc.), or Hematall LA-Hgb reagent (Fisher Scientific).
2. Rapid Giemsa stain: Diff-Quik (Baxter Scientific Products) or Wright's Dip Stat (Medical Chemical). Follow the manufacturer's instructions or use Giemsa stain.
3. Giemsa stain: azure B alcoholic stock (Harleco, Philadelphia, Pa.) diluted 1:20 with phosphate buffer containing 0.01% Triton X-100.
4. Buffers prepared from stock buffers for the Giemsa stain:
 - A. Alkaline buffer NaHPO_4 M/15 solution is 9.5 g of Na_2HPO_4 dissolved in 1 liter of distilled water.
 - B. Acid buffer NaHPO_4 M/15 solution is 9.2 g of $\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$ dissolved in 1 liter of distilled water.

These buffers can be kept for 12 months. To prepare buffered water for the stain, add 39 ml of acid buffer and 61 ml of alkaline buffer to 900 ml of water.

Reagents for Rapid Methenamine Silver Stain (Microwave) (6)

Chromic Acid (10% Solution)

Chromic acid (CrO_3).....	100.0 g
Distilled deionized water.....	1,000.0 ml

Solution is stable for up to 1 year.

Methenamine (3% Solution)

Hexamethylenetetramine, USP	
$[(\text{CH}_2)_6\text{N}_4]$	12.0 g
Distilled deionized water.....	400.0 ml

Solution is stable for up to 6 months.

Silver Nitrate (5% Solution)

Silver nitrate (AgNO ₃).....	5.0 g
Distilled deionized water.....	100.0 ml

Solution is stable for 1 to 6 months at 4°C.

Sodium Borate (Borax) (5% Solution)

Sodium borate (Na ₂ B ₄ O ₇ · 10H ₂ O).....	5.0 g
Distilled deionized water.....	100.0 ml

Solution is stable for up to 1 year.

Sodium Bisulfite (1% Solution)

Sodium bisulfite (NaHSO ₃).....	1.0 g
Distilled deionized water.....	100.0 ml

Solution is stable for up to 1 year.

Gold Chloride (1% Solution)

Gold chloride.....	5.0 g
Distilled deionized water.....	500.0 ml

Solution is stable for up to 1 year.

Sodium Thiosulfate (5% Solution)

Sodium thiosulfate (Na ₂ S ₂ O ₃ · 5H ₂ O).....	50.0 g
Distilled deionized water.....	1,000.0 ml

Solution is stable for up to 1 year.

Stock Light Green

Light green, S.F. (yellow) (C.I. no. 42095).....	0.2 g
Distilled deionized water.....	100.0 ml
Glacial acetic acid (CH ₃ COOH).....	0.2 ml

Solution is stable for up to 1 year.

Working Light Green

Stock light green.....	10.0 ml
Distilled deionized water.....	40.0 ml

Solution is stable for up to 1 month.

Ethanol, 100% (Absolute) and 95%**Methanol, 100% (Absolute)****Xylene or Xylene Substitute**

All reagents can be stored at 25°C except for the silver nitrate, which must be refrigerated. Although stable for up to 6 months, silver nitrate may have to be discarded and replaced after storage for 1 month.

Procedure for Rapid Methenamine Silver Stain (Microwave) (6)

1. Place specimen smear slides and control slides on stain rack.
2. Add 10% chromic acid to cover smears, and let stand for 10 min.
3. During this time, prepare working methenamine-silver nitrate by placing the following in order in a plastic Coplin jar: 20 ml of 3% methenamine, 1 ml of 5% silver nitrate, 1.5 ml of 5% sodium borate, and 17 ml of distilled deionized water.
4. Wash slides with distilled deionized water.
5. Cover slides with 1% sodium bisulfite for 1 min.
6. Wash slides with water, place them in a plastic Coplin jar containing methenamine-silver nitrate, and cover with cap.
7. Place in microwave oven at 50% power for approximately 35 s, rotate 90°, and heat for another 35 s; leave slides in hot liquid for 2 min. Solution should turn brown (fresh reagent may appear almost clear if the stock methenamine is freshly prepared; with time and use, the working solution will turn more brown).
8. If a water bath is used, heat it to 80°C. Place plastic Coplin jar containing stain reagents in bath for 6 min prior to placing slides in jar, add slides, and leave jar in bath for an additional 5 min. Solution should turn brown (fresh reagent may appear almost clear if the stock methenamine is freshly prepared; with time and use, the working solution will turn more brown).
9. Remove slides; wash in distilled deionized water.
10. Dip slides up and down in 1% gold chloride, wash in distilled deionized water, and place on rack again.
11. Cover slides with 5% sodium thiosulfate for 1 min.
12. Wash in distilled deionized water.
13. Cover with 0.2% fast green in acetic acid, counterstain for 1 min; use working solution.
14. Wash with distilled deionized water, and stand slides on end to drain and dry.
15. Examine with oil immersion or mount slides.
16. Fill Coplin jar used for staining with bleach (full strength), and let stand for at least 1 h.

Reagents for Rapid Methenamine Silver Stain (No Microwave) (37)

In another rapid methenamine silver-staining procedure, a 5% (rather than 10%) chromic acid solution is used,

the gold chloride is present at 0.2% (rather than 1%), the sodium thiosulfate is present at 2% (rather than 5%), and the microwave oven is not used (37). Another difference from the microwave method involves fixation of the smears prior to staining. Heat fix all smears at 70°C for 10 min on a heating block for specimens that could contain *Mycobacterium tuberculosis*. Place the air-dried smears in absolute methyl alcohol for 5 min. Fix a control smear (microsporidia, fungus, or *P. jiroveci*) at the same time. It is mandatory that control smears be used every time patient specimens are stained.

Chromic Acid (5% Solution)

Chromic acid (CrO₃) 5 g
Distilled water 100 ml

Solution is stable for up to 1 year.

Methenamine (3% Solution)

Hexamethylenetetramine, USP
[(CH₂)₆N₄] 3 g
Distilled water 100 ml

Solution is stable for up to 1 year.

Sodium Bisulfite (1% Solution)

Sodium bisulfite (NaHSO₃) 1 g
Distilled water 100 ml

Solution is stable for up to 1 year.

Sodium Thiosulfate (Hypo) (2% Solution)

Sodium thiosulfate
(Na₂S₂O₃ · 5H₂O) 2 g
Distilled water 100 ml

Solution is stable for up to 1 year.

Stock Light Green

Light green, S.F. (yellow)
(C.I. no. 42095) 0.2 g
Distilled water 100 ml
Glacial acetic acid
(CH₃COOH) 0.2 ml

Solution is stable for up to 1 year.

Silver Nitrate (5% Solution)

Silver nitrate (AgNO₃) 5 g
Distilled water 100 ml

Solution is stable for 1 to 6 months at 4°C.

Sodium Borate (Borax) (5% Solution)

Borax, photographic or USP

(Na₂B₄O₇ · 10H₂O) 5 g
Distilled water 100 ml

Solution is stable for up to 1 year.

Gold Chloride (0.2% Solution)

Gold chloride, 1% solution
(AuCl · HCl · 3H₂O) 10 ml
Distilled water 40 ml

This solution is stable for 1 year; however, when toning begins to fail and the organisms come out too black, it should be changed.

Note The 1% gold chloride solution is made from ampoules and is diluted as specified in the accompanying directions (dilute with tap water).

Stock Methenamine-Silver Nitrate

Silver nitrate, 5% solution 5 ml
Methenamine, 3% solution 100 ml

A white precipitate forms but immediately dissolves on shaking. Clear solutions remain stable for months at refrigerator temperature (4°C).

Working Light Green

Light green, stock solution 10 ml
Distilled water 40 ml

Solution is stable for up to 1 month.

Working Methenamine-Silver Nitrate

Borax, 5% solution 2 ml
Distilled water 25 ml

Mix, and add:

Methenamine-silver nitrate,
stock solution 25 ml

Caution The working methenamine-silver nitrate solution must be prepared fresh each time the stain is run. Do not try to reuse, even for a stain run immediately following one previously performed.

Procedure for Rapid Methenamine Silver Stain (No Microwave) (37)

1. While slides are fixing, fill one Coplin jar (with a lid) with 5% chromic acid. In a screw-cap Coplin jar, prepare the working methenamine-silver nitrate solution.
2. Place fixed slides into chromic acid, and put both Coplin jars into the 80°C water bath. Warm the jars and their contents in a stream of hot water for approximately 30 s before placing them in the water

bath, to prevent the jars from cracking. Place smears into the heated 5% chromic acid, and incubate them in the water bath for 2 min (oxidation step).

3. Wash slides briefly in running tap water.
4. Place slides into 1% sodium bisulfite for 30 s.
5. Rinse slides in three changes of distilled water.
6. Place slides into the jar of working methenamine-silver nitrate solution in the 80°C water bath for 4.5 min (reduction step).
7. Rinse slides with three changes of distilled water. Wipe backs of slides with a paper towel to remove excess methenamine-silver nitrate.
8. Tone in 0.2% gold chloride for 30 s.
9. Rinse in three changes of distilled water.
10. Place slides into 2% sodium thiosulfate for 30 s (removes reduced silver).
11. Rinse in three changes of distilled water.
12. Counterstain in working light green solution for 30 s.
13. Rinse in three changes of distilled water.
14. Dehydrate and clear for 30-s intervals in two changes each of 95% ethyl alcohol, 100% ethyl alcohol, and xylene or xylene substitute, respectively.
15. Mount slides in Permount.

The fungi generally stain gray to black; *P. jiroveci* exhibits a delicately stained wall, usually brownish or grayish, which is somewhat transparent. Structures described as “parentheses” are usually seen and are stained dark gray or black (Figure 30.4, upper). If the organisms are too dark, it is probably time to change the solutions (Figure 30.4, lower). It is also important to prepare the smears so that the material is thin and evenly spread on the glass slide. Glycerin, red blood cells, and mucin stain rose taupe to dark gray. The inner parts of mycelia and hyphae stain “old rose.” The background usually appears pale green. Microsporidial spores stain dark gray to black; the horizontal or diagonal “stripe” or polar filament is not visible in every spore (Figure 30.4).

Note The examination of specimens for the diagnosis of microsporidia is not often considered to be a STAT procedure and may be handled in the anatomic pathology division. The stained smears can be difficult to read and interpret, hence the need for available experienced personnel.

Rapid Giemsa Stain (Diff-Quik or Giemsa Plus)

1. Keep stain solutions in dropper bottles. Place 1 or 2 drops of red stain (solution 1) on specimen smear and control slide (normal blood film), hold for 10 s, and drain.

Figure 30.4 (Upper) *Pneumocystis jiroveci*. Note that the “parentheses” are visible; this is a well-stained preparation (methenamine silver stain). (Lower) Microsporidial spores. Note polar tubule within circle (methenamine silver stain).

2. Add drops of blue (solution 2), hold for 10 s, drain, and rinse very briefly with deionized water.
3. Stand slides on end to drain and air dry.
4. Slides must be examined with oil or mounted with mounting medium.

Giemsa Stain

Make Giemsa working solution fresh each day. Discard and make new solution after 10 slides have been stained

in a Coplin jar. Additional directions can be found in chapter 31.

1. Place 2 ml of Giemsa (azure B) stain in a Coplin jar. Remove stain from stock stain in bottle with a clean, dry pipette.
2. Add 40 ml of phosphate buffer (pH 7.0 to 7.2) containing 0.01% Triton X-100.
3. Place fixed specimen smears and control smears in Giemsa stain for 30 min.
4. Remove slides, dip in phosphate buffer, stand slides on end, and allow to drain and air dry.
5. Examine with oil or mount slides.

Giemsa Staining for Microsporidia

1. Internal morphology may be difficult to interpret (spores with polar tubules).
2. Giemsa stain may be more relevant for specimens other than stool (urine, sputum, eye).
3. Perform modified trichrome stains on stool.

Potential Problems with Stain Interpretation

In the procedures in which the spores are stained, spores and fungi may appear very much alike. If rare organisms are seen, it may be almost impossible to differentiate microsporidia from various fungi, particularly if no budding organisms are seen.

Although a second type of stain can be used (Giemsa, which stains the spores), the organisms may be very difficult to differentiate from cellular debris. Consequently, few laboratories rely on the Giemsa stain alone (Figure 30.5).

Other methods such as fluorescent-antibody and immunoperoxidase techniques have been used for *P. jiroveci* (1, 25, 27, 32, 34, 35, 44, 55). The development of tissue culture procedures for *P. jiroveci* may lead to additional diagnostic procedures for this infection. Immunoassay reagents are also available (19, 27, 32, 34, 44, 55) and are being widely used in many diagnostic laboratories.

When noninduced sputum and the direct fluorescent-antibody technique were used, the sensitivity was 55%; this is within the range reported in the literature for the diagnosis of *Pneumocystis* pneumonia from induced sputum (39). Although detection of *P. jiroveci* has increased with the use of PCR, particularly in sputum specimens, some workers recommend that sputum samples of human immunodeficiency virus-infected patients be tested by both PCR and immunofluorescence. The results of PCR in this patient group could be misleading without careful clinical evaluation (47). However, the level of sensitivity seen using PCR indicates that these procedures should be

Figure 30.5 *Pneumocystis jiroveci* trophozoites within the cyst wall (stained with Giemsa stain). Note that the cyst wall is not visible when Giemsa stain is used.

considered for patients in whom *Pneumocystis* pneumonia is suggestive clinically and the specimen is negative by the immunofluorescence test (23).

Quality Control Measures

Quality control measures for all stains should include the following, and control slides must be incorporated into all stain procedures.

1. Examine a control slide for each stain prior to examination of specimen stains. The stain intensity of controls will be a guide to the stain appearance of organisms in specimens.
2. Examine stained specimen smears by systematically moving from field to field until the majority of the smear has been covered (total area for silver stain).
3. In Giemsa stains, trophozoite clumps of various sizes may be detected. In large clumps, it may be difficult to differentiate individual organisms. *Look at organisms at the edges of clumps, and look for small, more dispersed clumps.*
4. In silver- or other cyst wall-stained smears, look for the various cyst forms, including those that show dark centers, cup-shaped cysts, and cysts with foldlike lines (they look like “punched-in” ping-pong balls). If dark-staining organisms appear more oval, look carefully for budding forms, which indicate that the organisms are yeasts. *It is important to review thinner areas of the smear for microsporidial spores.*
 - A. *P. jiroveci* cysts: 70% should have delicately stained walls, usually brown or gray. They

appear somewhat transparent, with structures described as “parentheses” staining black; these curved structures are usually thick (much thicker than the cyst wall) rather than thin like a line drawing.

- B. Other fungi and actinomycetes: gray to black. Microsporidial spores stain dark gray to black.
 - C. Glycogen, mucin, and red blood cells: rose taupe to gray.
 - D. Background: pale green (from the light green counterstain).
5. Detection of *P. jiroveci* in specimen smears from one type of stain always suggests a careful examination of the other stain, hopefully to confirm the identification.
 6. Retain all positive stained specimen slides and control slides for reference.

Reporting Smear Results

1. Report *P. jiroveci* as follows (high dry power; total magnification, $\times 400$).
 - A. “No *Pneumocystis jiroveci* seen.”
 - B. “*Pneumocystis jiroveci* seen” (no quantitation should be included).
2. Report other fungi that may be present as follows (low power; total magnification, $\times 100$).
 - A. “No mycotic elements seen.”
 - B. “Budding yeasts” or “Budding yeasts and pseudohyphae resembling *Candida* species” are quantitated as few, moderate, or many.
 - C. Hyphae are reported with no quantitation:
 - a. “Septate hyphae seen.”
 - b. “Nonseptate hyphae seen.”
3. Report actinomycetes (oil immersion; total magnification, $\times 1,000$) as follows.
 - A. “No filamentous branching bacteria seen.”
 - B. “Filamentous branching bacteria seen” (no quantitation).
4. Report microsporidia (oil immersion; total magnification, $\times 1,000$) as follows.
 - A. “No microsporidial spores seen.”
 - B. “Microsporidial spores seen; identification to genus not possible.”

Notes on Staining Procedures

1. Use at least two stains for detection and identification of *P. jiroveci*. With traditional histochemical stains, a trophozoite stain such as Giemsa and a cyst wall stain such as methenamine-silver nitrate are recommended.

2. There are many cyst wall stains in addition to the one described (5), and there are other modifications of the silver stain (28, 33, 37).
3. Stain effectiveness varies (36). Other counterstains may be used; a counterstain with Giemsa is useful if referral slides will be submitted for examination (51).
4. When selecting a cyst wall stain, consider stain quality, reagent stability, and potential testing frequency (including STAT requests). Toluidine blue O stains vary in dye lots and in the stability of sulfation reagents (42). In the modified procedure, the sulfation reagent made of glacial acetic acid and concentrated sulfuric acid presents disposal problems.
5. The rapid silver stain described is a modification of the procedure described by Brinn (6). Heating the chromic acid may cause nonspecific staining, making the background too dark. Also, buildup of silver on the stain container may interfere with staining. Bleach should be added to the stain jar after staining, and jars should be scrubbed periodically with a brush. Additional tips for getting good stain results include the following.
 - A. Before use, inspect glassware to ensure that it does not have residual silver deposits.
 - B. Use fresh reagents for each run (5% chromic acid, 1% sodium bisulfite, methenamine-silver nitrate working solution, and 2% sodium thio-sulfate).
 - C. Distilled deionized water must be used throughout the procedure, including slide rinses (microwave procedure).
 - D. Methenamine-silver nitrate working solution must be clear; if it becomes opaque at any time, the reduction step may take longer or may not occur at all. Check the distilled deionized water source, and prepare fresh methenamine-silver nitrate working solution.
6. If mounted slides appear opaque or cloudy, the dehydration and clearing with xylene (or xylene substitute) were not adequate. Soak slides in xylene to remove the coverslips. Using fresh ethanol and xylene, repeat the dehydration steps.
7. Degenerating polymorphonuclear leukocytes may resemble *P. jiroveci*.
8. Monoclonal antibodies specific for human strain *P. jiroveci* are now available. The commercial systems vary; some are indirect stains, and some are direct stains. Reports with all systems have been variable (25, 35). Many laboratories are now using these immunospecific stains.

9. Select an organism stain and a cyst wall stain or immunospecific stain; use of a pair of stains will help avoid both false-negative and false-positive reporting.
10. In addition to organism detection, cytocentrifuge preparations of sputum (40) can be used to determine cell populations for further patient evaluation.

Aspirates

The examination of aspirated material for the diagnosis of parasitic infections may be extremely valuable, particularly when routine testing methods have failed to demonstrate the organisms. These types of specimens should be transported to the laboratory immediately after collection. Aspirates include liquid specimens collected from a variety of sites where organisms might be found. Aspirates most commonly processed in the parasitology laboratory include fine-needle aspirates and duodenal aspirates. Fluid specimens collected by bronchoscopy include bronchoalveolar lavage fluid and bronchial washings.

Procedural details for sigmoidoscopic aspirates and scrapings for the recovery of *E. histolytica* are presented in chapter 29. Techniques for preparation of duodenal aspirate material are also presented in that chapter.

Specimens Obtained from Aspiration Procedures

Fine-needle aspirates are often collected by cytopathology staff, who process the specimens, or they may be collected and sent to the laboratory directly for slide preparation and/or culture. Suggested stains are Giemsa and methenamine silver for *P. jiroveci*, Giemsa for *Toxoplasma gondii* (4), trichrome for amebae, modified acid-fast stains for *Cryptosporidium* (7, 9), and modified trichrome stains for the microsporidia (see chapter 27).

Aspirates of cysts and abscesses to be evaluated for amebae may require concentration by centrifugation, digestion, microscopic examination for motile organisms in direct preparations, and cultures and microscopic evaluation of stained preparations.

Duodenal aspirates to be evaluated for *S. stercoralis*, *Giardia lamblia*, *Cryptosporidium* spp., *Cyclospora cayentanensis*, or the microsporidia may require concentration by centrifugation prior to microscopic examination for motile organisms and permanent stains (3, 17, 48, 49).

Bone marrow aspirates to be evaluated for *Leishmania* amastigotes, *Trypanosoma cruzi* amastigotes, or *Plasmodium* spp. require Giemsa staining (21, 46).

Fluid specimens collected by bronchoscopy may be lavages or washings, with bronchoalveolar lavages preferred. Specimens usually are concentrated by centrifugation prior to microscopic examination of stained

preparations. Organisms included here which may be detected are *P. jiroveci*, *Toxoplasma gondii*, and *Cryptosporidium*.

Lungs and Liver

Pneumocystosis

Although formerly classified with the sporozoa, *P. jiroveci* has been reclassified with the fungi. It is an important cause of pulmonary infections, particularly in patients who are immunosuppressed as a result of therapy or from congenital or acquired immunologic deficiencies (14, 38, 45, 50). Clinically, the infection may involve both lungs diffusely, may be localized, or may be disseminated (22, 31). For immunosuppressed patients, in whom the disease may progress very quickly, correct specimen collection and rapid diagnostic techniques are very important. The organisms can be demonstrated in stained impression smears of lung material obtained by open or brush biopsy. *P. jiroveci* can also be seen in stained smears of tracheobronchial aspirates, although examination of lung tissue is more likely to reveal the organisms. Sputum specimens are generally considered unacceptable for the recovery of *P. jiroveci*; however, in patients with severe, progressive disease, such specimens may be acceptable. To avoid the possibility of false-negative results, acceptance of sputum specimens should be carefully monitored and reviewed. Also, even for patients with fulminant disease, multiple specimens may have to be submitted to recover and identify the organisms. With a number of the stains that are available, the cyst walls stain but the cyst contents do not (Figure 30.1) (24); however, only the methenamine silver stain is discussed here (5, 32).

Amebiasis

Examination of aspirates from lung or liver abscesses may reveal trophozoites of *E. histolytica* (Figure 30.6); demonstration of the organisms is often very difficult. In many cases, serologic confirmation is recommended (54). Liver aspirate material should be taken from the margin of the abscess rather than the necrotic center (Figure 30.7). The organisms are often trapped in the viscous pus or debris and may not exhibit typical motility. The Amoebiasis Research Unit, Durban, South Africa, has recommended using proteolytic enzymes to free the organisms from the aspirate material.

The digestion technique is performed as follows.

1. A minimum of two separate portions of exudate should be removed (more than two are recommended). The first portion of the aspirate, usually yellowish white, rarely contains organisms. The last portion of the aspirated abscess material is reddish and is more likely to contain amebae. The

best material to examine is that obtained from the actual wall of the abscess.

2. Add 10 U of streptodornase per ml of thick pus; incubate this mixture for 30 min at 37°C, and shake repeatedly.
3. Centrifuge the mixture at $500 \times g$ for 5 min. The sediment may be examined microscopically as wet mounts or used to inoculate culture media. Some of the aspirate can be mixed directly with polyvinyl alcohol on a slide and examined as a permanent stained smear.

Figure 30.7 Liver abscess caused by *Entamoeba histolytica*. Amebae would be found at the advancing margin of the lesion; the last portion of the aspirated material might reveal the organisms. (Illustration by Sharon Belkin.)

Hydatid Disease

Aspiration of cyst material for the diagnosis of hydatid disease is a dangerous procedure and is normally performed only when open surgical techniques are used for cyst removal. Aspirated fluid usually contains hydatid sand (intact and degenerating scolices, hooklets, and calcareous corpuscles) (Figure 30.8). Some older cysts contain material that resembles curded cottage cheese, and the hooklets may be very difficult to see. Some of this material can be diluted with saline or 10% KOH; usually, scolices or daughter cysts will have disintegrated. However, the diagnosis can be made by seeing the hooklets.

Examination of hydatid cyst material is carried out as follows.

1. If the cyst material is fluid, centrifuge at $500 \times g$ for 3 min.
2. Carefully remove some of the sediment and prepare a wet mount.

Figure 30.6 *Entamoeba histolytica* containing ingested red blood cells within the cytoplasm; morphologically this organism is *E. histolytica*, and this would be the species designation if organisms were isolated from liver abscess material.

3. Examine the material under low (100 \times) and high dry (430 \times) power (remember to use low light intensity, since some of the material may be very transparent).
4. If the cyst material is more viscous or solid, the material can be mixed with saline or 10% KOH and then centrifuged at $500 \times g$ for 3 min.
5. Some of the very viscous material can be placed on a glass slide (undiluted). Another glass slide can be placed on top of the first (material will now lie between the two slides). Rub the glass slides back and forth over each other and listen for a grating sound (like grains of sand being scratched). If this occurs, you may be hearing evidence of the presence of calcified hooklets. Place the material from the smears (may be diluted with saline) under the microscope to try to confirm the presence of hooklets (which may be extremely difficult to see with only low power).

Note Remember, the absence of scolices or hooklets does not rule out the possibility of hydatid disease, since some cysts are sterile and contain no scolices and/or daughter cysts. Review of the cyst wall from pathology (tissue sections) should be able to confirm the diagnosis.

Lymph Nodes, Spleen, Liver, Bone Marrow, Spinal Fluid, Eyes, and Nasopharynx

African Trypanosomiasis, Leishmaniasis, Chagas' Disease, Primary Amebic Meningoencephalitis, Granulomatous Amebic Encephalitis, Amebic Keratitis, and Microsporidial Keratitis

Material from lymph nodes, spleen, liver, bone marrow, spinal fluid, eye specimens, or nasopharynx may be examined for the presence of parasites and should be processed as follows.

Figure 30.8 Hydatid disease (*Echinococcus granulosus*). (Upper left) Hydatid cyst with scolices budding off from the germinal layer. (Upper right) Immature scolices, with the dark area being the hooklets. (Lower left) Higher magnification of the scolices taken from the hydatid cyst fluid. (Lower right) Hooklets from disintegrating scolices. Reprinted from reference 15.

1. A portion of the fluid material can be examined under low ($\times 100$) and high dry ($\times 400$) power as a wet mount (diluted with saline) for the presence of motile organisms. Spinal fluid should not be diluted before examination.
2. Impression smears from tissues should be prepared and stained with Giemsa stain. The material is pressed between two slides, and a smear is formed when the slides are pulled apart (one across the other).
3. The smears are allowed to air dry and then processed like a thin blood film (fixed in absolute methanol and stained with Giemsa stain).
4. Appropriate culture media should be inoculated with any remaining material (see chapter 32).
5. If microsporidia are suspected, modified trichrome stains can be used; calcofluor white and immunoassay methods (currently under development) are also excellent options (8, 10–13, 20, 26, 30, 56).

Primary amebic meningoencephalitis is rare, but the examination of spinal fluid may reveal the amebae, usually *Naegleria fowleri* (Figure 30.9). Granulomatous

amebic encephalitis is caused by *Acanthamoeba* spp., *Balamuthia mandrillaris*, or *Sappinia diploidea*. Uncentrifuged sedimented spinal fluid should be placed under a coverslip on a slide and observed for motile amebae; smears can also be stained with Wright's or Giemsa stain. Spinal fluid, exudate, or tissue fragments can be examined by light microscopy or phase-contrast microscopy. Care must be taken not to confuse leukocytes with actual organisms and vice versa. The appearance of the spinal fluid may vary from cloudy to purulent (with or without red blood cells), with a cell count from a few hundred to over 20,000 white blood cells (primarily neutrophils) per ml. Failure to find bacteria in this type of spinal fluid should alert one to the possibility of primary amebic meningoencephalitis. These organisms can be isolated from tissues or soil with special media (see chapter 32).

Note When spinal fluid is placed in a counting chamber, any organisms that settle to the bottom of the chamber will tend to round up and look very much like a white blood cell. For this reason, it is better to examine the spinal fluid on a slide directly under a coverslip, not in a counting chamber.

A rapid method for the diagnosis of *Acanthamoeba* or microsporidial keratitis involves the use of calcofluor white, which is a chemofluorescent dye with an affinity for the polysaccharide polymers of amebic cysts and microsporidial spores (Figures 30.10 and 30.11). The following method has proven to be very successful for examination of corneal scrapings or biopsy material (24, 53).

1. Place corneal scrapings on slides, and air dry them.
2. Fix the slides in absolute methyl alcohol for 3 to 5 min.

Figure 30.9 *Naegleria fowleri*. Note the large karyosome and lobate pseudopodia. Spinal fluid should be examined on a slide, not in a counting chamber, where protozoan trophozoites could mimic white blood cells. (Armed Forces Institute of Pathology photograph.)

3. Add several drops of solution (0.1% calcofluor white and 0.1% Evans blue dissolved in distilled water); leave on for 5 min.
4. Turn the slide on its side, and allow excess stain to run off onto paper towels.
5. Add a coverslip, and examine under the fluorescence microscope for pale blue chemofluorescence of the amebic cysts (will not stain trophozoite). The microsporidial spores usually stain brighter; however, fluorescence can vary between 1+ and 3+.

Note Select UV irradiation with an exciter filter which transmits the 365-nm group of intense mercury spectral emission lines (Zeiss UGI or G365). View through a barrier filter which removes UV while emitting visible blue light and longer wavelengths (Zeiss no. 41 or LP420).

Cutaneous Ulcer

Leishmaniasis

Material containing intracellular *Leishmania* organisms must be aspirated from below the ulcer bed through the uninvolved skin, not from the surface of the ulcer (Figure 30.12). It is very important that the surface of the ulcer be thoroughly cleaned before specimens are taken; any contamination of the material with bacteria or fungi may prevent recovery of organisms from culture. An actual cutaneous ulcer before and after therapy can be seen in Figure 30.13.

Biopsy Material

Biopsy specimens are recommended for the diagnosis of tissue parasites. The following procedures may be used for this purpose in addition to standard histologic preparations:

Figure 30.10 *Acanthamoeba* cyst. Note the fluorescence of the cyst wall. Trophozoites do not fluoresce when calcofluor white is used.

Figure 30.11 Microsporidial spores. (Upper left) Spores in a corneal scraping specimen; (upper right) spores in a fecal specimen (both images stained with silver stain). (Lower left) Microsporidial spores in a urine sediment; (lower right) spores from nasopharyngeal aspirate (both images stained using calcofluor white).

impression smears and teased and squash preparations of biopsy tissue from the skin, muscle, corneas, intestines, liver, lungs, and brain. Tissue to be examined by permanent sections or electron microscopy should be fixed as specified by the laboratories that will process the tissue. In certain cases, examination of a biopsy specimen may be the only means of confirming a suspected parasitic infection. Specimens that are going to be examined as fresh material rather than as tissue sections should be kept moist in saline and submitted to the laboratory immediately.

Figure 30.12 Proper way to aspirate material from below the ulcer bed (*Leishmania* spp.); sterile saline (0.5 to 1.0 ml) can be injected under the ulcer prior to aspiration. (Illustration by Sharon Belkin.)

Figure 30.13 *Leishmania* cutaneous lesion. (Upper) Lesion prior to therapy; (lower) lesion after therapy.

Importance of Biopsy Specimens

Success in detection of parasites in tissue depends in part on specimen collection and on the presence of sufficient material to perform the recommended diagnostic procedures. Biopsy specimens are usually quite small and may not be representative of the diseased tissue. Examination of multiple tissue samples often improves diagnostic results. To optimize the yield from any tissue specimen, examine all areas and use as many procedures as possible. Tissues are obtained by invasive procedures, many of which are very expensive and lengthy; consequently, these specimens deserve the most comprehensive procedures possible. It is also important to remember that if the tissue specimen is not sufficient for all diagnostic procedures requested, the procedures should be prioritized after consultation with the physician.

Submission of Specimens

Tissue submitted on a sterile sponge dampened with saline in a sterile container may be used for cultures of protozoa after mounts for direct examination or impression smears for staining have been prepared. If cultures for parasites will be included, sterile slides should be used for smear and mount preparation.

1. Use sterile slides for impression smears; slides can be either autoclaved or prepared by an alternative method in which they are soaked in 95% ethyl alcohol and flamed prior to use.
2. Use sterile (autoclaved or flamed) forceps for handling tissue.
3. Place tissue in sterile petri dish to examine macroscopically and select a sample for microscopic evaluation. Provided that it is kept sterile, minced tissue can be used.
 - A. If biopsy tissue is several millimeters to a centimeter in size, select the specimen from an abnormal area (granulomatous lung or ulcerated area of intestinal tissue). Generally, the tissue fragments are too small to permit such a judgment to be made.
 - B. If several small pieces of tissue that look alike are submitted, use one piece. However, if they look different, use one of each type for microscopic examination. Again, sometimes this assessment is difficult to make.
4. Prepare impression smears.
 - A. Blot the tissue sample on sterile toweling. If the sample size is sufficient, cut the tissue with a scalpel (very sharp cut) and use the cut surface to touch the slide.
 - B. Press tissue against the sterile slide, lift, and press again. Turn the sample over, and press the other end against the slide to make two more impressions. Keep impressions close together to speed the screening process with the microscope.
 - C. Air dry and fix smears in absolute methanol for 1 min for subsequent Giemsa, methenamine-silver nitrate, modified acid-fast, and modified trichrome staining. If the amount of tissue is sufficient, multiple smears should be prepared for each stain (Figure 30.14).
 - D. Place wet slide in Schaudinn's fixative for subsequent trichrome staining.
 - E. Fix the slide as specified by the manufacturer for immunospecific staining.
5. Teased preparations are made as follows.
 - A. Place sample in the bottom of a plastic petri dish, and cover with 2 to 4 drops of saline.
 - B. Gently tease tissue apart with needles, or hold the tissue with forceps while pulling apart with a scalpel or needles.
 - C. Put a cover on dish, and leave at room temperature for 30 min.
6. Squash preparations are made as follows.
 - A. Using a scalpel, cut selected tissue portions into very fine pieces.

- B. Place a piece of tissue on a 1- by 3-in. slide, add 1 drop of saline, cover with a second 1- by 3-in. slide, and hold together with membrane clips (from a surgical supply company). If these are not available, paper clips can be used but are not as efficient. *You can also press the slides together with your fingers, but always wear gloves and be careful not to contaminate the microscope stage with tissue fluids.*
7. Skin scrapings should be submitted in a small vial.
 8. Prepare cultures to demonstrate the following organisms (see chapter 32): *E. histolytica*, *Acanthamoeba* and *Naegleria* spp., and *Leishmania* spp.
 9. Mouse passage for *Toxoplasma gondii*:
 - A. Grind tissue in 0.85% NaCl into a fine suspension.
 - B. Inject 0.2 to 0.4 ml of suspension intraperitoneally into three to five mice of any laboratory strain weighing ~20 g.

- C. Maintain mice in isolation.
- D. Every day, check for signs of central nervous system dysfunction; if symptoms are detected, perform an autopsy on the animal.

Examination of Specimens

1. Examination of impression smears is summarized in Table 30.1.
2. Examine skin snips in teased preparations for detection of microfilariae of *Onchocerca volvulus* and *Mansonella streptocerca* as follows.
 - A. Tease the small bit of tissue apart in a few drops of saline to release the microfilariae.
 - B. Remove drops of saline to a 1- by 3-in. glass slide, cover with a no. 1 coverslip, and examine under low light for microfilariae.
 - C. For a permanent preparation, place 100% methanol under the coverslip to fix filariae, partially dry, remove the coverslip, and stain with Giemsa.
3. Examine squash preparations for detection of *Trichinella* spp. in muscle microscopically at low power ($\times 100$) and under low light.
4. Examine scrapings of skin for *Sarcoptes scabiei* (scabies) microscopically at low power ($\times 100$) and under low light. Confirmation at high dry power ($\times 400$) may be necessary (Figure 30.15).
5. Inoculate cultures with ground tissue suspensions (to release organisms from the cells).
 - A. Place a small tissue sample in a sterile tissue grinder (Ten Broeck or Dounce) in 0.5 ml of sterile saline, and grind until tissue is broken up but not totally liquefied.
 - B. Add several drops of ground tissue to culture medium as follows.
 - a. NNN medium (see chapter 32): add drops of tissue to the bottom of the slant, where they will “pool” with condensed moisture. Incubate at room temperature (isolation of *Leishmania* spp.).
 - b. TYSGM-9 medium (see chapter 32): add drops of tissue to the liquid medium, add 3 drops of the starch suspension, and incubate at a 45 to 50° angle at 35°C for 48 h (isolation of *E. histolytica*).
 - c. Nonnutrient agar plate seeded with bacteria (see chapter 32): add drops to center of seeded agar plate, and incubate at 35 to 37°C (isolation of *Acanthamoeba* or *Naegleria* spp.).

Figure 30.14 (Upper) *Leishmania donovani* amastigotes in a cell, stained with Giemsa stain. (Lower left) *Cryptosporidium* spp. oocysts stained with modified acid-fast stain. Note that the sporozoites are visible within some of the oocysts. (Lower right) Microsporidial spores stained with methenamine silver stain. Note the similarity to small yeast cells.

Table 30.1 Examination of impression smears

Tissue	Possible parasite	Stain	
Lung	<i>Pneumocystis jiroveci</i> (now classified with the fungi)	Giemsa, methenamine silver or other cyst wall stain, optical brightening agent (calcofluor), immunospecific reagent	
	Microsporidia	Modified trichrome, acid-fast stain, Giemsa, optical brightening agent (calcofluor), methenamine silver, EM ^a	
	<i>Toxoplasma gondii</i>	Giemsa, immunospecific reagent	
	<i>Cryptosporidium</i> spp.	Modified acid-fast stain, immunospecific reagent	
	<i>Entamoeba histolytica</i>	Giemsa, trichrome	
Liver	<i>Toxoplasma gondii</i>	Giemsa	
	<i>Leishmania donovani</i>	Giemsa	
	<i>Cryptosporidium</i> spp.	Modified acid-fast stain, immunospecific reagent	
	<i>Pneumocystis jiroveci</i> (now classified with the fungi)	Giemsa, methenamine silver or other cyst wall stain, optical brightening agent (calcofluor), immunospecific reagent	
	<i>Entamoeba histolytica</i>	Giemsa, trichrome	
Brain	<i>Naegleria</i> sp.	Giemsa, trichrome	
	<i>Acanthamoeba</i> sp.	Giemsa, trichrome	
	<i>Balamuthia mandrillaris</i> (Leptomyxid ameba)	Giemsa, trichrome	
	<i>Sappinia diploidea</i>	Giemsa, trichrome	
	<i>Entamoeba histolytica</i>	Giemsa, trichrome	
	<i>Toxoplasma gondii</i>	Giemsa, immunospecific reagent	
	Microsporidia (<i>Encephalitozoon</i> spp.)	Modified trichrome, acid-fast stain, Giemsa, optical brightening agent (calcofluor), methenamine silver, EM	
Skin	<i>Leishmania</i> spp.	Giemsa	
	<i>Onchocerca volvulus</i>	Giemsa	
	<i>Mansonella streptocerca</i>	Giemsa	
	<i>Acanthamoeba</i> sp.	Giemsa, trichrome	
Nasopharynx, sinus cavities	Microsporidia	Modified trichrome, acid-fast stain, Giemsa, optical brightening agent (calcofluor), methenamine silver, EM	
	<i>Acanthamoeba</i> sp.	Giemsa, trichrome	
	<i>Naegleria</i> sp.	Giemsa, trichrome	
Intestine	Small intestine	<i>Cryptosporidium</i> spp. (both small and large intestine)	Modified acid-fast stain, immunospecific reagent
		<i>Cyclospora cayentanensis</i>	Modified acid-fast stain
	Jejunum	Microsporidia (<i>Enterocytozoon bieneusi</i> , <i>Encephalitozoon intestinalis</i>)	Modified trichrome, acid-fast stain, Giemsa, optical brightening agent (calcofluor), methenamine silver, EM
	Duodenum	<i>Giardia lamblia</i>	Giemsa, trichrome
	Colon	<i>Entamoeba histolytica</i>	Giemsa, trichrome
	Cornea, conjunctiva	Various genera of microsporidia	Acid-fast stain, Giemsa, modified trichrome, methenamine silver, optical brightening agent (calcofluor), EM
		<i>Acanthamoeba</i> sp.	Giemsa, trichrome, calcofluor for cysts
Muscle	<i>Trichinella</i> spp.	Wet examination, squash preparation	
	Microsporidia (<i>Pleistophora</i> sp., <i>Trachipleistophora</i> sp., <i>Brachiola</i> sp.)	Modified trichrome, acid-fast stain, Giemsa, optical brightening agent (calcofluor), methenamine silver, EM	

^a EM, electron microscopy.

Figure 30.15 *Sarcoptes scabiei* mites from skin scrapings. (Upper) Note the two mites to the left of center. (Lower) Note the two eggs, the small nymph, and the adult mite (photographed at a higher magnification). If the light is too strong when examining the scrapings in saline, the mites will probably not be seen.

6. Examine cultures (*wear gloves at all times*).
 - A. NNN agar for promastigotes of *Leishmania* spp. (see chapter 32): using a Pasteur pipette, remove a drop of fluid from interface of agar slant and culture tube, place on glass slide, cover with coverslip, and examine microscopically ($\times 400$) under low light for motile promastigotes (Figure 30.16).
 - B. TYSGM-9 medium for amebae (see chapter 32): using a sterile Pasteur pipette, remove 1 or 2 drops of material from interphase of agar and overlay, place on glass slide, cover with coverslip, and examine microscopically ($\times 100$) under low light for trophozoite motility.
 - C. Nonnutrient agar plate with lawn of *Escherichia coli* or *Enterobacter* sp. for detection of free-living amebae (see chapter 32): examine microscopically at low power ($\times 100$) for changes in bacterial lawn, particularly patches and tracks, indicating that the protozoan trophozoites have ingested bacteria as they move over the agar.

- D. Mouse passage for detection of *Toxoplasma gondii*:
 - a. Wear canvas gloves to handle mice; sacrifice the animal(s).
 - b. Pin mouse to board, spray with 70% ethyl alcohol, and open peritoneal cavity with sterile scissors.
 - c. Using a sterile Pasteur pipette, remove fluid from the peritoneal cavity, and place in small tube or prepare smears.
 - d. Prepare Giemsa-stained smears of peritoneal exudate, and examine microscopically at a magnification of $\times 1,000$ for *T. gondii* tachyzoites.
 - e. Place mice and all contaminated disposable materials in bag to be autoclaved and destroyed. Place nondisposable materials (scissors) in bag to be autoclaved prior to washing.
7. Correlate all examination results (wet mount, stains, and cultures) to determine presence of organisms.

Results

The majority of the protozoa are found on the permanent stained smears (impression smears, touch or squash preparations, or teased preparations). When culture is used, permanent stained smears of the culture medium or sediment may also reveal some of the protozoa. Although infrequently used, material from animals (at autopsy) can be examined as both wet and permanent stained preparations for confirmation of protozoa. Filarial infections may be confirmed by the recovery and identification of microfilariae in skin scrapings and/or biopsy specimens.

If identifications are certain, report the organisms detected; if a presumptive identification is made, confirmation by another laboratory is suggested.

Figure 30.16 *Leishmania* culture sediment. Note the promastigotes from the culture sediment. The typical “rosette” formation in the left image is frequently seen.

Skin

Onchocerca volvulus and *Mansonella streptocerca*

The use of skin snips is the method of choice for the diagnosis of human filarial infections with *O. volvulus* and *M. streptocerca*. Microfilariae of both species occur chiefly in the skin, although *O. volvulus* microfilariae are on rare occasions found in the blood and occasionally in the urine. For best results, the skin snip specimens should be thick enough to include the outer part of the dermal papillae. Snips may be taken in various ways. A small slice may be cut (using a razor blade) from a skin fold held between thumb and forefinger, or a slice may be taken from a small “cone” of skin pulled up by a needle. The skin snip should be so thin that significant bleeding does not occur, just a slight oozing of fluid. Corneal-scleral punches (either Holth or Walser type) have been found to be successful in taking skin snips of uniform size and depth and an average weight of 0.8 mg (range, 0.4 to 1.2 mg); this procedure is easy to perform and is painless. It has been demonstrated that in African onchocerciasis, it is preferable to take skin snips from the buttock region (above the iliac crest); in Central American onchocerciasis, the preferred skin snip sites are from the shoulders (over the scapula).

Skin snips are placed immediately in a drop of normal saline or distilled water and covered so that they will not dry; teasing the specimen with dissecting needles is not necessary but may facilitate release of the microfilariae. Microfilariae tend to emerge more rapidly in saline; however, in either fluid, the microfilariae usually emerge within 30 min to 1 h and can be examined under low-intensity light with the 10× objective of the microscope. To see definitive morphologic details of the microfilariae, allow the snip preparation to dry, fix it in absolute methyl alcohol, and stain it with Giemsa stain (Figure 30.17). For the differential diagnosis of *O. volvulus* and *M. streptocerca*, see chapter 12.

Cutaneous Amebiasis and Cutaneous Leishmaniasis

Skin biopsy specimens for the diagnosis of cutaneous amebiasis and cutaneous leishmaniasis should be processed for tissue sectioning and subsequently stained by the hematoxylin-eosin technique.

Lymph Nodes

Trypanosomiasis, Leishmaniasis, Chagas' Disease, and Toxoplasmosis

Material obtained from lymph nodes should be processed for tissue sectioning and as impression smears that should be processed as thin blood films and stained with Giemsa or other blood stains. Appropriate culture media can also be inoculated, again making sure that the specimen has been collected under sterile conditions.

Muscle

Trichinosis

The presumptive diagnosis of trichinosis is often based on a combination of facts: history of ingestion of raw or rare pork, walrus meat, or bear meat; diarrhea followed by edema and muscle pain; and the presence of eosinophilia. Usually, by the time the patient is symptomatic, the suspected food is no longer available for examination. The diagnosis may be confirmed by finding larval *Trichinella* spp. in a muscle biopsy specimen. The encapsulated larvae (which may be few) are easily seen in fresh muscle if small pieces are pressed between two slides and examined under the microscope (Figure 30.18). Larvae are usually most abundant in the diaphragm, masseter muscle, or tongue and may be recovered from these muscles at necropsy. Routine histologic sections can also be prepared.

A portion of the specimen can be digested in artificial digestive fluid at 37°C, with the larvae recovered by centrifugation; however, very young larvae might also be digested.

Artificial Digestive Fluid

Pepsin.....	5 g
Hydrochloric acid (concentrated).....	7 ml
Distilled water.....	1,000 ml

1. Prepare the tissue by grinding (with a tissue grinder or commercial meat grinder or blender). The tissue should be medium grind; do not overgrind, particularly in a blender.
2. Add the tissue to the digestive fluid in the ratio of 1 part tissue to 20 parts fluid in an Erlenmeyer flask.
3. Place the flask in an incubator at 37°C, on a shaker table or magnetic stirrer if available; leave for 12 to 24 h.

Figure 30.17 Microfilariae (Giemsa stain). (Left) In this image, the microfilariae from a skin snip saline preparation are visible after staining. (Right) Microfilariae from blood; note that the characteristic nuclei are more easily seen in this preparation.

4. Add warm water (37°C) to the digestive fluid mixture. (Add enough water to triple the original volume.)
5. Pour the diluted mixture into a Baermann funnel, and add water up to the screen.
6. Allow the mixture to stand for 1 to 2 h; the larvae will settle out in the lower part of the funnel.
7. Remove a few drops of fluid, and examine the material under the microscope (10× objective) for the presence of larvae.
8. If no larvae are present, centrifuge 50 ml and examine the sediment.

Cestode Larval Stages

Human infection with any of the larval cestodes may present diagnostic problems, and frequently the larvae are referred for identification after surgical removal. In addition to *Echinococcus granulosus* (hydatid disease) and the larval stage of *Taenia solium* (cysticercosis), other larval cestodes occasionally cause human disease. The larval stage of tapeworms of the genus *Multiceps*, a parasite of dogs and wild canids, is called a coenurus and may cause human coenurosis. The coenurus resembles a cysticercus but is larger and has multiple scolices developing from the germinal membrane surrounding the fluid-filled bladder. These larvae occur in extraintestinal locations, including the eye, central nervous system, and muscle (see chapter 14).

Human sparganosis is caused by the larval stages of tapeworms of the genus *Spirometra*, which are parasites of various canine and feline hosts; these tapeworms are closely related to the genus *Diphyllobothrium*. Sparganum

Figure 30.18 *Trichinella* spp. larvae in a squash preparation of muscle biopsy tissue; note the encysted larvae. This specimen is unstained.

larvae are elongated, ribbonlike larvae without a bladder and with a slightly expanded anterior end lacking suckers. They are usually found in superficial tissues or nodules, although they may cause ocular sparganosis, a more serious disease (see chapter 14).

The diagnosis of larval cestodes is frequently facilitated by the recognition of prominent calcareous corpuscles occurring in the tapeworm tissue; specific identification usually depends on referral to specialists.

Rectum and Bladder

Schistosomiasis

Often when a patient has an old, chronic infection or a light infection with *Schistosoma mansoni* or *S. japonicum*, the eggs may not be found in the stool and an examination of the rectal mucosa may reveal the presence of eggs. The fresh tissue should be compressed between two microscope slides and examined under the low power of the microscope (low-intensity light). Critical examination of these eggs should be made to determine whether living miracidia are still found within the egg. Treatment may depend on the viability of the eggs; for this reason, the condition of the eggs should be reported to the physician.

Mucosa from the bladder wall may reveal eggs of *Schistosoma haematobium* when they are not being recovered in the urine. As with rectal biopsy specimens, the eggs in the bladder wall should be checked for viability (Figure 30.19).

Viability Testing of Schistosome Eggs

1. With careful observation of the egg, using the 40× objective (low-intensity light), the cilia of the flame cells of the miracidium within the shell can be seen to move in a rapid flickering motion.
2. The eggs within the tissue can be removed (carefully tease the tissue apart in saline solution) and subjected to a hatching procedure. If the miracidia are released from the egg and swim to the top of the hatching flask, this movement is also proof of viability. (The procedure can be found in chapter 28.)

Digestion Procedure in Diagnosis of Schistosomiasis

Small pieces of tissue may be digested in 4% potassium hydroxide (4% sodium hydroxide may be used) for 2 to 3 h at 60 to 80°C. The material may then be concentrated by sedimentation or centrifugation and examined under the microscope for eggs (low power with low-intensity light).

Figure 30.19 (Upper) *Schistosoma haematobium* eggs seen in a squash preparation of a bladder biopsy specimen. This specimen is unstained. (Armed Forces Institute of Pathology photograph.) (Lower) *Schistosoma mansoni* eggs from a rectal biopsy specimen.

Delafield's hematoxylin

Depending on the life cycle, a number of parasites may be recovered in a blood specimen, either whole blood, buffy coat preparations, or various types of concentrations. These parasites include *Plasmodium*, *Babesia*, and *Trypanosoma* species, *Leishmania donovani*, and microfilariae. Although some organisms are motile in fresh, whole blood, species identification is normally accomplished from the examination of both thick and thin permanent stained blood films. Blood films can be prepared from fresh, whole blood collected with no anticoagulants, anticoagulated blood, or sediment from the various concentration procedures. The recommended stain of choice is Giemsa stain; however, the parasites can also be seen on blood films stained with Wright's stain, a Wright-Giemsa combination stain, or one of the more rapid stains such as Diff-Quik. Delafield's hematoxylin stain is often used to stain the microfilarial sheath; in some cases, Giemsa stain does not provide sufficient stain quality to allow differentiation of the microfilariae. A complete discussion of the proper way to examine a blood film is presented later in this chapter. This information is important and particularly relevant when one is examining proficiency testing blood films in the absence of clinical information about patient history and possible etiologic agents.

It is important to remember that standard precautions should be used at all times when blood or body fluids are handled (12). Remember that all requests for malaria diagnosis are considered STAT requests, and specimens should be collected, processed, examined, and reported accordingly.

Preparation of Thick and Thin Blood Films

Some parasites (microfilariae and trypanosomes) can be detected in fresh blood by their characteristic shape and motility, but specific identification of the organisms requires a permanent stain. Two types of blood films are recommended. Thick films allow a larger amount of blood to be examined, which increases the possibility of detecting light infections (24). However, species identification by thick film, particularly for malaria parasites, can usually be made only by experienced workers. The morphologic characteristics of blood parasites are best seen in thin films, in which the red blood cell (RBC) morphology is preserved and the size relationship between infected and uninfected red cells can be determined after staining. This characteristic is often valuable in determining the species of *Plasmodium* present from the thin blood film.

The accurate examination of thick and thin blood films and identification of parasites depend on the use of absolutely clean, grease-free slides for preparation of all blood films. Old (unscratched) slides should be cleaned first with detergent and then 70% ethyl alcohol; new slides should also be cleaned with alcohol before use. When a new box of slides is opened, the slides are coated with a substance that allows them to be pulled apart; these slides should be cleaned before use for preparation of blood films. The advantages and disadvantages of the thin and thick blood films can be seen in Table 31.1.

Blood films are usually prepared when the patient is admitted. When malaria is a possible diagnosis, after the first set of negative smears, samples should be taken at intervals of 6 to 8 h for at least three successive days. After a finger stick, the blood should flow freely; blood that has to be “milked” from the finger will be diluted with tissue fluids, decreasing the number of parasites per field. If the specimen is sent directly to the laboratory, thus eliminating laboratory-patient contact, the following approach can be used. Unless you are positive that you will receive well-prepared slides, request a tube of fresh blood (EDTA anticoagulant is preferred) and prepare the smears. For detection of stippling, the smears should be prepared within 1 h after the specimen is drawn. After that time, stippling may not be visible on stained films; however, the overall organism morphology will still be acceptable. Potential problems with anticoagulants can be seen in Table 31.2. Although blood films can be prepared from the small amount of blood left in the needle after the venipuncture collection using anticoagulant, it is not recommended for several reasons. The blood tends to clot fairly quickly in the needle, and there are safety recommendations that limit the handling of needles. Therefore, the finger stick and EDTA venipuncture are recommended for collection of specimens for blood film preparation.

The time when the specimen was drawn should be clearly indicated on the tube of blood and also on the result report. The physician will then be able to correlate the results with any fever pattern or other symptoms that the patient may have. There should also be some indication on the report that is sent back to the physician that one negative specimen does not rule out the possibility of a parasitic infection.

Note Although most laboratories use commercially available blood collection tubes, the following approach can be used when necessary. EDTA (Sequestrene) can be prepared and tubed as follows. Dissolve 5 g of EDTA in 100 ml of distilled water. Aliquot 0.4 ml into tubes, and evaporate the water. This amount of anticoagulant is sufficient for 10 ml of blood. One can also use 20 mg of EDTA (dry) per tube (20 mg/10 ml of blood). The tube should be filled with blood to provide the proper blood/anticoagulant ratio.

Thick Blood Films

Fresh Blood

To prepare the thick film, place 2 or 3 small drops of fresh blood (no anticoagulant) on an alcohol-cleaned slide. With the corner of another slide and using a circular motion, mix the drops and spread them over an area ~2 cm in diameter. Continue stirring for 30 s to prevent the formation of fibrin strands that may obscure the parasites after staining.

Anticoagulant

If blood containing an anticoagulant is used, 2 or 3 drops may be spread over an area about 2 cm in diameter; it is not necessary to continue stirring for 30 s, since fibrin strands do not form. If the blood is too thick or any grease remains on the slide, the blood may flake off during staining.

Table 31.1 Advantages of the thin and thick blood films

Thin blood film advantages	Thick blood film advantages
RBC morphology (size, shape, stippling) can be seen after fixation with methanol prior to staining (Giemsa) or as a part of the staining process (Wright). RBCs are laked in the thick film.	Larger number of parasites per field compared with the thin blood film. RBCs are laked, and so WBCs, platelets, and parasites are visible after staining.
Identification to <i>Plasmodium</i> species easier, since the parasite can be seen within the RBC. The size of the parasites within the RBCs can provide information necessary for identification to species.	Phagocytized malaria pigment may be seen within the WBCs, even with a low parasitemia.
Parasitemia can be calculated from the thin film; determination of parasitemia is mandatory for all species of <i>Plasmodium</i> and is particularly important for monitoring therapy for <i>P. falciparum</i> . Parasitemia should be reported with every set of positive blood films for malaria.	Stippling may be seen in a well-stained thick film. However, this depends on how long the blood has been in contact with anticoagulant if it is not collected as a fresh specimen (finger stick).

Table 31.2 Potential problems of the use of EDTA anticoagulant for the preparation of thin and thick blood films

Potential problem	Comments
Adhesion to the slide; blood falls off slide during staining	Incorrect ratio of anticoagulant to blood; fill tube completely with blood (7 ml or pediatric draw tube).
Distortion of parasites; same type of distortion can also be seen after blood is refrigerated (not recommended)	Prolonged storage of blood in EDTA may lead to distortion: trophozoites (<i>P. vivax</i>) and gametocytes (<i>P. falciparum</i>) tend to round up, thus mimicking <i>P. malariae</i> .
Change in ring form size	Ring forms of <i>P. falciparum</i> continue to grow and enlarge, thus resembling rings of the other species. Typical “small” rings appear larger than usual.
Use of EDTA anticoagulant (primarily used by hematology laboratories because the cellular components and morphology of the blood cells are preserved)	EDTA prevents coagulation of blood by chelating calcium. Calcium is necessary in the coagulation cascade, and its removal inhibits and stops a series of events, both intrinsic and extrinsic, which cause clotting. In some individuals, EDTA may cause inaccurate platelet results. These anomalies, platelet clumping and platelet satellitism, may be the result of changes in the membrane structure occurring when the calcium ion is removed by the chelating agent, allowing the binding of preformed antibodies. Proper mixing of the whole-blood specimen ensures that EDTA is dispersed throughout the sample. Evacuated blood collection tubes with EDTA should be mixed by 8–10 end-to-end inversions immediately following venipuncture collection. Microcollection tubes with EDTA should be mixed by 10 complete end-to-end inversions immediately following collection. They should then be inverted an additional 20 times prior to analysis.
<ol style="list-style-type: none"> 1. Blood smears for differentials from acceptable specimens should be prepared within 2 h of collection 2. Blood counts from acceptable venipuncture specimens should be performed within 6 h of collection 	
Underfilling the EDTA blood collection tube can lead to erroneously low blood cell counts and hematocrits, morphologic changes to RBCs, and staining alteration; excess EDTA can shrink red cells; conversely, overfilling the blood collection tube will not allow the tube to be properly mixed and may lead to platelet clumping and clotting	
Loss of Schüffner’s dots (stippling) in <i>P. vivax</i> and <i>P. ovale</i>	Schüffner’s dots (true stippling) occur in both <i>P. vivax</i> and <i>P. ovale</i> ; in the absence of stippling, identification to the species level may be more difficult or impossible.
Prolonged storage of EDTA blood (room temperature with stopper removed)	The pH, CO ₂ , and temperature changes may reflect conditions within the mosquito. Thus, exflagellation of the male gametocyte may occur while still in the tube of blood prior to thin and thick blood film preparation. Microgametes may be confused with <i>Borrelia</i> or may be ignored as debris.
Release of merozoites from the schizonts into the blood; normally, merozoites are not found outside of the RBCs, in contrast to <i>Babesia</i> spp., where rings may be seen outside of the RBCs	Small rings may be seen outside of the RBCs or appear to be appliqué forms, thus suggesting <i>P. falciparum</i> . It is important to differentiate these true rings (both cytoplasmic and nuclear colors) from platelets (uniform color).
Incorrect submission of blood in heparin	EDTA has less impact on parasite morphology than does heparin.

Allow the thick film to air dry (room temperature) in a dust-free area. Never apply heat to a thick film, since heat will fix the blood, causing the RBCs to remain intact during staining; the result is stain retention and inability to identify the parasites. After the thick films are thoroughly dry, they can be laked to remove the hemoglobin. Rupture of the RBCs during laking removes the RBCs from the final stained blood film; the only structures remaining on the thick film are the white blood cells (WBC), the platelets, and any parasites present. To lake the films, place them in buffer solution before staining or directly into Giemsa stain, which is an aqueous stain. If thick films are to be stained later, they should be laked before storage. Potential problems with

Table 31.3 Potential problems with thick blood film preparation and staining

Potential problem	Comments
Blood films flake off during staining	The blood film was not dry or did not dry evenly; the film was too thick; incorrect blood/anticoagulant ratio (excess EDTA); dirty or greasy slides; blood kept in EDTA too long before film preparation
Inadequate staining	Blood film too thick; staining time incorrect; stain concentration incorrect
Potential for loss of organisms	Incorrect staining technique; blood film too old prior to staining; poor environmental conditions and/or incomplete drying

the preparation and staining of thick blood films can be seen in Table 31.3.

Thin Blood Films

The thin blood film is routinely used for specific parasite identification, although the number of organisms per field is much reduced compared with the thick film. The thin film is prepared exactly as one used for a differential count (Figure 31.1). A well-prepared film is thick at one end and thin at the other (one layer of evenly distributed RBCs with no cell overlap). The thin, feathered end should be at least 2 cm long, and the film should occupy the central area of the slide, with free margins on both sides. The presence of long streamers of blood indicates that the slide used as a spreader was dirty or chipped. Streaks in the film are usually caused by dirt, and holes in the film indicate the presence of grease on the slide. After the film has air dried (do not apply heat), it may be stained. The necessity for fixation before staining will depend on the stain selected. Since Giemsa is an aqueous stain, laking of the RBCs occurs during the staining process. However, when Wright's stain is used, a fixing agent is incorporated into the stain, so that laking of the blood films must occur prior to staining.

The instrument-prepared monolayer method or coverslip methods generally do not provide the best morphology for malarial parasites within the RBCs. However, the selection of a slide preparation method can be dictated by personal preference, since a malarial infection can be diagnosed from either type of slide. Potential problems with the preparation and staining of thin blood films can be seen in Table 31.4.

Figure 31.1 Method for preparation of thin blood film. (A) Position of spreader slide; (B) well-prepared thin film. Arrows indicate the area of the slide (feather edge) used to observe accurate cell morphology. (Illustration by Nobuko Kitamura.)

Table 31.4 Potential problems with thin blood film preparation and staining

Potential problem	Comments
Blood films are too thick	Too much blood was used; no feathered edge; blood was pulled too quickly, spreader slide was held at the wrong angle (too high)
Blood films are too thin	Blood with a low hematocrit tends to spread too thin; let the blood settle or remove some plasma; angle of the spreader slide was too low; insufficient amount of blood for film preparation
Blood films have rough edges; lack of or poor feather edge	Blood was in front of the spreader slide; uneven contact with spreader slide; spreader slide chipped; possible fibrin formation; slides greasy

Combination Thick and Thin Blood Films (on the Same Slide)

In some instances (field surveys), it is helpful to prepare slides with both a thick and a thin film on the same slide. With this type of preparation, remember the following.

1. Sufficient time must be allowed for the thick portion of the smear to dry before staining.
2. The thin film only must be fixed in absolute methanol before staining.

Combination Thick and Thin Blood Films (Can Be Stained as Either)

To prepare a slide containing blood that can be stained for either a thick or thin blood film, the following method was developed (Figure 31.2). The specimen usually consists of fresh whole blood collected by finger stick or whole blood containing EDTA collected by venipuncture less than 1 h earlier.

Visually, the smear should consist of alternating thick and thin portions throughout the length of the glass slide. One should be able to barely read newspaper through the wet or dry film. Also, the film itself should not have any clear areas or smudges, indicating that grease or fingerprints were on the glass.

Detailed Procedure

1. Wear gloves when performing this procedure or preparing any blood films.
2. The procedure depends on the source of the specimen.

Figure 31.2 Method of thick-thin combination blood film preparation. (a) Position of the drop of EDTA-containing blood. (b) Position of the applicator stick in contact with blood and glass slide. (c) Rotation of the applicator stick. (d) Completed thick-thin combination blood film prior to staining. (Illustration by Sharon Belkin. Reprinted from L. S. Garcia, *Practical Guide to Diagnostic Parasitology*, ASM Press, Washington, D.C., 1999.)

- A. Blood from a finger puncture is not recommended, since the procedure does not lend itself to “stirring” to prevent fibrin strands.
- B. For blood from venipuncture, place a clean 1- by 3-in. glass microscope slide on a horizontal surface. Place a drop (30 to 40 μ l) of blood onto one end of the slide about 0.5 in. from the end. Using an applicator stick lying across the glass slide and keeping the applicator in contact with the blood and glass, rotate (do not “roll”) the stick in a circular motion while moving the stick down the glass slide to the opposite end. The appearance of the blood smear should be alternate thick and thin areas of blood that cover the entire slide. Immediately place the film over some small print and be sure that the print is just barely readable.
3. Allow the film to air dry horizontally and protected from dust for at least 30 min to 1 h. Do not attempt to speed the drying process by applying any type of heat, because the heat fixes the RBCs and they subsequently will not lyse (lake) in the staining process.
4. This slide can be stained as either a thick or thin blood film.
5. Label the slide appropriately.
6. If staining with Giemsa is delayed for more than 3 days or if the film is to be stained with Wright’s stain, lyse the RBCs in the thick film by placing the slide in buffered water (pH 7.0 to 7.2) for 10 min, remove it from the water, and place it in a vertical position to air dry. Rapid stains are also acceptable.

Procedure Limitations

1. If the smears are prepared from anticoagulated blood that is more than 1 h old, the morphology of the parasites may not be typical and the film may wash off the slide during the staining procedure.

If a tube of blood containing EDTA cools to room temperature and the cap has been removed, several parasite changes can occur. The parasites within the RBCs will respond as if they were now in the mosquito after being taken in with a blood meal. The morphology of these changes in the life cycle and within the RBCs can cause confusion when examining blood films prepared from this blood (11, 35, 46, 69).

 - A. Stippling (Schüffner’s dots) may not be visible.
 - B. The male gametocyte (if present) may exflagellate and may resemble spirochetes (Figure 31.3).
 - C. The ookinetes of *Plasmodium* species other than *P. falciparum* may develop as if they were in the mosquito and may mimic the crescent-shaped gametocytes of *P. falciparum*.
2. Identification to species, particularly between *P. ovale* and *P. vivax* and between the ring forms of *P. falciparum* and *Babesia* spp., may be impossible without examining one of the slides stained as a thin blood film. Also, *Trypanosoma cruzi* trypomastigotes are frequently distorted in thick films.
3. Excess stain deposition on the film may be confusing and make the detection of organisms difficult.

Figure 31.3 (Left) Photograph of exflagellation of the malarial microgametocyte. This may occur when anticoagulated blood is left standing at room temperature for some time prior to smear preparation. The life cycle of the parasite continues in the tube of blood as it would if the parasite had been ingested by the mosquito during a blood meal. (Right) *Borrelia* in blood. Note that the *Plasmodium* microgametes can resemble these organisms, particularly if they appear free in the background of the smear.

Fixation of Thin Blood Films: Acetone Dip for Thick Blood Films

Thin-Film Fixation. Thin blood films must be completely dry before being fixed in absolute methanol (Giemsa staining). Drying times will be extended if the humidity is high; drying films as quickly as possible produces the best results. However, they should never be heated to decrease drying times; heat tends to produce distorted parasite and blood cell morphology. Absolute methanol tends to absorb moisture from the air, so that absolute methanol for fixation should not be reused from day to day but needs to be fresh daily. Do not store this fixative in a Coplin jar. Thin blood films should be fixed and stained within 24 h; some deterioration may occur if the slides are held too long before being processed. However, the slides can be frozen for long-term storage. All thin blood films must be fixed prior to shipment to a reference laboratory; both these fixed slides and the tube of blood should be sent to the reference laboratory.

If the thin blood films are fixed for too long, some of the morphologic details may be reduced or lost. If they are fixed for too short a time, the RBCs may be distorted or partially lysed and the thin film will not be uniformly stained. If the thin films are fixed in methanol that contains water, the RBCs will be distorted and there will appear to be “holes” in the thicker areas of the films. As a reminder, do not reuse absolute methanol for fixation; discard after each use.

Thick-Film Acetone “Quick Dip.” Although thick blood films are not fixed with absolute methanol, after the thick films are thoroughly dry, they can be dipped twice in acetone and allowed to dry before being stained.

This extra step does not interfere with RBC lysis that occurs either prior to or during staining. The acetone “quick dip” makes the thick film less likely to fall off during staining and provides a cleaner background for microscopic examination.

Buffy Coat Blood Films

For patients with suspected malaria (negative thick and thin blood films), trypanosomiasis, filariasis, or leishmaniasis, concentration procedures increase the number of organisms recovered from blood specimens. The buffy coat containing WBCs and platelets, and the layer of RBCs just below the buffy coat layer, can be used to prepare thick and thin blood films. The sensitivity of this approach is greatly enhanced over that of the thick film.

L. donovani, trypanosomes, and *Histoplasma capsulatum* (a fungus with intracellular elements resembling those of *L. donovani*) are occasionally detected in the peripheral blood. The parasite or fungus is found in the large mononuclear cells in the buffy coat (a layer of white cells resulting from centrifugation of whole citrated blood). The nuclear material stains dark red-purple, and the cytoplasm is light blue (*L. donovani*). *H. capsulatum* appears as a large dot of nuclear material (dark red-purple) surrounded by a clear halo area. Trypanosomes in the peripheral blood also concentrate with the buffy coat cells.

After centrifugation and aliquoting of the appropriate layers, some of the material can be examined as a wet mount; trypomastigotes and microfilariae may be seen as motile objects in the wet mount. After staining, *L. donovani* amastigotes may be found in the monocytes and *Plasmodium* parasites may be seen in the thick and thin films. Advantages and disadvantages of buffy coat films can be seen in Table 31.5.

Detailed Procedure

1. Wear gloves when performing this procedure or preparing any blood films.
2. Whole blood should be collected using EDTA anticoagulant. Although heparin can be used, if malaria films are to be prepared, EDTA is recommended.
3. Although capillary hematocrit tubes have been used in the past, the cutting and breaking of these tubes to remove the cells for film preparation is not considered a safe procedure and is *not* recommended. However, if you use a microhematocrit tube, the tube should be carefully scored and snapped at the buffy coat interface, and the white cells are prepared as a thin film. The tube can also

Table 31.5 Advantages and disadvantages of the buffy coat films

Buffy coat film advantages	Buffy coat film disadvantages
The volume of blood is considerably larger than with both thick and thin films	It takes some practice to remove the correct blood layers from the centrifuged blood in order to prepare thick and thin films
More sensitive than thick films for diagnosis of malaria	Same potential problems may occur as with traditional thick or thin blood films
Malaria pigment, which is phagocytized by the WBCs, may be seen more easily in the concentrated WBCs	Some organisms and/or stages of parasites might be damaged due to high centrifugation; however, centrifugation at $500 \times g$ for 15 to 20 min should not cause damage
Detection of parasitemia easier for larger stages such as schizonts and gametocytes	Increased number of platelets may be confusing in terms of parasite differentiation

be examined before removal of the buffy coat, at the low and high dry powers of the microscope. If trypanosomes are present, the motility may be observed in the buffy coat. Microfilarial motility would also be visible.

- Using a capillary pipette, fill a Wintrobe tube with blood containing anticoagulant (EDTA is preferred), cap the tube, and centrifuge it for 30 min at $100 \times g$. Another option is to centrifuge the tube of anticoagulated blood at $100 \times g$ for 15 min, transfer that buffy coat to another tube, and centrifuge the tube at $300 \times g$ for 30 min. After centrifugation, the tube contains three layers: plasma on top, a layer of white cells (buffy coat), and the packed RBCs on the bottom.
- Remove and discard most of the plasma above the buffy coat, leaving a small amount on top of the buffy coat layer. Then remove the remaining plasma, buffy coat, and the RBCs *right below the buffy coat*. Transfer this aliquot to a separate tube.
- Examine the buffy coat directly for motile trypomastigotes and microfilariae by mixing 0.5 drop of saline with 1 drop of buffy coat sediment on a microscope slide. Add a coverslip, and examine at low power ($10\times$ objective).
- Mix the aliquot gently (avoid bubbles), and prepare thick and thin blood films on alcohol-cleaned slides.
- Allow the films to air dry horizontally and protected from dust for at least 30 min to 1 h. Do not attempt to speed the drying process by applying

any type of heat, because the heat fixes the RBCs and they subsequently will not lyse (lake) in the staining process for the thin films.

- Label the slide appropriately.
- If staining with Giemsa is delayed for more than 3 days or if the film is to be stained with Wright's stain, lyse the RBCs in the thick film by placing the slide in buffered water (pH 7.0 to 7.2) for 10 min, remove it from the water, and place it in a vertical position to air dry.

Staining Blood Films

For accurate identification of blood parasites, a laboratory should develop proficiency in the use of at least one good staining method (24, 26, 65, 66). It is better to select one method that will provide reproducible results than to use several on a hit-or-miss basis. Blood films should be stained as soon as possible, since prolonged storage may result in stain retention. Failure to stain positive malarial smears within a month may result in failure to demonstrate typical staining characteristics for individual species.

The most common stains are of two types. Wright's stain has the fixative in combination with the staining solution, so that both fixation and staining occur at the same time; therefore, the thick film must be laked before staining. Giemsa stain has the fixative and stain separate; therefore, the thin film must be fixed with absolute methanol before staining.

When slides are removed from either type of staining solution, they should be dried in a vertical position. After being air dried, they may be examined under oil immersion by placing the oil directly on the uncovered blood film. If films are to be kept for a permanent record, they should be protected with a coverglass after being mounted in a medium such as Permount.

Note Blood films stained with any of the Romanowsky stains that have been mounted with Permount or other resinous mounting media are susceptible to fading of the basophilic elements and generalized loss of stain intensity. Hollander (31) has recommended the addition of 1% (by volume) 2,6-di-*t*-butyl-*p*-cresol (butylated hydroxytoluene [Sigma Chemical Co. catalog no. B1253]) to the mounting medium. Without the addition of this antioxidant, mounted stained smears eventually become pink; stains protected with this compound remain unchanged in color for many years.

Note Any slide that is protected by a coverglass and is going to be examined with an oil immersion lens must be covered by a no. 1 coverglass. If a no. 2 coverglass is used, the extra thickness may prevent the oil immersion lens from focusing properly.

Giemsa Stain

Giemsa stain is sold as a concentrated stock solution. Each new lot should be tested for optimal staining times before being used on patient specimens. If the blood cells appear to be adequately stained, the timing and stain dilution should be appropriate to demonstrate the presence of malarial and other parasites. Giemsa stain is also available as a powder for those who wish to make up their own stain. The use of prepared liquid stain or stain prepared from the powder depends on personal preference; there is apparently little difference between the two preparations. Directions for preparing the stain follow (26, 35, 36).

Note Quality control for blood film stains can be any negative or positive blood film; it is not necessary for the control slides to contain actual parasites. If the RBCs and WBCs stain correctly, any parasites present would also stain correctly with the same nuclear and cytoplasmic colors as the blood cells.

Reagents

Stock Giemsa Stain

Giemsa stain powder, certified
(azure B type) 0.6 g
Methanol, absolute and certified
neutral, acetone free 50 ml
Glycerin, neutral, certified..... 50 ml

1. Grind together small portions of stain and glycerin in a mortar, and collect mixtures in a 500- or 1,000-ml flask until all measured material is mixed.
2. Stopper the flask with a cotton plug, cover the plug with heavy paper, and place the flask in a 55 to 60°C water bath for 2 h. Make sure the water in the water bath is above the level of the stain. Shake gently at 30-min intervals.
3. After grinding the powder and glycerin in the mortar, use the 50 ml of methyl alcohol to wash the last bit of stain from the mortar; then pour the alcohol into a small, airtight bottle.
4. Remove the glycerin-stain powder mixture from the water bath, and allow it to cool to room temperature. Add alcohol washing from the mortar, and shake well.
5. Before use, filter through Whatman no. 1 paper into a brown bottle. Although the stain can be used immediately, it is better to let it stand for 2 to 3 weeks with intermittent shaking.
6. Label and store protected from light; the shelf life is 36 months, provided that results are within quality control guidelines.

Note The stock stain is stable for many years; however, it must be protected from moisture. The staining reaction is oxidative; any oxygen in water will initiate the staining reaction and destroy the stock stain. This is why the aqueous working solution of stock stain is good only for 1 day.

10% Stock Solution of Triton X-100

Triton X-100 10 ml
Distilled water 90 ml

Mix thoroughly, and store at room temperature. This solution will keep indefinitely if kept tightly stoppered.

Stock Buffers

Disodium Phosphate (Dibasic)

Na₂HPO₄, anhydrous 9.5 g
Distilled water 1,000 ml

Monosodium Phosphate (Monobasic)

NaH₂PO₄ · H₂O 9.2 g
Distilled water 1,000 ml

Phosphate-Buffered Water (Table 31.6)

Triton-Phosphate Buffer

0.01% Triton-Buffered Water

Stock 10% aqueous Triton X-100 1 ml
Phosphate buffer 1,000 ml

0.1% Triton-Buffered Water

Stock 10% aqueous Triton X-100 10 ml
Phosphate buffer 1,000 ml

For thin blood films or a combination of thin and thick blood films, use 0.01% Triton-buffered water; for thick blood films, use 0.1% Triton-buffered water.

Liquid

The commercial liquid stain or the stock solution prepared from powder should be diluted approximately the same amount to prepare the working stain solution. Stock Giemsa liquid stain is diluted 1:10 with buffer for thin blood films; for thick films, a dilution of up to 1:50 may be used. Some people prefer to stain both thick and thin smears for a longer period in a more dilute solution. Phosphate buffer used in dilution of the stock stain should be neutral or slightly alkaline. Phosphate buffer solution may be used to obtain the right pH (Table 31.6). In some laboratories, tap water has a satisfactory pH and may be used for the entire staining procedure and the final rinse. Some workers recommend using pH 6.8 to emphasize Schüffner's dots.

Table 31.6 Phosphate buffer solutions

pH	Amt (ml) of:		
	Na ₂ HPO ₄ (9.3 g/liter, anhydrous)	NaH ₂ PO ₄ · H ₂ O, (9.2 g/liter)	Distilled water
6.6	37.5	62.5	900
6.8	49.6	50.4	900
7.0	61.1	38.9	900
7.2	72.0	28.0	900

Procedure for Staining Thin Films

1. Fix blood films in absolute methyl alcohol (acetone free) for 1 min.
2. Allow the slides to air dry.
3. Immerse the slides in a solution of 1 part Giemsa stock (commercial liquid stain or stock prepared from powder) to 10 to 50 parts phosphate buffer (pH 7.0 to 7.2). Stain for 10 to 60 min. *Fresh working stain should be prepared from stock solution each day.*

Note A good general rule for stain dilution versus staining time is as follows. If the dilution is 1:20, stain for 20 min; if the dilution is 1:30, stain for 30 min, etc. However, a series of stain dilutions and staining times should be tried to determine the best dilution and time for each batch of stock stain.

4. Dip the slides briefly in phosphate-buffered water, or rinse under gently running tap water.

Note Excessive washing will decolorize the film.

5. Drain thoroughly in a vertical position, and allow to air dry. The bottom of the slide should be wiped to remove excess stain before drying.

Procedure for Staining Thick Films

The procedure to be followed for thick films is the same as for thin films, except that the first two steps are omitted. If the slide has a thick film at one end and a thin film at the other, fix only the thin portion and then stain both parts of the film simultaneously. Normally, a stain/buffer dilution of 1:50 (vol/vol) for a staining time of 50 min is recommended for thick films. The longer staining time seems to give better results than do the shorter times that can be used for the thin film.

Results

Giemsa stain colors the components of blood as follows: RBCs, pale red; nuclei of WBCs, purple with pale purple cytoplasm; eosinophilic granules, bright purple-red; and neutrophilic granules, deep pink-purple. If malaria para-

sites are present, the cytoplasm stains blue and the nuclear material stains red to purple-red. Schüffner's dots and other inclusions in the RBCs will stain red (Figures 31.4 and 31.5). Nuclear and cytoplasmic staining characteristics of the other blood parasites such as *Babesia* spp., trypanosomes, and leishmaniae are like those of the malaria parasites. While the sheath of microfilariae may not always stain with Giemsa, the nuclei within the microfilaria itself stain blue to purple.

Wright's Stain

Wright's stain is available commercially in liquid form, ready to use, and also as a powder which must be dissolved in anhydrous, acetone-free methyl alcohol before use. Directions for preparing the stain follow.

Reagent

Wright's Stain

- Wright's stain.....0.9 g
- Methanol, absolute and certified
neutral, acetone free.....500.0 ml

1. Grind 0.9 g of Wright's stain powder with 10 to 15 ml of methanol (anhydrous, acetone free) in a clean mortar. Gradually add methanol while grinding. As the dye is dissolved in the methanol, pour that solution off and add more methanol to the mortar. Repeat this process until the entire 500 ml of methanol has been used.
2. Store the stain in a tightly stoppered glass bottle at room temperature. Shake the bottle several times daily for at least 5 days.
3. Allow the precipitate to settle, and pour off some of the supernatant fluid into dropping bottles for use. If the stock solution has been disturbed, the supernatant fluid can be filtered through Whatman no. 1 paper into a brown bottle.
4. Label and store protected from light; the shelf life is 36 months, provided that results are within quality control guidelines.

The staining procedure requires phosphate buffer solutions (see directions in the preceding discussion of Giemsa stain); the pH required for Wright's stain is 6.6 to 6.8.

Procedure for Staining Thin Films

Since Wright's stain contains alcohol, the slides do not require fixation before staining.

1. Place a slide on a rack in a horizontal, level position, and cover the surface with stain.
2. Count the number of drops of stain needed to cover the surface. Let stand for 1 to 3 min (the optimal staining time varies with each batch of stain).

3. Add an equal number of drops of phosphate-buffered water to the slide; mix the stain and buffer by blowing on the surface of the fluid.
4. After 4 to 8 min, flood the stain from the slide with phosphate buffer. Do not pour the stain off before washing. If you do, a precipitate will be deposited on the slide.
5. Wipe the bottom of the slide to remove excess stain.
6. Allow the slide to drain and air dry.

Procedure for Staining Thick Films

Thick films stained with Wright's stain are usually inferior to those stained with Giemsa solution. Great care should also be taken to avoid excess stain precipitate on the slide during the final rinse. Before being stained, thick films must be laked in distilled water (to rupture and remove RBCs) and air dried. The staining procedure is the same as for thin films, but the staining time is usually somewhat longer and must be determined for each batch of stain.

Results

Wright's stain colors blood components as follows: RBCs, light tan, reddish, or buff; nuclei of WBCs, bright blue with contrasting light cytoplasm; eosinophilic granules, bright red; and neutrophilic granules, pink or light purple.

If malaria parasites are present, the cytoplasm stains pale blue and the nuclear material stains red. Schüffner's dots and other inclusions in the RBCs usually do not stain or stain very pale with Wright's stain. Nuclear and cytoplasmic staining characteristics of the other blood parasites such as *Babesia* spp., trypanosomes, and leishmaniae are like those of the malaria parasites (Figures 31.6 and 31.7). While the sheath of microfilariae may not always stain with Wright's stain, the nuclei within the microfilaria itself stain pale to dark blue.

General Notes on Staining Procedures

1. When large numbers of slides are being processed, remember that dry films should be stored in dust-free containers before staining, to protect fresh smears from insects.

2. If the slides cannot be stained within 48 h, thin films should be fixed in methyl alcohol and thick films should be laked in distilled water before storage. Rapid stains can also be used. Parasites will stain like the WBCs.
3. Slides should be stored at reasonably low temperatures (below 80°F [ca. 27°C]) before being stained. If the slides are exposed to high temperatures, thick films that have not been laked will become heat fixed; hemoglobin will remain fixed in the RBCs, and heavy stain retention will then prevent parasite identification. Thin films also stain poorly after exposure to high temperatures.
4. Fresh working stain should be prepared just before use. If a large number of thick films are being laked during staining, the stain should be changed after 50 slides because of the accumulation of excess hemoglobin.

Proper Examination of Thin and Thick Blood Films

Thin Blood Films

In any examination of thin blood films for parasitic organisms, the initial screen should be carried out with the low-power objective of a microscope. Microfilariae may be missed if the entire thin film is not examined. Microfilariae are rarely present in large numbers, and frequently only a few organisms occur in each thin-film preparation. Microfilariae are commonly found at the edges of the thin film or at the feathered end of the film, because they are carried to these sites during the process of spreading the blood. The feathered end of the film where the RBCs are drawn out into one single, distinctive layer of cells should be examined for the presence of malaria parasites and trypanosomes. In these areas, the morphology and size of the infected RBCs are most clearly seen.

Depending on the training and experience of the microscopist, examination of the thin film usually takes 15 to 20 min (200 to 300 oil immersion fields) at a magnification of $\times 1,000$. Although some people use a $50\times$ or $60\times$ oil immersion objective to screen stained

Figure 31.4 *Plasmodium* spp. seen in stained thin blood films. (Left column from top to bottom) *Plasmodium vivax*. (1) Developing ring (note the enlarged RBC, Schüffner's dots, and ameboid ring); (2) developing trophozoite (note the enlarged RBC and Schüffner's dots); (3) large trophozoite prior to the development of schizonts (note the enlarged RBC and Schüffner's dots); (4) mature schizont with approximately 16 merozoites. (Center column from top to bottom) *Plasmodium ovale*. (1) Young ring form (note the nonameboid ring and Schüffner's dots that appear earlier than in rings of *P. vivax*); (2) developing trophozoites (note Schüffner's dots and fimbriated edges of the infected RBCs); (3) maturing schizont containing merozoites and Schüffner's dots; (4) gametocyte. (Right column from top to bottom) *Plasmodium malariae*. (1) Young ring (note the normal-sized RBC and no stippling); (2) developing trophozoite (note the normal-sized RBC and "band form" configuration of the trophozoite); (3) developing schizont (note the size of the RBC); (4) more mature schizont containing developing merozoites.

Figure 31.6 Trypomastigotes. (Left) *Trypanosoma brucei gambiense*. (Right) *Trypanosoma cruzi* (note the undulating membrane on both trypomastigotes and the larger kinetoplast in *T. cruzi*).

blood films, there is some concern that small parasites such as plasmodia, *Babesia* spp., or *L. donovani* may be missed at this smaller total magnification ($\times 500$ or $\times 600$) compared with the $\times 1,000$ total magnification obtained with the more traditional $100\times$ oil immersion objective. Because people tend to scan blood films at different rates, it is important to examine a minimum number of fields, regardless of the time it takes to perform this procedure. If something suspicious has been seen in the thick film, the number of fields examined on the thin film is often considerably more than 200 to 300. The request for blood film examination should always be considered a STAT procedure, with all reports (negative as well as positive) being reported by telephone to the physician as soon as possible. Appropriate governmental agencies (local, state, and federal) should be notified within a reasonable time frame in accordance with guidelines and laws.

Diagnostic problems with the use of automated differential instruments have been reported (4, 27). Both malaria and *Babesia* infections were missed with these instruments, and therapy was delayed (Figures 31.8 and 31.9). Although these instruments are not designed to detect intracellular blood parasites, the inability of the automated systems to discriminate between uninfected RBCs and those infected with parasites may pose serious diagnostic problems.

Thick Blood Films

In the preparation of a thick blood film, the greatest concentration of blood cells will be in the center of the

Figure 31.7 *Leishmania donovani* in an impression smear. Note the numerous small amastigotes containing a nucleus and bar-shaped primitive flagellum.

film. A search for parasitic organisms should be carried out initially at low magnification to detect microfilariae more readily. Examination of a thick film usually requires 5 to 10 min (approximately 100 oil immersion fields). Search for malarial organisms and trypanosomes is best done under oil immersion (total magnification, $\times 1,000$). Intact RBCs are frequently seen at the very periphery of the thick film; such cells, if infected, may prove useful in malaria diagnosis, since they may demonstrate the characteristic morphology necessary to identify the organisms to the species level.

Determination of Parasitemia

It is important to report the level of parasitemia when blood films are reviewed and found to be positive for malaria parasites. Because of the potential for drug resistance in some of the *Plasmodium* species, particularly *P. falciparum* and *P. vivax*, it is important that every positive smear be assessed and the parasitemia reported exactly the same way on follow-up specimens as on the initial specimen. This allows the parasitemia to be monitored after therapy has been initiated. In cases where the patient is hospitalized, monitoring should be performed at 24, 48, and 72 h after initiating therapy. Generally, the parasitemia drops very quickly within the first 2 h; however, in cases of drug resistance, the level may not decrease but actually may increase over time (Figure 31.7).

Figure 31.5 *Plasmodium* spp. seen in stained thick films. (Top row from left to right) *Plasmodium falciparum*. (1) Numerous ring forms (note differences: nuclei and cytoplasm); (2) low parasitemia with a single ring form in the field; (3) crescent-shaped gametocyte (note that the RBC around the gametocyte is not visible). (Row two from left to right) *Plasmodium vivax*. (1) Ring forms and developing trophozoites; (2) some larger rings with developing trophozoite; (3) developing schizonts. (Row three from left to right) *Plasmodium malariae*. (1) Mature schizonts containing about eight merozoites (photographed at higher magnification); (2) developing schizonts and two mature schizonts; (3) single ring form and several mature schizonts. (Bottom row from left to right) *Plasmodium ovale*. (1) Developing trophozoites (note that the organisms do not appear to be amoeboid like those normally seen in *P. vivax*); (2) developing trophozoite; (3) developing trophozoite (note that panels 2 and 3 are photographed at a higher magnification).

Figure 31.8 *Babesia* sp. in a thin blood film. Note the “Maltese cross” formation that is diagnostic but not always seen in blood films. The ring forms are very pleomorphic, much more so than *P. falciparum* ring forms; there tend to be numerous rings per RBC.

Malarial infections should be reported as the percentage of infected RBCs per 100 RBCs counted (0.5%, 1.0%, etc.) (11). Considering the low parasitemia frequently seen in patients within the United States, several hundred RBCs may have to be counted to arrive at an accurate count and determination of the percentage. The thin blood film must be used for this approach.

Another approach is to count the number of parasites per 100 WBCs on the smear. Either the thick or thin film can be used for this purpose. This figure can be converted to the number of parasites per microliter of blood; divide the number of parasites per 100 WBCs by 100, and multiply that figure by the number of WBCs per microliter of blood. Depending on the parasitemia, 200 or more WBCs may have to be counted, so the denominator may vary (it may be 200 or even more). In this case, blood for both the peripheral smears and cell counts must be collected at the same time.

It is critical that the same reporting method be used consistently for every subsequent set of blood films so that the parasitemia can be tracked for decrease or possible increase, indicating resistance. Also, remember that drug resistance may not become evident for a few days. The parasitemia may initially appear to decline but may then begin to increase after several days. Therefore, it is very important that patient parasitemia be monitored, particularly if an infection with *P. falciparum* has been diagnosed. Drug resistance has also been reported in *P. vivax* cases; mixed infections are also much more common than suspected.

Diagnosis of Malaria: Review of Alternatives to Conventional Microscopy

It is well known that malaria causes significant morbidity and mortality worldwide, including in countries where imported cases are seen (7, 40, 67). In many developing countries where malaria is highly endemic, diagnostic testing is often inadequate or unavailable due to a lack of trained personnel or funds or both. Although microscopic examination of Giemsa-stained thick and thin blood films remains the standard of practice, this approach is time-consuming, is based on the need for a great deal of expertise in microscopic morphology, and requires the purchase and maintenance of expensive equipment. Rapid diagnostic tests (RDTs) offer great potential to improve the diagnosis of malaria, particularly in remote areas. There are a number of new approaches to the diagnosis of malaria, including the use of fluorescent stains (QBC), dipstick antigen detection of histidine-rich protein 2 (HRP2) and parasite lactate dehydrogenase (pLDH) (ParaSight F, NOW Malaria Pf and NOW Malaria Pf/Pv, and Flow anti-pLDH *Plasmodium* monoclonal antibodies) (71), PCR, and automated blood cell analyzers. Parasitemia and its clinical correlates are given in Table 31.7, while some of the newer testing options for malaria and other blood parasites can be found in Table 31.8. Field trial data from various test methods can be seen in Table 31.9.

Histidine-rich protein 2 of *P. falciparum* (PfHRP2) is a water-soluble protein that is produced by the asexual stages and gametocytes of *P. falciparum*, expressed on the RBC membrane surface, and shown to remain in the blood for at least 28 days after the initiation of antimalarial therapy. Many RDTs are based on the detection of PfHRP2, but reports from field tests have questioned their sensitivity and reliability. However, the variability in the results of PfHRP2-based RDTs may be related to the variability in the target antigen (1). This hypothesis was tested by examining the genetic diversity of PfHRP2, which includes numerous amino acid repeats, in 75 *P. falciparum* lines and isolates originating from 19 countries and testing a subset of parasites by use of two PfHRP2-based RDTs. There is extensive diversity in PfHRP2 sequences, both within and between countries. Logistic regression analysis indicated that two types of repeats were predictive of RDT detection sensitivity (87.5% accuracy), with predictions suggesting that only 84% of *P. falciparum* parasites in the Asia-Pacific region are likely to be detected at densities of ≤ 250 parasites/ μl . Data also indicate that PfHRP3 may play a role in the performance of PfHRP2-based RDTs. These findings provide an alternative explanation for the variable sensitivity in field tests of malaria RDTs that is not due to the quality of the RDTs (1).

The persistence of parasite HRP2 in the circulation after parasite clearance has been considered a drawback

Figure 31.9 *Plasmodium falciparum*. (Upper row) Note the ring forms (multiple rings per RBC and presence of the “headphone” ring configuration). The photograph at the right is a good mimic of *Babesia* organisms, but the rings are not quite as pleomorphic as in *Babesia* spp. (Lower row) Three examples of *P. falciparum* gametocytes, two of which appear to be outside the RBC and one of which is inside.

for RDTs targeting HRP2 and a major cause of false-positive results. In one study when PCR was used as the gold standard rather than microscopy, the high rate of RDT false-positive parasitemia results in comparison with microscopy was shown to predominantly represent cases that had a parasite density below the threshold for detection by microscopy (3). Despite the generally low disease-endemic prevalence of malaria in the area, there was a high prevalence of chronic infections with low, fluctuating parasite densities that were better detected by RDT. In areas known to have low-density parasitemias, RDTs targeting HRP2 may increase the diagnostic sensitivity in comparison with microscopy. While microscopy remains the standard for comparison of the diagnostic accuracy for malaria, the limitations of microscopy, and the possibility that RDTs may have superior accuracy in some circumstances, should be taken into account when interpreting the results of diagnostic trials.

To determine the accuracy of RDTs for ruling out malaria in nonimmune travelers returning from areas where malaria is endemic, 21 studies and 5,747 individuals were surveyed from the published literature (53). Diagnostic accuracy studies of nonimmune individuals with sus-

pected malaria were included if they compared rapid tests with expert microscopic examination or PCR tests. The authors concluded that RDTs for malaria may be a useful diagnostic adjunct to microscopy in centers without major expertise in tropical medicine. Initial decisions on treatment initiation and choice of antimalarial drugs can be based on travel history and posttest probabilities after rapid testing. However, expert microscopy is still required for species identification and confirmation.

QBC Microhematocrit Centrifugation Method

Microhematocrit centrifugation with use of the QBC malaria tube (glass capillary tube and closely fitting plastic insert; CBC malaria blood tubes [Becton Dickinson, Tropical Disease Diagnostics, Sparks, Md.]) has been used for the detection of blood parasites (9, 10, 50). At the end of centrifugation of 50 to 60 μ l of capillary or venous blood (5 min in a QBC centrifuge; $14,387 \times g$), parasites or erythrocytes containing parasites are concentrated into a small, 1- to 2-mm region near the top of the RBC column and are held close to the wall of the tube by the plastic float, thereby making them readily visible by mi-

Table 31.7 Parasitemia determined from conventional light microscopy: clinical correlation^a

Parasitemia (%)	No. of parasites/ μ l	Clinical correlation
0.0001–0.0004	5–20	Number of organisms that are required for a positive thick film (sensitivity) Examination of 100 thick-blood-film fields (0.25 μ l) may miss up to 20% of infections (sensitivity, 80–90%); at least 300 fields should be examined before reporting a negative result Examination of 100 thin-blood-film fields (0.005 μ l); at least 300 should be examined before reporting a negative result; both thick and thin blood films should be examined for every specimen submitted for a suspect malaria case One set (thick plus thin blood films) of negative blood films does not rule out a malaria infection
0.002	100	Patients may be symptomatic below this level
0.2	10,000	Level above which immune patients will exhibit symptoms
2	100,000	Maximum parasitemia of <i>P. vivax</i> and <i>P. ovale</i> (which infect young RBCs only)
2–5	100,000–250,000	Hyperparasitemia, severe malaria ^b ; increased mortality
10	500,000	Exchange transfusion may be considered; high mortality

^a Adapted from reference 30.

^b World Health Organization criteria for severe malaria are parasitemia of >10,000/ μ l and severe anemia (hemoglobin, <5 g/liter). Prognosis is poor if >20% of parasites are pigment-containing trophozoites and schizonts and/or if >5% of neutrophils contain visible pigment.

croscopy. Tubes precoated with acridine orange provide a stain which induces fluorescence in the parasites. This method automatically prepares a concentrated smear, which represents the distance between the float and the walls of the tube. Once the tube is placed into the plastic holder (Paraviewer) and immersion oil is applied onto the top of the hematocrit tube (no coverslip is necessary), the tube is examined with a 40 \times to 60 \times oil immersion objective (there must be a working distance of 0.3 mm or greater) (Figure 31.10).

Note Although a malaria infection could be detected by this method (which is much more sensitive than the thick or thin blood smear), *appropriate thick and thin blood films must be examined to accurately identify the species of the organism causing the infection.*

The range of sensitivities for the QBC test has been as low as 55% to >90% compared with microscopy. While most workers think the method is rapid, some think there are some disadvantages such as the high cost of capillary tubes and equipment, problems in species identification and quantification, technical problems, broken capillaries, and the fact that the capillaries cannot be stored for later reference. This may not be the most appropriate approach for a laboratory that receives a small number of specimens for malaria testing, but it could be helpful in other settings. In a recent study of 745 specimens from an area of low endemicity along the Colombian Pacific coast, the agreement between the QBC method and thick blood smear was reported to be 99.5% (6). An excellent review of this and other methods is provided in reference 30.

This method has been reported to have a high degree of sensitivity in the detection of cases of human filariasis (76). In one study evaluating the technique in the detection of canine *Dirofilaria immitis* as a model for human filariasis, the QBC analysis was more sensitive (55%) than the thick blood smear (39%) and was more efficient (79% versus 72%). However, accurate identification to the species level was impossible using the QBC method.

Diagnosis of tick-borne relapsing fever has also been reported using the QBC system with a high level of sensitivity, more so than the thick blood smear. This method seems to be useful for this purpose and might be considered in the management of fever in travelers returning from tropical regions (8, 74).

ParaSight F Test

A *P. falciparum* antigen detection system, the ParaSight F test (Becton Dickinson), is very effective in field trials (20, 64). This procedure is based on an antigen capture approach and has been incorporated in a dipstick format; the entire test takes approximately 10 min (Figures 31.11 and 31.12) (64). The overall performance of the ParaSight F test was reviewed in 1995 at a World Health Organization meeting looking at 15 studies with a total of 7,926 assays for the detection of *P. falciparum*. Overall, the sensitivity ranged from 84 to 94%, with specificities ranging from 81 to 99% (78). However, the test detects only *P. falciparum*, and at low parasitemias (<100/ μ l) the sensitivity drops to 11 to 40%. Also, since HRP2 is not present in mature gametocytes, cases where only

gametocytes were present could be missed. There is also a possibility that some false-negative results, even at high parasitemias, are due to the lack of the HRP2 gene (72). After successful therapy, many patients continue to have circulating HRP2 antigen for 7 to 14 days after microscopic and clinical cure. Also, as many as 60% of patients positive for rheumatoid factor have a false-positive test

(34, 47). The ParaSight F test may be used in situations where no trained microscopists are available or where malaria is strongly suspected and the microscopy results are negative (5, 14, 68). This kit has proven to be very useful in many areas of the world.

negative test almost absolutely excludes infection, while in settings of high prevalence the same result still gives a substantial chance of infection being present. The authors conclude that the ParaSight F test is a simple and accurate test for the diagnosis of *P. falciparum* infection. The test could be of particular value in the diagnosis of malaria in travelers returning from areas of endemic infection (16).

NOW Malaria Test

The ICT Malaria P.f. test (ICT Diagnostics, Brookvale, New South Wales, Australia) was the first malaria rapid diagnostic device designed for convenience of use in a booklet format with the test strip mounted on cardboard. Like other nonmicroscopic malaria rapid tests, ICT

Figure 31.12 ParaSight F test showing (from left to right) the positive test strip with a reagent control mark above the positive test result and a negative test strip with the reagent control mark.

Malaria P.f. was an immunochromatographic assay. The original ICT assay detected only *P. falciparum* HRP2. By 1999, AMRAD (French's Forest, New South Wales, Australia) acquired ICT Diagnostics and continued manufacturing the product. At about the same time, the product was enhanced by adding the capability to detect non-*falciparum* malaria. The refined assay was renamed ICT Malaria P.f./P.v. This improvement was achieved by using monoclonal antibodies to capture *Plasmodium* aldolase, in addition to the HRP2 test. *Plasmodium* aldolase is an enzyme of the parasite glycolytic pathway expressed by the blood stages of *P. falciparum* as well as the non-*falciparum* malaria parasites. Monoclonal antibodies against *Plasmodium* aldolase are panspecific in their reaction and have been used in a combined *P. falciparum*-*P. vivax* immunochromatographic test that targets the panmalarial antigen along with PfHRP2.

In July 2000, AMRAD ceased the production of ICT and sold its ICT division to Binax, Inc. (Portland, Maine), where further developmental work was done to refine the test. The new ICT test was released under the name NOW ICT Malaria P.f./P.v. for Whole Blood and is presently called the NOW malaria test for whole blood (Binax, Inc.). The NOW malaria test uses an immunochromatographic format (Figure 31.13).

Prior to the development of the improved product (NOW malaria test), in a number of studies testing over 1,300 assays, the overall sensitivity ranged from 80 to 100% (25). Although some of the same issues apply to this test as to the ParaSight F test, the false-positive rate from the presence of rheumatoid factor appears to be less of an issue (29, 61).

In many areas of the world where both *P. falciparum* and *P. vivax* occur, rapid diagnostic tests for malaria

RESULTS INTERPRETATION		
Positive Test Result	<div style="display: flex; align-items: center;"> <div style="margin-right: 10px;">C T1 T2</div>  </div>	<p>P.f. infection: A positive test result is indicated by any visible line in the test window next to T1 together with a line in area C.</p> <p>P.f. infection or a mixed infection (P.f., P.o., P.m., P.v.): A positive test result is indicated by any visible line in the test window next to T1 and T2, together with a line in area C.</p> <p>P.v., P.m., P.o. or a mixed infection of all three: A positive test result is indicated by any visible line in the test window next to T2, together with a line in area C.</p>

Figure 31.13 Diagram of the NOW malaria test format. (Adapted from package insert, Binax, Portland, Maine.)

must be able to differentiate the two species. It is also interesting that when a mixed-species infection with both *P. falciparum* and *P. vivax* is misdiagnosed as a single-species *P. vivax* infection, treatment for *P. vivax* can lead to a surge in *P. falciparum* parasitemia (54). The combined *P. falciparum*-*P. vivax* immunochromatographic test (NOW ICT Malaria Pf/Pv) was used in Indonesia, where both species occur (71). Blinded microscopy was used as the gold standard, with all discordant and 20% of concordant results cross-checked blindly. Of those with a presumptive clinical diagnosis of malaria, only 50% were parasitemic. The NOW ICT Malaria Pf/Pv test was sensitive (95.5%) and specific (89.8%) for the diagnosis of *P. falciparum* malaria, with a positive predictive value of 88.1% and a negative predictive value of 96.2%. Although the specificity and negative predictive value for the diagnosis of *P. vivax* malaria were 94.8 and 98.2%, respectively, the overall sensitivity of 75% and positive predictive value of 50% were lower than desired. With parasitemias of $>500/\mu\text{l}$, the sensitivity for the diagnosis of *P. vivax* malaria was 96%; with parasitemias of $<500/\mu\text{l}$, it was only 29%. However, by using this test, under-treatment rates would be reduced from 14.7 to 3.6% with a modest increase in the rate of overtreatment of microscopy-negative patients from 7.1 to 15.4%. Unfortunately, cost remains an obstacle to widespread implementation.

In a study using the improved product (NOW malaria test), the sensitivity for *P. falciparum* was 100% and the specificity was 96%; the sensitivity for *P. vivax* was 89%, and the specificity was 98%. Testing was performed using *P. falciparum*- and *P. vivax*-positive specimens. These results suggest improved performance over NOW ICT predecessors (Figure 31.13) (77). In another study, the NOW ICT test showed a sensitivity of 94% for the detection of *P. falciparum* malaria (96% for pure

P. falciparum infection) and 84% for non-*P. falciparum* infections (87% for pure *P. vivax* infections and 62% for pure *P. ovale* and *P. malariae* infections) compared with PCR, with an overall specificity of 99% (22). The Binax NOW ICT may represent a useful adjunct for the diagnosis of *P. falciparum* and *P. vivax* malaria in febrile returned travelers. However, the rapid test should be performed in association with more traditional methods such as examination of thick and thin blood films (2, 21).

Flow Anti-pLDH *Plasmodium* Monoclonal Antibodies

pLDH is a soluble glycolytic enzyme produced by the asexual and sexual stages of the live parasites and is present in and released from the parasite-infected erythrocytes. It has been found in all four human malaria species, and different isomers of pLDH for each of the four species exist. With pLDH as the target, a quantitative immunocapture assay, a qualitative immunochromatographic dipstick assay using monoclonal antibodies, an immunodot assay, and a dipstick assay using polyclonal antibodies have been developed.

Flow anti-pLDH *Plasmodium* monoclonal antibodies detect a malaria pLDH antigen by using an antibody incorporated into the dipstick format (62) (Figure 31.14). The test is positive only when viable parasites are present. Although the test has both a *P. falciparum*-specific and a panspecific antibody against all four species, the panspecific antibody detects only *P. vivax* with any degree of consistency (51, 59). The sensitivity and specificity of the Flow monoclonal antibodies are comparable to those of microscopy in detecting malaria infections at a parasitemia of $>100/\mu\text{l}$; however, the test failed to identify more than half of the patients with a parasitemia of $<50/\mu\text{l}$. In one study, the sensitivity of the Flow monoclonal

Figure 31.14 Flow anti-pLDH *Plasmodium* monoclonal antibodies rapid malaria test. (Left) Diagram of blood flow on the membrane through the timed test; note the positive control line and positive test line. (Right) Diagram of negative control, a positive *Plasmodium vivax* result, and a positive *P. falciparum* result. Note that the line for *P. vivax* is a panspecific antibody against all four species; however, the panspecific antibody has been shown to detect only *P. vivax* with any degree of consistency. (Photographs adapted from Flow's website, with permission.)

antibodies was 97% at a high parasitemia ($>100/\mu\text{l}$) but fell to 39% at $<50/\mu\text{l}$ (33). Therefore, the test is similar to the HRP2 assays and should not replace conventional microscopy in the diagnosis of malaria infection (38). However, a definite advantage is the ability to confirm a cure, since the test detects only viable organisms. Also, the number of false-positive results due to rheumatoid factor is much smaller than for some of the other tests. In a comparison of results with the ICT Malaria Pf and ParaSight F tests, Flow monoclonal antibodies correctly identified *P. falciparum* malaria in patient blood samples more often than the other two procedures did. In this study, the Flow monoclonal antibodies exhibited 94% sensitivity and 100% specificity for *P. vivax* and 88% sensitivity and 99% specificity for *P. falciparum* (59). In another study, compared with PCR, the sensitivity was 93% and the specificity was 99.5%. The authors felt that the test had sufficient sensitivity and specificity to detect *P. vivax* under laboratory conditions and could also be useful for malaria diagnosis in the field in Mexico (28). As with the other rapid malaria tests, cost is always an issue; however, Flow monoclonal antibodies provide a simple, rapid, and effective test in the diagnosis of malaria, especially where well-trained microscopists are not available or the work load is too high (42).

PCR

Although the first PCR methods were developed to identify *P. falciparum*, many can now detect several or all four species. It has been well demonstrated that PCR can detect lower parasitemias than any of the traditional blood film or nontraditional dipstick methods, and it

may be preferable to microscopy as the reference standard when evaluating new diagnostic tests (6, 30, 32, 33, 39, 61). One advantage of PCR is the ability to confirm false-negative results by microscopy as true positives. Another advantage is the enhanced ability to identify organisms to the species level, particularly in mixed infections, compared with microscopy. However, even PCR may miss some cases as a result of PCR inhibitors, DNA degradation, or genotypic variants. Unfortunately, the time required for PCR presents a problem for the clinical laboratory; this approach does not lend itself to routine use. With the development of automation for PCR, these tests may become much more user friendly for the routine laboratory; however, currently PCR is reserved for reference centers and special circumstances. As PCR becomes more widely used, it will be important to remember that the mode of collection and storage of blood samples may influence the sensitivity of *Plasmodium* detection. This may be critical in studies of individuals with low parasitemia or mixed infections and in comparison of data from different settings, including field settings (23).

A more recent development is the post-PCR/ligase detection reaction-fluorescent microsphere assay (LDR-FMA) (56). This assay, which uses Luminex FlexMAP microspheres, provides simultaneous, semiquantitative detection of infection by all four human malaria parasite species at a sensitivity and specificity equal to those of other PCR-based assays. In blinded studies using *P. falciparum*-infected blood from in vitro cultures, the authors identified infected and uninfected samples with 100% concordance. Also, in analyses of *P. falciparum* in vitro cultures and *P. vivax*-infected monkeys,

comparisons between parasitemia and LDR-FMA signal intensity showed very strong positive correlations ($r > 0.95$). Application of this multiplex *Plasmodium* LDR-FMA diagnostic assay will increase the speed, accuracy, and reliability of diagnosing human *Plasmodium* infections.

Automated Blood Cell Analyzers

Although the use of automated blood cell analyzers is not yet clinically relevant for the diagnosis of blood parasites, improvements in the systems may offer future information that will supplement the routine microscopy procedures currently in use (44, 70). Unfortunately, when the parasitemia is light, automation tends to have some of the same problems seen with other alternative procedures. In many cases, the changes seen using analyzers are not specific to malaria infection and could occur in many other diseases (increases in the number of large, unstained cells and thrombocytopenia).

The Cell-Dyn 4000 automated hematology analyzer (Abbott, Chicago, Ill.) has the ability to detect 91.2% of malaria patients. In one study on day 3 of follow-up posttreatment, the sensitivity was 96.7% that of microscopy. The atypical polarizing events, which indicate the presence of malarial parasites in the analyzer, were highly correlated with the levels of parasitemia in serially diluted samples of the leukocyte-depleted blood; parasites were detected down to the level of $288 \pm 17.7/\mu\text{l}$. These data suggest that the atypical light depolarization could be influenced by parasitemia and could be used as a screening method for *P. vivax* malaria patients, as well as for therapeutic monitoring (70). Microscopy is still required for species determination and parasite quantitation.

The potential of automated depolarization analysis in detecting malaria infection as part of the routine full blood count performed by the Cell-Dyn 4000 analyzer has been described previously (70). In these cases, abnormal depolarizing patterns are due to the presence of leukocyte-associated malaria hemozoin, a pigment which depolarizes the laser light. Abnormal polarizing events have also been described for samples from three individual patients infected by the nematode *Mansonella perstans*. The observed depolarizing pattern consisted of a normal depolarizing eosinophil population plus an abnormal depolarizing population that showed a close "linear" relationship between "granularity" (90° depolarization) and "lobularity" (90° polarization). This atypical population was smaller than that of normal leukocytes and thus clearly different from the patterns associated with malaria infection. Abnormal depolarization patterns of *M. perstans* clearly do not reflect leukocyte-

associated malaria hemozoin. It is possible, however, that the erythrocyte-lysing agent used to facilitate leukocyte analysis by the instrument may have caused microfilaria fragmentation and thus the distinctive straight-line features of the abnormal scatter plots (15).

Diagnosis of Leishmaniasis: Review of Alternatives to Conventional Microscopy

ICT for Detection of Anti-rK-39 Antibodies

In a recent study, the diagnostic utility of an immunochromatographic test for detection of anti-rK-39 antibodies for the diagnosis of kala azar and post-kala azar dermal leishmaniasis (PKDL) was evaluated (55). Of the 120 samples tested, 57 were positive by ICT; 51 of these were diagnosed as kala azar, and 6 were diagnosed as PKDL. The controls included individuals from areas of endemic (50) and nonendemic (19) infection with malignancies, hemolytic disorders, chronic liver disease, hypersplenism, portal hypertension, metabolic disorders, or sarcoidosis. In addition, 47 sera from patients with confirmed cases of tuberculosis, malaria, typhoid, filariasis, leptospirosis, histoplasmosis, toxoplasmosis, invasive aspergillosis, amebic liver abscess, AIDS, leprosy, cryptococcosis, strongyloidiasis, and cyclosporiasis, as well as from patients with collagen vascular diseases and patients with hypergammaglobulinemia, were tested to check the specificity of the test. Of the 51 patients with kala azar, all had fever lasting from <1 month to 1.5 years (median, 4.5 months). All six PKDL patients gave a history of having kala azar in the past, and their slit skin test smears were microscopically positive for Leishman-Donovan bodies. The strip test was positive in all the cases of kala azar and PKDL (estimated sensitivity, 100%), and all control sera were negative by the ICT (specificity, 100%). The rK-39 ICT is a highly sensitive and specific test and may be suitable for a rapid, cost-effective, and reliable field diagnosis of kala azar and PKDL (55).

Concentration Procedures

Cytocentrifugation Technique

Cytocentrifugation (cytospin), which uses an apparatus for concentrating cells in suspension on a microscope slide, is commonly used in most histopathology laboratories. The use of a hemolyzing and isotonic saponin solution to lyse RBCs and platelets, which contains formalin as a fixative, has led to an improved technique for the detection of *Plasmodium* spp., *L. donovani*, microfilariae, and WBCs containing malaria pigment. The concentration of the parasites present in the sediment from 100 μl of blood spread on a 6-mm-diameter circle results in good

morphology that is well stained using Giemsa, Wright's, or rapid stains. This new method costs very little to perform and offers the possibility of isolating and identifying the main blood-stage parasites in the same sediment. The possible exception would be young trophozoites of *P. falciparum*, which do not concentrate well due to their small size (60).

Knott Concentration Procedure

The Knott concentration procedure is used primarily to detect the presence of microfilariae in the blood, especially when a light infection is suspected (35, 45) (Figure 31.15). The disadvantage of the procedure is that the microfilariae are killed by the formalin and are therefore not seen as motile organisms.

1. Place 1 ml of whole or citrated blood into a centrifuge tube containing 10 ml of 2% formalin. Thoroughly mix the tube contents.
2. Centrifuge for 2 min at $500 \times g$ or 5 min at $300 \times g$.
3. Decant the supernatant fluid, examine some sediment as a wet mount at low ($\times 100$) and high dry ($\times 400$) power, prepare thick films from the remaining sediment, and allow the films to air dry.
4. Stain films with Giemsa, Wright's, or rapid stains.

Note Use alcohol-cleaned slides for preparation of the films made from the sediment.

Figure 31.15 *Loa loa* microfilaria at low power from a Knott concentration stained with Giemsa stain. Note that the sheath is not visible.

Membrane Filtration Technique

The membrane filtration technique as modified by Desowitz and others has proved highly efficient in demonstrating filarial infections when microfilaremias are of low density. It has also been successfully used in field surveys (11, 17–19, 35).

1. Draw 1 ml of fresh whole blood or anticoagulated blood into a 15-ml syringe containing 10 ml of distilled water.
2. Gently shake the mixture for 2 to 3 min to ensure that all blood cells are lysed.
3. Place a 25-mm Nuclepore filter (5- μm porosity) over a moist 25-mm filter paper pad. (This method is unsatisfactory for the isolation of *M. perstans* microfilariae because of their small size. A 3- μm -pore-size filter could be used for recovery of this organism. Other filters of similar pore size are not as satisfactory as the Nuclepore filter.) Place the filter in a Swinney filter adapter.
4. Attach the Swinney filter adapter to the syringe containing the lysed blood.
5. With gentle but steady pressure on the piston, push the lysed blood through the filter.
6. Without disturbing the filter, remove the Swinney adapter from the syringe and draw approximately 10 ml of distilled water into the syringe. Replace the adapter, and gently push the water through the filter to wash the debris from the filter.
7. Remove the adapter again, draw the piston of the syringe to about half the length of the barrel, replace the adapter, and push the air in the barrel through the filter to expel excess water.
8. To prepare the filter for staining, remove the adapter, draw the piston about half the length of the barrel, and then draw 3 ml of absolute methanol into the syringe. Holding the syringe vertically, replace the adapter and push the methanol followed by the air through the filter to fix the microfilariae and expel the excess methanol.
9. To stain, remove the filter from the adapter, place it on a slide, and allow it to air dry thoroughly. Stain with Giemsa stain as for a thick film (with 0.1% Triton X-100) or with Delafield's hematoxylin.
10. To cover the stained filter, dip the slide in toluene before mounting the filter with neutral mounting medium and a coverslip. This will lessen the formation of bubbles in or under the filter.

Gradient Centrifugation Technique

The gradient centrifugation technique is another technique for the concentration of microfilariae (52).

1. Mix 30 ml of 50% Hypaque with 14 ml of distilled water; add 1 part of this mixture to 2.4 parts of 9% Ficoll.
2. Place 4 ml of the Ficoll-Hypaque mixture in a 15-ml plastic centrifuge tube; overlay this mixture with 4 ml of heparinized venous blood.
3. Centrifuge the tube at $400 \times g$ for 40 min.
4. Microfilariae will be found in the middle Ficoll-Hypaque layer, which separates the overlying plasma and WBC layers from the underlying RBCs.

Triple-Centrifugation Method for Trypanosomes

The triple-centrifugation procedure may be valuable in demonstrating the presence of trypanosomes in the peripheral blood when the parasitemia is light (26, 35).

1. Centrifuge anticoagulated blood for 10 min at $300 \times g$.
2. Remove the supernatant fluid, and transfer it to another centrifuge tube.
3. Centrifuge this fluid for 10 min at $500 \times g$.
4. Again, remove the supernatant fluid to another centrifuge tube.
5. Centrifuge this fluid for 10 min at $900 \times g$.
6. Decant the supernatant fluid, and examine the sediment as a wet preparation.
7. The sediment may be used to prepare thin films that can then be stained with any of the blood stains.

Note Remember, you are saving the supernatant fluid in step 2 for subsequent centrifugation; do not accidentally pour this fluid off for disposal. The final sediment after the third centrifugation step is used to prepare stained films for examination.

Special Stain for Microfilarial Sheath

Delafield's Hematoxylin

Some of the material that is obtained from the concentration procedures can be allowed to dry as thick and thin films and then stained with Delafield's hematoxylin, which demonstrates greater nuclear detail as well as the microfilarial sheath, if present. In addition, fresh thick films of blood containing microfilariae can be stained by

this hematoxylin technique (Figures 31.16 and 31.17) (26, 35).

Preparation of Stain

Dissolve 180 g of aluminum ammonium sulfate in 1 liter of distilled water (saturated solution). Heat until dissolved. The cooled supernatant fluid is saturated aluminum alum.

Hematoxylin Solution

Hematoxylin crystals.....	4 g
95% ethyl alcohol.....	25 ml
Ammonium alum (saturated solution).....	400 ml

Dissolve the hematoxylin in alcohol, and add it to the alum solution. Expose the solution to sunlight and air for ripening in a clear, cotton-plugged bottle for approximately 1 week; then filter and add the following:

Glycerin.....	100 ml
95% ethyl alcohol.....	100 ml

Age for 1 month or longer in sunlight, and then run test smears to determine whether the solution is properly aged. Nuclei should stain blue, and cytoplasm should stain different shades of red.

Procedure

1. Prepare thick films from the concentration material or from fresh blood.
2. Allow the films to air dry.

Figure 31.16 *Brugia malayi* microfilaria on a thick film stained with Delafield's hematoxylin. Note the presence of the sheath.

Figure 31.17 *Wuchereria bancrofti* microfilaria. (Upper) Microfilaria stained with Giemsa stain. Note that the sheath is not visible. (Lower) Microfilaria stained with Delafield's hematoxylin stain. Note that the sheath is visible.

3. Lake the films in 0.85% sodium chloride or distilled water for 15 min (not necessary for films prepared from the Knott sediment). Allow to air dry.
4. Fix all films in absolute methanol for 5 min. Allow to air dry.
5. Stain in undiluted Delafield's hematoxylin for 10 to 15 min.
6. Wash off excess stain in tap water.
7. Intensify the blue color by placing the films into tap water containing several drops of ammonia (NH_4OH) for several minutes.
8. Rinse again in running tap water for 5 min.
9. Air dry.
10. Mount in Permount or some other mounting medium; use a no. 1 coverglass.

Parasite Recovery: Culture Methods, Animal Inoculation, and Xenodiagnosis

Culture methods

Intestinal protozoa

Pathogenic free-living amebae

Pathogenic flagellates

Flagellates of blood and tissue

Toxoplasma gondii

Plasmodium and *Babesia* spp.

Cryptosporidium spp.

Microsporidia

Animal inoculation

Leishmania spp.

Trypanosoma spp.

Toxoplasma gondii

Xenodiagnosis

Culture Methods

Very few clinical laboratories offer specific culture techniques for parasites. The methods for in vitro culture are often complex, while quality control is difficult and not really feasible for the routine diagnostic laboratory. In certain institutions, some techniques may be available, particularly when consultative services are provided (reference laboratory situation) and for research purposes. However, most laboratories do not offer these techniques.

Few parasites can be routinely cultured, and the only procedures that are in general use are for *Entamoeba histolytica*, *Naegleria fowleri*, *Acanthamoeba* spp., *Trichomonas vaginalis*, *Toxoplasma gondii*, *Trypanosoma cruzi*, and the leishmanias. Often, when specimens are cultured for potential pathogens, nonpathogenic protozoa could also be recovered. These procedures are usually available only after consultation with the laboratory and on special request. For those who may be interested in trying these techniques, the several different media presented below are representative of those available. More extensive options can be found in the literature (1, 7, 24, 31, 52–55, 58, 62, 64, 65).

Cultures of parasites grown in association with an unknown microbiota are referred to as xenic cultures. A good example of this type of culture would be stool specimens cultured for *E. histolytica*. If the parasites are grown with a single known bacterium, the culture is referred to as monoxenic. An example of this type of culture would be clinical specimens (corneal biopsy specimens) cultured with *Escherichia coli* as a means of recovering species of *Acanthamoeba* and *Naegleria*. If parasites are grown as pure culture without any bacterial associate, the culture is referred to as axenic. An example of this type of culture would be the use of media for the isolation of *Leishmania* spp. or *Trypanosoma cruzi*. All three types of cultures are discussed in this chapter.

Pancreatic digests of casein are major ingredients of media used in the axenic cultivation of lumen-dwelling parasitic protozoa. Unfortunately, the digest used almost exclusively in the development of these media has not been available since the early 1980s. Many digest products have been tried in the interim with marginal results in supporting the growth of *E. histolytica*. Diamond et al. (13) have developed a casein-free medium, YI-S, consisting of a nutrient broth, vitamin mixture, and serum. This may serve as a replacement for TYI-S-33, widely used for the axenic culture of *E. histolytica* and other intestinal protozoa.

Intestinal Protozoa

Specimens include stool material, mucus, or a combination of the two. The clinical specimen(s) should be no more than 24 h old; a maximum of 2 to 3 h is recommended.

Balamuth's Aqueous Egg Yolk Infusion Medium for Amebae

Balamuth's aqueous egg yolk infusion medium is used to detect the presence of amebae. The specific solutions required are phosphate buffer and whole-liver concentrate solution (36).

Balamuth's Aqueous Egg Yolk Infusion Medium

Phosphate buffer

(A) Potassium phosphate, tribasic (K_3PO_4)	212.27 g
Distilled water	1,000 ml
(B) Potassium phosphate, monobasic (KH_2PO_4)	136.092 g
Distilled water	1,000 ml

Mix the solution in the ratio of 3 parts tribasic (A) to 2 parts monobasic (B) to make 1 M phosphate buffer stock. Dilute the stock buffer to 0.067 M before use (add 492 ml of distilled H_2O to 1 liter of 1 M phosphate buffer).

Whole-liver concentrate solution

Liver concentrate powder (Wilson or Lilly)	5 g
Distilled water	100 ml

Suspend the powder in cold water, and autoclave. Filter through a Büchner funnel to remove sediment, dispense in 10-ml quantities, and reautoclave.

Preparation of Complete Medium (20)

- Using a blender, blend 12 fresh hard-boiled egg yolks with 375 ml of 0.8% sodium chloride.
- Autoclave at 7 lb/in² pressure for 10 min, repressurize slowly, and stir.
- Autoclave again for 45 min at 7 lb/in² pressure.
- Allow to cool slightly, and add distilled water to replace evaporation loss. Transfer the material to a muslin bag, and express the liquid portion, saving all the fluid. Return the volume to 375 ml with 0.8% sodium chloride.
- Autoclave for 20 min at 121°C; cool to 5°C. Do not agitate the fluid at this point or during filtration.
- Decant the fluid carefully through gauze into a Büchner funnel with Whatman no. 3 filter paper. Filter papers can be replaced as necessary.

- Measure the filtrate, add an equal volume of 0.067 M phosphate buffer, and autoclave for 20 min at 121°C. After cooling, add stock liver concentrate (1 part stock liver to 9 parts medium).
- Material can then be decanted into sterile flasks, which are stored until the medium is dispensed.

Procedure

Tubes should contain 6 to 8 ml of fluid and should be incubated for 4 days at 37°C as a sterility check. Before inoculation, a loopful of sterile rice powder or starch (can be autoclaved in a screw-cap tube) is added to each tube. To each tube, add stool material, mucus, or a combination of the two (about the size of a small pea), break it up thoroughly in the medium, and incubate at 37°C. The cultures should be checked at 2, 3, and 4 days by examining 0.1 ml of sediment under the microscope (low-intensity light) for characteristic motility. Although the initial culture may appear to be negative, subcultures may reveal organisms (Figure 32.1).

Figure 32.1 Protozoa from culture systems. (Upper left) *Entamoeba histolytica*/*E. dispar* trophozoite from liquid medium containing rice starch (note that there are no definitive erythrocytes within the cytoplasm, so that it is not possible to differentiate the true pathogen, *E. histolytica*, from the nonpathogen, *E. dispar*). (Upper right) *Naegleria fowleri* trophozoite from nonnutrient agar culture with bacterial overlay (note that this trophozoite has been stained). (Lower left) *Acanthamoeba* spp. trophozoite from nonnutrient agar culture with bacterial overlay (note the spiky acanthopodia). (Lower right) *Acanthamoeba* spp. cysts from nonnutrient agar culture with bacterial overlay (note the double hexagonal wall appearance).

According to Dolkart and Halpern (14), the addition of gastric mucin to the egg component is reported to improve the performance of Balamuth's medium.

The addition of rice flour (prerinsed with distilled water) to Balamuth's medium is reported to support abundant growth of *Balantidium coli*.

Boeck and Drbohlav's Locke-Egg-Serum (LES) Medium for Amebae

Boeck and Drbohlav's LES medium is another culture medium used to diagnose the presence of amebae (36).

Boeck and Drbohlav's LES Medium

Locke's solution

NaCl	9.0 g
CaCl ₂	0.2 g
KCl.....	0.4 g
NaHCO ₃	0.2 g
Glucose	2.5 g
Distilled water.....	1,000 ml

Autoclave before storage.

Preparation of Complete Medium

1. Wash four eggs, wipe the shells with 70% alcohol, and break the eggs into a sterile flask containing glass beads.
2. Add 50 ml of Locke's solution, and shake until homogenous.
3. Dispense the medium so that a slant of 1 to 1.5 in. (1 in. = 2.54 cm) is produced in the bottom of the tube. (Tube size is not critical.)
4. Plug the tubes, and place them in a slant position in an inspissator at 70°C until the slant solidifies. Inspissator conditions may be achieved in the autoclave by leaving the door ajar (nonpressurized system).
5. Autoclave the tubes at 121°C for 20 min. Discard any damaged slants.
6. Prepare a mixture of 8 parts sterile Locke's solution to 1 part sterile inactivated human serum. Sterilize the mixture by filtration, and incubate at 37°C for 24 to 48 h as a sterility check before use. Cover the slants to a depth of <1 cm with the sterile solution, and inoculate in the same manner as for Balamuth's medium. LES medium should have a loopful of sterile rice powder added before inoculation.

Diphasic LE Medium (*Blastocystis hominis*)

LE medium is the NIH modification of Boeck and Drbohlav's medium.

Locke's Solution

NaCl	8.0 g
CaCl ₂	0.2 g
KCl.....	0.2 g
MgCl ₂	0.01 g
Na ₂ HPO ₄	2.0 g
NaHCO ₃	0.4 g
KH ₂ PO ₄	0.3 g
Distilled water.....	1,000 ml

Autoclave for 15 min at 121°C under a pressure of 15 lb/in². Cool to room temperature, and remove any precipitate by filtration (Whatman no. 1 paper). Reautoclave to sterilize.

Preparation of Complete Medium

1. To prepare the egg slant, surface sterilize fresh hen eggs by flaming in 70% ethanol and break into a graduated cylinder.
2. Add 12.5 ml of Locke's solution per 45 ml of egg.
3. Emulsify in a Waring-type blender, and filter through gauze into a flask.
4. Place under vacuum to draw out all air bubbles.
5. Add 5-ml amounts of the emulsified egg to standard culture tubes (16 by 125 mm), and autoclave at 100°C for 10 min with the tubes at an angle that produces a 12- to 15-mm (ca. 0.5-in.) butt. The resulting egg slants should be free of bubbles.
6. Cool to room temperature, overlay slants with 6 ml of Locke's solution, and autoclave for 15 min at 121°C under a pressure of 15 lb/in².
7. Let the slants cool to room temperature, tighten the caps, and refrigerate the slants for up to 6 months.

TYI-S-33 Medium for *Entamoeba histolytica* (8)

TYI Broth

Biosate (BBL) Peptone	30.0 g
Dextrose (do not use glucose)	10.0 g
NaCl	2.0 g
L-Cysteine HCl (Sigma).....	1.0 g
Ascorbic acid (J. T. Baker).....	0.2 g
K ₂ HPO ₄	1.0 g
KH ₂ PO ₄	0.6 g
Ferric ammonium citrate (Mallinckrodt)	22.8 mg
Distilled water up to	870 ml

Note Biosate may be replaced with 20 g of Trypticase (BBL) and 10 g of yeast extract (BBL). Some lots of Biosate, Trypticase, yeast extract, or serum may inhibit growth.

1. Adjust pH to 6.8 with 1 N NaOH, and filter through Whatman no. 1 paper. Autoclave at 121°C for 15 min.
2. Cool, and add:
 - Heat-inactivated bovine serum (shelf life, 6 months at 4°C) 100 ml
 - Special 107 Vitamin Mix (below) 30 ml
3. Aseptically dispense 13 ml of complete medium into 16- by 125-mm screw-cap tubes. To prepare Special 107 Vitamin Mix, aseptically combine the following:

Solution 1 (see below)	0.4 ml
Solution 2 (see below)	1.2 ml
Solution 3 (see below)	0.4 ml
Sterile distilled water	18.0 ml
Diamond's TPS-1, vitamin solution, 40× (NABI) diluted to 1×	100.0 ml

Total volume of complete Special 107 Vitamin Mix is 120 ml.

Solution 1 (Filter Sterilized)

D,L-6,8-Thioctic acid, oxidized (Sigma)	100 mg
Absolute ethanol	100 ml

Solution 2 (Filter Sterilized)

Vitamin B ₁₂ (Sigma)	40 mg
Distilled water	100 ml

Solution 3 (Filter Sterilized)

Tween 80 (Sigma)	50 g
Absolute ethanol	100 ml

Note The shelf life of solutions 1, 2, and 3 is 22 months.

TYI-S-33 (Keister's Modification) for *Giardia lamblia*

For TYI-S-33 (Keister's modification [7]), prepare TYI broth exactly as for *E. histolytica* with the following changes. (i) Increase the amount of L-cysteine hydrochloride to 2.0 g/liter. (ii) Add 500 mg of dehydrated bovine bile per liter. (iii) Adjust the pH to 7.0 to 7.1. (iv) Sterilize by filtration through a 0.22- μ m-pore-size filter. Do not autoclave! The complete medium is made by addition of bovine serum to 10%.

TYSGM-9 Medium for *Entamoeba histolytica*

Nutrient Broth

Potassium phosphate, dibasic (K ₂ HPO ₄)	2.8 g
Potassium phosphate, monobasic (KH ₂ PO ₄)	0.4 g

NaCl	7.5 g
Casein digest peptone (BBL, product no. 97023)	2.0 g
Yeast extract (BBL)	1.0 g
Glass-distilled water	970.0 ml

The nutrient broth may be stored for several months at -20°C (11, 12).

5% Tween 80 Solution

1. Vigorously stir, with a magnetic stirrer, 95 ml of glass-distilled water in a bottle.
2. Add 5 g of Tween 80 (very thick solution; must be weighed), and keep stirring for a few minutes.
3. Filter sterilize through a 0.22- μ m-pore-size membrane.
4. Aseptically dispense into a number of sterile screw-cap test tubes, 10 ml per tube.
5. Label as 5% Tween 80 solution, with the preparation date and an expiration date of no longer than 1 month. Store at 4°C.

Phosphate-Buffered Saline (PBS no. 8), pH 7.2

NaCl	9.5 g
K ₂ HPO ₄	3.7 g
KH ₂ PO ₄	1.1 g
Glass-distilled water to	1,000.0 ml

1. Dissolve the salts in the distilled water with a magnetic stirrer.
2. Autoclave for 15 min at 121°C.
3. When cool, label as PBS no. 8 with the preparation date and an expiration date of 3 months.

Rice Starch

For best results use rice starch obtained from British Drug Houses Ltd. or Gailard Schlesinger, Inc.

1. Dispense 500 mg of rice starch into each of several 16- by 125-mm screw-cap tubes; do not tighten the caps.
2. Place the tubes horizontally in a dry-heat sterilizer or an oven. Make sure that the rice starch is uniformly distributed loosely over the undersurface of the tubes.
3. Heat the tubes for 2.5 h at 150°C.
4. When cool, tighten caps and label as rice starch with the date of preparation and an expiration date of 3 months.

Rice Starch Suspension

1. Add 9.5 ml of sterile PBS no. 8 to each tube of rice starch.

- Shake vigorously or use a vortex machine to uniformly suspend the rice starch at the time of use.

Stock Antibiotic Solution

- Using a 6-ml syringe and 20-gauge needle, add 5 ml of sterile distilled water to a vial of penicillin G sodium (10^6 U).
- Using a 6-ml syringe and 20-gauge needle, add 5 ml of sterile distilled water to a vial of streptomycin sulfate (10^6 µg/ml).
- Shake gently, and let stand for 30 min to dissolve the antibiotics completely in the distilled water.
- Mix the two antibiotics in a graduated flask or cylinder, and bring the volume to 125 ml with distilled water. The stock concentration of antibiotics is 8,000 U of penicillin/ml and 8,000 µg of streptomycin/ml.
- Filter sterilize the antibiotic solution through a 0.22-µm membrane filter, dispense the filtrate into a number of sterile screw-cap vials or sterile cryovials (1 ml per vial), and label as stock antibiotic solution with the preparation date and an expiration date of 6 months. Store at 120°C in a cryovial box.

Buffered Methylene Blue Solution

Solution A, 0.2 M acetic acid

Glacial acetic acid	11.55 ml
Distilled water	988.50 ml

Add the acetic acid to the water, mix, and store in a glass-stoppered bottle. Label with the date of preparation and an expiration date of 1 year.

Solution B, 0.2 M sodium acetate

Sodium acetate ($\text{CH}_3\text{COONa} \cdot 3\text{H}_2\text{O}$)	16.4 g
Distilled water to.....	1,000.0 ml

Dissolve the sodium acetate in 400 ml of distilled water in a volumetric flask, bring the volume to the 1,000-ml mark, mix well, and store in a glass-stoppered bottle. Label with the date of preparation and an expiration date of 1 year.

Acetate buffer, pH 3.6

Solution A	46.3 ml
Solution B	3.7 ml
Distilled water to.....	100.0 ml

Mix solutions A and B in a volumetric flask, and bring the volume to 100.0 ml with distilled water. The pH should be 3.6. Store in a glass-stoppered bottle. Label with the date of preparation and an expiration date of 1 year.

Methylene blue stain

Methylene blue dye	60.0 mg
Acetate buffer (from previous step).....	100.0 ml

Dissolve the dye in the buffer, and store in a glass-stoppered bottle. Label with the date of preparation and an expiration date of 1 year.

Complete Medium (TYSGM-9 Medium)

- Place 200 mg of gastric mucin (U.S. Biochemical Corp., catalog no. 16025) in a 125-ml screw-cap bottle or Erlenmeyer flask.
- Add 97 ml of nutrient broth; using a magnetic stirrer, stir vigorously for at least 1 h or until the medium becomes clear.
- Autoclave for 15 min at 121°C ; cool to room temperature.
- Add aseptically, in a biological safety cabinet, 5.0 ml of heat-inactivated bovine serum.
- Add 0.1 ml of the 5% Tween 80 solution.
- Dispense aseptically, in a biological safety cabinet, into a number of sterile 16- by 125-mm screw-cap tubes, 8 ml per tube.
- Add 0.25 ml of rice starch solution after vigorously shaking the tube.
- Store the tubes at 4°C for not more than 1 month.
- The final pH of the medium should be 7.2.

Robinson's Culture

Robinson's medium is a complex medium that has nevertheless found widespread use for the isolation of enteric amebae. To prepare Robinson's medium, prepare the six following stock solutions (7).

Solution 1 (0.5% Erythromycin) (Filter Sterilized)

Prepare 0.5% erythromycin in distilled water and filter sterilize. Refrigerate.

Solution 2 (20% Bacto Peptone) (Autoclave)

Prepare 20% Bacto Peptone in distilled water. Autoclave and refrigerate.

Solution 3 (10× Phthalate Solution, Stock) (Autoclave)

Potassium hydrogen phthalate.....	102 g
40% sodium hydroxide.....	50 ml

Bring to 1 liter at pH 6.3. Autoclave for 15 min at 121°C under a pressure of 15 lb/in². Store at room temperature. Dilute 1:10 with sterile water before use.

A stock solution of phthalate-Bacto Peptone can be made by adding 1.25 ml of 20% Bacto Peptone per 100 ml of 1× phthalate solution. Store refrigerated.

Solution 4 (10× R Medium Stock) (Autoclave)

NaCl	25.0 g
Citric acid	10.0 g
Potassium phosphate, monobasic (KH ₂ PO ₄)	25.0 g
Ammonium sulfate	5.0 g
Magnesium sulfate · 7H ₂ O.....	0.25 g
85% lactic acid solution.....	20 ml

Bring to 500 ml. Dilute stock 1:10, adjusting pH to 7.0. Autoclave for 15 min at 121°C under a pressure of 15 lb/in² in 20-ml amounts.

Solution 5 (BR Medium)

To prepare BR medium, inoculate 1× R medium with a standard *Escherichia coli* strain such as O111. Incubate at 37°C for 48 h, and store at room temperature (good for several months).

Solution 6 (BRS Medium)

To prepare BRS medium, add an equal volume of heat-inactivated bovine serum to BR medium and incubate at 37°C for 24 h. Store at room temperature (good for several months).

1. To prepare agar slants, many people use screw-cap glass bijou bottles (total volume, 7 ml), but standard culture tubes also work well.
2. Autoclave a solution of 1.5% Noble agar in 0.7% NaCl–distilled water for 15 min at 121°C under a pressure of 15 lb/in².
3. Dispense in 5-ml (tube) or 3-ml (bottle) amounts, reautoclave, and slant until cool and set. For slants in tubes, use an angle that produces a 12- to 15-mm (ca. 0.5-in.) butt.
4. When cool, tighten lids and store at room temperature or refrigerated.
5. To one tube or bottle, add the following: 3 ml of 1× phthalate-Bacto Peptone, 1 ml of BRS medium, and 50 µl of erythromycin. This must be done on the same day as the inoculation. Note that although erythromycin is added to Robinson's medium at every subculture, this does not lead to a monoxenic culture as occasionally stated. Additional antibiotic treatment would be needed for this to be the case.

Xenic Culture

When initiating xenic cultures, the stool samples should be inoculated into at least two tubes, one with and the other without antibiotics. In some cases, some

component of the natural bacterial flora may be helpful or even necessary for the amebae to become established (27).

1. Warm several tubes of TYSGM-9 medium in the incubator (35°C for 1 to 2 h).
2. Add 0.1 ml of stock antibiotics to each tube of medium. The final concentration of antibiotics is 100 U of penicillin per ml and 100 µg of streptomycin per ml.
3. After vortexing or vigorously shaking the tube, use a Pasteur pipette to add 3 drops of the starch suspension to each tube of the medium.
4. Place a pea-sized portion of stool sample into the bottom of the tube, and break up the stool gently with the pipette.
5. Tightly cap the tubes, and incubate at a 45 to 50° angle at 35°C for 48 h.
6. Examine the tubes with an inverted microscope and the 10× objective for the presence of amebae. Amebae, if present, are usually seen attached to the underside of the tubes, interspersed with the fecal material and rice starch. Sometimes it is necessary to gently invert the tubes in order to disperse the stool material and rice starch to uncover the amebae. If you do not have an inverted microscope, proceed to step 13.
7. If amebae are not seen, stand the tubes upright for about 30 min at 35°C.
8. With a Pasteur pipette, remove from the bottom of each tube the entire sediment and inoculate the sediment into fresh tubes containing rice starch and antibiotics.
9. Incubate as above for another 48 h.
10. Examine the tubes as before and discard the tubes if amebae are still not seen. Report patient results as negative.
Note These patient results should not be reported unless the quality control organisms and cultures are growing, thus indicating the culture system is performing according to expected results.
11. If amebae are present in small numbers, chill the tube in ice-water for 5 min and centrifuge the tube for 5 min at 250 × g. Aspirate and discard the supernatant, and inoculate the sediment into a fresh tube as before.
12. If amebae are present in large numbers, let the tube stand upright for 30 min and remove about 0.2 ml of sediment from the bottom. Inoculate the sediment into fresh tubes as before.
13. If you do not have an inverted microscope, stand the tubes upright for about 30 min at 35°C. With a sterile pipette, remove about 0.5 ml of sediment from the bottom of the tube and place a couple

of drops onto each of two slides. Add 2 drops of methylene blue solution to one of the slides. Cover both with coverslips, and examine the slides under the microscope for amebae. Amebae may appear rounded or with pseudopodial extrusions. The nuclei may be clearly seen in the methylene blue preparation. Proceed to steps 7 through 12.

Axenic Culture

Axenic culture is used for research when strains of organisms are necessary for work requiring a culture system free from bacterial contaminants. If the axenic culture tubes become contaminated, 1,000 U of penicillin per ml and 1,000 µg of streptomycin or 50 µg of gentamicin per ml can be added to each tube. If, however, the contaminant happens to be *Pseudomonas* spp., it is probably better to discard the tube and use an uncontaminated tube for subculture purposes (20, 24).

1. Remove tubes containing TYI-S-33 medium from 4°C, and incubate at 35°C for 1 to 2 h.
2. With an inverted microscope, examine stock culture tubes of *E. histolytica* for any signs of bacterial contamination (no longer acceptable for use). Select one or several tubes showing good growth of amebae. Since the tubes are incubated in a slanted position, usually at an angle of 5 to 10°, a thick button of amebae will be seen at the bottom of the tube. Gently invert the tubes once or twice to disperse the amebae uniformly, and examine the tubes again. A majority of the amebae should be attached to the tube walls and show pseudopodial motility. If you do not have an inverted microscope, examine organisms from the bottom of the tube (as a wet smear). If you can see pseudopodial motility, proceed to step 3.
3. Immerse the tubes in a bucket of ice-cold water for about 5 to 10 min to dislodge the amebae from the tube walls. Invert the tubes several times to distribute the amebae.
4. Remove, with a Pasteur pipette, about 1.0 to 1.5 ml of culture medium; inoculate 0.5 to 1 ml into a fresh tube. Inoculate the rest of the fluid into nutrient agar, brain heart infusion, and thioglycolate broth for routine monitoring of bacterial contamination. Inoculate several tubes this way, and incubate the cultures slanted at 5 to 10° at 35°C as before.
5. If amebic growth is not good but some amebae are attached to the tube walls, remove about 10 ml of medium from the bottom with a serologic pipette and add 10 ml of fresh medium.

6. If amebic growth is not good and only few amebae are present along with a lot of debris, centrifuge the tube at 250 × g for 10 min, aspirate the supernatant fluid, and transfer the sediment to a fresh tube and incubate as before.

Quality Control for Intestinal Protozoan Cultures

The following control strains should be available when using these cultures for clinical specimens (24): ATCC 30925 (*Entamoeba histolytica* HU-1: CDC), ATCC 30015 (*Entamoeba histolytica* HK-9), and ATCC 30042 (*Entamoeba histolytica*-like, Laredo strain, culture at 25°C) (8).

1. Check all reagents and media (Balamuth's aqueous egg yolk infusion medium, Boeck and Drbohlav's LES medium, PBS solution no. 8, rice starch suspension, Tween 80 solution, and TYSGM-9 and TYI-S-33 media) each time they are used or periodically (once a week). The media and all solutions should be free of any signs of precipitation and bacterial and/or fungal contamination.
2. Maintain stock cultures of *E. histolytica* at 35°C (ATCC 30925 [strain HU-1: CDC] and ATCC 30015 [strain HK-9]). Maintain *E. histolytica*-like Laredo strain (ATCC 30042) at 25°C.
 - A. Transfer stock culture (ATCC 30925) every other day with TYSGM-9 medium.
 - B. Transfer stock culture (ATCC 30015) once every 3 days with TYI-S-33 medium.
 - C. Transfer stock culture (ATCC 30042) once a month with TYSGM-9 medium.
 - D. *E. histolytica* trophozoites measure 10 to 60 µm and demonstrate directional motility by extruding hyaline, finger-like pseudopodia from the cytoplasm. Cysts are not usually found in cultures.
 - E. Trophozoites are uninucleate and characterized by finely granular, uniform, evenly distributed peripheral chromatin. The nucleolus is small and usually centrally located but may be eccentric.
3. Depending on its use, the microscope(s) may need to be calibrated (within the last 12 months), and the original optics used for the calibration should be in place on the microscope(s). The calibration factors for all objectives should be posted on the microscope for easy access.

Note If the tubes containing fecal material are positive for amebae after 48 h of incubation, confirm the identification with the permanent stained smear. If the tubes do not show any amebae, subculture the contents of the tubes as described above and incubate for an additional

48 h. If the tubes are still negative for amebae, report the specimen as negative and discard the tubes. Even when the culture system is within quality control guidelines, a negative culture is still not definitive in ruling out the presence of *E. histolytica*. Xenic cultures of *E. histolytica* serve only as a supplemental procedure and never replace the primary diagnosis by microscopic examination of concentration sediments and permanent stained smears. Axenic culture is used to maintain quality control strains and for research purposes.

Pathogenic Free-Living Amebae

Specimens would include cerebrospinal fluid (CSF), biopsy tissue, and autopsy tissue of the brain; for *Acanthamoeba* spp., corneal scrapings or biopsy material, contact lenses and contact lens paraphernalia such as lens cases and solutions, skin abscess material, ear discharge, or feces can also be used. All clinical specimens should be processed within 24 h; 2 to 3 h is recommended. However, eye-related specimens can be shipped by mail with apparently few problems (27, 33, 37, 48, 51, 63). The procedure for growing *Naegleria* and *Acanthamoeba* from clinical specimens involves the use of a nonnutrient agar spread with *E. coli* or some other nonmucoic bacteria. Amebas begin feeding on bacteria and soon grow to cover the agar surface in 1 to 2 days at 37°C. The presence of the protozoa can be confirmed by examining the agar surface using an inverted microscope or with a conventional microscope by inverting the plate on the stage and focusing through the agar with a 10× objective (Figure 32.1).

Diagnostic methods include direct microscopy of wet mounts of CSF or stained smears of CSF sediment, light or electron microscopy of tissues, in vitro cultivation of *Acanthamoeba*, and histologic assessment of frozen or paraffin-embedded sections of brain or cutaneous lesion biopsy material. Immunocytochemistry, chemifluorescent-dye staining, PCR, and analysis of DNA sequence variation also have been used for laboratory diagnosis. Several approaches to specimen handling and diagnostic methods can be seen in Table 32.1.

Environmental Issues

There continue to be ongoing discussions and publications regarding the association of free-living amebae and their intracellular bacterial flora, particularly within the context of environmental transmission of infection, contamination of equipment, and overall environmental concerns. The recognition that *Acanthamoeba* spp. can sequester a variety of bacteria with known potential for causing human disease suggests that these amebae serve as reservoirs for bacterial pathogens. The increase in the reported incidence of *Acanthamoeba* infections may be

due to greater recognition of the disease potential of these amebae. Also, a number of factors may account for an increased incidence of infection, such as a large number of human immunodeficiency virus-infected individuals and more patients undergoing chemotherapy or immunosuppressive therapy for organ transplantation (35). Some of these recent issues can be seen in Table 32.2.

Acanthamoeba Medium

For the isolation of *Naegleria* or *Acanthamoeba* spp. from tissues or soil samples, the following procedure is recommended (31).

Acanthamoeba Medium

Page's saline (10×)

NaCl	60 mg
MgSO ₄ · 7H ₂ O.....	2 mg
CaCl ₂ · 2H ₂ O.....	2 mg
Na ₂ HPO ₄	71 mg
KH ₂ PO ₄	68 mg
Distilled water.....	500 ml

1. Autoclave at 121°C for 15 min.
2. Store refrigerated in a glass bottle for up to 6 months.

Nonnutrient agar

Page's saline (10×).....	100 ml
Difco agar	15 g
Double-distilled water.....	900.0 ml

1. Dissolve agar in Page's saline and distilled water with gentle heating; stir or swirl.
2. Aliquot 20 ml into screw-cap tubes (20 by 150 mm).
3. Autoclave at 15 lb/in² for 15 min; label deeps with 12-month expiration date, and store in the refrigerator.
4. Melt agar deeps, and pour into petri dishes as needed. Plates may be stored in the refrigerator for up to 3 months.

Monoxenic culture

1. Remove the nonnutrient agar plates from the refrigerator, and place them in a 37°C incubator for 30 min.
2. Add 0.5 ml of ameba saline to a slant bacterial culture of *E. coli* or *Enterobacter aerogenes*. Gently scrape the surface of the slant (do not break the agar surface). Suspend the bacteria uniformly by gently pipetting with a Pasteur pipette, and add 2 or 3 drops of this suspension to the middle of

Table 32.1 Approaches to isolation of free-living amebae^a

Approach 1	Approach 2	Approach 3	Approach 4
Tissue sample (central nervous system tissue, corneal scrapings, skin scrapings or biopsy specimen)	Tissue sample (central nervous system tissue, corneal scrapings, skin scrapings or biopsy specimen)	CSF	Environmental sample (soil, water)
Antibiotics (Pen-Strep, gentamicin, amphotericin B)	Nonnutrient agar (plus <i>Escherichia coli</i>)	Wet mounts, stains	Nonnutrient agar (plus <i>Escherichia coli</i>)
Tissue culture (monkey kidney, rat glioma, human lung fibroblasts)	Wet mounts, stains; enflagellation (identification of <i>Naegleria</i>)	Nonnutrient agar; wet mounts, stains; enflagellation (identification of <i>Naegleria</i>)	Wet mounts, stains; enflagellation (identification of <i>Naegleria</i>)

^aThe decision to examine a specimen as a wet mount and/or permanent stained smears will depend on the amount of specimen received. If the amount is quite small, direct inoculation of nonnutrient agar seeded with bacteria is recommended. Once organisms have been isolated, they can be frozen. (Adapted from reference 53.)

Table 32.2 Issues related to free-living amebae and symbiotic bacteria

Issue	Comments	Reference
Eyewash stations and flushing regimens; amebic and bacterial concentrations temporarily decreased with various flushing regimens	The lower amebic concentrations were not sustained	5
Bath basins (whirlpool baths) in which <i>Hartmanella</i> and <i>Vannella</i> were isolated tended to harbor large number of <i>Legionella</i>	Management practices such as frequent washing of filter elements and/or frequent addition of tap water to bath basins are highly recommended to reduce microbial contaminants	29
Survival and growth of <i>Burkholderia cepacia</i> was documented in <i>Acanthamoeba polyphaga</i>	These findings should be taken into account when reviewing environmental reservoirs of <i>B. cepacia</i>	30
<i>Legionella</i> and amebae from the same hospital water system were cocultures; in 14 of 16 cocultivations, growth of legionellae was found	This is important for the disinfection process since bacteria within the amebae are protected and are more resistant to environmental manipulation	47
Amebae, in addition to serving as protective hosts, may play a role in the thermotolerance, invasiveness, and antibiotic resistance of bacteria	Considering the reduced immune status of many patients, this "symbiosis" of free-living amebae and bacteria might still be an underestimated but important hospital hygiene issue	66
A <i>Legionella</i> organism was isolated from a soil ameba; this bacterium is distinct from previously described species within the genus <i>Legionella</i>	Each time another different organism is isolated from free-living amebae, one wonders how many are capable of this symbiotic relationship and how many could ultimately be or become human pathogens	43
Free-living amebae are well adapted to their hostile environment and are resistant to desiccation, elevated temperatures, and various disinfectants	There is increasing interest in the potential role of free-living amebae as reservoirs and vectors of pathogenic bacteria	68
In a longitudinal study of 20 dental units, 96% of all water samples contained one or several ameba species; they were all within the <i>Naegleria gruberi</i> complex (no pathogenic strains are found within this group)	The occasional protective intracellular inclusion of legionellae in trophozoites of various species and cysts of acanthamoebae might provide an explanation for the resistance of legionellae to disinfection measures	41
The presence of adhered <i>Pseudomonas aeruginosa</i> on hydrogel contact lenses facilitated the binding of <i>Acanthamoeba</i> spp.	Cocontamination of lens systems with bacteria may be a prime factor in the development of amebic keratitis	21
Intracellular multiplication of <i>P. aeruginosa</i> has been found in free-living amebae	With their well-known resistance to chlorine, the amebae and their cysts are considered vectors for these intracellular bacteria	42
Studies indicate that the viability of <i>Acanthamoeba</i> cysts may be 25 years, during which they can maintain their invasive properties	This has tremendous environmental ramifications in terms of viability and virulence of the acanthamoebae	39

the warmed agar plate. Spread the bacteria on the surface of the agar with a bacteriological loop.

3. Inoculate the specimen on the center of the agar plate as described below.
 - A. For CSF samples, centrifuge the CSF at $250 \times g$ for 10 min. With a sterile serologic pipette, carefully transfer all but 0.5 ml of the supernatant to a sterile tube and store at 4°C (for possible future use). Mix the sediment in the rest of the fluid, and, with a Pasteur pipette, place 2 or 3 drops in the center of the nonnutrient agar plate that has been precoated with bacteria. After the fluid has been absorbed, seal the plates with a 5- to 6-in. length of 1-in.-wide Parafilm strip. Incubate the plate inverted at 37°C in room air. Using a wax pencil or laboratory marker, you may want to make a circle on the underside of the plate to indicate exactly where the specimen was inoculated onto the agar.
 - B. For tissue samples, triturate a small piece of the tissue (brain, lung, skin abscess, corneal biopsy, or similar specimens) in a small quantity (ca. 0.5 ml) of ameba saline. Process as above. Corneal smear, ear discharge material, etc., may be placed directly on the agar surface. Incubate central nervous system tissues at 37°C (room air) and tissues from other sites at 30°C .
 - C. Water samples of 10 to 100 ml may be processed to isolate these amebae. First, filter the water sample through three layers of sterile gauze or cheesecloth to remove leaves, dirt, etc. Next, either (i) filter the sample through a sterile $5.0\text{-}\mu\text{m}$ cellulose acetate membrane (47 mm in diameter), invert the membrane over a nonnutrient agar plate precoated with bacteria, seal, and incubate the plates as above; or (ii) centrifuge the water sample for 10 min at $250 \times g$. Aspirate the supernatant, suspend the sediment in about 0.5 ml of ameba saline, and deposit this suspension in the center of the nonnutrient agar plate precoated with bacteria. Seal and incubate the plate at 37°C as before.
 - D. For soil samples, mix about 1 g of the soil sample with enough ameba saline (ca. 0.5 to 1 ml) to make a thick slurry. Inoculate this slurry in the center of the nonnutrient agar plate precoated with bacteria, and incubate as above.
 - E. For contact lens solutions, small volumes (ca. 1 to 2 ml) may be inoculated directly onto the nonnutrient agar plates precoated with bacteria. Larger volumes (2 to 50 ml) should be centrifuged as in step 3, and the sediment should be inoculated onto the center of the nonnutrient agar plate and incubated as above.
4. Using the low-power ($10\times$) objective, examine the plates microscopically for amebae (cysts or trophozoites) every day for 10 days. Thin linear tracks (areas where amebae have ingested bacteria) might also be seen. If amebae are seen, circle that area with a wax pencil, carefully remove the Parafilm seal in a biological safety cabinet, open the lid of the petri dish, and carefully cut out the marked area from the agar with a spatula that has been heated to red hot and cooled before use to prevent contamination. Transfer the piece face down onto the surface of a fresh agar plate coated with bacteria, seal the plate with Parafilm, and incubate as before. *Naegleria* and *Acanthamoeba* spp. can be cultured by this method and, with periodic transfers, can be maintained in the laboratory indefinitely. In lieu of subcultures, the organisms can also be frozen for long-term storage. Under the microscope, the amebae resemble small uneven spots; observation for several seconds may reveal organism motility. After 4 to 5 days of incubation, the amebae begin to encyst and both trophozoites and cysts are visible. Unfortunately, *Balamuthia* spp. cannot be grown by using this system; they can be grown by using tissue culture methods on monkey kidney or lung fibroblast cell lines.
5. The enflagellation experiment is carried out as follows.
 - A. Examine the plates every day for signs of amebae. If present, amebae will feed on bacteria, multiply, and cover the entire surface of the plate within a few days. Once the food supply is exhausted, the amebae will differentiate into cysts.
 - B. Use a wax pencil to mark the area containing a large number of amebic trophozoites.
 - C. Using a bacteriological loop, scrape the surface of the agar at the marked area and transfer several loopfuls of the scraping to a sterile tube containing about 2 ml of sterile distilled water. Alternately, flood the surface of the agar plate with about 10 ml of sterile distilled water, gently scrape the agar surface with a loop, transfer the liquid to a sterile tube, and incubate at 37°C .
 - D. Periodically examine the tube with an inverted microscope for the presence of flagellates.
 - a. *N. fowleri*, the causal agent of primary amebic meningoencephalitis, undergoes transformation to a pear-shaped flagellate, usually with two flagella but occasionally with three or four flagella; the flagellate stage is a temporary nonfeeding stage and usually reverts to the trophozoite stage

(Figure 32.2). *N. fowleri* trophozoites are typically ameba-like and move in a sinuous way. They are characterized by a nucleus with a centrally located, large nucleolus. The trophozoites are also characterized by the presence of a contractile vacuole that appears once every 45 to 50 s and discharges its contents. The contractile vacuole looks like a hole or a dark depression inside the trophozoite and can be easily seen when examining the plate under the 10× or 40× objective. When the food supply is exhausted, *N. fowleri* trophozoites differentiate into spherical, smooth-walled cysts.

- b. In contrast, *Acanthamoeba* spp., which cause keratitis and granulomatous amebic encephalitis, do not transform into the flagellate stage. *Acanthamoeba* trophozoites are characterized by the presence of fine, thorn-like processes that are constantly extended and retracted. The trophozoites produce double-walled cysts characterized by a wrinkled outer wall (ectocyst) and a polygonal, stellate, oval, or even round inner wall (endocyst). The trophozoites are also characterized by the presence of the contractile vacuole, which disappears and reappears at regular intervals (45 to 50 s).
- c. The cysts of both *Acanthamoeba* and *Naegleria* spp. are uninucleate.

- d. Immunofluorescence and immunoperoxidase tests with monoclonal or polyclonal antibodies (available at the Centers for Disease Control and Prevention) are helpful in differentiating *Acanthamoeba* and *Balamuthia* spp. in fixed tissue.

Quality Control for Pathogenic Free-Living Amebae

The following control strains should be available when using these cultures for clinical specimens: ATCC 30010 (*A. castellanii*) and ATCC 30215 (*N. fowleri*). ATCC strains of *E. coli* or *E. aerogenes* are not necessary. Any routine clinical isolate or stock organism is acceptable.

1. Check all reagents and media (ameba saline, distilled water, and nonnutrient agar plates) each time they are used or periodically (once a week).
 - A. The media and all solutions should be free of any visible signs of precipitation and bacterial and/or fungal contamination.
 - B. Examine the nonnutrient agar plates under the 4× objective of an inverted or binocular microscope, and make sure that no fungal contamination has occurred.
2. Maintain stock cultures of *A. castellanii* and *N. fowleri* at 25°C.
 - A. Transfer stock cultures monthly, using nonnutrient agar plates prepared with Page's ameba saline and the bacterial overlay of *E. coli*.
 - B. *N. fowleri* measures 10 to 35 μm and demonstrates an eruptive locomotion by producing smooth hemispherical bulges. The cyst produces smooth (7- to 15-μm) walls. The flagellate stage does not have a cytostome.
 - C. *A. castellanii* is 15 to 45 μm and produces fine, tapering, hyaline projections called acanthopodia. It has no flagellate stage but produces a double-walled cyst with a wrinkled outer wall (10 to 25 μm).
 - D. Trophozoites of *Naegleria* and *Acanthamoeba* spp. are uninucleate, characterized by a large, dense central nucleolus.
 - E. For staining, a slide prepared from a stock strain of amebae is run in parallel with the patient slide. Staining results are acceptable when the control amebae stain well.
 - F. Plate both stock cultures onto fresh media, and incubate at 37°C parallel with the patient culture. Culture results are acceptable when growth appears by day 7.
 - G. Run *N. fowleri* in parallel with the patient culture being observed for enflagellation. The test results are acceptable when free-swimming,

Figure 32.2 *Naegleria fowleri* flagellate stage. When placed in distilled water (enflagellation test), *N. fowleri*, the causal agent of primary amebic meningoencephalitis, undergoes transformation to a pear-shaped flagellate, usually with two flagella but occasionally with three or four flagella; the flagellate stage is a temporary nonfeeding stage and usually reverts to the trophozoite stage.

pear-shaped flagellates with two flagella are observed in 2 to 24 h on the control slide.

- Depending on use, the microscope(s) may have to be calibrated (within the last 12 months), and the original optics used for the calibration should be in place on the microscope(s). The calibration factors for all objectives should be posted on the microscope for easy access.

Note For patient specimens, if a plate is positive for amebae and the amebae transform into flagellates, the specimen should be reported as positive for *N. fowleri*. If the amebae do not transform into flagellates even after overnight incubation, if the trophozoites possess the characteristic acanthopodia, if they show a large centrally placed nucleolus in the nucleus on trichrome stain, and if the trophozoites differentiate into the characteristic double-walled cysts, the specimen should be reported as positive for *Acanthamoeba* sp. For contact lens solution, if the plates are positive for amebae and the amebae do not transform into flagellates but differentiate into cysts with a wrinkled outer ectocyst and an inner stellate, polygonal, oval, or round endocyst, the specimen should be reported as positive for *Acanthamoeba* sp. *Naegleria* spp. have not been isolated from contact lens solutions; however, small amebae (e.g., hartmannellid or vahlkampfiid amebae, which produce smooth-walled cysts), probably contaminants, have occasionally been isolated from these solutions. Plates inoculated with water samples are usually positive for many genera and species of small free-living amebae (freshwater is their normal habitat). Therefore, the sample should be reported as positive for small free-living amebae. The physician should be notified immediately if patient specimens are positive for *Acanthamoeba* or *Naegleria* spp.

Most patient specimens, especially CSF, should be examined microscopically as soon as they arrive in the laboratory. However, if the specimen is very clear with no visible sediment, it should be cultured without being examined microscopically.

- After centrifugation, remove a small drop of the CSF sediment, place it on a microscope slide, cover it with a no. 1 coverslip, seal the edges of the coverslip with Vaspar (optional), and examine it immediately with the 10× or 40× objective (phase-contrast/differential interference contrast optics are preferred). If bright-field microscopy is used, reduce the illumination by adjusting the iris diaphragm.
 - The *N. fowleri* trophozoite is highly motile and can be identified by its sinuous movement. A warmed penny may be applied to the bottom surface of the slide to activate the movement

of the trophozoite. Occasionally, a flagellate is seen traversing the field.

- Acanthamoeba* trophozoites are rarely seen in the CSF. If present, they may be recognized by their characteristic acanthopodia, which are constantly extended and retracted. Both amebae, especially *Acanthamoeba* spp., may be recognized by the contractile vacuole.
- Contact lens care solutions (opened) can be processed and examined like CSF.
 - If very small amounts of tissue are received, they should be reserved for culture. If the specimen received is visibly contaminated with bacteria and/or fungi, the tube containing the specimen should be placed in an ice-water bath for 3 min prior to centrifugation. This causes any trophozoites attached to the walls of the tube to come off and drop into the fluid prior to centrifugation.
 - Material from the surface of a positive agar plate can be removed, fixed, and stained with trichrome for microscopic examination at a higher magnification (×1,000). Results obtained with wet mounts should always be confirmed by performing permanent stained smears (trichrome, iron hematoxylin) for nuclear characteristics to differentiate the amebae from host cells. Organisms may not be recovered if appropriate centrifugation speeds and times are not used.

Liquid Culture Media for Pathogenic Free-Living Amebae

Although *Acanthamoeba* spp. can be grown in serum-free liquid medium, *N. fowleri* requires the addition of fetal calf serum or brain extract to grow in a liquid medium. Peptone-yeast extract-glucose medium for *Acanthamoeba* spp. and Nelson's medium for *N. fowleri* are described below.

Peptone-Yeast Extract-Glucose (PYG) Medium for *Acanthamoeba* spp.

Proteose peptone (Difco)	20.0 g
Yeast extract (Difco)	2.0 g
Magnesium sulfate (MgSO ₄)	0.980 g
Calcium chloride (CaCl ₂)	0.059 g
Sodium citrate (Na ₃ C ₆ H ₅ O ₇ · 2H ₂ O)	1.0 g
Ferric ammonium sulfate [Fe(NH ₄) ₂ (SO ₄) ₂ · 6H ₂ O]	0.02 g
Potassium phosphate, monobasic (KH ₂ PO ₄)	0.34 g
Sodium phosphate, dibasic (Na ₂ HPO ₄ · 7H ₂ O).....	0.355 g
Glucose	18.0 g
Distilled water to.....	1,000.0 ml

Final pH is 6.5 ± 0.2 .

1. Dissolve all ingredients except CaCl_2 in about 900 ml of distilled water in a bottle or flask with a magnetic stirrer.
2. Add CaCl_2 while stirring.
3. Bring the volume to 1,000 ml with distilled water.
4. Dispense into 16- by 125-mm screw-cap tubes, 5 ml per tube.
5. Autoclave at 121°C for 15 min.
6. When tubes have cooled, label the tubes as *Acanthamoeba* medium with the preparation date and an expiration date of 3 months.
7. Store at 4°C .

Nelson's Medium for *N. fowleri*

Panmede (ox liver digest) (Difco) 1.0 g
 Glucose 1.0 g
 10× ameba saline (p. 917)..... 100.0 ml
 Double-distilled water to..... 900.0 ml

1. Add ameba saline to distilled water to make 1× ameba saline.
2. Dissolve the ingredients in ameba saline with a magnetic stirrer.
3. Dispense into 16- by 125-mm screw-cap tubes, 10 ml per tube.
4. Autoclave for 15 min at 15 lb/in².
5. Cool, and label as Nelson's medium with the preparation date and an expiration date of 3 months.
6. Store at 4°C .
7. Add 0.2 ml of heat-inactivated fetal calf serum to each tube before inoculating with the amebae.

Cell Culture

Acanthamoeba, *Balamuthia*, and *Naegleria* spp. can be inoculated onto a number of different mammalian cell lines. Culture options for *Sappinia diploidea* are not yet well defined. The organisms grow very well and demonstrate cytopathic effects, similar to those seen in routine viral cultures. However, most laboratories do not offer these methods on a routine basis.

Standard Commercial Media for Growth and Isolation of *Acanthamoeba* spp.

Several studies have reported on the use of standard commercial media used for growth and isolation of *Acanthamoeba* spp. Buffered charcoal-yeast extract agar (BCYE) is an excellent commercially available culture medium for the recovery of *Acanthamoeba* spp. (49, 50). Good trophozoite recovery was obtained using BBL Trypticase soy agar (TSA) with 5% rabbit blood, TSA with 5% horse blood, and

Remel TSA with 5% sheep blood. BBL TSA with 5% horse blood or 5% rabbit blood yielded good recovery of cysts. Nonnutrient agar with either live or dead bacteria yielded good recovery of trophozoites; however, live bacteria were required for good cyst recovery (49).

Pathogenic Flagellates

Specimens from women may consist of vaginal exudate collected from the posterior fornix on cotton-tipped applicator sticks or genital secretions collected on polyester sponges. Specimens from men can include semen, urethral samples collected with polyester sponges, or urine. Urine samples collected from the patient should be the first voided specimen in the morning. It is critical that clinical specimens be inoculated into culture medium as soon as possible after collection (11, 12, 32, 40, 57). Although collection swabs can be used, there are often problems with specimens drying prior to culture; immediate processing is mandatory for maximum organism recovery. The culture method is considered to be the most sensitive for the diagnosis of trichomoniasis; however, because of the time and effort involved, some laboratories have decided to use some of the new monoclonal antibody detection kits (6). Another approach would be to use the plastic envelope method for *Trichomonas vaginalis* (InPouch TV [BIOMED Diagnostics, San Jose, Calif.]), a simplified technique for the transport and culture that is illustrated in Figures 32.3 and 32.4 (6). Because of its long shelf life, relatively low expense, and high sensitivity, studies confirm that the pouch system provides a good diagnostic culture method for *T. vaginalis* (4, 46). It has been found to be more sensitive than either Diamond's or Trichosel medium (4).

Lash's Casein Hydrolysate-Serum Medium

Lash's casein hydrolysate-serum medium is a culture medium used to diagnose *T. vaginalis* (36).

Lash's Casein Hydrolysate-Serum Medium

Casamino Acids (Difco) 14.0 g
 Maltose 1.5 g
 Dextrose..... 2.0 g
 Sodium lactate (60% solution)..... 0.5 g

Dissolve in 500 ml of distilled water. To this solution, add:

NaCl 6.0 g
 KCl..... 0.1 g
 CaCl_2 0.1 g

1. Adjust the pH to 6.0 with concentrated phosphoric acid. Dispense in 5-ml aliquots, plug the tubes, and autoclave at 121°C for 15 min.

2. Prepare serum solution:

Whole beef blood serum	200 ml
Distilled water	300 ml
NaHCO ₃	0.1 g
3. Sterilize the serum solution by filtration.
4. The complete medium contains 5 ml of serum solution and 5 ml of basic solution for each tube.
5. Incubate the cultures at 37.5°C, and examine 24 and 48 h after inoculation.

T. vaginalis has been studied for a number of years with agar plate cultures for both cloning and diagnosis (2, 3, 28). Hollander (23) also suggests that colony morphology may be related to pathogenicity as well as being diagnostic. Many media are available for the isolation of *T. vaginalis*; some of these can be purchased commercially and have a relatively long shelf life.

CPLM (Cysteine-Peptide-Liver-Maltose) Medium

Ringer's solution

Sodium chloride (NaCl)	0.6 g
Sodium bicarbonate (NaHCO ₃)	0.01 g
Potassium chloride (KCl).....	0.01 g
Calcium chloride (CaCl ₂)	0.01 g
Double-distilled water to.....	100.0 ml

Dissolve the ingredients in the order listed, and bring the volume up to 100.0 ml with distilled water.

Liver infusion

Double-distilled water	330.0 ml
Bacto Liver Infusion powder (Difco)	20.0 g

1. Place the distilled water in a large beaker.
2. Add the liver infusion powder.
3. Infuse for 1 h at 50°C.
4. Raise the temperature to 80°C for 5 min to coagulate the protein.
5. Filter through a Whatman no. 1 paper with a Büchner funnel.

Figure 32.3 Illustration of the InPouch TV culture system for *Trichomonas vaginalis*. From top to bottom: (1) introduction of the specimen into the upper chamber containing a small amount of medium; (2) application of a plastic holder for microscope viewing prior to expressing medium into the lower chamber (optional); (3) transfer of a small amount of medium in the upper chamber to the lower chamber; (4) rolling down the upper chamber and sealing it with the tape; (5) plastic viewing frame used to immobilize the medium in the pouch for examination under the microscope. Specific photographs can also be seen in Figure 5.22. (Courtesy of BIOMED Diagnostics.)

Figure 32.4 InPouch TV culture system for *Trichomonas vaginalis*. Note the pouch, swabs, and plastic pouch holder for microscopic examination of the pouch contents. (Courtesy of BIOMED Diagnostics.)

Methylene blue solution

Methylene blue.....	0.5 g
Glass-distilled water.....	100.0 ml

Mix well until dissolved.

CPLM (Cysteine-Peptone-Liver-Maltose)

Complete Medium

Bacto Peptone (Difco)	32.0 g
Bacto Agar (Difco)	1.6 g
Cysteine HCl.....	2.4 g
Maltose	1.6 g
Bacto Liver Infusion (Difco).....	320.0 ml
Ringer's solution	960.0 ml

1. With a magnetic stirrer, mix Ringer's solution and the liver infusion in a large beaker.
2. Add peptone, maltose, cysteine HCl, and agar in that order, and heat the mixture until dissolved.
3. Add 0.7 ml of aqueous methylene blue.
4. Adjust the pH to 5.8 to 6.0 with 1 N NaOH or 1 N HCl.
5. Dispense 8-ml volumes into culture tubes.
6. Autoclave at 121°C for 15 min.
7. Aseptically add 2 ml of human serum, heat inactivated at 56°C for 30 min and cooled, per tube. Horse serum is recommended as a replacement for human serum, particularly when considering safety issues such as handling human blood and blood products.
8. Label as CPLM medium with the preparation date.

9. Store at room temperature. Use as long as the amber zone indicating an anaerobic condition persists.

Diamond's TYM (Trypticase-Yeast Extract-Maltose) Complete Medium

Trypticase (BBL)	20.0 g
Yeast extract (BBL).....	10.0 g
Maltose	5.0 g
L-Cysteine HCl	1.0 g
L-Ascorbic acid.....	0.2 g
Potassium phosphate, dibasic (K ₂ HPO ₄)	0.8 g
Potassium phosphate, monobasic (KH ₂ PO ₄)	0.8 g
Bacto Agar (Difco)	0.5 g
Double-distilled water	900.0 ml

1. Dissolve the buffer salts in the distilled water with a magnetic stirrer.
2. Add the remaining ingredients except the agar, in the order given, one at a time until dissolved.
3. Adjust the pH to 6.0 with 1 N HCl.
4. Add agar, and heat to dissolve.
5. Autoclave at 121°C for 15 min.
6. Cool to 45°C, and add 100 ml of bovine, sheep, or horse serum that has been inactivated for 30 min at 56°C.
7. Aseptically dispense 10-ml volumes to 16- by 125-mm screw-cap tubes.
8. Label as TYM medium with the preparation date and an expiration date of 10 days.
9. Store at 4°C.

Hollander's Modification of TYM Complete Medium

Hollander's modification of TYM complete medium differs from TYM medium by the replacement of cysteine with additional ascorbic acid and the addition of potassium chloride, potassium carbonate, and ferrous sulfate (7).

Casein digest peptone

(Trypticase, BBC)	20.0 g
Yeast extract	10.0 g
Maltose	5.0 g
Ascorbic acid	1.0 g
Potassium chloride (KCl).....	1.0 g
Potassium bicarbonate.....	1.0 g
Potassium phosphate, monobasic (KH ₂ PO ₄)	1.0 g
Potassium phosphate, dibasic (K ₂ HPO ₄)	0.5 g
Ferrous sulfate	0.1 g
Distilled water	600 ml

Proceed as described above for Diamond's TYM complete medium.

Note Hollander also includes agar to 0.05%.

Diamond's Complete Medium (Modified by Klass)

Trypticase (BBL)	24.0 g
Yeast extract (BBL).....	12.0 g
Maltose	6.0 g
Cysteine HCl	1.2 g
Ascorbic acid.....	0.24 g
Double-distilled water	900.0 ml

1. Dissolve the ingredients one at a time in the order given.
2. Adjust the pH to 6.0 with 1 N HCl or 1 N NaOH.
3. Dispense in 12.5-ml aliquots to 16- by 125-mm screw-cap tubes.
4. Autoclave at 121°C for 15 min.
5. When cool (50°C), add 1 ml of sterile inactivated horse serum and 0.5 ml of antibiotic mixture to each tube.
6. Label as modified TYM medium with the date of preparation and an expiration date of 3 weeks.

Antibiotic Mixture

Sodium penicillin G.....	1,000,000 U
Streptomycin sulfate	1,000,000 µg
Fungizone (amphotericin B).....	2,000 µg
Sterile double-distilled water	50.0 ml

1. Mix thoroughly.
Concentration of stock solution is:
Penicillin
 20,000 U/ml |
- Streptomycin.....
 20,000 µg/ml |
- Fungizone
 40 µg/ml |
2. Dispense 1 ml of the antibiotic mixture into sterile screw-cap vials or sterile cryovials.
3. Label as antibiotic solution with the date of preparation and an expiration date of 1 year.
4. Store at -20°C in cryoboxes.

Serum Substitutions

Bovine, sheep, or horse serum can be substituted in the step involving CPLM complete medium.

Axenic Culture

1. Inoculation of culture medium.
 - A. Remove tubes containing culture medium from 4°C, and incubate at 37°C for 1 to 2 h.
 - B. Vigorously shake the cotton-tipped portion of the applicator stick containing the patient

specimen in the medium, and then break off the tip with sterile forceps and drop it into the medium.

- C. If the material is collected on polyester sponges, drop the sponges into the medium and shake the tube.
 - D. Centrifuge urine samples for 10 min at 250 × g, aspirate the supernatant, and inoculate the sediment into the medium.
 - E. Examine the tubes daily for several days, and subculture if necessary. To subculture, first shake the tube to disperse the organisms uniformly, remove about 1 to 2 ml, and inoculate into a warmed, fresh tube.
 - F. Incubate the tubes in a slanted position (45° angle).
 - G. Incubate the control tubes and those containing patient material for at least 72 to 96 h.
 - H. Examine the entire length of the tube. If the specimen is positive, *T. vaginalis* will be found freely swimming or attached to the tube walls.
 - I. Do not report negative results until 96 h.
2. To maintain stock cultures,
 - A. With an inverted microscope, examine stock culture tubes of *T. vaginalis* for any signs of bacterial contamination. Select one or more tubes showing good growth. Since the tubes are incubated in a slanted position, usually at an angle of 45°, a thick button of organisms is seen at the bottom of the tube. Gently invert the tube once or twice to disperse the trichomonads uniformly, and examine the tubes again. A large number of the organisms should be freely swimming, and a few will be attached to the tube walls.
 - B. Immerse the tubes in a bucket of ice-cold water for about 5 to 10 min to dislodge the trichomonads from the tube walls. Invert the tubes several times to distribute the organisms.
 - C. With a sterile Pasteur pipette, remove about 1.0 to 1.5 ml; inoculate 0.5 to 1.0 ml into a fresh tube. Inoculate the rest of the fluid into nutrient agar, brain heart infusion, and thioglycolate broth for routine monitoring of bacterial contamination. Inoculate several additional tubes this way, and incubate the cultures slanted at a 45° angle at 37°C as before.
 - D. If growth is poor and only few organisms are present along with a lot of debris, centrifuge the tube at 250 × g for 10 min, aspirate the supernatant, transfer the sediment to a fresh tube, and incubate as before.

Quality Control for Pathogenic Flagellates

ATCC 30001 (*T. vaginalis*) should be available as a control strain when these cultures are used for clinical specimens.

1. Check all reagents and media (at least once a week). All media, including Ringer's solution, should be free of any signs of precipitation and bacterial and/or fungal contamination.
2. Depending on use, the microscope(s) may have had to be calibrated within the last 12 months, and the original optics used for the calibration should be in place on the microscope(s). The calibration factors for all objectives should be posted on the microscope for easy access.
3. Maintain stock cultures of ATCC 30001 (*T. vaginalis*).
 - A. Transfer stock cultures weekly.
 - a. Stock organisms should always be cultured at the same time a patient specimen is inoculated into culture medium.
 - b. If the stock organisms multiply and remain viable during the 96 h, patient results can be reported.
 - B. Stain
 - a. A slide prepared from a stock strain of *T. vaginalis* is run in parallel with the patient slide.
 - b. Staining results are acceptable when the control organisms stain well.
4. Control organisms must be cultured each time a patient specimen is inoculated into the culture medium.

Note If no trophozoites are seen after 4 days of incubation, discard the tubes and report the culture as negative. Results of patient specimens should not be reported as positive unless control cultures are positive. Cultivation is the most sensitive method for the diagnosis of trichomoniasis. Every effort, therefore, must be made to inoculate patient materials into culture medium. However, since this method may take as long as 3 to 4 days and the patient materials occasionally contain nonviable organisms, it is imperative that microscopic examination of wet smears and/or stained smears (Giemsa) also be performed.

Axenic Cultivation of *T. vaginalis* in a Serum-Free Medium

Mammalian serum or bovine serum albumin is required for *T. vaginalis* grown under axenic conditions. However, these components inhibit several biological properties of these parasites. PACSR is a serum replacement, free of bovine serum albumin, which is used for axenic cultivation of *E. histolytica*. Studies indicate that PACSR added to several

of the standard media used for the cultivation of *T. vaginalis* can support growth in the absence of serum (38).

Flagellates of Blood and Tissue

The first types of media used to culture the blood and tissue flagellates, which are still useful for establishment of cultures, were undefined and contained a complex mixture of ingredients. Improvements led to semidefined formulations that included tissue culture media as a base and, as a next step, addition of tissue culture cells as a feeder layer to promote parasite growth. Newer developed media are completely defined, having replaced the feeder cells with various supplements. Serum, a variable component of the media, can now be replaced by various serum substitutes. Fully defined formulations are available for the cultivation of many of these organisms (55).

For the hemoflagellates found in the bloodstream, probably the most direct means of diagnosis is by examination of a Giemsa-stained blood smear under the microscope. However, if isolation of the parasite is required for confirmation, culture can be used. The easiest approach involves the use of NNN medium. Because of its relatively short shelf life (2 to 4 weeks with refrigeration) and the infrequent need for culture, most clinical laboratories would not routinely stock NNN medium. However, the CDC (Division of Parasitic Diseases, Atlanta, Ga.) can provide NNN medium for inoculation with blood or skin biopsy specimens, which can be returned to CDC for workup. In other parts of the world, major reference laboratories may provide a similar service. The procedure for isolating *Leishmania* spp. from patients with suspected cases of cutaneous, mucocutaneous, and visceral leishmaniasis is basically similar to that for isolating *Trypanosome* spp. The amastigote found within host cells, or the promastigote that develops from the amastigote in culture, would be confirmatory. Punch biopsy specimens or needle aspirates serve as the inocula for NNN medium or Schneider's *Drosophila* medium with 30% fetal bovine serum. Other procedures such as splenic puncture and liver biopsy can also yield material but are invasive and less likely to be performed (55).

Specimens for culturing *Leishmania* spp. may consist of aspirates, scrapings, or biopsy material from skin lesions of patients with cutaneous leishmaniasis; bone marrow aspirates or, more rarely, splenic aspirates from visceral leishmaniasis patients; or normal skin biopsy specimens, lymph node aspirates, or pieces of liver and spleen from suspected or potential wild- or domestic-animal reservoirs. Ensure that the skin surrounding the ulcer is thoroughly cleaned and swabbed with 70% alcohol (sterile saline is not acceptable as a cleansing agent) and allowed to dry before the sample is removed. Also

ensure that alcohol does not get into the ulcerated area or broken skin. A punch biopsy specimen taken from the advancing margin of the lesion is often recommended. If skin biopsy fragments are placed in transport medium (RPMI medium supplemented with 10% fetal calf serum) maintained at ambient temperature, delays in transit through the mail will still not prevent recovery of the organisms. In one study, after being received in the laboratory (transit time as long as 3 to 17 days), the biopsy specimens were ground in sterile saline and inoculated into NNN culture tubes. The tubes were incubated at 25°C and subcultured every week until the fifth week. Cultures were positive in 9 of 16 cases in all seasons and for three different *Leishmania* species. Thus, delayed culture can still yield valuable results from biopsy specimens obtained taken under field conditions (9).

It is imperative that only a few drops of bone marrow juice or spleen aspirate be inoculated into tubes. Inoculate several tubes with a few drops each rather than inoculating a single tube with a large volume (1 to 2 ml), since the serum in the specimen may contain leishmanicidal or inhibitory factors that prevent the growth of organisms. Alternatively, bone marrow juice may be centrifuged for 10 min at 250 × g and the sediment may be washed in 0.85% saline by centrifugation and then inoculated into culture tubes. Buffy coat from the blood sample rather than whole blood should be inoculated. Because the leishmanias are fastidious organisms and all isolates may not grow in any one medium, it is imperative that at least two media be used; for example, use NNN or modified Tobie's medium and Schneider's *Drosophila* medium.

Specimens for culturing *Trypanosoma cruzi* may consist of blood or the gut contents of the triatomid bug. It is advisable to use two different media such as liver infusion-tryptose (LIT) and NNN for the initial isolation of *T. cruzi*. Once growth is established, use the medium in which best growth is obtained for subculture. According to James Sullivan, LIT medium, when used as an overlay on Tobie's slants, is excellent for isolation and diagnosis (55). The major culture form is the epimastigote; occasionally, however, trypomastigotes and amastigotes are also seen.

NNN Medium (Leishmaniasis or Chagas' Disease) (22)

Bacto Agar (Difco)	1.4 g
Sodium chloride (NaCl).....	0.6 g
Double-distilled water	90.0 ml

1. Mix the NaCl and agar in the distilled water in a 500-ml flask.
2. Heat the mixture until the agar melts.
3. Autoclave at 121°C for 15 min.
4. Cool to about 50°C.

5. Add 10 ml of aseptically collected, defibrinated rabbit blood.

Note Although blood collected with EDTA as the anticoagulant can be used for routine stock culture subcultures, it may not be quite as effective as defibrinated blood in isolating organisms from patient specimens. Certainly, if defibrinated blood is not available, blood collected with EDTA as the anticoagulant can be used. Make sure that the rabbit blood is fresh (no older than 10 days). It should be aseptically collected and stored at 4°C until used.

6. Dispense 4 ml into 16- by 125-mm sterile screw-cap culture tubes.
7. Place the tubes at a 10° angle (shallow slant position) until the agar sets.
8. Immediately transfer the tubes into test tube stands, and let stand upright at 4°C so that the bottom portion of the slants is covered with the water of condensation. Rapid cooling increases the water of condensation (Figure 32.5).
9. Label as NNN medium with the preparation date and an expiration date 3 weeks from the date of preparation.
10. Store at 4°C.

NNN Medium, Offutt's Modification (Leishmaniasis)

Blood Agar Base (Difco)	8.0 g
Double-distilled water	200.0 ml

1. Heat until the agar is dissolved in the distilled water in a 500-ml flask.
2. Autoclave at 121°C for 15 min.
3. Cool to about 50°C.
4. Add 15 ml of aseptically collected, defibrinated rabbit blood.
5. Dispense 4 ml into 16- by 125-mm sterile screw-cap culture tubes.
6. Place the tubes at a 10° angle (shallow slant position) until the agar sets.
7. Immediately transfer the tubes to test tube stands, and let stand upright at 4°C so that the bottom portion of the slants is covered with the water of condensation. Rapid cooling increases the water of condensation.
8. Label as Offutt's medium with the preparation date and an expiration date 3 weeks from the date of preparation.
9. Store at 4°C.

Overlay Solution (To Be Used with NNN or NNN Modified)

Sodium chloride (NaCl).....	4.5 g
Double-distilled water	500.0 ml

1. Autoclave at 121°C.
2. Dispense 4 ml aseptically into 16- by 125-mm sterile culture tubes.
3. Label as 0.9% saline with the preparation date and an expiration date 3 weeks from the date of preparation.
4. Store at 4°C.

Evan's Modified Tobie's Medium (Leishmaniasis or Chagas' Disease) (22)

Beef extract (Oxoid Lab-Lemco L29)	0.3 g
Bacteriological peptone (Oxoid L37).....	0.5 g
Sodium chloride (NaCl).....	0.8 g
Agar (Oxoid purified).....	2.0 g
Double-distilled water	100.0 ml

1. Mix all the ingredients in the distilled water in a large beaker with a magnetic stirrer.
2. Heat the mixture until the agar melts.
3. Dispense 5 ml into 16- by 125-mm screw-cap culture tubes.
4. Autoclave at 121°C for 15 min.
5. Cool to about 50°C.
6. Add 1.2 ml of aseptically collected, defibrinated horse blood.
7. Hold the tubes upright in the palm of your hand, and roll the tubes gently to mix the blood and the agar well.
8. Place the tubes at a 10° angle (shallow slant position) until the agar sets.
9. Immediately transfer the tubes into test tube stands, and let stand upright at 4°C so that the bottom portion of the slants will be covered with the water of condensation. Rapid cooling increases the water of condensation.
10. Label as Evan's modified Tobie's medium with the preparation date and an expiration date 3 weeks from the date of preparation.
11. Store at 4°C.

Overlay Solution (To Be Used with Tobie's Medium)

Potassium chloride (KCl).....	0.4 g
Sodium phosphate, dibasic (Na ₂ HPO ₄ · 12H ₂ O)	0.06 g
Potassium phosphate, monobasic (KH ₂ PO ₄)	0.06 g
Calcium chloride (CaCl ₂ · 2H ₂ O)	0.185 g
Magnesium sulfate (MgSO ₄ · 7H ₂ O)	0.1 g
Magnesium chloride (MgCl ₂ · 6H ₂ O).....	0.1 g
NaCl.....	8.0 g
L-Proline	1.0 g

Phenol red	0.5 ml
Double-distilled water	1,000.0 ml

1. Place 750 ml of double-distilled water in a 1-liter beaker, and add the above ingredients one at a time in the order listed until dissolved. Use a magnetic stirrer.
2. Adjust the pH to 7.2 by adding slowly, while stirring, solid Tris.
3. Bring up the volume to 1,000 ml with distilled water.
4. Dispense 100 ml into each of several screw-cap flasks or bottles.
5. Autoclave at 121°C for 15 min.
6. Label as overlay solution with the preparation date and an expiration date of 1 month.
7. Store at 4°C.

NIH Method for Trypanosomes and Leishmaniae

Solution 1

Lean beef, desiccated.....	25.0 g
Neopeptone.....	10.0 g
Agar	10.0 g
NaCl	2.5 g
Distilled water.....	500 ml

Solution 2 (Locke's Solution)

NaCl	8.0 g
KCl.....	0.2 g
CaCl ₂	0.2 g
KH ₂ PO ₄	0.3 g
Dextrose.....	2.5 g
Distilled water.....	1,000 ml

1. Infuse the beef and distilled water in a water bath at 37°C for 1 h. Heat for 5 min at 80°C.
2. Filter through filter paper (Whatman no. 2V).
3. Add the rest of the above ingredients (solution 1), and adjust the pH to 7.0 to 7.4 with NaOH.
4. Autoclave at 121°C for 20 min.
5. Cool to 45°C, and aseptically add 10% defibrinated rabbit blood.
6. Dispense 5-ml quantities in sterile tubes. Slant and cool.
7. Just before inoculation, overlay with 2 ml of sterile Locke's solution.

4 N Medium for Trypanosomes and Leishmaniae

The 4 N medium was adapted from the original formula described by Novy and McNeal (44, 45, 58).

4 N Medium for Trypanosomes and Leishmaniae**Agar base**

Oxoid blood sugar base no. 2	40 g
Distilled water	1,000 ml

1. Mix the agar and water, and dissolve by autoclaving or steaming.
2. Dispense liquid agar in 5-ml aliquots into 30-ml screw-cap glass bottles.
3. Autoclave again if necessary for sterility.
4. When the medium has cooled to 45°C, add aseptically to each bottle approximately 1 ml of fresh rabbit blood and allow the agar to solidify in a slant.

Overlay for 4 N medium

1. Add 1 ml of Locke's (see NIH method for trypanosomes and leishmaniae) solution to each bottle containing 5 ml of agar.
2. Incubate the bottles at 37°C for 12 to 24 h to check for sterility.
3. Store the bottles at 4°C for 24 h or more before use.

Yaeger's LIT Medium (for Chagas' Disease) (22)

Liver infusion (Difco)	35.0 g
Tryptose (Difco)	5.0 g
NaCl.....	4.0 g
KCl.....	0.4 g
Sodium phosphate, dibasic (Na ₂ HPO ₄ · 12H ₂ O)	8.0 g
Glucose.....	2.0 g
Hemin (stock solution)	4.0 ml
Double-distilled water	1,000.0 ml

1. Add all the ingredients to the distilled water, and mix well with a magnetic stirrer until dissolved. Heat, if necessary, to dissolve all the ingredients.
2. Using a Whatman no. 42 filter paper in a Büchner funnel, filter with suction. Repeat this filtration one more time.
3. Adjust pH to 7.2 with 1 N NaOH or 1 N HCl.
4. Sterilize by filtration through a 0.22- μ m-pore-size membrane filter.
5. Dispense 4.5 ml into each tube.
6. Label as LIT medium, with the date of preparation and an expiration date of 1 month.

Hemin Stock Solution

Hemin.....	100.0 mg
Triethanolamine.....	10.0 ml
Sterile double-distilled water.....	10.0 ml

1. Mix triethanolamine with water, add the mixture to a tube containing hemin, shake well, and let dissolve.

2. To make the complete medium, just before inoculation, add 0.5 ml of inactivated fetal bovine serum and 0.25 ml of antibiotic solution. The final concentrations of the antibiotics are 100 U of penicillin per ml, 100 μ g of streptomycin per ml, and 0.2 μ g of Fungizone per ml.

USAMRU Blood Agar Medium for Leishmaniae (67)

Blood agar base (Difco, B45).....	40.0 g
Defibrinated rabbit blood.....	150.0 ml
Double-distilled water	1,000.0 ml

1. Dissolve 40 g of agar in 1,000 ml of distilled water by heating.
2. Cool the solution, and add 150 ml of defibrinated rabbit blood.
3. Dispense 5-ml portions into 125- by 16-mm screw-cap tubes. Position the tubes at a slant, and allow to cool, preferably on ice, to produce moisture of condensation in the tubes.
4. Incubate the tubes at 35°C for 24 h to ensure sterility. Antibiotics (penicillin and streptomycin) can be added if necessary (see the antibiotic formula in this chapter). The final concentrations of antibiotics are 100 U of penicillin per ml and 100 μ g of streptomycin per ml.
5. Inoculate the medium with aspirate material or triturated tissue from biopsy specimen.

Note This medium has been especially useful for primary isolation of the *Leishmania braziliensis* complex in Latin America.

Liquid Media for Cultivation of Hemoflagellates

Hendricks et al. have reported on the highly successful use of liquid culture media for the rapid cultivation of various species of *Leishmania* and *Trypanosoma* (22). Schneider's *Drosophila* medium (GIBCO, Grand Island, N.Y.), supplemented with 30% (vol/vol) fetal calf serum, has been used in making primary isolates from human and animal infections as well as for routine maintenance of a wide variety of leishmanial and trypanosomal species in the laboratory. Both Schneider's medium and Grace's insect tissue culture medium (GIBCO) promote better growth of organisms and are less costly than the widely used blood-agar-based media. In addition, Schneider's medium may be freeze-dried for at least 2 years and reconstituted with distilled water in the field, and it will provide excellent culture results.

Stock Antibiotic Solution (To Be Used with All Media)

Sodium penicillin G	1,000,000 U
Streptomycin sulfate	1,000,000 μ g

Fungizone 2,000 µg
 Sterile double-distilled water 50.0 ml

- Mix the components thoroughly. The concentration of the stock solution is:
 - Penicillin..... 20,000 U/ml
 - Streptomycin 20,000 µg/ml
 - Fungizone..... 40 µg/ml
- Dispense 1 ml of the antibiotic mixture into sterile screw-cap vials or sterile cryovials.
- Label as antibiotic solution with the date of preparation and an expiration date of 1 year.
- Store at -20°C in cryoboxes.

Axenic Culture

- Remove tubes containing culture medium (one of NNN, modified NNN, or Tobie's medium and one of Schneider's for *Leishmania*; one of NNN or Tobie's medium and one of LIT for *T. cruzi*) from 4°C , add fetal bovine serum and antibiotics if required, and incubate at 20 to 23°C for 1 to 2 h.
- Inoculate the specimen (aspirate, scraping, or biopsy material from skin lesions from cutaneous leishmaniasis patients; bone marrow aspirates or splenic aspirates from visceral leishmaniasis patients; or normal skin biopsy specimens, lymph node aspirates, or pieces of liver and spleen from suspected or potential wild- or domestic-animal reservoirs) into the culture tubes. For Chagas' disease, inoculate a few drops of buffy coat into the culture tubes.
- Add 0.5 ml of overlay (either saline or other overlay, depending on the medium). The organisms will develop in the fluid condensate and overlay at the bottom of the slant (Figure 32.5).
- Incubate the tubes at 20 to 24°C .
- Once every 2 to 3 days, remove a drop of medium and examine it under the low power ($100\times$) of a microscope, preferably one equipped with phase-contrast optics.
- If promastigotes are seen, inoculate a couple of drops of the medium into fresh culture tubes. Add a couple of drops of 0.85% saline or the overlay solution (depending on the culture medium used) to the old tube.
- If visible contamination occurs, add antibiotics to the overlay (to contain 200 U of penicillin/ml and 200 µg of streptomycin/ml). The parasites will not proliferate if bacterial contamination is present.
- Incubate the tubes containing the patient specimen for at least 2 weeks at 28°C or room temperature.

Figure 32.5 Illustration of a tube of NNN medium, used for the culture and recovery of *Leishmania* spp. (A) Fluid condensate and tissue culture medium overlay containing the developing organisms. (B) Blood agar medium. (Illustration by Sharon Belkin.)

- If no organisms are seen even after 2 weeks of incubation, examine several drops of fluid under the microscope for promastigotes. The culture should be observed for 1 month before being signed out as negative. Transfers to fresh medium should be made once or twice a week after the culture is established.

Quality Control for Flagellates of Blood and Tissue

The following control strains should be available when using these cultures for clinical specimens: ATCC 30883 (*Leishmania mexicana*) and ATCC 30160 (*T. cruzi*).

- Check all reagents and media at least once a week. The media should be free of any signs of precipitation and bacterial and/or fungal contamination.
- The microscope(s) should have been calibrated within the last 12 months, and the original optics used for the calibration should be in place on the microscope(s). The calibration factors for all objectives should be posted on the microscope for easy access.
- Maintain stock cultures of *Leishmania* spp.
 - Transfer stock cultures weekly.
 - Stock organisms should always be cultured at the same time a patient specimen is inoculated into culture medium.

- b. If the stock organisms multiply and remain viable during the 96 h, patient results can be reported.

B. Stain

- a. Stain a slide prepared from stock culture in parallel with the patient slide.
b. Staining results are acceptable when the control organisms stain well.

Note Cultivating the organism from suspected materials provides a definitive diagnosis, but it may take as many as 3 to 7 days. Every effort, therefore, must be made to microscopically examine wet smears and/or permanent stained smears so that appropriate therapy can be instituted without delay if findings are positive (Figure 32.6) (16, 17).

Toxoplasma gondii

The diagnosis of toxoplasmosis may be difficult, because the clinical symptoms mimic a number of various infectious and noninfectious diseases. Serologic tests that are often used for diagnosis may be insensitive in patients lacking normal immune responses. Sometimes even examination of histologic material does not reveal the organisms. With the increase in the number of laboratories

Figure 32.6 *Leishmania* spp. from culture systems. (Upper left) Wet mount of culture fluid sediment showing promastigotes of *Leishmania* spp. (Upper right) Stained smear of culture fluid sediment showing promastigotes of *Leishmania* spp. (Lower left) Stained *Leishmania* spp. promastigotes. (Lower right) Stained *Leishmania* promastigotes (note the round nucleus, bar-shaped kinetoplast, and flagella).

using tissue culture techniques for viral pathogens, these techniques have been used for the isolation and identification of *T. gondii*. The following procedure has been recommended for biopsy specimens, brain, liver, spleen tissue, CSF, amniotic fluid, and buffy coat preparations, and they may be particularly helpful in making the diagnosis in immunosuppressed patients (56). The procedure for buffy coat cells is as follows.

1. Collect 10 ml of blood anticoagulated with preservative-free heparin.
2. Allow the blood to sediment via gravity.
3. Remove the buffy coat (by an aseptic technique), and separate the cells from the plasma by centrifugation at $800 \times g$ for 10 min.
4. Wash the buffy coat cells three times with Eagle's minimal essential medium (GIBCO).
5. Inoculate the washed buffy coat material onto complete human foreskin fibroblast (HFF) monolayers (in tubes and shell vials). One HFF tube and two HFF vials should be inoculated for each patient specimen.
6. Observe the cultures weekly for cytopathic effect.
7. The shell vial coverslips can be fixed and stained at 7 and 14 days postinoculation for an indirect fluorescent-antibody (IFA) assay and observed for the tachyzoites.

Note CSF, placental tissue, or other tissues can also be used to inoculate tissue culture monolayers. Uncentrifuged CSF (0.1 to 1 ml) can be used. If more than 1 ml is submitted, the specimen should be centrifuged for 10 min at $500 \times g$. Positive and negative controls must be tested with each set of patient specimen vials.

Three continuous cell lines (HeLa, LLC, and Vero) and three cell culture methods (culture in conventional flasks, culture in membrane-based flasks, and an automated culture system) were investigated. Overall, HeLa was the cell line of choice. Continuous passage in flasks was successful, and HeLa-derived tachyzoites can be used for the dye test, if applicable in your laboratory setting (18).

Plasmodium and *Babesia* spp.

Techniques for the culture of *Plasmodium falciparum* were described in 1976 (59, 61) and have been improved and modified since that time (10, 15, 19, 25, 26, 60; S. Waki, T. Miyagami, S. Nakazawa, I. Igarashi, and M. Suzuki, Letter, *Trans. R. Soc. Trop. Med. Hyg.* 78:418, 1984). Life cycle stages of the four *Plasmodium* spp. that infect humans have been established in vitro. Of these four, *P. falciparum* is the only species for which all stages have been cultured in vitro. The life cycle includes the

exoerythrocytic stage (within liver cells), the erythrocytic stage (within erythrocytes or precursor reticulocytes), and the sporogonic stage (within the vector). Culture media generally consist of a basic tissue culture medium to which serum and erythrocytes are added. Most of the culture methods have been directed toward the stage found in the erythrocyte. This stage has been cultivated in petri dishes or other containers in a candle jar to generate elevated CO₂ levels or in a more controlled CO₂ atmosphere. Later developments employed continuous-flow systems to reduce the labor-intensive requirement for replenishing the system with fresh media. The exoerythrocytic and sporogonic life cycle stages have also been cultivated in vitro. Although cultivation is of great help in understanding the biology of *Plasmodium*, it does not lend itself to use for routine diagnostic purposes (54).

The availability of the microaerophilous stationary phase (MASP) culture technique, in which the parasites proliferate in a settled layer of blood cells, has provided an opportunity to study *Babesia*, a formerly obscure disease agent regarded as within the purview of veterinary parasitology, in the laboratory. A number of *Babesia* spp. have been established in continuous culture using the MASP technique. It is possible to study the basic biology of the organism—as well as host-microbe interactions, immune factors triggered by the parasite, factors involved in innate resistance of young animals to infection, and antimicrobial susceptibility—to a degree not possible before the availability of cultures. These culture systems can produce quantities of parasite nucleic acid needed for defining phylogenetic relationships, developing diagnostic methods for parasite detection in asymptomatic individuals, and producing parasite antigens and attenuated strains of *Babesia* that could be used for immunization (52).

Cryptosporidium spp.

The in vitro cultivation of *Cryptosporidium* has improved significantly in recent years. These obligate intracellular parasites colonize the epithelium of the digestive and respiratory tracts, are often difficult to obtain in significant numbers, produce durable oocysts that defy conventional chemical disinfection methods, and are persistently infectious when stored at refrigerator temperatures (4 to 8°C). While continuous culture and oocyst production have not yet been achieved in vitro, routine methods for parasite preparation and cell culture infection and assays for parasite life cycle development have been established. Parasite yields tend to be limited, but in vitro growth is sufficient to support a variety of research studies, including assessing potential drug therapies, evaluating oocyst disinfection methods, and characterizing life cycle stage development and differentiation (1).

Microsporidia

Although various microsporidia that infect humans can be identified from clinical specimens by serologic and/or molecular methods, none of these methods are commercially available. Unfortunately, in some cases microscopic examination of biopsy specimens does not yield conclusive results. It is also possible that microsporidial organisms may be present in very small numbers, which can be easily missed during routine histologic examinations. Some microsporidia such as *Encephalitozoon* and *Brachiola* spp., even when they are present in small numbers, can become established in cell cultures, thus facilitating their identification at a later time. Therefore, attempts at culturing these organisms should be made whenever possible, since many clinical laboratory personnel are familiar with cell culture methodology (64).

Animal Inoculation

Most routine clinical laboratories do not have the animal care facilities necessary to provide animal inoculation capabilities for the diagnosis of parasitic infections. Host specificity for many animal parasite species is a well-known fact which limits the types of animals available for these procedures. In certain suspect infections, animal inoculation may be requested and can be very helpful in making the diagnosis, although animal inoculation certainly does not take the place of other, more routine procedures.

Leishmania spp.

The hamster is the laboratory animal of choice for the isolation of any form of *Leishmania* spp. A generalized infection results after intraperitoneal inoculation; spleen impression smears should be examined for the presence of organisms.

1. Aspirates or biopsy material obtained under sterile conditions from cutaneous ulcers, lymph nodes, spleen, liver, bone marrow, buffy coat cells, or CSF may be used for inoculation.
2. Material (0.25 to 1 ml) obtained from these sources should be inoculated under sterile conditions by the intraperitoneal route. Material from patients with mucocutaneous leishmaniasis should be inoculated by the intranasal route or into the feet.
3. Young (either sex) hamsters (2 to 4 months old) should be used for this procedure.
4. If the animal dies several days after inoculation, splenic aspirates should be examined for the presence of organisms. The material should be

prepared as thick blood films and stained with Giemsa or other blood stains.

Note The infection develops slowly in hamsters; several months may be required to produce a detectable infection. For this reason, culture procedures are usually selected as more rapid means of parasite recovery. Intranasal lesions or those in the feet may develop very slowly; experimental animals should be kept for 9 to 12 months before a negative report is sent out.

Trypanosoma spp. (20)

Several laboratory animals can be used for the recovery of trypanosomes. Organisms are usually found in the blood of the animals within the first week after inoculation; however, if no organisms are found, the animals should be checked at the end of 2 and 4 weeks before results are reported as negative. *Trypanosomes are infectious, so extreme care should be used when examining any blood or tissue suspected to contain these organisms.*

1. Blood, lymph node aspirates, tissue, or CSF obtained under sterile conditions may be used for inoculation.
2. Material (up to 2 ml) should be inoculated intraperitoneally into guinea pigs or white rats for *Trypanosoma gambiense* and *T. rhodesiense* and into white mice for *T. cruzi*.
3. The number of organisms in the blood may vary; therefore, smears should be prepared frequently (every few days) over a 4-week period after inoculation.

Note Rats should be checked for the presence of *T. lewisi* (common parasite in rats) before inoculation to prevent a possible false-positive result.

Toxoplasma gondii

All common laboratory animals can be infected by *T. gondii*. White rats and mice are generally used. White rats develop a chronic infection that can be a useful means of maintaining a strain of organisms. Mice that have been inoculated by the intraperitoneal route develop a fulminating infection that leads to death within a few days. Tremendous numbers of organisms can be recovered from the ascitic fluid. These specimens should be handled carefully to avoid an accidental laboratory infection.

General Procedure

1. The *Toxoplasma* organisms are found throughout the body after dissemination via the bloodstream. Any body tissue or fluid can be used for animal

inoculation; the most common specimens are blood, lymph node fluid, and CSF.

2. The material used for inoculation (the amount may be very small [less than 0.25 ml]) should be obtained under sterile conditions and should be inoculated via the intraperitoneal route.
3. White mice of either sex and any age can be used. The animals should be checked daily for symptoms of illness.
4. After several days, the organisms can be recovered at necropsy from the peritoneal fluid of the mouse. The material should be prepared as thick blood films and stained with Giemsa or other blood stains.
5. Blind passage of peritoneal fluid to additional mice is recommended if the original mice appear to be negative.
6. If mice survive for up to 6 months, serum can be tested for the presence of antibody.

Procedure for Tissue

1. Grind the tissue in sterile 0.85% NaCl.
2. Prepare a 10% suspension (10% tissue, 90% NaCl).
3. Inoculate six mice via the intraperitoneal route. Each mouse should receive 1 ml.
4. The mice can be reinoculated the following day with an additional 1-ml dose.
5. Check the mice daily for symptoms.
6. If the animals are not sick at the end of 6 days, examine 1 drop of peritoneal fluid from each mouse directly and then stain it with Giemsa stain.

Xenodiagnosis

Xenodiagnosis is a technique that uses the arthropod host as an indicator of infection. Uninfected reduviid bugs are allowed to feed on the blood of a patient who is suspected of having Chagas' disease (*T. cruzi* infection) (34) (Figure 32.7). After 30 to 60 days, feces from the bugs are examined over a 3-month time frame for the presence of developmental stages of the parasite, which are found in the hindgut of the vector. This type of procedure is used primarily in South America for field work, and the appropriate bugs are raised in various laboratories specifically for this purpose.

The term "xenodiagnosis" has also been applied to the diagnosis of trichinosis (*Trichinella spiralis*). Muscle tissue from a patient suspected of having the disease is fed to uninfected rats; the rats are then checked after the appropriate time for the presence of *T. spiralis* larvae, particularly in the diaphragm. This procedure is rarely requested and is not available in most clinical laboratories.

Figure 32.7 Illustration of the process of xenodiagnosis used for the diagnosis of Chagas' disease. (Illustration by Sharon Belkin.)

Fixation of Parasite Specimens and Arthropods

Adequate fixation of parasites is important not only for diagnostic procedures but also as a means of preserving positive material for personnel and student training. There are many fixatives and preservatives available; however, only the more common ones are presented here.

Although this chapter does not include commentary related to the histopathology laboratory, some information about formalin fixatives may be helpful. Concerns about the toxicity of formalin, particularly in the quantities used in a routine histology laboratory, have led to trials of alternative methods of tissue fixation that do not require formalin. Alcohol-based fixatives have been proposed as optimal for immunohistochemical and nucleic acid methods and may be useful for diagnostic light microscopy. Some laboratories have converted to use of an alcoholic fixative (containing 56% ethanol and 20% polyethylene glycol). Although comparative scores between the two were slightly in favor of the formalin, there were no significant differences in terms of tissue architecture, cell borders, cytoplasm, nuclear contours, chromatin texture, red blood cell membranes, and uniformity of staining. Alcohol-polyethylene glycol appears to be a satisfactory alternative to formalin in routine diagnostic surgical pathology (3). In another study, Histochoice produced a staining intensity that was comparable, and in many cases superior, to that of formalin (26).

Formalin-fixed and paraffin-embedded tissues present particular challenges for proteomic analysis. However, most archived tissues in pathology departments and tissue banks worldwide are available in this form. Different approaches to removal of the embedding medium and protein digestion have been developed, thus releasing tryptic peptides, which are suitable for analysis by liquid chromatography-mass spectrometry. Peptide identifications made using this approach are comparable to those from matched fresh frozen tissue. Apparently, a high level of sequence coverage can be seen for proteins under study (21).

The effect of fixation on the degradation of nuclear and mitochondrial DNA in different tissues has been examined (19). Samples of different tissues were preserved in seven fixatives for periods extending from 1 to 336 days to determine which fixatives reduce the time-dependent degradation of DNA and preserve the histologic structure. For long-term storage in combination with amplification of nuclear and mitochondrial DNA, consistent results were

obtained with Carnoy's solution and glutaraldehyde. Variable results were observed for buffered formalin. In regard to comparison of the different tissues, the quantities recovered from skeletal muscles and kidneys were larger than from other tissues. These fixative studies will become even more important as molecular methods applied to fixed tissues become more common.

Molecular characterization of morphologic change requires precise tissue morphology and RNA preservation; however, traditional fixatives usually result in fragmented RNA. To optimize molecular analyses of fixed tissues, morphologic and RNA integrity in rat liver was assessed when sections were fixed in 70% neutral-buffered formalin, modified Davidson's II medium, 70% ethanol, UMFIX, modified Carnoy's solution, modified methacarn, Bouin's medium, phosphate-buffered saline, or 30% sucrose. Each sample was treated with standard or microwave fixation and standard or microwave processing, and sections were evaluated microscopically. RNA was extracted and assessed for preservation of quality and quantity (4). Modified methacarn, 70% ethanol, and modified Carnoy's solution resulted in tissue morphology providing a reasonable alternative to formalin. Modified methacarn and UMFIX best preserved RNA quality. Neither microwave fixation nor processing affected RNA integrity relative to standard methods, although morphology was somewhat improved. Modified methacarn, 70% ethanol, and modified Carnoy's solution provided acceptable tissue morphology and RNA quality with both standard and microwave fixation and processing methods. Of these three fixatives, modified methacarn provided the best results and can be considered a fixative of choice where tissue morphology and RNA integrity are being assessed in the same specimens.

PCR has also been used to identify tissue-embedded ascarid nematode larvae. Two sequences of the internal transcribed spacer regions of the rRNA gene of the ascarid parasites (ITS1 and ITS2) were compared with those registered in GenBank. PCR amplification of the ITS regions was sensitive enough to detect a single larva of *Ascaris suum* mixed with porcine liver tissue. These results suggest that even a single larva embedded in tissues from patients with larva migrans could be identified by sequencing the ITS regions (13).

Although formalin fixation is the most common storage, transportation, and preservation method for stool samples, it dramatically reduces the ability to extract DNA from stool samples for PCR-based diagnostic tests. Apparently, the deleterious effects of formalin are both time and concentration dependent and may result from fragmentation of fixed DNA during its purification. This has been seen in studies of the effect of formalin fixation on PCR of *Entamoeba histolytica* (22).

Parasites found in feces can be preserved in one of two ways (9). One procedure involves thorough mixing of the fecal specimen directly in the fixative. This mixture can then be stored at room temperature without any additional processing. There are several disadvantages of this method: (i) if mixing is not complete, some of the organisms will not be well preserved and will disintegrate during storage; (ii) if the number of organisms is small, a random aliquot may not reveal the parasites; and (iii) the proper ratio of fixative to specimen may not be correct when one is working with larger volumes of material.

The second approach is to clean and separate the organisms from excess debris and concentrate them before fixation. The specimens can be mixed with a large volume of water, passed through a series of screens (large to small pore size), and finally allowed to sediment in a conical container (pilsner glass). After approximately 1 h, the sediment can be washed several times, resedimented, and finally fixed with hot (60 to 63°C) fixative to quickly preserve and stop any further development of certain helminth (*Ascaris* and *Trichuris*) eggs. The main disadvantage of this method is extensive washing and manipulation, which may lead to some organism distortion or destruction before fixation.

The adult forms of most helminths must be relaxed prior to fixation. If this preliminary step is not performed, the worms often contract and curl up when they come in contact with the fixative, thus preventing visual examination of some of the key morphologic characteristics. Several methods, including those involving tap water, physiologic saline, and dilute menthol, are available for this purpose.

Protozoa

Definitive morphology needed for identification of protozoan trophozoites and cysts is best seen on the permanent stained smear, which can be prepared from fresh fecal specimens or from stool that has been submitted to the laboratory in fixative. No washing techniques should be used before bulk fixation, because the trophozoites will be destroyed. Immediately after collection or submission to the laboratory, the specimens should be thoroughly mixed with the fixative of choice. The ratio of fixative to stool should be at least 3 parts fixative to 1 part stool, and the fixation time should be at least 4 h (or less, depending on the amount of specimen used). The normal collection vial systems usually require a fixation time of at least 30 min. If an entire fecal specimen is used, 4 h is recommended. Individual slides can then be prepared from bulk-fixed material by a technique described by Scholten and Yang (24). This method involves centrifugation and smear preparation from the sediment. Although

formalin-preserved specimens, except for sodium acetate-acetic acid-formalin-preserved fecal material, are not recommended for the preparation of permanent stained smears, formalin fixation for cyst preservation is recommended for the preservation of teaching specimens. The morphology of cysts can often be seen in formalinized wet mounts sufficiently well to identify organisms to the species level or certainly to be highly suggestive.

Streck tissue fixative has also been tested as a substitute for formalin and polyvinyl alcohol in fecal preservation. Stool samples were examined microscopically as follows: (i) in wet mounts (by bright-field and epifluorescence microscopy), (ii) in modified acid-fast-, trichrome-, and safranin-stained smears, and (iii) with two commercial test kits. Specific results showed that *Cyclospora* oocysts retained full fluorescence, modified acid-fast- and safranin-stained smears of *Cryptosporidium* and *Cyclospora* oocysts were equal in staining quality, and results were comparable in the immunofluorescence assay and enzyme immunoassay commercial kits. However, stool fixed in Streck tissue fixative and stained with trichrome showed unacceptable staining quality compared with stool fixed in polyvinyl alcohol. Thus, Streck fixative is an excellent substitute for formalin; however, modifications to the trichrome procedure will be required to improve the staining characteristics of protozoan parasites (20).

Formalin-Saline Solution

Although formalin is generally used at room temperature for routine diagnostic work, hot (60 to 63°C) 5% formalin in a ratio of 3 parts fixative to 1 part stool is recommended for bulk specimens containing intestinal protozoa. Long-term storage of protozoa is enhanced with buffered formalin; *the solution should be replaced every 6 months*. Acceptable morphology for teaching purposes can be maintained for 6 months to several years, depending on the organism and the lag time between specimen collection and fixation. The organism cytoplasm will tend to become glassy or granular with very poor nuclear definition. Cysts of *Entamoeba coli* and *Giardia lamblia* tend to maintain their morphologic characteristics for years, whereas cysts of *E. histolytica* and *E. hartmanni* do not preserve well (Figure 33.1). All of these cysts retain their ability to take up iodine in a wet, direct smear.

The standard 10% formalin will fix protozoan cysts; however, it does not preserve morphology as well as does the buffered 5% formalin.

Formalin-Saline Solution

- Formaldehyde..... 5 ml
- 0.85% saline solution..... 95 ml

Figure 33.1 (Left) *Entamoeba coli* cyst (unstained). (Right) *Giardia lamblia* cyst (unstained).

Formaldehyde is normally purchased as a 37% HCHO solution; however, for dilution, it should be considered to be 100%.

Buffered Formalin-Saline Solution

- Formaldehyde..... 400 ml
- 0.85% saline solution..... 7,600 ml
- Na₂HPO₄ 6.10 g
- NaH₂PO₄ 0.15 g

10% Formalin Solution

- Formaldehyde..... 10 ml
- Distilled water..... 90 ml

Solutions To Induce Relaxation in Adult Helminths (1)

Tap Water or Physiologic Saline

1. Place living worms into a dish containing tap water or 0.85% NaCl solution.
2. Refrigerate the dish for 2 to 4 h.

Note Tap water generally works better than saline; also, the trematodes expel their eggs, thus allowing the internal morphology to be seen more clearly.

Dilute Menthol (17)

1. Dissolve 24 g of menthol crystals in 10 ml of 95% ethyl alcohol, and mix well.
2. Store the solution until needed.
3. Place living worms into a dish containing 100 ml of tap water or 0.85% NaCl.
4. Add 1 drop of menthol solution to the dish containing the worms.
5. Refrigerate the dish for 2 to 3 h.

Note The use of menthol accelerates relaxation of the worms. When this approach is used, the rostellum on

the scolex of adult cestodes remains extruded during fixation.

Nematodes

Roundworms can be preserved with several different fixatives (Figure 33.2). Formalin is usually not recommended, since it tends to harden the tissues. Nematodes can be killed with hot water (60 to 63°C) and then transferred to a preservative, such as alcohol-glycerin or alcohol-formalin-acetic acid (AFA). It is recommended that nematode larval stages be fixed in hot water. Direct fixation in preservatives may cause the cuticle to become “sticky,” and the larvae will be damaged when they adhere to the glass container (9).

Alcohol-Glycerin

Alcohol (70%) containing 5% glycerin is an excellent fixative for most nematodes and should be used hot (60 to 63°C). Specimens can be left in this original fixing solution indefinitely. The glycerin will protect the specimen if the alcohol evaporates. Fixative evaporation is another reason why fixed specimens should be routinely checked every 6 months for possible fixative replacement.

Alcohol-Glycerin

95% ethyl alcohol.....	70 ml
Distilled water.....	25 ml
Glycerin.....	5 ml

AFA Solution

A solution of alcohol, formalin, and acetic acid can be routinely used for nematodes, trematodes, and cestodes.

Figure 33.2 Adult *Ascaris lumbricoides* nematode (male worm).

The fixative should be used hot (60 to 63°C); after fixation for 24 h, parasites can be stored in the alcohol-glycerin mixture.

AFA Solution

Formaldehyde.....	10 ml
95% ethyl alcohol.....	50 ml
Acetic acid, glacial.....	5 ml
Distilled water.....	45 ml

Glacial Acetic Acid

Undiluted glacial acetic acid is recommended for fixation of the smaller nematodes (Figure 33.3). They are killed instantly in an extended position. This fixative is not recommended for the larger worms, such as *Ascaris lumbricoides*. The acetic acid will clear the worm tissue so that the internal structure becomes visible. Morphologic characteristics can be seen under the microscope if the worm is placed in water on a slide. Worms fixed with acetic acid can be placed in AFA for 24 h and then into alcohol-glycerin for long-term storage.

Dilute Formalin

Although formalin is not recommended as a general fixative for nematodes, a dilute solution (1 to 2%) can be used to kill *A. lumbricoides*. Higher concentrations should not be used since the differences in osmotic pressure may cause the worms to rupture. After storage in dilute formalin for at least 24 h, the worms can be transferred to 10% formalin for long-term storage.

Note *Ascaris* eggs continue to develop in formalin (10% or less) to the infective stage and remain viable and infective for a number of months (Figure 33.4). Worms should be handled with caution, particularly if they are to be dissected.

Figure 33.3 Adult *Trichuris trichiura* nematode (note the “whiplike” appearance; this is a much smaller adult worm than *Ascaris lumbricoides*).

Figure 33.4 *Ascaris lumbricoides* fertilized eggs. Note the fully developed larva within each egg; these eggs were viable when photographed. In some cases, the moving larva can be seen, even in formalin-preserved specimens.

Trematodes

Most trematodes are very muscular and may contract when placed in fixatives. Living specimens should be placed in cold 0.85% saline for 30 min to several hours (depending on the size of the worm) before fixation. Specimens can be placed on a slide in a petri dish and then covered with another slide or coverglass to flatten the worm. Do not apply pressure, since doing so may distort internal organs (Figure 33.5).

Note Formalin is never recommended for the fixation of trematodes (9).

Figure 33.5 Adult *Fasciola hepatica* trematodes. (Upper) Preserved but unstained fluke; (lower) stained fluke (note the morphologic details that can be seen after staining).

AFA fixative (see above) should be used hot (60 to 63°C); the worms can be stored in AFA or transferred to 70% alcohol for long-term storage.

Cestodes

Acid fixatives dissolve the characteristic calcareous corpuscles found in tapeworm tissue and should not be used. Since these corpuscles may be used to diagnosis tapeworm tissue in histologic sections, buffered formalin or non-acid-containing fixatives are recommended (9).

Formalin

Hot (60 to 63°C) buffered formalin is recommended for the fixation of cestodes. If the whole worms are immediately swirled around in the container of fixative, they will be rapidly fixed with minimal contraction of the proglottids.

AFA Solution

AFA fixes tapeworm tissue well; however, the acid dissolves the calcareous corpuscles. The worms can be transferred to 70% alcohol for long-term storage (Figure 33.6).

Note All tapeworms and proglottids should be handled with care, especially if the species has not been determined. The eggs of *Taenia solium* (cysticercosis) and *Hymenolepis nana* are infectious for humans (Figure 33.7).

Helminth Eggs and Larvae

Whole fecal specimens can be mixed directly with an appropriate fixative, although it is recommended that the organisms be concentrated before fixation. The use of formalin-saline as described for the fixation of protozoa is recommended for helminth eggs and larvae. If well preserved, most helminth eggs maintain their morphologic characteristics indefinitely.

Arthropods

Clinical laboratory personnel may receive arthropods for identification from various patient sources (surface of the body, stool, sputum, etc.) (6, 12). Specimens may be

Figure 33.6 *Taenia* unstained proglottid. Note that morphologic details cannot be seen in this preserved but unstained preparation.

Figure 33.7 (Left) *Taenia* spp. egg (note the striated shell and hooklets seen on the oncosphere). (Right) *Hymenolepis nana* egg (note the six-hooked embryo and the polar filaments that are found between the oncosphere and the shell).

submitted when the actual source is unknown (implicated in a bite, found in the house or yard, etc.). Small, wingless insects and other arthropods should be placed in alcohol (70 to 95%), where they can remain indefinitely. Formalin fixative is not recommended for such specimens. Most flying insects should be killed in a chloroform tube or cyanide bottle and then preserved as a dry mount. Large maggots and other larvae can be killed in hot water first to prevent body shrinkage and contraction when placed in alcohol (8). A number of books also contain detailed information on the collection, preservation, and mounting of arthropods (10, 16, 25).

DNA sequencing has become much more common in surveys of archival research collections, particularly in reviewing rare taxa of arthropods. As an example, marine invertebrates have historically been maintained in ethanol following initial fixation in formalin. These collections often represent rare or extinct species or populations, provide detailed time series samples, or come from presently inaccessible or difficult-to-sample localities. Results obtained from preserved crustaceans in archival research collections indicate that in the absence of fresh or frozen tissues, archived formalin-fixed, ethanol-preserved specimens will prove a useful source of material for gene sequence data analysis by PCR and direct sequencing (7). It has also been determined that the now widespread use of critical-point drying of wasps and other insects from alcohol is advocated as a potential source of DNA from rare taxa (5).

Another problem that has been documented involves morphology changes seen using various fixatives. Thus, fixation and mounting can significantly influence the morphometric analysis of mites and other arthropods. It is recommended that morphometric studies be conducted using consistent methods to reduce experimental bias and that the methods used be reported in publications dealing with morphometric analyses (23).

Modified Berelese's medium is an all-purpose medium that kills, fixes, and preserves many arthropod specimens. No dehydration in alcohol is necessary.

Modified Berelese's Medium

Gum acacia.....	8 g
Distilled water	8 ml
Glycerin.....	5 ml
Chloral hydrate	70 g
Acetic acid, glacial.....	3 ml

Mounting and Staining of Parasite Specimens for Examination

Following preservation, many staining and mounting techniques for the preparation of permanent or semi-permanent mounts of helminth eggs and larvae and of arthropods may be used.

Nematodes

Because the cuticle of nematodes prevents the uptake of stain, these worms are usually rendered transparent with glycerin or lactophenol. In this way, the internal morphology can be observed for identification purposes. Specific morphologic features that can be seen include the cuticle, alimentary tract, and reproductive structures. Small nematodes can be mounted in glycerin jelly. Standard mounting media containing resins and dehydrating agents are generally not satisfactory because the worms tend to collapse and become distorted during dehydration.

Glycerin Jelly Preparation

Specimens are transferred from pure glycerin directly into the glycerin jelly, a medium that will gel at room temperature, thus providing a semipermanent mount.

Glycerin Jelly (Refractive Index, 1.47)

Gelatin, granulated.....	10 g
Distilled water	60 ml
Glycerin, pure	70 ml
Phenol crystals, melted.....	0.5 ml

Dissolve the gelatin in water in a beaker in a water bath. Add the glycerin and melted phenol. Store in small, wide-mouth bottles, and refrigerate. Remelt in a hot water bath before use. Dispense with a dropper onto the slide.

1. Nematodes should first be killed in glacial acetic acid, AFA, or alcohol-glycerin.
2. Place nematodes in a small dish containing 70% alcohol–5% glycerin solution (several millimeters deep).
3. Partially cover the dish to allow gradual evaporation of the alcohol and water for approximately 24 to 36 h. The larger the nematodes, the longer the time needed to complete the evaporation.

Note The evaporation procedure should be done slowly to prevent collapse of the worm; the larger the specimen, the longer the evaporation time.

4. Transfer the worms to another dish containing a few milliliters of glycerin. The specimen should be placed just below the surface; it will eventually (within a few hours) sink to the bottom of the dish. It is then ready to be mounted.
5. Place a drop of liquefied glycerin jelly on the slide, and transfer the specimen into the drop. When the coverglass is added, the glycerin jelly should flow out to the edges of the coverglass. Allow the glycerin jelly to begin to solidify, and apply the coverglass. If the specimen is large, place the coverglass onto small pieces of broken glass to provide more depth under the coverglass.
6. Allow the preparation to gel overnight (horizontal position). The following day, the coverglass can be sealed with Vaspar or enamel paint. These preparations usually last for several years, particularly if no unnecessary pressure is applied to the coverglass.

Note If personnel are not experienced in preparation of these permanent mounts, remember that the worms can be stored indefinitely in vials of pure glycerin. They can be studied in this medium as temporary mounts and then carefully returned to the vial of glycerin.

Glycerin

Nematode specimens can be examined as temporary mounts and subsequently stored in pure glycerin. This approach is particularly helpful for larger specimens (Figure 33.8).

Lactophenol

Lactophenol is recommended when larger specimens are to be examined as temporary mounts. The worms can be placed into lactophenol from alcohol or formalin; clearing

Figure 33.8 Semipermanent mounts of small nematodes. (Left) Small nematode from soil sample. (Right) Female *Enterobius vermicularis* (pinworm) nematode.

will occur, with the length of time depending on the size of the worm. The worms can then be washed in alcohol.

Lactophenol (Refractive Index, 1.44)

Glycerin, pure	20 ml
Lactic acid	10 ml
Phenol crystals, melted	10 ml
Distilled water	10 ml

Trematodes

Trematodes are usually studied as stained whole mounts (Figure 33.9). Two stains that are recommended are carmine and hematoxylin. Many modifications are found in the literature, and most give excellent results. The stains are usually available commercially, and they can also be easily prepared in the laboratory.

Semichon’s Acid Carmine

Carmine powder	5 g
Distilled water	50 ml
Acetic acid, glacial	50 ml

Add glacial acetic acid slowly to the water. Add the carmine powder, and heat to 95 to 100°C for 15 min. Cool and filter (stock solution). Add few drops of stock solution to 70% alcohol, making the working stain pink.

Van Cleave’s Combination Hematoxylin Stain

Van Cleave’s combination hematoxylin stain is a combination of Delafield’s hematoxylin and Ehrlich’s hematoxylin that rarely overstains trematode specimens.

Figure 33.9 Stained trematodes. (Left) *Eurytrema* sp. (Right) *Heterophyes* sp. Note that the morphologic details are clearly visible after staining.

Delafield's Hematoxylin Stain

Hematoxylin powder	4 g
Ethyl alcohol, 95%	25 ml
Aluminum ammonium sulfate [AlNH ₄ (SO ₄) ₂], saturated aqueous solution (aluminum alum solution).....	400 ml
Glycerin.....	100 ml
Methyl alcohol	100 ml

Dissolve the hematoxylin in ethyl alcohol, add aluminum alum solution, and let stand for 1 week exposed to air and light (in a paper-capped container). Filter; add glycerin and methyl alcohol. Age for 6 to 8 weeks in a tightly capped bottle in the refrigerator. This is the working stain solution (no dilution is needed).

Ehrlich's Hematoxylin Stain

Hematoxylin powder	2 g
Ethyl alcohol, 95%	100 ml
Glycerin.....	100 ml
Distilled water.....	100 ml
Acetic acid, glacial.....	10 ml
Potassium aluminum sulfate [K ₂ SO ₄ Al ₂ (SO ₄) ₃ · 12H ₂ O] (potassium alum)	3 g

Dissolve hematoxylin powder in alcohol; add the other ingredients. Expose to air and light for at least 2 weeks (in a paper-capped container). The solution can be ripened immediately by the addition of 0.4 g of sodium iodate (NaIO₃). Store refrigerated in a tightly capped bottle. This is the working solution (no dilution is needed).

Van Cleave's Hematoxylin Staining Solution

Delafield's hematoxylin stain.....	1 ml
Ehrlich's hematoxylin stain	1 ml
Distilled water	100 ml
Potassium aluminum sulfate.....	6 g

Dissolve the potassium alum in water and add the two hematoxylin stains. This is the working solution.

1. Staining should be done in dilute solutions of carmine or hematoxylin (at least overnight). Specimens stained in carmine are placed into the dilute stain from 70% ethyl alcohol. Those stained in hematoxylin are placed in the stain from water. It is best to overstain and then destain.
2. Rinse in 70% ethyl alcohol.
3. Destain in weak acid-alcohol (2 to 4 drops of concentrated HCl in 100 ml of 70% ethyl alcohol). Leach the color from tissues until they are clear but

the internal organs remain well stained. Destaining may take several minutes to hours; however, the specimens must be periodically checked to avoid overdestaining.

4. Rinse in 70% alcohol.
5. Place the specimens for 30 min to 1 h in a solution of 70% ethyl alcohol containing 1 or 2 drops of saturated aqueous Na₂CO₃, NaHCO₃, or LiCO₃. This step neutralizes the acid step and prevents continued destaining.
6. Rinse in 70% ethyl alcohol.
7. Dehydrate through 80, 95, and 100% ethyl alcohol, with 11 to 15 min for each alcohol change.
8. Clear the specimens in xylene for at least 15 min.
9. Mount in Permount or other permanent mounting medium.

Cestodes

Cestodes can also be examined as stained whole mounts, although the *Taenia* tapeworms can be examined more rapidly with India ink in a temporary mount. The same carmine and hematoxylin stains as used for trematodes can be used for cestodes.

India Ink Procedure for Tapeworm Proglottids

Identification of adult worms usually involves examination of a tapeworm proglottid. A *Taenia* proglottid must be gravid, containing the fully developed uterine branches. Using a syringe (1 ml or less) and a 25-gauge needle, India ink is injected into the central uterine stem of the proglottid, filling the uterine branches with ink, or into the uterine pore. The proglottid can then be rinsed in water or saline, blotted dry on paper towels, pressed between two slides, and examined. After the identification has been made, the proglottid can be left between the two slides (place a rubber band around the slides), dehydrated through several changes of ethyl alcohol (50, 70, 90, and 100%), cleared in two changes of xylene, and mounted with Permount for a permanent record. After the xylene step, the proglottid will be stuck to one of the two slides; do not try to remove it (it is very brittle and will crack) but merely add the Permount to the proglottid and then add the coverglass (Figure 33.10).

Euparal Mounts of Tapeworm Proglottids

Most helminth eggs mounted in Euparal (Flatters and Garnett, Ltd., Manchester, England) exhibit excellent optical and drying properties, and this mounting medium can also be used to mount tapeworm proglottids (2). Proglottids should be placed in 100% ethyl alcohol for 5 to 10 min and then pressed between two slides as described above. They should then be placed in Euparal; transparency

Figure 33.10 *Taenia* gravid proglottids after India ink injection of the uterine branches. (Left) *Taenia solium*. (Right) *Taenia saginata*.

will occur in 2 to 3 h. The best results have been obtained by keeping the slides in a 50°C incubator overnight.

Double-Coverglass Method for Microscopic Mounts of Cysts, Eggs, and Larvae

Slides prepared by the double-coverglass technique will last for several weeks to several years, depending on the organisms and the care taken in preparation. The procedure is as follows (9).

1. Place a small drop of 10% formalin or formalin-saline suspension (containing cysts, eggs, and/or larvae) in the center of a 22-mm round or square coverglass.
2. Using forceps, very carefully apply a smaller coverglass (12, 15, or 18 mm round or square) to the suspension so that the fluid flows to the edges of the small coverglass (with no bubbles). If excess fluid flows beyond the small coverglass, it should be blotted dry or allowed to evaporate. Do not allow it to dry too long; otherwise, bubbles will accumulate under the coverglass.
3. Place a large drop of Permount or other permanent mounting medium in the center of a 1- by 3-in. (1 in. = 2.54 cm) microscope slide. Using forceps, place the double-coverglass preparation (small coverglass side down) onto the mounting medium so that the medium flows to the edges of the large coverglass.
4. Allow the preparation to thoroughly dry in a horizontal position (this may take several days).

Mounting of Arthropods for Examination (11, 14, 15, 18)

Before being mounted, specimens in which xylene is used as a solvent require dehydration through 50, 70, and 95% ethyl alcohol. Clearing can be done in clove oil, carbol-xylene (3 parts xylene to 1 part phenol crystals), or absolute ethyl alcohol followed by xylene. The specimens should remain in each solution for at least 15 to 20 min. Specimens mounted in balsam or Permount will take several days to harden; however, those mounted in isobutyl methacrylate will dry very rapidly (within a few hours). With this type of permanent mount, ringing or sealing of the coverglass is not necessary. Some specific recommendations are presented below.

Mites

Temporary mounts can be made with a drop of 50% ethyl alcohol, which is gently heated. Clearing and extension of the specimen occur, revealing the typical morphology (Figure 33.11). Permanent mounts of living specimens can be made by placing the specimen in a drop of chloral-gum medium, adding a coverglass, and then gently heating until bubbling begins. Specimens originally preserved in alcohol must first be washed in distilled water to remove the alcohol.

Chloral-Gum Medium

Distilled water	35 ml
Chloral hydrate	30 g
Gum arabic.....	20 g
Glycerin.....	12 ml
Glucose syrup (e.g., Karo syrup)	3 ml

Fleas and Lice

Specimens may be preserved in 70% alcohol or mounted on slides for identification (Figure 33.12).

Figure 33.11 *Sarcoptes scabiei* itch mites in wet mounts. These specimens could be seen using the high dry objective (magnification, ×400).

Figure 33.12 (Left) Body louse, *Pediculus humanus*. (Right) Flea, *Pulex irritans*.

1. Drop living fleas or preserved specimens into 10% KOH for a few days until sufficiently cleared.
2. Transfer for 30 min to a small volume of water containing a few drops of concentrated HCl.
3. Dehydrate in 50% ethyl alcohol for 30 min.
4. Dehydrate in 95% ethyl alcohol for 30 min.
5. Clear in beechwood creosote for 1 h, or place in several changes of absolute ethyl alcohol and clear in clove oil or xylene.
6. Mount on slides in balsam, Permount, or isobutyl methacrylate.

Ticks

Specimens should be preserved in 70% alcohol or cleared and mounted on slides. They can be fixed in an extended position by gently being pressed between two slides while being immersed in hot water. Clearing in KOH, dehydration in alcohols, and mounting with balsam, Permount,

Figure 33.13 Ticks. (Left) Example of a hard tick, *Ixodes scapularis*. (Right) Example of a soft tick, *Argas* sp.

Figure 33.14 Example of a large hard-body insect, which is a triatomid bug. These large insects can be pinned, labeled, and stored in boxes containing naphthalene flakes or paradichlorobenzene.

or isobutyl methacrylate can be done as recommended for fleas (Figure 33.13).

Miscellaneous Arthropods

Spiders, scorpions, centipedes, lice, bedbugs, maggots and other larvae, nymphs, and soft-bodied insects can be preserved in 70% ethyl alcohol containing a small amount of glycerin to prevent drying and shrinkage. Containers should remain tightly sealed and should be checked periodically. Larger, hard-bodied insects can be pinned, labeled, and stored in boxes containing naphthalene flakes or paradichlorobenzene to prevent damage from mold and living insects (Figure 33.14).

Note Identification of the many species of arthropods can best be handled by an entomologist or specialist working with a particular arthropod group. Additional help with identification may be obtained at a local university entomology department, a military base (over 100 entomologists are employed by the Army and Navy), or the entomology department of natural history museums or the Smithsonian Institution.

Lymphocytes

Red blood cells

Charcot-Leyden crystals

Nonhuman elements seen in feces (yeast cells)

Insect larvae

Spurious infections

Delusory parasitosis

Although many body sites and specimens can be examined for the presence of parasites, the most difficult specimen in which to differentiate parasites from artifacts is usually fecal material. Feces consist of a number of components, including (i) undigested food residue; (ii) digestive by-products; (iii) epithelial cells, mucus, and other secretions from the digestive tract; and (iv) many types of microorganisms such as bacteria and yeasts. Considering the ratio between fecal debris and parasites, it is not surprising that many artifacts are responsible for incorrect identifications of protozoan trophozoites and cysts and of helminth eggs and larvae. Often, many yeast cells and other artifacts are confused with coccidian oocysts or microsporidial spores. Appropriate training, adherence to protocols, use of quality control measures, and availability of reference materials and consultants should help minimize identification errors.

Protozoa

A number of cells and other organisms can easily be confused with intestinal protozoa. These are listed in Tables 34.1 and 34.2 and illustrated in Figure 34.1.

Amebae

Occasionally, free-living amebae are found in feces or as contaminants in water. Morphologically, they differ from parasitic amebae in having one or more large contractile vacuoles in the trophozoite form and having very thick cyst walls. They can also be differentiated on the basis of cultivation; i.e., they are much easier to culture than the pathogenic protozoa. Amebae which have been recovered from stool material include *Entamoeba moshkovski*, *Naegleria gruberi*, *Hartmanella hyalina*, *Sappinia diploidea*, *Vahlkampfia punctata*, and *V. lobospinosa*. Contamination of specimens can be avoided by using dry collection containers, saline, or formalin for the concentration rinses and dilution of the specimen and by rapid fixation or examination of the specimen immediately after passage (4).

Table 34.1 Artifacts and other confusing cells and organisms^a

Artifact	Resemblance	Differential characteristics of artifacts (permanent stain)		
		Saline mount	Cytoplasm	Nucleus
PMNs ^b (seen in dysentery and other inflammatory bowel diseases)	<i>E. histolytica</i> <i>E. dispar</i> cysts	Usually not a problem if cells are from fresh blood. Granules in cytoplasm. Cell border irregular	Less dense, often frothy. Border less clearly demarcated than that of ameba. May look very similar to that in protozoa	More coarse. Larger, relative to size of organism. Irregular shape and size. Chromatin unevenly distributed. Chromatin strands may link nuclei or may appear to be 4 separate nuclei
Macrophages (seen in dysentery and other inflammatory bowel diseases; may be present in purged specimens)	Amebic trophozoites, especially <i>E. histolytica</i> / <i>E. dispar</i>	Nuclei larger and of irregular shape, with irregular chromatin distribution. Cytoplasm granular; may contain ingested debris. Cell border irregular and indistinct. Movement irregular; pseudopodia indistinct but may mimic protozoa	Coarse. May contain inclusions. May include RBCs; if RBCs present, will mimic <i>E. histolytica</i>	Large and often irregular in shape. Chromatin irregularly distributed. May appear to have karyosome. Will have more nuclear material per cell than protozoan trophozoite (nucleus may be absent)
Squamous epithelial cells (from anal mucosa)	Amebic trophozoites	Nucleus refractile and large. Cytoplasm smooth. Cell border distinct	Stains poorly	Large and single. Large chromatin mass may resemble karyosome
Columnar epithelial cells (from intestinal mucosa)	Amebic trophozoites	Nucleus refractile and large. Cytoplasm smooth. Cell border distinct	Stains poorly	Large with heavy chromatin on nuclear membrane. Often large central chromatin mass resembling karyosome
<i>Blastocystis hominis</i> (protozoan)	Protozoan cysts of other species or yeasts	Spherical to oval, 0.6–15 µm long. Central clear area. Peripheral nuclei may be confusing	Central mass may stain light or dark. Prominent wall	Peripheral nuclei may look like large karyosomes (no peripheral nuclear chromatin)
Yeasts (normal constituent of feces)	Protozoan cysts, microsporidia	Oval. Thick wall. No internal structure. Budding forms may be seen. Some are round and overlap size of protozoan cysts	Oval to round. Little internal structure. Refractile cell wall. Budding forms may be seen; will resemble microsporidia	None
Bacteria (normal constituent of feces)	Microsporidia	Small, oval; no internal structure. May have terminal spores that resemble vacuoles in microsporidian spore	Various colors on modified trichrome stains; generally pink and will resemble large, gram-negative rods that mimic microsporidian spores	None
Starch granules	Protozoan cysts	Rounded or angular. Very refractile. No internal structure. Stain pink to purple in iodine mounts	Not a problem in permanently stained slides	

^a Other artifacts, such as contaminating plant cells and pollen grains, are occasionally seen. These should not be difficult to differentiate.

^b Stools containing many human cells are usually soft or diarrheic; consequently, they would be unlikely to contain amebic cysts, and cells containing what appear to be four nuclei are almost certain to be PMNs.

Table 34.2 Artifacts that resemble parasites^a

Clinical specimen and artifact	Resemblance
Stool	
Free-living amebae, flagellates, ciliates	Parasitic amebae, flagellates, ciliates
Free-living helminths, helminth eggs, or mite eggs	Helminth eggs, larvae, or adult worms
Yeast cells	<i>Cryptosporidium</i> spp., <i>Cyclospora</i> spp., microsporidia, helminth eggs, or protozoan cysts
Bacteria	Microsporidian spores
Fungi	Helminth eggs
Plant material	
Cells	Protozoan cysts, helminth eggs
Root hairs	Nematode larvae
Pollen grains	Helminth eggs (<i>Ascaris</i> or <i>Taenia</i> spp.)
Pineapple juice crystals	Charcot-Leyden crystals
Human cells	
PMNs	
Fresh bleeding (fresh cells)	Regular PMNs as in peripheral blood smear
Old blood (disintegrating cells)	<i>Entamoeba histolytica</i> / <i>E. dispar</i> cyst
Macrophages	<i>Entamoeba histolytica</i> / <i>E. dispar</i> trophozoite
RBCs	<i>Cryptosporidium</i> spp., <i>Cyclospora</i> spp.
Epithelial cells	Amebic trophozoites
Blood	
Platelets	Malaria parasites, <i>Babesia</i> spp.
Abnormal RBC inclusions (Howell-Jolly bodies, Cabot's rings)	Malaria parasites, <i>Babesia</i> spp.
Contaminants	
Yeast	Fungemia, parasitemia
Bacteria	Bacteremia
Plant or dust fibers	Microfilariae
Stain precipitate	Malaria, <i>Babesia</i> spp.
Body fluids	
Detached ciliary tufts	Flagellate or ciliate protozoa
Respiratory specimens	
Yeast	<i>Pneumocystis jiroveci</i> , <i>Cryptosporidium</i> spp.
Urine	
<i>Pentatrichomonas hominis</i> (from stool contamination)	<i>Trichomonas vaginalis</i>
Bacteria	Microsporidian spores

^a Adapted from reference 7.

Some protozoa, such as *Entamoeba coli*, may contain fungi. *Sphaerita* spp. can be found in the cytoplasm, and *Nucleophaga* spp. can be found in the nucleus. *Sphaerita* spp. (sometimes called *Polyphaga* spp.) measure approximately 0.5 to 1.0 μm and are found in tightly packed clusters (Figure 34.2).

Flagellates

Flagellates can be difficult to differentiate, and free-living organisms are occasionally seen in a stool specimen that has been contaminated with water or saline containing *Bodo caudatus* and *Cercomonas longicauda*. These two organisms are classified in the same family as *Retortamonas intestinalis*.

Ciliates

Apparently, free-living ciliates are found in stagnant water, sewage, and soil and may be seen in fecal specimens contaminated with water or saline. Organisms that have been reported are *Uronema nigricans*, *Lembus pusillus*, and *Balantiophorus minutis* (mistakenly called *Balantidium minutum*) (4, 11).

Coccidia and Microsporidia

Cryptosporidium spp. and *Cyclospora cayetanensis*

Cryptosporidium measures approximately 4 to 6 μm and overlaps in size with a number of objects, including yeasts and debris that are found in stool specimens.

Figure 34.1 Various structures that may be seen in stool preparations. (Top row) Macrophage (left) and epithelial cells (right) that can be confused with *Entamoeba histolytica*/*E. dispar* trophozoites. (Second row) Polymorphonuclear leukocyte with a fragmented nucleus (left) and artifact (right) that can be confused with *Entamoeba* spp. cysts. (Third row) Two artifacts that can resemble protozoan cysts. (Fourth row) Yeast cells (left) and an artifact (right) that can be confused with *Cryptosporidium* spp. and *Cyclospora cayetanensis*, respectively, on positive acid-fast stains; it is important to measure the structures/organisms carefully before confirming organism identification. (Bottom row) Yeast cells (left) that can be confused with microsporidial spores (however, notice the budding cell within the circle), and artifacts (right) that can also be confused with microsporidial spores; these were thought to be bacteria.

Cyclospora cayetanensis measures approximately 8 to 10 μm and can be easily confused with other coccidia or artifacts, especially if careful measurements are not taken. Without the use of modified acid-fast stains or immunoassay detection methods, a light infection with coccidia will probably be missed; the more normal the stool consistency, the fewer oocysts and more artifacts that will be present. The oocysts can also be confused with artifact material when the staining results are of poor quality; they appear nonuniform and more like debris (Figure 34.1).

Isospora belli

When *Giardia lamblia* shrinks within the cyst wall, it can resemble *Isospora belli* in the immature form (a single developing sporoblast; the two mature sporocysts within the oocyst wall have not yet formed). Although this error is occasionally made, the easiest way to differentiate the two is by size. *Giardia* cysts measure approximately 11 to 14 μm long by 7 to 10 μm wide, and *I. belli* measures 20 to 33 μm long by 10 to 19 μm wide. This represents another situation in which measurement of the organisms can help prevent diagnostic errors.

Figure 34.2 Fungi parasitizing *Entamoeba coli*. (A) *Sphaerita* (or *Polyphaga*) sp. within the cytoplasm; (B) *Nucleophaga* sp. within the nucleus.

Microsporidia

Microsporidian spores in humans measure approximately 1 to 4 μm , with the majority being 1 to 2 μm . These spores are round to oval and can mimic yeast cells and bacteria. Although they do stain in a modified trichrome procedure (see chapter 27), the color is usually pale and both the size and color overlap with those of many of the yeasts or bacteria present in the specimen (Figure 34.1). The spores usually stain light to dark pink; they can be confused with bacteria looking like large gram-negative rods. Also, some of the bacilli contain terminal spores that mimic the large vacuole often seen at one end of the microsporidian spore. Size and staining color are rarely that helpful. It is important to prepare very thin smears prior to staining; the spores will be more visible, and the stain will penetrate more successfully. Without confirmation of the presence of the polar tubule in at least some of the spores (diagonal or horizontal line across the spore), it is almost impossible to confirm a microsporidial infection by using routine modified trichrome stains for fecal material.

Blood and Body Fluids

Malaria Parasites and *Babesia* spp.

One of the most common errors in examining blood smears is the incorrect identification of platelets as parasites. When mature schizonts rupture, the merozoites almost immediately penetrate another red blood cell (RBC) and are not seen outside of the RBCs. Extracellular “organisms” are almost always platelets. It is important to focus constantly when examining blood smears; the platelets are often on top of the RBCs. Another tip relates to color; parasites always have two colors, blue nuclei and red cytoplasm, and they are separate. Platelets tend to be uniform in color with no real internal structure; there are red and blue components, but the colors almost blend to form purple. Other internal structures within the RBCs such as Howell-Jolly bodies and Cabot’s rings may be confusing (Figures 34.3 to 34.5). If the blood is held too long in EDTA anticoagulant or the ratio of blood to anticoagulant is incorrect, *Plasmodium* organisms can become distorted and may resemble other malaria stages or different species. Potential problems with using EDTA anticoagulant for the preparation of thin and thick blood films are discussed in chapter 31 (Table 31.2).

If a tube of blood containing EDTA cools to room temperature and the cap has been removed, the parasites can undergo several changes. The parasites within the RBCs will respond as if they were now in the mosquito after being taken in with a blood meal. The morphology of these changes in the life cycle and within the RBCs can cause confusion when examining blood films prepared from this blood (Figure 34.5).

Figure 34.3 Various structures within the RBC. (A) Malarial “ring” form (early trophozoite); (B) platelet on the RBC surface; (C) Howell-Jolly body; (D) Cabot’s ring. (Illustration by Sharon Belkin.)

Leishmaniae and Trypanosomes

Although they are rarely seen, intracellular amastigotes called Leishman-Donovan bodies may be found in the monocytes in peripheral blood smears from patients with visceral leishmaniasis. When they are found in a bone marrow or splenic aspirate preparation, they are easier to find, probably because at that point there may be a high index of suspicion regarding the etiologic agent. In any suspected case of visceral leishmaniasis, peripheral blood buffy coat preparations are usually examined before more extensive procedures are undertaken. The amastigotes range from 3 to 5 μm , and a defined nucleus and kinetoplast may be difficult to see, particularly if a number of organisms are packed in the cell (see chapter 8). The amastigotes may resemble *Histoplasma capsulatum* if the kinetoplast bar structure is not easily seen (Figure 34.6).

Microfilariae

Any laboratory using staining reagents must use good quality control measures to ensure that the solutions do not become contaminated with artifacts or free-living organisms. Bits of cotton fiber, lint, and other components of dust can mimic microfilariae in wet mounts or when stained. However, the artifacts do not contain any internal nuclei. Rarely, nonhuman parasites can also be

Figure 34.4 (Top row and second row) Stain deposition on the surface of uninfected RBCs that could easily be confused with developing *Plasmodium* spp. stages. (Third row) *Plasmodium falciparum* gametocytes that have rounded up and no longer appear as the typical crescent-shaped gametocytes that are normally seen (could be due to low temperatures and/or storage for too many hours in EDTA blood). (Fourth row) Developing *Plasmodium vivax* trophozoites that appear to resemble *P. falciparum* gametocytes (found on blood smears prepared from EDTA blood that had been collected more than 8 h previously). (Bottom row) RBCs containing Howell-Jolly bodies that could be confused with very small, young ring forms of *Plasmodium* spp.

confused if they appear on the stained blood smears. One laboratory used to dry the blood films upright, leaning against a fish tank (many years ago, before more stringent safety measures were instituted). Examination of one of the stained blood films suggested that the patient had a filarial infection. Since the patient history did not support this diagnosis, further studies were performed. When samples of the fish tank water were centrifuged and examined, the “microfilariae” were found! This is just one example of the many unusual sources of artifact contamination (Figure 34.7).

Figure 34.5 Exflagellation of *Plasmodium vivax* microgametocyte; these microgametes could easily be confused with some type of spirochete. These forms were seen in blood films prepared from blood stored for longer than 12 h in EDTA prior to additional smear preparation.

Figure 34.6 (Left) *Histoplasma capsulatum*. (Right) *Leishmania donovani*. Note that the *Leishmania* amastigotes have the bar while the *Histoplasma* amastigotes do not; *Histoplasma* also has the “halo” around the organisms.

Figure 34.8 Bronchial epithelium cells. When these cells disintegrate, the ciliary tufts may be visible and may be confused with protozoan flagellates or ciliates (detached ciliary tufts = ciliocytophthoria).

Body Fluids: Ciliated Epithelial Cells

Detached ciliary tufts (ciliocytophthoria) have been seen in a variety of body fluids (especially peritoneal and amniotic fluids; also respiratory specimens). These tufts are the remnants of ciliated epithelium that are found as a part of normal cellular turnover in a number of sites: respiratory tract and sinuses, ventricles of the brain, central canal of the spinal cord, and epithelia of the male and female reproductive tracts. The tufts are motile, measure 10 to 15 μm in diameter, and can be confused with ciliated or flagellated protozoa. However, when they are carefully examined on a stained smear, there is no internal structure like that seen in protozoa (1, 6, 9). Bronchial epithelium cells can be seen in Figure 34.8; ciliocytophthoria are anucleate remnants of these ciliated cells. The ciliated tufts can be seen on the cells in this figure.

Figure 34.7 Artifacts that can resemble microfilariae in wet mounts; these structures are not parasites but instead are some type of threads. Note that there is no internal structure visible.

Helminths

Adult Worms and Larvae

Plant or root hairs, such as the fuzz on peaches, may resemble nematode larvae. The root hairs tend to be clear and refractile, while the larvae pick up stain (iodine), which reveals internal structures (Figure 34.9). It is important to recognize this potential error when examining formalin-fixed specimens submitted as proficiency-testing specimens. In fecal specimens from patients with diarrhea, partially digested plant material, such as bean sprouts or other vegetable material, can mimic adult nematodes or tapeworm proglottids. Also, all stages of free-living nematodes can occur in feces or as contaminants of the water used in making fecal suspensions.

Hairworms (often called horsehair worms) belonging to the phylum Nematomorpha can be confused with human parasites (3). These adult worms are slender, measuring 10 to 50 cm long, and have a blunt, rounded anterior end. “The caudal end of the male is bifurcate or has a dorso-ventral groove; that of the female is entire or trilobate” (3) (Figure 34.10). The adult worms are free living in water, while the larvae are parasites of insects. Human infection is quite rare and accidental, although in the past literature, serious health problems were attributed to “hair snakes” in the human body. Generally, human infection occurs through ingestion of free-living adult worms or adolescent worms within their insect hosts in drinking water or food.

Figure 34.9 (Top) Root hair. (Middle) Root hair. Note that there is no internal structure visible within the root hairs. (Bottom) *Strongyloides stercoralis* rhabditiform larva. Note the short buccal cavity at the head end of the larva and the genital primordial packet of cells within the curved portion of the body.

Worms have been reported as passing from the urethra in several cases. They have been identified as being in the genera *Gordius*, *Chordodes*, *Parachordodes*, *Paragordius*, *Pseudogordius*, and *Neochordodes*. Worms have been recovered in vomitus, urine, and feces; often, the stated origin of the worms in the body was not well documented. In spite of the reported cases, no evidence of pathogenicity has been demonstrated (3). Often symptoms were attributed to other causes or were psychological.

Figure 34.10 *Gordius* worms. (Upper) Adult worms (called hairworms or horsehair worms), which measure 20 to 50 cm long and are very slender. (Lower) Characteristic structure of *Gordius* worms. (A) Diagram of anterior end; (B) diagram of posterior end of a male worm in the genus *Gordius*; (C) whole worm. Bar, 1 cm. (Illustration by Sharon Belkin.)

Eggs

Plant cells tend to have thick, smooth walls and are not as symmetrical as helminth eggs (Figures 34.11 and 34.12). Some of these plant cells range from 15 to 150 μm in diameter and may be confused with *Ascaris* eggs. Pollen grains are also thick-walled, symmetrical structures that stain very darkly with iodine, may be round or trilobed, and are 15 to 20 μm in diameter (Figure 34.13). They may resemble *Taenia* eggs. Another example is the “Beaver body.” This structure is *Psorospermium haeckelii*, a stage of an alga that occurs in the tissues of crayfish. It is sometimes confused with helminth eggs when found in fecal specimens from individuals who have ingested crayfish (5) (Figure 34.14). Accidental ingestion or contamination of food or water containing the eggs of plant nematodes, such as *Heterodera* species or mites or mite eggs, can also lead to confusing situations.

Human Cells

The human cells most likely to cause problems with identification are the polymorphonuclear leukocytes (PMNs) and the macrophages (Table 34.1; Figure 34.15). These cells are frequently present in patients with nonspecific inflammatory bowel disease (ulcerative colitis). Therapy for this condition often includes

Figure 34.11 Various artifacts that may be seen in stool preparations (wet mounts or permanent stained smears). Many of these structures are pollen grains or egglike objects. Visually, they can be confused with some of the following helminth eggs: *Hymenolepis nana*, *Ascaris lumbricoides*, hookworm, and *Enterobius vermicularis*.

Figure 34.12 Various artifacts that may be seen in stool preparations (wet mounts). Note the egg-like structure in the fourth row (right). There is a small bubble (within the circle) that mimics the small knob found at the abopercular end of a *Diphyllobothrium latum* egg.

Figure 34.13 Various types of pollen grains and a root hair. These structures can mimic various helminth eggs (*Ascaris lumbricoides*, *Trichuris trichiura*), as well as nematode larvae.

immunosuppressive agents; this therapy would definitely be contraindicated in patients with amebiasis (4). These cells should be reported and quantitated (rare, few, moderate, many).

Polymorphonuclear Leukocytes

Large numbers of PMNs are often found in patients with bacterial dysentery, and they may also be present in patients with intestinal amebiasis or ulcerative colitis (Figure 34.15). These cells may be distinguished from *Entamoeba histolytica* as follows.

PMNs	<i>E. histolytica/E. dispar</i> (cysts)
1. Average size, 14 μm (10 to 12 μm on permanent stained smear)	1. Average size, 20 μm (less on permanent stained smear)
2. Ratio of nuclear material to cytoplasm, 1:1	2. Ratio of nuclear material to cytoplasm, 1:10–1:12 (trophozoite), 1:2–1:3 (cyst)
3. Nucleus: 2–4 segments connected by narrow, short chromatin bands. Segments may appear as separate nuclei like those of <i>E. histolytica/E. dispar</i> cyst—focus carefully to reveal connecting chromatin strands	3. Nucleus: round with central karyosome and peripheral chromatin
4. Granular cytoplasm	4. Uniform, agranular cytoplasm—may contain RBCs
5. Trichrome staining characteristics similar to <i>E. histolytica/E. dispar</i>	5. Trichrome: green cytoplasm, dark red nuclear material

Eosinophils

The identification of eosinophils in a fecal specimen usually indicates the presence of an immune response in the host. This allergic response may be caused by a parasitic infection or by other antigens such as pollen or food. Eosinophils are essentially the same size as PMNs and are characterized by the presence of large, purple-staining granules (trichrome) and usually a bilobed nucleus, which may be obscured by the granules.

Macrophages

Macrophages (monocytes) are large, mononuclear, phagocytic cells that may resemble *E. histolytica/E. dispar* trophozoites (Figure 34.15). These cells may be found in patients with intestinal amebiasis and ulcerative colitis and can be differentiated from amebae as follows.

Macrophages	<i>E. histolytica/E. dispar</i> (trophozoites)
1. Size: 30–60 μm , may be 5–10 μm less on permanent stained smear	1. Size: 12–60 μm ; average, 20 μm (less on permanent stained smear)
2. Ratio of nuclear material to cytoplasm, 1:4–1:6	2. Ratio of nuclear material to cytoplasm, 1:10–1:12
3. One large nucleus that may be irregular in shape (like monocyte nucleus)	3. One nucleus, round, with central karyosome and peripheral chromatin
4. Usually contains ingested debris, PMNs, and RBCs	4. May contain RBCs and some debris; no PMNs
5. May contain red-staining round bodies and <i>nucleus may be absent</i>	5. <i>Nucleus always present</i>
6. Trichrome staining characteristics similar to <i>E. histolytica/E. dispar</i>	6. Trichrome: green cytoplasm, dark red nuclear material

Lymphocytes

Lymphocytes have a large, dense, dark-staining nucleus surrounded by very little cytoplasm. They are approximately two-thirds the size of PMNs.

Red Blood Cells

In a buffy coat preparation, some RBCs may be present. These cells measure $\sim 7.5 \mu\text{m}$ in a wet preparation and may be present in the stool as an indication of ulceration (parasitic or nonspecific) or other vascular or hemorrhagic problems. In the trichrome-stained slide, they appear as round or elongate (distortion may occur during smear preparation) red-purple bodies with no granules or inclusions and may be somewhat smaller than $7.5 \mu\text{m}$.

Charcot-Leyden Crystals

Charcot-Leyden (CL) crystals are formed from the breakdown products of eosinophils and basophils and may be present in the stool or sputum with eosinophils or alone. They are slender crystals with pointed ends, and they stain red-purple with trichrome stain. Many different crystal sizes can be seen in the same specimen (Figure 34.16). They indicate that an immune response has taken place, but the cause may or may not be parasitic. The presence of eosinophils and/or CL crystals in the stool may not correlate with an increased eosinophilia on the peripheral blood smear.

Identification of CL crystals in body fluids and secretions is considered an indicator of eosinophil-associated allergic inflammation. The overall structural fold of CL crystal protein is similar to that of galectins, and this is the first structure of an eosinophil protein to be determined (8).

Figure 34.14 (Upper) “Beaver bodies,” which are algae occasionally found in stool; (lower) leaf structure which resembles a trematode. (Courtesy of Joseph Dipersio.)

The protein exhibits weak carbohydrate binding activity for simple saccharides. There may be a potential intracellular and/or extracellular role(s) for the galectin-associated activities of CL crystal protein in eosinophil and basophil function in allergic diseases and inflammation (8).

It has also been reported that pineapple crystals sometimes mimic CL crystals in stool specimens. Apparently, these crystals can be found in fresh and canned pineapple and pineapple juice; also, they are not digested in the alimentary canal of humans. They range from 30 to 130 μm in length and 1 to 2 μm in width. They appear to have parallel edges and are pointed at both ends. In wet preparations, they can resemble CL crystals. Those who routinely examine stool specimens for parasites should probably examine some pineapple juice under the microscope to become familiar with the appearance of these crystals.

Nonhuman Elements Seen in Feces (Yeast Cells)

There are many yeast cells that may be round to oval and measure ~ 4 to $8 \mu\text{m}$ which can be seen in fecal material. On a wet mount, they may resemble small protozoan

Figure 34.15 (Upper) Polymorphonuclear leukocytes. Note the lobed nuclei; if these cells have been in the stool for some time (unpreserved), the nuclei may fragment into four or five pieces, thus resembling multiple nuclei seen in amebic cysts. (Lower) Macrophages. Although these cells often resemble amebic trophozoites, the ratio of nuclear material to cytoplasm is quite different than that seen in actual protozoa.

cysts (*Endolimax nana* or *Entamoeba hartmanni*). After staining, they appear fairly uniform in color (red to green with trichrome stain) without many inclusions; if granules are seen, they are usually small but may resemble small protozoan karyosomes. Depending on the stain used, small yeast cells can be confused with coccidian oocysts or microsporidial spores. It is important to note the presence of budding yeast cells and/or pseudohyphae (clinically relevant only in freshly preserved specimens). The presence of branching pseudohyphae may be an indication of pathogenicity of the particular yeast present (usually *Candida* spp.) and should be reported. Large numbers of budding yeast cells in a fresh or freshly preserved specimen, indicating a potential source for a systemic infection,

Figure 34.16 Charcot-Leyden crystals. These crystals are formed from the breakdown products of eosinophils and basophils and may be present in the stool or sputum with or without eosinophils. They tend to stain quite dark on the permanent stained fecal smears, often darker than nuclear material; and although the shape is consistent, there is a large size range in a single fecal smear or sputum mount.

particularly in immunosuppressed patients, should also be reported (Figure 34.17).

Insect Larvae

Finding insect larvae in stool is not common but may occur as a result of ingestion of whole larvae or adult insects with food. The presence of live larvae may suggest myiasis or, probably more common, contamination of the stool specimen. In these situations, it is always important to find out how and when the specimen was collected prior to submission, particularly if it was submitted as a fresh stool. Proper fixation of the suspected object is important for further identification (see chapter 33).

Spurious Infections

Spurious infections occur when individuals ingest liver from various animals. The eggs are digested free when the liver is eaten and will be passed in the stool for several days. Repeat ova and parasite examinations are recommended for several days to rule out a true infection. Examples are eggs of *Fasciola hepatica*, *Dicrocoelium dendriticum*, or *Capillaria hepatica*, which are present in the livers of cattle, sheep, and rodents, respectively. Occasionally, rarer eggs are found and may represent spurious infections acquired by eating the flesh of fish, birds, or other animals,

Figure 34.17 Yeast cells in permanent stained fecal smears. Depending on the size and permanent stain used (trichrome, modified acid-fast, modified trichrome), single yeast cells can often be confused with the coccidia or microsporidia.

both vertebrates and invertebrates (Figure 34.18). In a true human infection with *Capillaria hepatica*, no eggs are found in the stool; diagnosis requires histologic examination. Eggs in liver biopsy specimens can be identified on the basis of their characteristic morphology.

Delusory Parasitosis

Occasionally, clinical specimens in which the patient has placed various objects or organisms to feign parasitism are submitted for examination. These patients are usually

Figure 34.18 (Upper row) *Fasciola hepatica* egg (130 to 150 μm by 63 to 90 μm) (left, image is lower magnification than *Dicrocoelium* egg) and *Dicrocoelium dendriticum* egg (38 to 45 μm by 22 to 30 μm) (right). (Lower row) *Capillaria hepatica* eggs (51 to 68 μm by 30 to 35 μm). (Left) Eggs passed in the stool (resembles egg of *Trichuris trichiura*). However, note the striated shell of *C. hepatica* compared with the nonstriated shell seen in a *Trichuris* egg.

mentally disturbed and have often seen numerous physicians and submitted clinical specimens to many laboratories. The objects placed in the specimens range from pieces of thread to plant material to earthworms. Often, these patients call the laboratory with extensive histories of “parasitic infections” and seek referrals to other experts or consultants. They may bring photographs or samples of the “parasites” that they have found, all of which will be submitted for identification. These “infections” are not limited to specimens such as stool but may include skin, urine, and other samples for analysis. Often, these patients are women older than 50 years, with possible other medical problems, who present with a wide variety of symptoms. It is likely that dopaminergic and serotonergic dysfunction may play a role in delusional parasitosis; dopamine and serotonin antagonists may be relevant for the treatment of this disorder (10, 12).

This disease can become a tremendous burden both for the patient and for the family. Patients can appear to be very rational about everything else, with the exception of their beliefs concerning infection or infestation with parasites (2, 10, 12). *However, actual infections have been misdiagnosed as delusory parasitosis when appropriate diagnostic procedures have not been used and the true infections have been missed.* A thorough investigation for parasites on the patient, on pets, and in the work and home environment should be completed before assigning a diagnosis of delusory parasitosis.

Equipment, Supplies, Safety, and Quality System Recommendations for a Diagnostic Parasitology Laboratory: Factors Influencing Future Laboratory Practice

Equipment

Microscope
Centrifuge
Fume hood
Biological safety cabinet
Refrigerator-freezer

Supplies

Glassware
Miscellaneous supplies
ATCC quality control organisms

Safety: personnel and physical facilities

General precautions
Handwashing
Personal protective equipment (OSHA 2001 blood borne)
Handling specimens
Processing specimens
Spills
Disposal of contaminated materials
Standard precautions
Hepatitis exposure protocol
Dangerous properties of industrial materials
Current OSHA regulations for the use of formaldehyde
Latex allergy

Quality systems

Extent of services
Proficiency testing
In-house quality control
Patient outcome measures
Continuous quality improvement, total quality management, or 10-step and FOCUS-PDCA for performance improvement activities
CLIA '88 inspection process

New quality guidelines

ISO guidelines
CLSI (NCCLS) model

Factors influencing future laboratory practice

Managed care
Financial considerations
Decentralized testing
Laboratory services
Technological trends
Clinical decision support
Personnel issues
Changing demographics
Emerging diseases

Some of the following information has been adapted from *Clinical Microbiology Procedures Handbook*, published by the American Society for Microbiology (34). Additional information on the following topics can also be found in that publication.

Equipment

Microscope

Good, clean microscopes and light sources are mandatory for the examination of specimens for parasites (Figure 35.1). Organism identification depends on morphologic differences, most of which must be seen under stereoscopic microscopes (magnification, $\leq \times 50$) or regular microscopes at low ($\times 100$), high dry ($\times 400$), and oil immersion ($\times 1,000$) magnifications. The use of a $50\times$ or $60\times$ oil immersion objective for scanning can be very helpful, particularly if the $50\times$ oil and $100\times$ oil immersion objectives are placed side by side. This arrangement on the microscope can help avoid accidentally getting oil on the $40\times$ high dry objective. Calibration of the microscope is discussed later in this chapter.

Types

Stereoscopic Microscope. A stereoscopic microscope is recommended for larger specimens (arthropods, tapeworm proglottids, and various artifacts). The total magnification usually varies from approximately $\times 10$ to $\times 45$, either with a zoom capacity or with fixed objectives ($0.66\times$, $1.3\times$, and $3\times$) that can be used with $5\times$ or $10\times$ oculars. Depending on the density of the specimen or object being examined, you must be able to direct the light source either from under the stage or onto the top of the stage.

Regular Light Microscope. The light microscope should be equipped with the following:

1. **Head.** A binocular head is recommended and should be equipped with a diopter adjustment to compensate for focus variation in the eyes.
2. **Oculars.** $10\times$ oculars are required; $5\times$ oculars can be helpful but are optional.

Figure 35.1 Microscopes routinely used in clinical laboratories.

3. *Objectives.* 10× (low power), 40× (high power), 100× (oil immersion). Some laboratories are currently using 50× or 60× oil immersion lenses for screening permanent stained smears. Examination with a combination of the 50× oil or 60× oil and the 100× oil immersion lenses allows screening to proceed more quickly and eliminates the problem of accidentally getting oil on the high dry objective lens when switching back and forth between the 40× (high dry) and 100× (oil immersion) objectives.
4. *Stage.* A mechanical stage for both vertical and horizontal movement is required. Graduated stages are mandatory for recording the exact location of an organism on a permanent stained smear and recommended for any facility performing diagnostic parasitology procedures. This capability is essential for consultation and teaching responsibilities. *However, remember that calibration numbers for the exact location of an organism may not be the same for different microscopes and different stages.*
5. *Condenser.* A bright-field condenser equipped with an iris diaphragm is required; however, an adjustable condenser is not required with the newer microscopes. The condenser numerical aperture should be equal to or greater than the highest objective numerical aperture.
6. *Filters.* Both clear blue glass and white ground-glass filters are recommended.
7. *Light source.* The light source, along with an adjustable voltage regulator, is usually contained in the microscope base. This light source should be aligned as specified by the manufacturer. If the light source is external, the microscope must be equipped with an adjustable mirror and an adjustable condenser containing an iris diaphragm. The light source should be a 75- to 100-W bulb.

Maintenance (54)

1. Use a camel hair brush to remove dust from all optical surfaces; remove oil and finger marks immediately from the lenses with *several thicknesses* of lens tissue. *Single-thickness lens tissue may permit corrosive acids from the fingers to damage the lens. Do not use any type of tissue other than lens tissue, otherwise you may scratch the lens. Use very little pressure, to prevent removal of the coatings on external surfaces of the lenses.*
2. Use water-based cleaning solutions for normal cleaning. If you have to use organic solvents, use them in very small amounts and only if absolutely necessary to remove oil from the lens. *Since microscope manufacturers do not agree on solvents to be used, each company's recommendations should be consulted. One recommended solvent is 1,1,1-trichloroethane; it is good for removing immersion oil and mounting media and does not soften the lens sealers and cements. Xylene, any alcohols, acetone, or any other ketones should never be used as cleaning fluids.*
3. After the lamp has been installed into the lamp holder, clean it with lens tissue moistened in 70% isopropyl or ethyl alcohol (to remove oil from

fingers). *Make sure that the lamp is cool and the switch is in the off position when replacing or removing the lamp.*

4. Clean the stage with a small amount of disinfectant (70% isopropyl or ethyl alcohol) when it becomes contaminated.
5. Using petroleum jelly or light grease, clean and lubricate the substage condenser slide as needed.
6. Cover the microscope when not in use. In extremely humid climates (a relative humidity of more than 50%), good ventilation is necessary to prevent fungal growth on the optical elements.
7. At least annually, schedule a complete general cleaning and readjustment to be performed by a factory-trained and authorized individual. If microscopes are in continual use, maintenance should be performed twice a year. Record all preventive maintenance and repair data (date, microscope identification number, names of company and representative, maintenance and/or repairs, part replacement, recommendations for next evaluation, estimated cost if you have such information). This information should be cumulative so that a review for each piece of equipment can be scanned quickly for continuing problems, justification for replacement requests, etc. Depending on the physical site and use of the microscope, laboratories may use different maintenance schedules.

Calibration

The identification of protozoa and other parasites depends on several factors, one of which is size. Any laboratory doing diagnostic work in parasitology should have a calibrated microscope available for precise measurements (25). Measurements are made with a micrometer disk that is placed in the ocular of the microscope; the disk is usually calibrated as a line divided into 50 units. Depending on the objective magnification used, the divisions in the disk represent different measurements. The ocular disk division must be compared with a known calibrated scale, usually a stage micrometer with a scale of 0.1- and 0.01-mm divisions. Although there is not universal agreement, it is probably appropriate to recalibrate the microscope once each year. This recommendation should be followed if the microscope has received heavy use or has been bumped or moved multiple times. Often, the measurement of red blood cells (approximately 7.5 μm) is used to check the calibrations of the three magnifications ($\times 100$, $\times 400$, and $\times 1,000$). Latex or polystyrene beads of a standardized diameter (Sigma, J. T. Baker, etc.) can be used to check the calculations and measurements. Beads of 10 and 90 μm in diameter are recommended.

Supplies

1. Ocular micrometer disk (line divided into 50 units) (any laboratory supply distributor [Fisher, Baxter, Scientific Products, VWR, etc.]
2. Stage micrometer with a scale of 0.1- and 0.01-mm divisions (Fisher, Baxter, Scientific Products, VWR, etc.)
3. Immersion oil
4. Lens paper
5. Binocular microscope with 10 \times , 40 \times , and 100 \times objectives. Other objective magnifications may also be used (50 \times oil or 60 \times oil immersion lenses).
6. Oculars of 10 \times . Some may prefer 5 \times ; however, smaller magnification may make final identifications more difficult.
7. Single 10 \times ocular to be used to calibrate all laboratory microscopes (to be used when any organism is being measured).

Note All measurements should be documented in quality control records.

Procedure

1. Unscrew the eye lens of a 10 \times ocular, and place the micrometer disk (engraved side down) within the ocular. Use lens paper (several thicknesses) to handle the disk; keep all surfaces free of dust and lint.
2. Place the calibrated micrometer on the stage, and focus on the scale. You should be able to distinguish the difference between the 0.1- and 0.01-mm divisions. Make sure that you understand the divisions on the scale before proceeding.
3. Adjust the stage micrometer so that the "0" line on the ocular micrometer is exactly lined up on top of the 0 line on the stage micrometer.
4. After these two 0 lines are lined up, do not move the stage micrometer any farther. Look to the right of the 0 lines for another set of lines that is superimposed. The second set of lines should be as far to the right of the 0 lines as possible; however, the distance varies with the objectives being used (Figure 35.2).
5. Count the number of ocular divisions between the 0 lines and the point where the second set of lines is superimposed. Then, on the stage micrometer, count the number of 0.1-mm divisions between the 0 lines and the second set of superimposed lines.
6. Calculate the portion of a millimeter that is measured by a single small ocular unit.
7. When the high dry and oil immersion objectives are used, the 0 line of the stage micrometer will

Figure 35.2 Ocular micrometer, top scale; stage micrometer, bottom scale. (Illustration by Nobuko Kitamura; modified from reference 42.)

increase in size whereas the ocular 0 line will remain the same size. The thin ocular 0 line should be lined up in the center or at one edge of the broad stage micrometer 0 line. Thus, when the second set of superimposed lines is found, the thin ocular line should be lined up in the center or at the corresponding edge of the broad stage micrometer line.

Example:

$$\text{A. } \frac{\text{Stage reading}}{\text{ocular reading}} \times \frac{1,000 \mu\text{m}}{1 \text{ mm}} = \text{ocular units } (\mu\text{m})$$

$$\text{B. Low power (10}\times\text{)} \\ \frac{0.8 \text{ mm}}{100 \text{ units}} \times \frac{1,000 \mu\text{m}}{1 \text{ mm}} = 8.0 \mu\text{m (factor)}$$

$$\text{C. High dry power (40}\times\text{)} \\ \frac{0.1 \text{ mm}}{50 \text{ units}} \times \frac{1,000 \mu\text{m}}{1 \text{ mm}} = 2.0 \mu\text{m (factor)}$$

$$\text{D. Oil immersion (40}\times\text{)} \\ \frac{0.05 \text{ mm}}{62 \text{ units}} \times \frac{1,000 \mu\text{m}}{1 \text{ mm}} = 0.8 \mu\text{m (factor)}$$

Example: If a helminth egg measures 15 ocular units by 7 ocular units (high dry objective), using the factor of 2.0 μm for the 40 \times objective (example C

above), the egg measures 30 by 14 μm and is probably *Clonorchis sinensis*.

Example: If a protozoan cyst measures 23 ocular units (oil immersion objective), using the factor of 0.8 μm for the 100 \times objective (example D above), the cyst measures 18.4 μm .

Results. For each objective magnification, a factor will be generated (1 ocular unit = certain number of micrometers). If standardized latex or polystyrene beads or a red blood cell is measured with various objectives, the size of the object measured should be the same (or very close), regardless of the objective magnification. The multiplication factor for each objective should be posted (either on the base of the microscope or on a nearby wall or bulletin board) for easy reference. Once the number of ocular lines per width and length of the organism is measured, then, depending on the objective magnification, the factor (1 ocular unit = certain number of micrometers) can be applied to the number of lines to obtain the width and length of the organism. Comparison of these measurements with reference measurements in various books and manuals should confirm the organism identification.

Procedure Notes for Microscope Calibration

1. The final multiplication factors will only be as good as your visual comparison of the ocular 0 and stage micrometer 0 lines.
2. As a rule of thumb, the high dry objective (40 \times) factor should be approximately 2.5 times more than the factor obtained from the oil immersion objective (100 \times). The low-power objective (10 \times) factor should be approximately 10 times that of the oil immersion objective (100 \times).

Limitations of Microscope Calibration

1. After each objective has been calibrated, the oculars containing the disk and/or the objectives cannot be interchanged with corresponding objectives or oculars on another microscope.
2. Each microscope used to measure organisms must be calibrated as a unit. The original oculars and objectives that were used to calibrate the microscope must also be used when an organism is measured.
3. The objective containing the ocular micrometer can be stored until needed. This single ocular can be inserted when measurements are taken. However, this particular ocular containing the

ocular micrometer disk must have also been used as the ocular during microscope calibration.

Centrifuge

A table or floor model centrifuge to accommodate 15-ml centrifuge tubes is recommended. It is also helpful to have a centrifuge that can hold 50-ml centrifuge tubes, particularly when some of the commercial concentration systems are used. Regardless of the model, a free-swinging or horizontal head is recommended. With this type of centrifuge, the sediment is deposited evenly on the bottom of the tube and the flat surface of the sediment allows removal of the supernatant fluid from the sediment, particularly when you cannot turn the tube upside down to pour out the supernatant fluid. Most laboratories are using carrier cups that have screw-cap closures; this feature, in addition to capped centrifuge tubes, will minimize any aerosol formation and/or distribution.

Maintenance (54)

1. Before each run, visually check the carrier cups, trunnions, and rotor for corrosion and cracks. If anything is found to be defective, replace it immediately or remove the equipment from service. Check for the presence and insertion of the proper cup cushions before each run.
2. At least quarterly, check the speed at all regularly used speeds with a stroboscopic light to verify the accuracy of a built-in tachometer or speed settings. Remember to record results. Some laboratories perform this function every 6 months or yearly.
3. Following a breakage or spill and at least monthly, disinfect the centrifuge bowl, buckets, trunnions, and rotor with 10% household bleach or phenolic solution. Following disinfection, rinse the parts with warm water and perform a final rinse with distilled water. Thoroughly dry the parts with a clean absorbent towel to prevent corrosion. At least quarterly, brush the inside of the cups with mild warm soapy water and use fine steel wool to remove deposits; the cups should then be rinsed in distilled water and thoroughly dried.
4. Follow manufacturer's recommendations for preventive maintenance (lubrication).
5. Semiannually, check brushes and replace if worn to 1/4 in. (1 in. = 2.54 cm) of the spring. Also semiannually, check the autotransformer brush and replace if worn to 1/4 in. of the spring.
6. Record all information relating to preventive maintenance and repair (date, centrifuge identification

number, names of company and representative, maintenance and/or repairs, part replacement, recommendations for next evaluation, estimated cost if you have such information). This information should be cumulative so that a review for each piece of equipment can be scanned quickly for continuing problems, justification for replacement requests, etc.

Fume Hood

Chemical fume hoods should be used when there is risk of exposure to hazardous fumes or splashes while preparing or dispensing chemical solutions. Airflow is generally controlled by a movable sash and should be in the range of 80 to 120 ft/min (1ft = 30.48 cm). Chemical fume hoods are certified annually. Although a fume hood is not required for diagnostic parasitology work, many facilities keep the staining setup and formalin (see below for a discussion of regulations regarding the use of formaldehyde) in a fume hood. Fume hoods may also be preferred for the elimination of odors. The placement of reagents, supplies, and equipment within the hood should not interfere with the proper airflow.

Maintenance

1. At least yearly, with the sash fully open and the cabinet empty, check the air velocity with a thermoanemometer (minimum acceptable face velocity, 100 ft/min) (7). Also, a smoke containment test should be performed with the cabinet empty to verify proper directional face velocity.
2. Lubricate the sash guides as needed.

Biological Safety Cabinet

Biological hazards are best contained within a class IIA or class IIB biological safety cabinet (BSC). BSCs operate at a negative air pressure with air passing through a HEPA filter, and the vertical airflow serves as a barrier between the cabinet and the user. Although a BSC is not required for processing routine specimens in a diagnostic parasitology laboratory, some laboratories use class I (open-face) or class II (laminar-flow) BSCs for processing all unpreserved specimens. Use of a biological safety cabinet is recommended if the laboratory is performing cultures for parasite isolation. However, remember that BSCs should not be used as fume hoods. Toxic, radioactive, or flammable vapors or gases are not removed by HEPA filters (63).

Maintenance (54)

1. After each use, disinfect the work area. Since UV radiation has very limited penetrating power, do not depend on UV irradiation to decontaminate the work surface (68). At least weekly, clean UV lamps (in the off position) with 70% isopropyl or ethyl alcohol.
2. At least annually, have class I BSCs certified. They should also be certified after installation but before use and after they have been relocated or moved. Certification should include the following and will be documented by the trained company representative (contracted to handle the BSC inspection).
 - A. Measurements of the air velocity are taken at the midpoint height approximately 1 in. behind the front opening. Measurements should be made approximately every 6 in.
 - B. The average face velocity should be at least 75 linear ft/min. A thermoanemometer with a sensitivity of ± 2 linear ft/min should be used (53).
 - C. With the cabinet containing the routine work items, such as a Bunsen burner, test tube rack, bacteriological loop and holder, etc., a smoke containment test should be performed to determine the proper directional velocity.
 - D. Record the date of recertification, the names of the individual and company recertifying the cabinet, and any recommendations for future service. Any maintenance performed should also be documented in writing.
3. Replace the filters as needed.
4. On installation, have a class II BSC certified to meet Standard 49 of the National Sanitation Foundation, Ann Arbor, Mich. (53). The cabinet must also be recertified at least annually and/or when it is moved, after filters are replaced, when the exhaust motor is repaired or replaced, and when any gaskets are removed or replaced. Record the date of recertification, the names of the individual and company performing the service, and any recommendations for future service.

Refrigerator-Freezer

Any general-purpose laboratory (non-explosion-proof) or household-type refrigerator-freezer (4 to 6°C) can be used in the parasitology laboratory. Solvents with flash points below refrigeration temperature should not be stored, even in modified (explosion-proof) refrigerators.

Maintenance

1. On a daily basis, monitor and record the temperature of the refrigerator. The thermometer should be placed into a liquid to permit stable temperature recording, or thermocouples may be used.
2. On a daily basis, monitor and record the temperature of the freezer. The thermometer should be placed in antifreeze (any brand with freezing point below that of the freezer, e.g., ethylene glycol-water solutions, glycerol-water solutions, or Prestone) to permit stable temperature recording. Thermocouples may be used instead.
3. Periodically when the door is opened, check to see if the fan is operational.
4. Monthly, check the door gasket for deterioration, cracks, and proper seal. Seal problems are often seen when ice begins to build up in a freezer or the temperature is not holding. Periodically, petroleum jelly can be rubbed onto the door gasket to lubricate the material and to help maintain flexibility for a tight seal when the door is shut.
5. Semiannually, clean the condenser tubing and air grill with a vacuum cleaner.
6. Semiannually, check to ensure that the drain tubes are kept open.
7. Annually, wash the interior with a warm solution of baking soda and water (approximately 1 tablespoon/qt [ca. 13 to 14 g/0.946 liter]). Rinse with clean water, and dry. Also, wash the door gasket and water collection tray with a mild soap and water. If the gasket accumulates a black mold, scrub with 50% household bleach solution and a small brush. Rinse with clean water, and dry.

Supplies

Supplies for the diagnostic parasitology laboratory are often identical to those needed for routine work in other areas of microbiology. Although not every size of glassware used is specified, the list below should be helpful for anyone setting up a laboratory for this type of work.

Glassware

1. Disposable glass or plastic pipettes and bulbs (some sterile for culture work)
2. Pipettes, 1, 5, and 10 ml (some sterile for culture work)
3. Glass slides (1 by 3 in., or larger if preferred). Slides with rounded edges are now available (safety-"sharps")

4. Coverslips (22 by 22 mm; no. 1 or larger if preferred)
5. Beakers, 250, 500, 1,000, and 2,000 ml
6. Covered Coplin jars or staining dishes (with slide rack)
7. Graduated cylinders, 50, 100, 500, and 1,000 ml
8. Mortar and pestle (range of sizes)
9. Flasks, Erlenmeyer, 500 and 1,000 ml
10. Flasks, volumetric, 500 and 1,000 ml
11. Bottles, brown, 150 to 200 ml
12. Bottles, clear, 100, 500, and 1,000 ml
13. Bottles, airtight, 50 ml
14. Funnel (glass) to hold filter paper
15. Büchner funnel
16. Centrifuge tubes, 15 and 50 ml (some with screw caps)
17. Petri dish, plastic, sterile
18. Tubes, screw-cap, 13 by 100 mm or 16 by 125 mm (some sterile for culture work)
19. Plastic syringe, 15 ml
20. Sterile syringes (glass or plastic), 1, 10, 20, and 50 ml
18. Stage micrometer with scale of 0.1- and 0.01-mm divisions
19. Disk micrometer divided into 50 units
20. Biohazard container with disinfectant for proper disposal of slides, tubes, and pipettes
21. Biohazard container for proper disposal of patient specimens

ATCC Quality Control Organisms

1. An 18- to 24-h-old culture of *Escherichia coli* or *Enterobacter aerogenes*
2. ATCC 30010 (*Acanthamoeba castellanii*)
3. ATCC 30133 (*Naegleria gruberi*)
4. ATCC 30925 (*Entamoeba histolytica* HU-1: CDC)
5. ATCC 30015 (*Entamoeba histolytica* HK-9)
6. ATCC 30001 (*Trichomonas vaginalis*)
7. ATCC 30883 (*Leishmania mexicana*)
8. ATCC 30160 (*Trypanosoma cruzi*)

Note None, some, or all of these QC organisms will be required, depending on the culture procedures performed in the laboratory.

Miscellaneous Supplies

1. Culture tube racks
2. Gauze (woven or pressed)
3. Applicator sticks (wood)
4. Sterile cryovials or screw-cap vials (to hold 1 ml)
5. Box for vial storage in freezer
6. Filter paper, Whatman no. 1 and Whatman no. 42
7. Sterile filtration system
8. Membrane filters (pore size, 0.22 μm) (to be used with sterile filter)
9. Nuclepore membrane filter, 25-mm, 5- μm , and 3- μm porosity
10. Swinney filter adapter (attaches to syringe, holds filter)
11. Filter paper pad, 25 mm (used to support the membrane filter in the Swinney adapter)
12. Bacteriological loop
13. Sterile syringe needles, 20 and 27 gauge
14. Vaspar
15. Parafilm (American Can Co.) or equivalent
16. Slide boxes for positive-slide storage
17. Forceps and scissors

Safety: Personnel and Physical Facilities

General Precautions (5, 7, 9, 10, 20, 23, 25, 28, 45, 48–51, 53–55, 59)

1. *Be careful!* All material to be received by or discarded from the laboratory must be considered potentially pathogenic.
2. Smoking, eating, or drinking in the laboratory is not permitted.
3. Do not work with uncovered open cuts or broken skin. Cover them with a Band-Aid, finger cot, or other suitable means, such as rubber or plastic gloves.
4. Mouth pipetting of specimens is not permitted.
5. Do not create aerosols. Remember, infectious diseases, such as infectious hepatitis, may be transmitted by aerosols produced by centrifuges, stirrers, pipettors, etc. Exercise extreme care when using such equipment. Cool inoculating loops or needles before touching colonies on plates or inserting into liquid material.
6. Develop the habit of keeping your hands away from your mouth, nose, and eyes. Wash hands well with soap before leaving the laboratory.

7. Do not lay personal articles, such as eyeglasses, on the bench in your work area.
8. Laboratory coats or gowns are not to be worn outside the laboratory, particularly not to the employee lounge or cafeteria or out of the building.
9. Wipe off benches in your working area with disinfectant *before and after* each day's work. Keep your area clean at all times.
10. In case of injury or unusual incident, however slight, the supervisor in charge must be immediately notified, and a report to occupational health facility is required. Also fill out an accident report form. Major accidents must be documented and reported in detail to the supervisor and chief of microbiology. The report should indicate:
 - A. Cause of the accident
 - B. Type of contamination or hazard
 - C. List of personnel possibly exposed and amount of exposure to possible pathogenic material
 - D. Decontamination procedures taken if pathogenic material was involved
 - E. Actions taken to prevent recurrence
 - F. Actions taken to safeguard or monitor employees
11. Infections may be spread by a number of routes in the laboratory. The actual occurrence of an infection depends on the virulence of the infecting agent, susceptibility of the host, route of entry, inoculating dose, etc. (Table 35.1).
 - A. *Airborne*. Droplets and aerosols may be formed by simply removing caps or cotton plugs or swabs from tubes. Heating liquids on needles too rapidly may also create an aerosol. Breakages in centrifuges are serious accidents (Table 35.2).
 - B. *Ingestion*. Ingestion can occur through mouth pipetting, failure to wash hands after handling specimens or cultures, or smoking, eating, and drinking in the laboratory.
 - C. *Direct inoculation*. Scratches, needlesticks, cuts from broken glass, or animal bites may permit direct inoculation.
 - D. *Skin contact*. Some very virulent organisms, and others not so virulent, can enter through small cuts or scratches or through the conjunctiva of the eye.
 - E. *Vectors*. Flies, mosquitoes, ticks, fleas, and other ectoparasites can be potential sources of infection in the laboratory, especially if animal work is performed.
12. Personnel who display risk-prone behavior or are pregnant, immunocompromised, or immunosuppressed should be restricted from performing work with highly infectious microorganisms and, in some situations, be restricted to a low-risk laboratory (62).

Handwashing

Handwashing is the most important procedure to reduce the duration of exposure to an infectious agent or chemical, to prevent dissemination of an infectious agent, and to reduce overall infection rates in a health care facility.

Table 35.1 Routes of exposure associated with diagnostic laboratory work

Route	Practice or potential cause
Ingestion	Mouth pipetting Splashes of infectious material into the mouth Contaminated articles or fingers placed in the mouth Eating or drinking within the working laboratory space
Inoculation	Needle sticks Cuts Animal and insect bites or scratches
Contamination of skin and mucous membranes	Spills or splashes into eyes, mouth, or nose or onto intact or nonintact skin Contaminated surfaces, equipment, and articles
Inhalation	Numerous procedures that can produce aerosols

Table 35.2 Laboratory functions that may produce aerosols

Laboratory function	Practice or potential cause (type of relevant culture)
Inoculating-loop manipulations	Subculturing or streaking culture plates “Cooling” a loop in culture medium Flaming a loop (Free-living ameba culture systems)
Pipette	Mixing microbiological suspensions or fresh specimens Pipette spills on hard surfaces and benches Blowing contents from pipettes (Any function involving pipettes and liquids)
Needle and syringe manipulation	Expelling air Withdrawing needle from stopper Injecting animals Spray created when needle separates from syringe (Any function involving syringe-needle combination)
Other laboratory functions	Centrifugation with open containers (centrifuge tubes and/or carriers) Blenders, shakers, sonicators, and mixing instruments (specimens, cultures) Pouring or decanting fluids (specimen processing) Opening culture containers (any parasitic culture) Spillage of infectious material Lyophilization and filtration under vacuum

Hand contamination occurs during manipulation of specimens and during contact with work surfaces, telephones, and equipment. Laboratory personnel should wash their hands immediately after removing gloves, after obvious contamination, after completion of work, before leaving the laboratory, and before hand contact with nonintact skin, eyes, or mucous membranes (63).

Handwashing sinks should be located at each entry/exit door; if possible, the faucet should be operated by a knee/foot control. If these controls are not available, the faucet should be turned on and off using a paper towel. Handwashing should be performed using soap or an antiseptic compound, starting at the wrist area and extending down between the fingers and around and under the fingernails, and rinsed from the wrists downward. Recently, the Centers for Disease Control and Prevention recommended that in addition to traditional soap and water handwashing, health care personnel can use alcohol-based gels (63).

Personal Protective Equipment (OSHA 2001 Blood Borne)

Occupational Safety and Health Administration (OSHA) standards for exposure to blood-borne pathogens require the laboratory to provide personal protective equipment

(PPE) for its employees. OSHA standards require that PPE be provided, used, and maintained for all hazards found in the workplace, including biological, environmental, and chemical hazards, radioactive compounds, and mechanical irritants capable of causing injury or illness through absorption, inhalation, or physical contact. Employees must be trained in the appropriate use of PPE for a specific task, the limitations of PPE, and procedures for maintaining, storing, and disposing of PPE.

Gloves

Gloves protect the wearer from exposure to potentially infectious material and other hazardous material and are available in material designed for specific tasks. Gloves must be provided by the employer and must be the proper size and appropriate material for the task. Due to latex hypersensitivity in some workers, only powder-free latex gloves should be used or gloves should be manufactured from nitrile, polyethylene, or other material.

Protective Clothing

Laboratory workers should wear long-sleeved coats or gowns that extend below the level of the workbench, and they should be worn fully closed. The material must be fluid resistant if there is any potential for splashing or

spraying. Fluid-proof clothing (plastic or plastic lined) must be worn when there is the potential for soaking by infectious material. Laboratory workers should not wear laboratory clothing outside the laboratory. All protective clothing should be changed immediately when contaminated to prevent the potentially infectious material or chemical from contacting the skin. Coats and gowns should not be taken home for cleaning but should be laundered by the institution.

Face and Eye Protection

Face and eye protection should be used when splashes or sprays of infectious material or chemicals may occur. Equipment includes goggles, face shields, and splashguards. Face shields provide the best protection for the entire face and neck, although splashguards provide an alternative method. If only goggles are worn, the user should also wear an appropriate mask to prevent contamination of mucous membranes.

Figure 35.3 Example of a commercially available disinfectant that can be used for countertops, small spills, and any hard surface that requires a disinfectant (www.med-chem.com).

Handling Specimens (45)

1. Specimens with *gross internal contamination* must not be accepted. Place the specimen in a plastic bag to protect subsequent handlers. The test request slips should be bagged separately from the specimen (keep paperwork clean and uncontaminated). Wear gloves when handling the specimen, and wash your hands thoroughly when you finish handling the specimen. Notify the supervisor immediately about a contaminated specimen so that further corrective action may be taken.
2. Specimens to be centrifuged *must* be placed in a sealed container to prevent aerosols.
3. All specimens other than bacterial or fungal blood culture bottles to be set up for isolation of organisms must be processed in a BSC. All “open-system” work is to be done on an absorbent surface (i.e., a towel) in a BSC, using appropriate protective techniques. Towels should be changed daily. We recommend that the immediate working area of the towel be dampened with 2.5% amphyl or any recommended disinfectant to handle small spills (Figure 35.3).

Processing Specimens (45)

1. *All specimens are potentially pathogenic—always use careful techniques* (Tables 35.3 and 35.4).
2. All discard material used in processing of specimens is considered contaminated.
 - A. Fluids used in the processing of specimens (buffers, etc.), as well as excess liquid specimens, should be poured into plastic screw-top autoclavable bottles and sterilized prior to disposal. A tongue depressor placed in the bottle can help to prevent splashing if liquid is poured down the slanting stick. These sticks can also be placed in disinfectant before being discarded. Disinfectants and incineration can also be used for decontamination of infectious materials.
 - B. Reusable items (tissue grinders, bottles, etc.) are placed in an autoclave pan. Once the pan is full, place it (without a cover) in a large brown autoclave bag and staple shut. After being autoclaved, the reusable items can be cleaned.
 - C. Specimen containers and centrifuge tubes are disposable. These items should be placed in plastic autoclave bags and secured with masking tape for sterilization. Slides can also be placed in containers of liquid disinfectant prior

Table 35.3 Potential routes of laboratory infection with human parasites

Organisms ^a	Mode of transmission	Comments
Intestinal protozoa <i>Entamoeba histolytica</i> ^b (C) <i>Entamoeba dispar</i> (C) <i>Entamoeba coli</i> (C) <i>Entamoeba hartmanni</i> (C) <i>Endolimax nana</i> (C) <i>Iodamoeba bütschlii</i> (C) <i>Blastocystis hominis</i> ^b (C) <i>Giardia lamblia</i> ^b (C) <i>Dientamoeba fragilis</i> ^b (T) <i>Cryptosporidium</i> ^b (O)	Accidental ingestion of infective cysts, trophozoites, oocysts, or spores in food or water contaminated with fecal material. Also direct transfer of stool material via fomites (fecal/oral transmission). Cysts (10–100) are required to initiate an infection with intestinal protozoa. (These modes apply to all intestinal protozoa.) Oocysts (as few as 30) are required to initiate an infection with <i>Cryptosporidium</i> spp.	Transmission becomes more likely when fresh stool specimens are being processed and examined; submission of fecal specimens in preservatives or fixatives would decrease the risks. (This applies to all intestinal protozoa.) Wearing gloves, using capped centrifuge tubes, and working in BSC would decrease the risk of acquiring <i>Cryptosporidium</i> infections; the use of potassium dichromate as collection fluid and use of sugar flotation on fresh stool is <i>not recommended</i> for <i>Cryptosporidium</i> .
<i>Cyclospora cayetanensis</i> ^b (O) <i>Isospora belli</i> ^b (O)	The infective dose for microsporidial spores has not been documented; however, one assumes the number would be small.	It is well documented that microsporidial spores can be inhaled, thus initiating an infection.
Microsporidia ^b (S)	Inhalation or ingestion of infective eggs Skin penetration of infective larvae from stool material	Very common in children, asymptomatic Exposure would be very possible or likely when working with stool cultures or concentrates for recovery of helminth larvae. Ingestion of infective eggs can lead to the adult worm in humans. Exposure is very likely when working with gravid proglottids (ink injection for worm identification).
Intestinal helminths <i>Enterobius vermicularis</i> (E) <i>Strongyloides stercoralis</i> (L)	Ingestion of infective eggs (fecal/oral) Inhalation or ingestion of infective eggs could lead to cysticercosis	Culture forms or organisms from hamster would be infectious.
<i>Hymenolepis nana</i> (E) <i>Taenia solium</i> (E)	Direct contact or inoculation of infectious material from patient lesion; accidental inoculation of material from culture or animal inoculation studies Same as for <i>Leishmania</i> spp.	Cultures and special concentration techniques would represent possible means of exposure. Blood should always be handled carefully (avoid open cuts, etc.).
Blood and tissue protozoa <i>Leishmania</i> spp.	Accidental inoculation could transmit any of the 4 species; infectious dose would be approximately 10 infected RBCs Inhalation or ingestion of oocysts in cat feces (veterinary situation); accidental inoculation of tachyzoites from culture, tube of blood, animal isolation (mouse peritoneal cavity)	Although many people already have antibodies to <i>Toxoplasma</i> , indicating past exposure, there have been documented laboratory accidents where the individual became ill due to the large infecting dose.
<i>Trypanosoma</i> spp. <i>Plasmodium</i> spp.	Inhalation or ingestion of oocysts in cat feces (veterinary situation); accidental inoculation of tachyzoites from culture, tube of blood, animal isolation (mouse peritoneal cavity)	(continued)

(continued)

Table 35.3 Potential routes of laboratory infection with human parasites (*continued*)

Organisms ^a	Mode of transmission	Comments
Ectoparasites		
<i>Pediculus</i> spp.	Specimens submitted on hair could be easily transmitted in the laboratory	Careful handling and fixation of the arthropods would prevent any potential problems with transmission
<i>Sarcoptes scabiei</i>	Transmission via skin scraping, etc., is possible but not very likely	Careful handling and preparation of specimens with KOH would tend to prevent any problems
Dipterous fly larvae (myiasis)	Transmission could occur anywhere	Protection from flies would solve the potential problem

^a C, cyst; T, trophozoite; O, oocyst; IL, infective larvae; E, egg; S, spore.

^b Potentially pathogenic intestinal protozoa.

to disposal. Remember, slides should be treated as sharps.

- D. Pipettes can be placed in a covered discard pan containing 5% amphyl or placed in autoclavable containers for sterilization before discarding.

Spills

1. Disinfectants in use at present
 - A. *Amphyl*. Amphyl (made up of soap, *o*-phenyl-phenol, and alcohol) is a lipophilic disinfectant with a phenol coefficient of 10.
 - B. *Chlorine*. Sodium hypochlorite was reported by Klein and Deforest (36) to be virucidal against 25 viruses tested (included enteroviruses). At 0.02% available free Cl₂, all viruses tested were inactivated in 10 min (6, 9, 60, 66).
 - C. *Alcohols*. Alcohols generally act by coagulating proteins and as organic solvents. Rapid evaporation may lead to inadequate “killing” time. Although there are some conflicting reports, 70% solutions generally have the best microbicidal activity. Caution is advised because of flammability.
2. Immediate actions
 - A. Clear the area at once.
 - B. Notify the supervisor and chief of microbiology.
 - C. Assess the type of spill and degree of hazard involved.
 - D. Determine the most effective and least hazardous approach to clean up and decontaminate.
3. “Dry spills” with no significant aerosol formation
 - A. Flood the area with disinfectant solution.
 - B. Soak up disinfectant and contaminated material with absorbent material (sand or paper towels), and dispose of it in a plastic biohazard bag or sealed container. Wear gloves for cleanup.
 - C. If routine cleanup is not possible, the unit may have to be decontaminated with a sterilizing gas such as paraformaldehyde.
 - D. Thoroughly wash the unit (if possible) after decontamination.
4. Liquid spills on the bench or floor
 - A. If significant aerosols were formed, the area should be evacuated and not reentered for at least 1 h.
 - B. Flood the area with disinfectant, and cover the spill with absorbent material (sand or paper towels). Wear gloves during cleanup.

Table 35.4 Risk assessment and exposure control plan for the parasitology laboratory^a

Parasitology task	Exposure risk		Personal protective equipment ^b				Engineering controls ^d	
	Blood and body fluid contact	Cultured biological agent exposure	Gloves	Lab coat/gown ^c	Face shield	Splash shield	BSC	Sharps containers readily accessible ^e
Concentrate fecal specimens, prepare smears and wet mounts	Low	BSL 2 ^f	R	Coat				Pipettes/sticks
Read fecal wet mounts	Low	BSL 2	R	Coat				Slides/coverlips
Prepare thick and thin blood films	High	BSL 2	R	Coat	A	A		Slides/coverlips
Perform blood concentrations	High	BSL 2	R	Coat	A			Pipettes
Read blood concentration wet mounts	Low	BSL 2	R	Coat				Slides/coverlips
Stain and read fecal or blood slides	Low	BSL 2		Coat				Slides/coverlips
Culture fecal protozoa	High	BSL 2	R	Coat				Pipettes
Culture blood parasites	High	BSL 2	R	Coat				Pipettes
Culture free-living amebae	High	BSL 2	R	Coat	A	A		Pipettes, slides/coverlips
Examine arthropod specimens	Low	BSL 2	R	Coat				Slides/coverlips
Perform antigen detection/PCR/DNA probes	High	BSL 2	R	Coat	A ^g	A ^g		Pipettes

^a Adapted from reference 34, protocol 15.3.2 (Risk Assessment).

^b Remove PPE when leaving the laboratory. R, required; A, one of the required alternatives.

^c Gowns with solid front and impervious to liquid. Many employers provide and launder gowns, thus eliminating the need for laboratory coats.

^d Recapping of needles is prohibited. Tubes should be carried in racks; alternatively, plastic tubes should be used. Wash hands when leaving the laboratory.

^e Sharps include scalpel blades, pipettes, plastic loops, sticks, needles, syringes, slides, and coverlips.

^f BSL 2, biosafety level 2.

^g Vortexing or other splatter-generating steps require the use of a BSC or safety shield.

- C. Dispose of absorbent and contaminated material in plastic bags or sealed containers, and autoclave.
 - D. Thoroughly wash the area after cleanup.
5. Centrifuge spills
- A. Shut off the instrument, and evacuate the area at once.
 - B. Do not reenter the area for at least 1 h until aerosols have settled.
 - C. The person entering the area to clean up should wear protective clothing, gloves, and a mask.
 - D. If liquids are present, soak up in absorbent material and handle as above. If liquids are not present, clean the instrument and room thoroughly before resuming work.
 - E. Wipe all surfaces with 2.5% amphyll or other disinfectant.
6. Spills in incubators, autoclaves, or other closed areas
- A. Flood with disinfectants, and soak up liquids with absorbent material.
 - B. Dispose of the material as specified above, if possible.

- C. If routine cleanup is not possible, the unit may have to be decontaminated with a sterilizing gas such as paraformaldehyde.
- D. Thoroughly wash the unit (if possible) after decontamination.

Disposal of Contaminated Materials

1. Autoclave screw-cap tubes before cleaning or discarding.
2. Discard specimens and cultures into containers with double plastic lining. Liners should be changed when the containers are about half full.
3. Place culture plates into "Biohazard" receptacles lined with autoclavable bags.
4. Materials or containers to be reused should be autoclaved before being cleaned. Place them in sealed and clearly labeled containers to minimize hazard to others before sterilization.
5. Any breakage of glass or leakage of contaminated materials should be reported to the supervisor or chief of microbiology at once for instructions on procedures for safe cleanup.

Standard Precautions

All laboratories should adhere to the concept of standard precautions, which state that all patients and all laboratory specimens are potentially infectious and should be handled accordingly (63). This concept arose from the observation that infections are often unrecognized in patients. “Standard precautions” replaces earlier terms such as Blood and Body Fluid Precautions, Universal Precautions, and Body Substance Precautions found in OSHA documents (63). The OSHA documents place the emphasis on blood-borne pathogens such as human immunodeficiency virus (HIV) and hepatitis B and C viruses, whereas the concept of standard precautions recognizes that all infectious agents and all other potentially infectious material, except sweat, pose a risk to the health care worker (63).

OSHA identifies a number of practices that should be implemented to protect the worker from exposure to blood-borne pathogens, including an exposure control and risk assessment plan (63). Methods that should be implemented to minimize exposure to infectious agents, to shield the laboratory worker from infectious material through a set of engineering and work practice controls, and to use personal protective equipment. In addition, the OSHA regulations require that employers provide hepatitis B vaccination and postexposure evaluation and follow-up; communicate the hazards to employees; and maintain appropriate records (63). Employees who decline immunization against hepatitis B virus are required to sign a hepatitis B vaccine declination form.

Note Under circumstances in which differentiation between body fluid types is difficult or impossible, all body fluids shall be considered potentially infectious.

1. All job positions with any exposure to blood and body fluids must be listed on an exposure form, which must match up with continuing education training records from the facility.
 - A. Training must be provided at no cost to the employee and during working hours.
 - B. Training shall be provided as follows:
 - a. At the time of initial assignment to job functions in which occupational exposure may occur
 - b. Within 90 days after the effective date of the standard
 - c. At least annually thereafter
2. A complete task assessment must be performed for employees who have any exposure; protective measures, including equipment, must be defined.
 - A. Engineering controls
 - B. Immunization programs

- C. Work practices (hand washing and procedures for handling sharps)
- D. Disposal and handling of infectious waste
- E. Use of personal protective gloves, gowns, and goggles
- F. Use of mouthpieces, resuscitation bags, or other ventilation devices
- G. Use of disinfectants
- H. Labeling and signs
- I. Training and education programs
- J. Postexposure follow-up

Some of the specifics are as follows:

- A. All procedures shall be performed to minimize splashing, spraying, spattering, and generation of droplets of these substances.
- B. When there is occupational exposure, the employer shall provide, at no cost to the employee, PPE such as (but not limited to) gloves (including hypoallergenic gloves, glove liners, powderless gloves, or other alternatives), gowns, laboratory coats, face shields or masks, and eye protection. Other options might include mouthpieces, resuscitation bags, pocket masks, or other ventilation devices.
- C. PPE is considered “appropriate” only if it does not permit blood or other potentially infectious materials to pass through or to reach the employee’s work clothes, street clothes, undergarments, skin, eyes, mouth, or other mucous membranes. The type and characteristics of outer garments depends on the tasks and degree of exposure anticipated.
- D. All working surfaces shall be cleaned and decontaminated after contact with blood or other potentially infectious materials. All spills shall be immediately contained and cleaned up by appropriate professional staff or others trained and equipped to work with potentially concentrated infectious materials.
- E. Specimens of blood or other potentially infectious materials shall be placed in a container which prevents leakage during collection, handling, processing, storage, transport, or shipping (46, 50, 64).
- F. Mouth pipetting or suctioning of blood or other potentially infectious material is prohibited.
- G. Certified BSCs or other combinations of personal protection or physical containment

devices shall be used for all activities that may pose a threat of exposure. BSCs shall be certified when installed, whenever they are moved, and at least annually.

3. Key questions that people ask concerning these rules are listed below (4).

A. How does OSHA define “occupational exposure”?

“Reasonably anticipated skin, eye, mucous membrane, or parenteral contact with blood or other potentially infectious materials that may result from the performance of an employee’s duties”

B. What does “reasonably anticipated” mean?

“Actual contact would be expected during an autopsy or surgery. In these cases, blood or other potentially infectious materials come in direct contact with the employee’s gloves or other protective clothing. In other cases, contact may not occur each time the task or procedure is performed, but when blood or other potentially infectious materials are an integral part of the activity, it is reasonable to anticipate that contact may result.”

C. What should the exposure control plan contain?

“The Exposure Control Plan is a key provision because it requires the employer to identify the individuals who will receive the training, protective equipment, vaccination, and other provisions of the standard.”

D. What is considered “appropriate” personal protective equipment?

“Gloves, gowns, lab coats, face shields or masks and eye protection, mouthpieces, resuscitation bags, pocket masks, or other ventilation devices. Such protection will be considered ‘appropriate’ only if it does not permit blood or other potentially infectious materials to pass through to or to reach the employee’s work clothes, street clothes, undergarments, skin, eyes, mouth, or other mucous membranes under normal conditions of use and for the duration of time which the protective equipment will be used. The type and characteristics of outer garments will depend upon the tasks and degree of exposure anticipated.”

E. Does this mean that protective clothing must be “impervious” or “fluid-proof”?

“Selection of personal protective equipment is performance-oriented. Selection of the type

and characteristics of necessary personal protective equipment is based upon the exposure anticipated to be associated with the task. In those instances where such equipment was incapable of halting penetration of blood or other potentially infectious materials normally encountered during a procedure, then additional protection such as a plastic apron should be worn or used.”

Note “Fluid-resistant” and “fluid-proof” no longer appear in the final rule.

F. How can the employer ensure that the employee uses appropriate PPE?

“It is not the intent that the employer ‘watch over everyone’s shoulder’ for compliance, but there are reasonable policies and regulations that employees follow.”

G. What does the standard say about accessibility, cleaning, repair, removal, and storage of PPE?

“The employer shall ensure that appropriate personal protective equipment in appropriate sizes is available and is accessible at the worksite; the employer shall clean, launder, and dispose of personal equipment; the employer shall repair or replace when necessary at no cost to the employee. If a garment is penetrated by potentially infectious materials, it shall be removed ASAP and replaced by clean garments. When these garments are removed, they must be placed in a designated area or container for storage, washing, decontamination or disposal.”

H. What is the employer’s responsibility if PPE or the hepatitis B vaccine is refused?

“The employer shall ensure that the employee uses appropriate personal protective equipment unless the employer shows that the employee temporarily and briefly declined to use personal protective equipment when, under rare and extraordinary circumstances, it was the employee’s professional judgment that its use would have prevented the delivery of health care services or would have created an increased hazard to the safety of the worker or co-worker. When an employee makes this decision, the circumstance shall be investigated and documented in order to determine whether changes need to be made to prevent such recurrences.”

If the employee declines to accept hepatitis B vaccination, a form indicating that fact must be signed by the employee and held in the file.

- I. What training is required for employees?
 “Training must be available at the worksite, at no cost to the employee, and during working hours. It shall be provided at the time of initial assignment to tasks where exposure may occur, within 90 days after the effective date of the Standard, and at least annually thereafter.”
- J. What type of training is required for personal protective equipment?
 “An explanation of the use and limitations of methods that will prevent exposure is required, including engineering controls (biosafety cabinets), work practices, and personal protective equipment. Information on types, proper use, location, removal, handling, decontamination, and disposal of personal protective equipment must be presented, in addition to an explanation of the basis for selection of such controls.”

Hepatitis Exposure Protocol

Laboratory personnel have a high risk of contracting hepatitis for the following reasons:

1. Frequent close personal contact with patients with hepatitis
2. Direct and frequent contact with biological specimens containing the virus
3. Frequent opportunity for accidental puncture wound with contaminated needles and sharp objects
4. Carelessness in handling specimens
5. Inadequate or unsafe disposal of contaminated needles, specimens, or other objects
6. Carelessness in proper and frequent hand washing technique

The prevention of hepatitis is the primary reason for the emphasis on infection control precautionary measures found in any safety manual (e.g., no smoking, eating, drinking, or mouth pipetting and procedures for safe specimen handling). These same procedures also apply to HIV.

All known hepatitis specimens must be so labeled; however, to minimize exposure to the virus, *every specimen should be handled as though it could transmit hepatitis*. Studies have shown that hepatitis may be transmitted to laboratory personnel in several ways:

1. Puncture or other wounds (HIV)
2. Abrasions of the skin (HIV)
3. Aerosols (inhaled into the respiratory tract)
4. By mouth (oral route)

5. Direct contact with the patient
6. Splashing material into the eyes

The following protocol should be followed in the event of exposure:

1. Immediately wash the exposed area with soap and water.
2. Report the incident to the supervisor and laboratory personnel office.
3. Consult with a physician in Employee Health Facility concerning possible recommendations (e.g., administration of immune serum globulin).

Dangerous Properties of Industrial Materials

OSHA requires each laboratory to develop a comprehensive, written chemical hygiene plan (CHP). Every hazardous chemical in the laboratory, regardless of the type of risk, volume, or concentration, must be included in the CHP. The plan should include storage requirements, handling procedures, location of OSHA-approved material safety data sheets, and the medical procedures that are to be followed if exposure occurs. The CHP must specify the clinical signs and symptoms of the environmental conditions (such as a spill) that would give the employer reason to believe that exposure had occurred. When such conditions exist, the CHP should indicate the appropriate medical attention required.

Ethyl ether (also known as ether, anesthesia ether, diethyl ether, ethyl oxide, sulfuric ether, and ethoxyethane) is so volatile that dangerous concentrations are readily built up in the laboratory atmosphere. It is highly flammable and has a tendency to form explosive peroxides. Its low flash point, low ignition temperature, wide explosive range, high volatility, and very heavy vapor (which tends to “pocket”) combine to make ethyl ether an extremely serious fire hazard. The spontaneous formation of explosive peroxides presents severe risks to the user who does not apply precautionary practices. Therefore, it is mandatory to follow these safety procedures (15, 16).

1. *Date* cans of ether immediately upon receipt.
2. *Do not attempt to open* a can that is 1 year old (after time of receipt); peroxides may form in sealed cans and explode when the cans are opened. Order appropriate quantities to avoid expensive waste.
3. *Date* the can of ether when opened; do not use after 1 month. Order cans of appropriate size to avoid waste.
4. *Store opened (corked) cans* of ether close to the floor, in a cool place, on a shelf, or in a cabinet

that is *not* airtight. The heavy vapors can dissipate along the floor, with less opportunity for contact with sources of ignitions such as an open flame and electric sparks.

5. *Never store* opened cans of ether in a refrigerator, since ether still vaporizes at refrigerator temperatures. If peroxides have formed from ether, merely opening the refrigerator door may trigger an explosion. The heavy vapors that collect in an airtight refrigerator may ignite on contact with the electrical refrigerator motor. This recommendation also applies to “shielded” refrigerators (those in which the electrical systems are protected).
6. Unopened cans may be stored with opened cans (near the floor on an open shelf or nonairtight cabinet), in a storage cabinet for flammable materials, or in a storage room for volatile substances.
7. Outdate and discard cans after storage for 1 month (if opened) or 1 year (if unopened).
8. Flush empty, or almost empty, ether cans with copious amounts of water before discarding. “Empty” cans have been known to explode! Do not flush more than the contents of a 0.25-lb (ca. 0.1-kg) can down the drain; consult the Research and Occupational Safety Office or the local fire department for proper disposal of large quantities. Empty, thoroughly rinsed cans may be discarded in the regular trash.
9. Do not attempt to open any containers of uncertain age or condition or those whose cap or stopper is tightly stuck. Peroxides have been known to form under the threads of caps! These containers should be discarded.
10. Unopened outdated cans must be delivered to Research and Occupational Safety for disposal (each institution may have a comparable office or safety office).
11. *Certain chemicals can be replaced by others that are safer.* Ethyl acetate (72), with a higher flash point (4.0°C), has replaced ether (flash point of -45°C) in the formalin-ether concentration technique. Hemo-De (Medical Industries, Los Angeles, Calif., or Fisher Scientific, Los Angeles, Calif.) can also replace ethyl acetate in the concentration procedure (56). Hemo-De has a flash point of 57.8°C and is generally regarded as safe by the U.S. Food and Drug Administration. Xylene, as used in the trichrome or iron hematoxylin staining of polyvinyl alcohol (PVA)-fixed fecal smears, poses potential toxic and fire haz-

ards. Again, Hemo-De has successfully replaced xylene in both the carbol-xylene and xylene steps of the trichrome procedure (55). Other substitutes are available as well (e.g., Hemo-Sol [Fisher Scientific]). Check with your local pathology departments or reagent suppliers for other alternatives.

12. Mercuric chloride, used in PVA and in Schaudinn’s fixative, presents both a toxic hazard and a disposal problem. Copper sulfate has been suggested as a substitute for mercuric chloride (26, 33); however, protozoan morphology is not as clear and precise when this formula is used. The use of zinc rather than copper gives fairly good morphology when the trichrome stain is used (27).

Note Information on other substances is provided in Table 35.5.

Current OSHA Regulations for the Use of Formaldehyde

Formaldehyde has been in use for over a century as a disinfectant and preservative; it is also found in a number of industrial products. There is disagreement about the carcinogenic potential of lower levels of exposure, and epidemiologic studies of the effects of formaldehyde exposure among humans have given inconsistent results. Studies of industry workers with known exposure to formaldehyde report little evidence of increased cancer risk (41). It also appears that persons with asthma respond no differently from healthy individuals following exposure to concentrations of formaldehyde up to 3.0 ppm (58).

OSHA requires all workers to be protected from dangerous levels of vapors and dust. Formaldehyde vapor is the most likely air contaminant to exceed the regulatory threshold in the clinical laboratory (13, 14). Current OSHA regulations require vapor levels not to exceed 0.75 ppm (measured as a time-weighted average [TWA]) and 2.0 ppm (measured as a 15-min short-term exposure). *OSHA requires monitoring for formaldehyde vapor whenever formaldehyde is used in the workplace. The laboratory must have evidence at the time of inspection that formaldehyde vapor levels have been measured, and both 8-h and 15-min exposure must have been determined.*

If each measurement is below the permissible exposure limit and the 8-h measurement is below 0.5 ppm, no further monitoring is required as long as laboratory procedures remain constant. If the 0.5-ppm 8-h TWA or the 2.0-ppm 15-min level is exceeded, monitoring must be repeated semiannually. If either the 0.75-ppm 8-h TWA or the 2.0-ppm 15-min level is exceeded (unlikely in a

Table 35.5 Potential hazards of industrial substances^a

Name of compound	Synonym	Hazard
Acids and bases		Extremely irritating and corrosive to the skin and mucous membranes. Can quickly cause burns and deep ulceration with ultimate scarring. Prolonged contact with dilute solutions has a destructive effect on tissue.
Ethyl acetate	Acetic ether	Absorbed through intact skin. Irritating to mucous surfaces, particularly the gums, eyes, and respiratory passages; is also mildly narcotic. Repeated or prolonged exposures cause conjunctival irritation and corneal clouding.
Formalin	Formaldehyde solutions	Severe local irritant. If swallowed, causes violent vomiting and diarrhea.
Mercury compounds		Local irritants and systemic poisons. Absorbed through intact skin. Strong allergens.
Methyl alcohol	Methanol	Absorbed through intact skin. Acutely, there is little or no danger, but with chronic use a toxic effect may develop because, once absorbed, it is eliminated very slowly, so that a cumulative effect can result with repeated low dosage.
Phenol	Carbolic acid	After skin contact, the area becomes white, wrinkled, and softened, and there is usually no immediate complaint of pain; later, intense burning is felt. Absorption is through intact skin and can be quite rapid. Upon spillage, death can occur within 30 min. In acute phenol poisoning, the main effect is on the central nervous system.
Potassium dichromate	Potassium bichromate	<i>Carcinogen.</i> Has a very corrosive action on the skin and mucous membranes. The ulcers produced are frequently painless and are slow to heal. Associated with cancer of the lungs.
<i>o</i> -Tolidine	3,3-Dimethylbenzidine	<i>Carcinogen.</i> One of the many aromatic amines that are recognized as carcinogens to the human bladder, ureter, and renal pelvis and suspected carcinogen to the intestines, lungs, liver, and prostate.
<i>o</i> -Toluidine	<i>o</i> -Methylaniline	<i>Carcinogen.</i> While it can be absorbed through intact skin, the main portal of entry is by inhalation. Can produce severe systemic disturbances.
Xylene	1-Dimethyl benzene	Acute toxicity may be greater than that of benzene or toluene. Absorption takes place chiefly through the lungs. Skin irritation may be serious. Extended exposure can cause gastrointestinal neurologic and tissue damage.

^a Data from I. N. Sax, *Dangerous Properties of Industrial Materials*, 4th ed., Litton Education Publications, 1975.

clinical laboratory setting), employees must be required to wear respirators. Accidental skin contact with aqueous formaldehyde must be prevented by the use of proper clothing and equipment (gloves and laboratory coats).

The amendments of 1992 add medical removal protection provisions to supplement the existing medical surveillance requirements for employees suffering significant eye, nose, or throat irritation and for those experiencing dermal irritation or sensitization from occupational exposure to formaldehyde. In addition, these amendments establish specific hazard-labeling requirements for all forms of formaldehyde, including mixtures and solutions composed of at least 0.1% formaldehyde in excess of 0.1 ppm. Additional hazard labeling, including a warning label that formaldehyde presents a potential cancer hazard, is required where formaldehyde levels, under reasonably foreseeable conditions of use, may potentially exceed 0.5 ppm. The final amendments also provide for annual training of all employees exposed to formaldehyde at levels of 0.1 ppm or higher (12).

Note The use of monitoring badges may not be a sensitive enough method to correctly measure the 15-min exposure level. Contact the Occupational Health and Safety Office within your institution for monitoring options. Usually, the accepted method involves monitoring airflow in the specific area(s) within the laboratory where formaldehyde vapors are found.

Latex Allergy

The incidence and evidence of clinical latex sensitivity appear to be increasing since its first description in 1979. Since the introduction of standard precautions, the use of latex gloves in health care workers has increased dramatically (7). Those at risk appear to be health care workers and employees working in latex industries, patients with atopic diathesis, and patients who underwent repeated surgical procedures during childhood (69). The allergic response occurs to one or more natural rubber latex proteins, resulting in contact urticaria, angioedema, allergic rhinitis, asthma,

or anaphylaxis. Early recognition of sensitization to latex is crucial to prevent the occurrence of life-threatening reactions in sensitized health care providers or patients (65). Latex allergy is now an important medical, occupational, medicolegal, and financial problem, and it is essential that policies be developed to reduce the problem (11, 40, 70). There also seems to be a relationship between allergies to natural latex rubber and allergies to avocados, chestnuts, and bananas. A high incidence of latex sensitivity has also been found in people with spina bifida (8, 21).

The use of cornstarch powder in gloves can sensitize healthy people and exacerbate the symptoms of allergic patients. The powder spreads the latex allergens into the environment (69). Accompanying this increase in latex allergy is evidence of positive circulating specific immunoglobulin E antibodies to latex (31). Unfortunately, the primary treatment for latex allergy is avoidance.

Quality Systems

The area of quality systems forms an integral part of any clinical laboratory operation. In many cases of clinical laboratory testing, various programs and guidelines for quality assurance procedures (including QC) have been thoroughly outlined. However, specific quality assurance recommendations within the parasitology section of microbiology have not been well defined in the past, and the information in this chapter should help clarify these recommendations. Although the diagnostic procedures in this area seldom yield numerical data, there are still a number of QC measures that can help to ensure accurate results.

Extent of Services

The range of services provided will vary from one laboratory to another. To comply with the Health Care Financing Administration (HCFA) guidelines, only two extent classifications (rather than the previous four) are recognized in parasitology by the College of American Pathologists (17).

1. *Extent 2*. "Limited parasitology performed. The laboratory is able to recognize the presence of parasites, including protozoa in clinical specimens, but may need to refer them for definitive identification. When permanently stained smears for intestinal protozoa are indicated, polyvinyl alcohol fixative (PVA) or other appropriate fixative is available, and such material is placed in a fixative and then referred to a reference laboratory for staining identification."
2. *Extent 3*. "Definitive identification of parasites present to the extent required to establish a correct clinical diagnosis and to aid in selection of safe and effective therapy. Laboratories are expected to

have a high degree of expertise and should be able to differentiate *Plasmodium falciparum* from other species of *Plasmodium*."

Note There is no longer a College of American Pathologists listing for extent 1 (no parasitologic procedures are performed and all specimens are submitted to a reference laboratory). However, in this situation, the laboratory would not be required to subscribe to outside proficiency testing specimens in this discipline.

Proficiency Testing

Based on the Extent of Services mentioned above and the requirements in the Clinical Laboratory Improvement Amendments of 1988 (CLIA '88), all (with rare exceptions) clinical laboratories (including physician office laboratories performing other than waived tests) must participate in an approved program of interlaboratory comparison testing that is consistent with the level and complexity of the work performed. The comprehensive microbiology and/or parasitology survey programs are recommended. The state Department of Health must be consulted to confirm which proficiency testing services fulfill the requirements related to a laboratory's particular accreditation, particularly if the laboratory accepts interstate specimens in parasitology.

There must be evidence of active review of the survey results by the laboratory director or the designated supervisor. There also must be written evidence of evaluation of the results and, if indicated, corrective action when unacceptable results have been reported. Corrective-action statements should review the correct answer and specific steps that will be taken to ensure that the same, or similar, error will not occur in the future. On the basis of the regulations within CLIA '88, HCFA or one of the HCFA-approved agencies (may include some state agencies) will be involved in the process of monitoring laboratory performance and coordinating any possible sanctions that might be involved as a result of unacceptable performance in proficiency testing programs.

Copies of the 28 February 1992 *Federal Register* containing the final CLIA regulations can be obtained by writing to Government Printing Office, Attn: New Order, P.O. Box 371954, Pittsburgh, PA 15250-7954. Specify the date of the issue requested (28 February 1992) and stock number (069-001-00042-4). A \$3.50 check or money order payable to "Superintendent of Documents" or a Visa or MasterCard number and expiration date should be enclosed. Orders may be made by telephone [(202) 783-3238] or fax [(202) 512-2250].

It is recommended that all of the proficiency testing specimens be saved for future review, particularly when students are being trained or technologists, pathologists,

Table 35.6 Recommendations for the handling and examination of proficiency-testing specimens

Specimen	Method	Comments
Formalin	Direct examination	Although some directions recommend sampling the vial after mixing, if organism numbers are small, they may be missed. Another option is to allow the vial to stand on the counter for a minimum of 30 min, then take one small drop from the bottom of the vial, and prepare the coverslip (usually 22 by 22 mm). If iodine is used, make sure the overall color is not too dark; helminth eggs may appear to be debris. The color should resemble strong tea. There is normally not sufficient material to perform a concentration procedure; this is not recommended. The entire coverslip preparation should be examined with the 10× low-power objective. At least 1/4 to 1/3 of the area should be examined with the 40× high dry objective. The use of immersion oil is not recommended for these preparations.
PVA fecal smear	Permanent stain (trichrome or iron hematoxylin)	Although many laboratories have switched to nonmercury fixatives, it is important to remember that some proficiency-testing fecal specimens for permanent staining have been preserved in mercury-based fixatives. This means that <i>you must include the iodine and subsequent alcohol rinse steps in your staining method to remove the mercury from the smear</i> . If this is not done, the overall result may be very poor. Both trichrome and iron hematoxylin staining methods can be used for these smears. At least 300 fields should be examined with the 100× oil immersion objective. These stained smears can be examined with a 50× or 60× oil immersion lens, but final organism identification often requires the 100× oil immersion objective. Consult your PT agency for mercury or nonmercury use.
Formalin or fecal smear (non-PVA)	Modified acid-fast stain	Special staining is required if the patient history is suggestive of possible cryptosporidiosis. Unless there is some indication (history of immunosuppression), it is unlikely that <i>Cryptosporidium</i> is a possibility. If you perform a modified acid-fast stain, either the hot or cold method is acceptable. Make sure that the destaining step is not too harsh; do not use acid-alcohol, commonly used in the routine Ziehl-Neelsen acid-fast stain. Generally, a mild destain is recommended (1 to 3% sulfuric acid). Although the organisms can be seen with the low-power (10×) objective, it is recommended that the high dry (40×) objective be used. The 50× oil immersion objective is also an accepted approach to screening the smear.
Thin blood film	These films arrive already stained	The <i>entire blood film</i> (including the area where the drop was placed on the slide) should be carefully examined with the 10× low-power objective. Often, when these films are prepared, any microfilariae present are at the edges of the blood or in the thick portion of the film. Without this type of examination, these microfilariae may be missed. With the 100× oil immersion lens, a minimum of 300 oil immersion fields should be examined. These stained blood films can be screened with a 50× or 60× oil immersion lens, but final organism identification often requires the 100× oil immersion objective. If young malarial rings are present, they could be missed if only the lower-power oil immersion lens is used.
Thick blood film	These films arrive already stained	The entire thick blood film should be examined with the 10× low-power objective. When these films are prepared, any microfilariae present may be at the edges of the blood or in any portion of the thick film. Without this type of examination, these microfilariae may be missed. If microfilariae are seen, morphologic details can be seen using the high dry 40× objective. With the 100× oil immersion lens, a minimum of 300 oil immersion fields should be examined. These stained blood films can be screened with a 50× or 60× oil immersion lens, but final organism identification often requires the 100× oil immersion objective. If young malarial rings are present, they could be missed if only the lower-power oil immersion lens is used.
Antigen detection using fecal immunoassays	Fluorescent-antibody assays, enzyme immunoassays, or the cartridge format tests are available	Enzyme immunoassays (antigen detection, no centrifugation recommended) <ol style="list-style-type: none"> Remember to thoroughly rinse the wells according to the instructions; do not eliminate any of the rinse steps. Make sure each well receives the total number of rinses required. Make sure the stream of buffer goes directly into the wells. Use a wash bottle with a small opening, so you have to squeeze the bottle to get the fluid to squirt directly into the wells. When the directions tell you to “slap” the tray down onto some paper towels to remove the last rinse fluid, make sure you slap it several times. Don’t be too gentle; the cups will not fall out of the holder. Before adding the last reagents, the wells should be empty of rinse buffer (not dry, but empty of excess fluid).

(continued)

Table 35.6 (continued)

Specimen	Method	Comments
		<p>Fluorescence (visual identification of the organisms)</p> <ol style="list-style-type: none"> 1. Since you will be looking for the actual organisms (cysts of <i>Giardia</i> and/or oocysts of <i>Cryptosporidium</i>), this test can be performed on centrifuged stool ($500 \times g$ for 10 min) to increase the sensitivity. 2. Remember to thin out the smear; it is important to make sure that the slides are thoroughly dry before adding reagents. The slides can be placed in a 35°C incubator for about 30 min to 1 h to make sure that they are dry before being processed. If the material on the wells is too thick, it may not dry thoroughly and may fall off of the glass. It is better to let them dry longer rather than for too short a time. A heat block is <i>not</i> recommended for this purpose. 3. <i>Gently</i> rinse the reagents from the wells; do not squirt directly into the wells, but allow the rinse fluid to flow over the wells. 4. Remember that not all clinical specimens provide the 3+ to 4+ fluorescence that we often see in the positive control. Also, from time to time, you may see fluorescing bacteria and/or some yeast in certain patient specimens. This is not that common, but the shapes can be distinguished from <i>Giardia</i> cysts and/or <i>Cryptosporidium</i> oocysts. The intensity of the fluorescence may vary, depending on the filters. If your filters demonstrate both the yellow-green fluorescence and the red-orange counterstain, the organisms may not appear quite as bright as when the yellow-green filter only is used. Both approaches are acceptable and may reflect personal laboratory preferences. 5. Make sure to examine the edges of the wells. Sometimes in a light infection, the edges contain organisms while the organisms in the middle of the well may be a bit more difficult to detect (thick area). <p>Lateral-flow cartridges (antigen detection, no centrifugation recommended)</p> <ol style="list-style-type: none"> 1. If the stool is too thick, the addition of reagents will not thin it out enough. If the specimen poured into the well remains too thick, the fluid will not flow up the membrane. If your specimens arrive in fixative and there is no fluid at the top of the vial overlaying the stool, this means that the vial may have been overfilled with stool. These specimens will have to be diluted with the appropriate diluent before being tested. 2. It is always important to see the control line indicated as positive all the way across the membrane, not just at the edges. 3. A positive test result is generally much lighter than the control line; this is normal. 4. At the cutoff time to read the result, any color at all visible in the test area should be interpreted as a positive. 5. Do not read/interpret the results after the time indicated in the directions; you may get a false-positive result.
Photomicrograph	Project to view	These 2×2 photomicrographs are generally accompanied by some type of history or measurements of the object. It is important to actually project the image. Observing the slide through a small slide holder may not reveal sufficient detail for the accurate identification of the specific organism shown in the slide.
All specimens	Data entry	It is important to remember to very carefully check your responses and entry of choices onto the appropriate forms. When being graded, your responses will be evaluated on data submitted. If the incorrect answer is marked, you may be penalized, depending on consensus and a number of other parameters. Prior to submitting data, familiarize yourself with the paperwork and information requested. It is important for the laboratory to establish some type of tracking system for these specimens. You should have a log book or something similar where the arrival date and due date for each proficiency-testing module can be clearly entered. One person should be responsible for communicating with the agency in the event of breakage, failure of the shipment to arrive, etc. Each agency will give you at the beginning of the year an anticipated schedule of dates for shipment of each set of samples for testing.

and residents are receiving review training. It is just as important to maintain negative specimens as to maintain positive ones, since many errors are made in which artifacts are identified as parasites. Specimens should be periodically checked to make sure that the volume of fixative is sufficient to prevent the specimens from drying out. These specimens should be cataloged for easy reference.

Specific recommendations for the handling and examination of proficiency testing specimens can be found in Table 35.6. These guidelines should assist the participant in the proper approach to these specimens.

CLIA '88 mandated universal regulation for all clinical laboratory testing sites in the United States, including previously unregulated sites in physician offices. Quality testing was to be achieved through a combination of total quality management and mandated minimum quality practices. Through both internal and external proficiency testing, performance standards were also mandated. After the implementation of CLIA '88, the percentage of laboratories passing proficiency testing requirements has improved and almost all laboratories are currently using quality practices for a more comprehensive quality system approach (22).

Survey results from the Laboratory Proficiency Testing Program, Toronto, Ontario, Canada, over the course of their program, which began in 1977, indicate a marked improvement in laboratory performance. They send four samples in each of four surveys per year consisting of specimens to be examined for gastrointestinal parasites. Improvement is thought to result from a combination of voluntary withdrawal by laboratories with poor performance and improved performance by the other laboratories. Extensive educational initiatives have also played a significant role in improved performance (71).

In-House Quality Control

Supervision

The QC program should be under surveillance by the chief technologist or section supervisor and should be reviewed at least once each month by the laboratory director, QC supervisor, or other supervisor designate. There should be written evidence of active review of all records (controls for routine procedures, instrument function tests, and equipment checks [temperature, humidity, systems, maintenance]). There should also be written evidence of corrective action when controls do not fall within acceptable limits. A written checking system should be in operation to help detect clerical errors, analytical errors, and/or unusual laboratory results. This system should also provide for error correction within acceptable time frames. With

the emphasis on outcome-oriented measures, it is very important to have the capability to track testing through the preanalytical, analytical, and postanalytical phases (specimen integrity, processing, testing, reporting, and consultation), with primary emphasis being placed on accurate, reliable, and timely diagnostic testing for good patient outcome. This approach to laboratory inspections will be emphasized by HCFA or other HCFA-designated agencies for outside inspections and should also be emphasized in all in-house quality assurance programs.

Procedure Manuals

Although card files and wall charts are acceptable for quick review, a well-written and complete procedure manual is very important for the routine operation of the laboratory and mandatory for accreditation requirements (Table 35.7). Instructions contained in manufacturers' package inserts are helpful but do not fulfill the requirements for a procedure manual. It is highly recommended that the National Committee for Clinical Laboratory Standards (NCCLS; now the Clinical Laboratory Standards Institute [CLSI]) format be followed for protocol preparation (47). This publication covers the design, preparation, maintenance, and use of technical procedure manuals for the clinical laboratory. The procedure manual should contain for each test (i) the principle of the test; (ii) acceptable specimens (including rejection criteria) and instructions for proper specimen collection and processing; (iii) preparation of reagents and solutions; (iv) all supplies and equipment necessary to perform the test; (v) QC procedures, results, and interpretation (including corrective action if QC is out of control); (vi) the test method; (vii) possible results; (viii) the correct way to report results; (ix) procedure notes (tips); (x) limitations of the procedure; (xi) additional tables and charts; and (xii) references. Complete parasitology protocols (written according to the NCCLS guidelines) can also be found in the *Clinical Microbiology Procedures Handbook* (34).

Specimen Handling and Record Storage

All specimens must be recorded in an accession book, log book, worksheet, computer, or other comparable record. If specimens are not examined as fresh material, they should be preserved in appropriate fixatives for later examination. On the basis of current guidelines, it is recommended that specimen and test result records be kept for at least 2 years (longer for pathology records and those from the blood bank). Also, remember that when your laboratory is inspected, you must be able to retrieve those records within no more than a few hours; this is particularly important if the inspector is actually checking this parameter.

^a Consult the regulations in question as to manual requirements for specific sections (e.g., microbiology, parasitology, hematology). For further information, see reference 47.

^b Consult state and local regulatory agencies for additional requirements.

^c X-1, AABB does not accept textbooks; X-2, required in procedure manuals of AABB-accredited blood banks and transfusion services by the National Committee on Inspection and Accreditation; X, listed as required; O, not listed specifically.

Test Request Requisitions

All requisitions should be designed to allow sufficient information for patient and physician identification and any clinically relevant information. Specific items should include (i) patient name, (ii) patient identification number, (iii) name of ordering physician, (iv) source of specimen, (v) specific procedure(s) ordered, (vi) time of specimen collection, and (vii) time of receipt or initial processing by the laboratory. Other helpful information, particularly in the parasitology division, is (i) suspected diagnosis, (ii) travel history, and (iii) recent medication. Since this infor-

mation is often not on the original requisition, the physician may have to be contacted for clarification.

Procedure QC and Documentation

QC measures for all procedures are included in the individual protocols within this section of the book. Not only must the QC checks be performed as indicated, but also complete documentation should be generated, including specific plans for out-of-control results and problem resolution. Result expectations and normal results or values must be specifically defined and posted on any QC check

sheets used in the laboratory. It is not sufficient to merely check a column that QC is within acceptable limits; you must also have on these sheets a definition of what normal or “acceptable limits” means. Dates and space for the initials or name of the person performing the QC checks must also be included. Specific procedure recommendations include the following (19, 25, 34, 42, 57).

1. The examination of formed stools should include a concentration procedure.
2. A permanent stained smear is recommended for every stool specimen submitted for testing (liquid, soft, or formed).
3. A direct wet mount should be performed for fresh stool specimens, in addition to the concentration and permanent stained smear. Since the direct wet mount is designed to allow the detection of organism motility, it is not necessary to perform the direct wet mount on preserved specimens or formed stools. Consequently, if the stool specimens are received in preservative, proceed directly to the concentration and permanent stained smear.
4. Both thick and thin blood films are prepared for examination for malarial parasites.
5. Stained smears are washed with buffered distilled water (pH 6.8 to 7.2).
6. Adequate numbers of oil immersion fields should be examined (at least 300) on both stained blood films and permanent stained fecal smears.

Test Result Reports

With few exceptions, the following methods of reporting are acceptable.

1. All parasites should be reported, regardless of whether they are considered nonpathogenic or pathogenic. The presence of any parasites within the intestine generally confirms that the patient has acquired the organism through fecal-oral contamination.

Table 35.8 Quantitation of organisms^a

Category	Quantitation	
	Protozoa	Helminths
Rare	2–5/cslp ^b	2–5/cslp ^c
Few	1/5–10 hpf	1/5–10 lpf
Moderate	1–2/hpf to 1/2–3 hpf	1–2/lpf
Many	Several/hpf	Several/lpf

^a This quantitation (based on a 22- by 22-mm coverslip) is used by the Centers for Disease Control and Prevention, Proficiency Testing Program, Microbiology–Parasitology, 1985. Abbreviations: cslp, 22- by 22-mm coverslip; hpf, high-power field (magnification, ×400); lpf, low-power field (magnification, ×100).

^b Total coverslip with high dry power (magnification, ×400).

^c Total coverslip with low power (magnification, ×100).

2. Generally, protozoa and helminths are not quantitated on the laboratory slip. However, the specific stage (i.e., trophozoites, cysts, oocysts, spores, eggs, or larvae) is indicated.
3. Exceptions to quantitation would be *Blastocystis hominis* (there may be some association between numbers and symptoms) and *Trichuris trichiura* (light infections may not be treated).
4. The complete genus and species name of the organism identified should be reported.
5. Charcot-Leyden crystals should be reported and quantitated.
6. If the specimen is fresh or freshly preserved, budding yeast cells should be mentioned and quantitated.
7. All quantitation should be consistent (Table 35.8).
8. Helminth eggs and larvae should be reported.
9. Special circumstances (additional specimens required to rule out this infection, etc.) require additional comments on the laboratory report.
10. Remember, the name of the laboratory actually performing the procedures must be indicated on the final report or elsewhere.

Reagents

All reagents should be properly labeled with (i) content, (ii) concentration, (iii) date prepared or received, (iv) lot number, (v) date placed in service, and (vi) expiration date. If reagents are prepared in-house, you should also have recorded (i) the name of person preparing the reagent and (ii) the date and results of the QC check.

The specific gravity of certain solutions (e.g., zinc sulfate) should be checked before use (this is particularly important if the solution is used infrequently). The hydrometer should have a scale large enough to differentiate between specific gravities of 1.18 for use with fresh specimens and 1.20 for use with formalinized specimens. This type of solution should be kept in a tightly stoppered bottle.

Stains should be routinely checked with control specimens for correct staining properties before use. Certainly, new lot numbers or new batches of stain should be checked. Also, if reagent use is infrequent, the stains should be checked before use. The same rule generally applies to fixatives.

With these basic recommendations in mind, the following specific QC methods can be used. While not every reagent used in diagnostic parasitology work is reviewed, these methods can be adapted to other reagents.

The examination of fecal material for ova and parasites may reveal, in addition to parasitic organisms, cells

of human origin (blood cells). Most of these cells are not usually found in the stool; however, they may be found in the presence of parasites and/or other disease-producing organisms. These cells may occur in the stool without the presence of a specific etiologic agent (allergic conditions, ulcerative colitis, etc.). The buffy coat cells (white blood cells [WBCs]) can also be used as a QC check for various fixatives. The WBCs normally found in the buffy coat portion of whole blood include polymorphonuclear neutrophils, eosinophils, lymphocytes, and monocytes (macrophages). When blood is visible in the stool (indicating the presence of fresh blood), the WBC morphology is very similar to that seen on the stained thin blood film used for a differential. However, if the blood has been in the gastrointestinal tract for some time, the cellular morphology changes slightly.

QC for Schaudinn's Fixative

1. Collect a fresh tube of blood (lavender top, EDTA anticoagulant), or get a tube from the hematology section (high WBC count, if possible).
2. Centrifuge the blood, and remove the buffy coat (layer containing WBCs).
3. Add the buffy coat to approximately 2 to 4 g of fresh, soft stool, and mix thoroughly *but gently*.
4. This stool-WBC mixture can be smeared onto several slides and immediately immersed in Schaudinn's fixative.
5. After staining, if the WBCs appear well fixed and typical morphology is visible, one can assume that any intestinal protozoa placed in the same lot number of Schaudinn's fixative would also be well fixed, provided that the fecal sample was fresh and fixed within recommended time limits.

QC for PVA Fixative

1. Mix approximately 2 g of fresh, soft stool with 10 ml of PVA (in solution, ready for use).
2. To this PVA-stool mixture, add several drops of buffy coat cells (collected as above) and mix gently.
3. After a 30-min fixation, pour a small amount of the stool-PVA-cell mixture onto a paper towel to absorb the excess PVA.
4. The material can then be smeared onto several slides, allowed to dry thoroughly (60 min at room temperature or 30 min at 35°C), and stained. After staining, if the WBCs appear well fixed and typical morphology is visible, one can assume that any intestinal protozoa placed in the same lot number

of PVA fixative would also be well fixed provided that the fecal sample was fresh and fixed within recommended time limits.

Note *Entamoeba coli* mature cysts are very difficult to fix properly and may be difficult to identify on the stained smear. For this reason, it is possible to have fixatives that are adequately QC checked but do not always yield good morphology for this particular organism. Use of a longer fixation time (60 min) sometimes produces better morphology after staining.

Note The same approach can be used for other stool preservatives (sodium acetate-acetic acid-formalin [SAF], zinc- and copper-based fixatives, and other single-vial collection systems).

QC for Stains (Trichrome, Iron Hematoxylin, etc.)

1. Slides may be prepared from a known positive fecal specimen preserved in PVA or SAF. These slides can then be stained and checked for typical organism morphology. Positive PVA-preserved samples can be purchased commercially; many slides can be prepared from one sample. QC slides (already prepared and ready for staining) are also available commercially.
2. Buffy coat cells (after appropriate fixation) may also be used to check the staining properties of each new lot number of stain.

Note Do not prepare too many slides in advance. If dry PVA fecal smears are held too long before staining, the organism or buffy coat cell morphology may be poor.

Instruments and Equipment

General requirements include the following: (i) all instruments and equipment should be on a routine preventive maintenance schedule, and records should be maintained in writing; (ii) instrument manuals and maintenance/service records should be available for technical personnel to review; (iii) all thermometers should be checked and calibrated against certified standard thermometers, and the information should be recorded in writing; and (iv) checked and calibrated thermometers should be in every refrigerator, freezer, incubator, water bath, heat block, etc., and temperatures should be recorded on each day of use. As specific requirements, (i) centrifuges should be calibrated for correct speed and the calibration should be recorded on the instrument, and (ii) all microscopes should be calibrated by using a stage and ocular micrometer, the calibrations should be posted on the instrument, and recalibrations should be performed if any ocular or objective is switched on that particular microscope. It is recommended that microscopes be recalibrated once

each year, even if the oculars and objectives have not been changed. This is particularly true if the microscopes receive heavy use.

Reference Materials

Reference materials should be available for comparison with unknown organisms, refresher training, and the training of additional personnel. Ideal reference materials include formalin-preserved specimens of helminth eggs, larvae, and protozoan cysts; stained fecal smears of protozoan oocysts, cysts, and trophozoites; and positive blood smears. Color slides and atlases are recommended, although the level of microscopic focus cannot be changed. Reference books and manuals from a number of publishers are available, and selected ones should be part of the parasitology library. It is also recommended that you maintain a list of consultants who can be called in case questions arise.

Patient Outcome Measures

Patient outcome measures often refer to aspects of quality assurance that are monitored in addition to more narrow parameters such as QC. Among the issues that are appropriate to monitor on an ongoing basis are the following:

1. Submission of the appropriate specimen within the correct time frame for collection
2. Condition of the specimen when received by the laboratory (too old, volume not sufficient, contains interfering substances, etc.)
3. Turnaround time for test results
4. Appropriateness of STAT requests
5. Improvements in compliance with established guidelines for the above, particularly after continuing-education efforts
6. Clinical relevance of and documented use of test results

All of these quality assurance parameters can be monitored by using the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) 10-step criteria for developing and implementing monitoring and evaluation activities (35). These 10 steps are listed below.

1. *Assign responsibility.* The designated individual identifies and assigns responsibilities to others within the department and ensures that these responsibilities are fulfilled.
2. *Delineate scope of care.* Delineating the scope of care involves identifying the diagnostic and therapeutic modalities used, times and locations where

services are provided, types of personnel providing care, and all clinical services within the laboratory.

3. *Identify important aspects of care.* To effectively use the institution's resources in quality assurance, activities selected should be those with the greatest impact on patient care (the function occurs frequently or affects large numbers of patients, serious consequences could occur if services are not provided correctly or within set time frames, and the issue has tended to cause problems for staff and/or patients in the past).
4. *Identify indicators.* Indicators are well-defined, objective variables that are used to monitor the quality and appropriateness of any selected aspect of patient care. Within the laboratory, indicators could include clinical situations in which it may be inappropriate to use a particular test, situations in which inappropriate tests are often used, correct sequencing of tests, and clinical outcomes that may indicate inappropriate test use for a given situation.
5. *Establish thresholds for evaluation.* The thresholds for evaluation must relate specifically to the indicator and establish a value below which one does not continue to monitor and above which one continues to monitor and work on improvement and reaching the threshold or moving below.
Note Some monitoring of an indicator usually occurs before a reasonable threshold can be identified. Once the threshold has been determined, monitoring and educational efforts continue, with the goal being to reach or go below the threshold. Once the threshold has been reached, consideration may be given to lowering it even more, thus leading to additional improvements in the indicator being monitored.
6. *Collect and organize data.* The following must be determined for each indicator: data sources, data collection method(s), sampling system, time frame for data collection, and process for comparing level of performance with set thresholds.
7. *Evaluate care.* If the data indicate that the acceptable threshold of performance has not been reached, extensive review occurs to identify problems or opportunities for improvement. An analysis of patterns or trends (specific shifts, units, personnel, skills) can help identify specific areas for improvement and changes. If the threshold of acceptance has been reached, it should be reevaluated in terms of keeping it where it is or possibly lowering it further to strive for additional improvements. If the decision is made to leave the threshold where it

is, monitoring may be performed on a less frequent basis (every 6 months and then every year), just to verify that the data do not indicate that performance has declined.

8. *Take actions to solve identified problems.* The laboratory develops a plan of action that specifies who or what is expected to change, what action is appropriate, and when the changes should be complete. Three of the most common causes of problems are insufficient knowledge or poor communication, defects in the process, and poor compliance with process expectations. Frequently, educational presentations by various means (one on one, verbal presentations, written information, newsletters) can be used to help resolve the problems.
9. *Assess the actions and document improvement.* After sufficient time is allowed for improvements to occur, follow-up assessments are very important in documenting what progress has been made. This process must focus on the problem or opportunity for improvement, not on the action taken. If improvement is found, less frequent monitoring may be necessary; if the problem remains, new action should be taken with subsequent assessment for evidence of improvements.
10. *Communicate relevant information to the organizationwide quality assurance program.* It is critical that the findings not only be reviewed within the area being examined but also be conveyed and discussed at all levels of management. In addition to these discussions, documentation of such discussions is mandatory; one method often used is meeting minutes.

Continuous Quality Improvement, Total Quality Management, or 10-Step and FOCUS-PDCA for Performance Improvement Activities

Continuous quality improvement (CQI) (or total quality management) is a continuous quality improvement process that evaluates processes from a customer satisfaction point of view. The aim is continuous process improvement. This approach is a natural extension and expansion of the quality assurance programs that laboratories have been using for the past few years. CQI uses familiar tools such as check sheets, run charts, and flowcharts in new ways. Issues for review in a quality improvement program include some of the issues involved in a quality assurance program, such as timeliness of response to requests, turnaround time, and effective communication. *The problem-solving process in a CQI laboratory is done by broad-based teams with members from all affected groups inside and outside the laboratory. Team members are trained in and use group process methods for identifying problems and generating solutions. Rather than management remaining "top down and autocratic," it becomes "bottom up and independent."*

CQI laboratories focus on improving customer satisfaction; however, "customers" may be defined differently from the traditional use of the word. A CQI customer can be anyone who uses the products of the production process—a ward clerk responsible for charting results, a patient needing blood drawn for preadmission tests, or a physician waiting for a STAT result. Anyone who is an "end user" of the laboratory process is a customer and should be satisfied with the laboratory's product.

Table 35.9 Ten-step and FOCUS-PDCA grid for organizing performance improvement activities

Ten-step		FOCUS-PDCA
1.	Assign responsibility	<u>F</u> ind a process to improve
2.	Delineate scope of care	<u>O</u> rganize a team that knows the process
3.	Identify important aspects of care	<u>C</u> larify current knowledge of the process
4.	Identify indicators	<u>U</u> nderstand sources of process variation
5.	Establish thresholds for evaluation	<u>S</u> elect the process improvement
6.	Collect and organize data	<u>P</u> lan (plan the improvement action)
7.	Evaluate care	<u>D</u> o (test the action)
8.	Take action	<u>C</u> heck (determine the effect of the action)
9.	Assess the effectiveness of actions	<u>A</u> ct (implement the action broadly)
10.	Communicate findings	

JCAHO uses the term “continuous quality improvement.” The concept of “quality assurance” has been changed to “quality assessment and improvement” and includes the major trends leading to quality improvement. The formal surveillance process is deemphasized in lieu of promoting activities that better reflect the principles of CQI. *However, this does not suggest that JCAHO will abandon the 10-step process.* The use of CQI requires a shift in the organization’s definition of quality from “good enough if it meets standards” to “we must work continuously to improve quality.” This whole process is similar to any recommendation for problem solving; however, there are specific differences to consider.

1. Empowerment of employees to become involved in analyzing, operating, recommending change, and

implementing solutions is necessary for CQI to be adopted.

2. CQI focuses on continuous monitoring of processes, not just limited issues.
3. The problems identified almost always cross over multiple departments or units.
4. The key issue always focuses on customer satisfaction and how we define it, measure it, monitor it for success, fix it when things go wrong, etc.
5. Groups who work on these identified problems include members from all areas relevant to the final service product (from initial ordering or product to final delivery).
6. The identification of areas for improvement originates from all levels within the institution.

Table 35.10 Information regarding the HCFA self-survey process (CLIA): alternate quality assessment survey

Issue	Comments
Survey process	Respond to 45 “Yes/No” questions; some may require a written response, review dates, or submission of documentation. A checklist is provided to help you identify which questions require documentation. <i>Do not send original laboratory documents.</i>
“Review” questions	Questions that concern review of laboratory’s policies, procedures, records, etc., refer to a periodic review that is sufficient to demonstrate effective policies and to correct/modify ineffective ones. Reviews must be documented.
“Representative sample”	This means a review of a variety of records, requisitions, etc., that is sufficient to demonstrate whether policies and procedures are being accurately and completely followed.
Time line	The form must be completed and returned within 15 days of receipt to the State Agency return address.
General laboratory information	Includes name, address, type of CLIA certificate, levels of test complexity performed (waived, provider-performed microscopy, moderate, high), and annual test volumes (all areas of the laboratory). Microbiology includes bacteriology, mycobacteriology, mycology, parasitology, virology, general immunology, and syphilis serology. Parasitology includes direct preps, ova and parasite preps, and wet preps. Key information includes any changes regarding testing, testing sites, and laboratory personnel. <i>Documentation must include demonstration of qualifications of newly hired personnel or changing positions since last CLIA on-site survey (licenses, diplomas, degrees, certificates, and education and experience).</i>
Laboratory assessment	Specific areas within this category include patient test management, QC, proficiency testing, comparison of test results (different methodologies), relationship of patient information to test results, personnel assessment, communications and complaint investigations, and quality assurance review.
Attestation statement	The director of the laboratory is required to sign in ink to attest to the accuracy and honesty of the data submitted in the questionnaire.
Checklist	This checklist is designed to help you prepare and include written documentation to accompany the completed questionnaire.
Appendix A	This list contains a list of analytes or tests; if your laboratory performs any of these procedures, you must be enrolled in a proficiency testing (PT) program for those analytes or tests. <i>You must be enrolled in PT for the full extent of testing being performed (e.g., Gram stain, acid-fast stain, direct antigen testing, isolation, identification, and susceptibility).</i>
Appendix B	This section contains guidelines for counting tests (per questions regarding annual test volumes).

7. A simplified version of the above is as follows.
 - A. Identify and choose a process to fix.
 - B. Analyze all aspects of the issue.
 - C. Select a possible solution.
 - D. Correct the process.
 - E. Monitor the results.
 - F. If results are satisfactory, solidify the change and move on to other issues.
 - G. Who does it? A group composed of representatives of all aspects of the process under review.

Another way to look at organizing performance improvement activities can be seen in Table 35.9. This approach merges the 10-step and FOCUS-PDCA approaches; similarities are certainly more numerous than differences.

CLIA '88 Inspection Process

HCFA began implementing the performance-based survey process in February 1996. This is a self-survey process, and the form used is titled the Alternate Quality Assessment Survey (AQAS). The form is designed to be used in certain laboratories for recertification purposes under the CLIA program in lieu of an on-site survey. Laboratories that were surveyed under the CLIA program via the State Agencies and found to have exceptional performance, i.e., no or few minor deficiencies and satisfactory proficiency testing, are potential candidates for the AQAS. The survey form contains questions that reflect an outcome-oriented, quality improvement type of assessment. Samples of some of the areas included in the questionnaire can be seen in Table 35.10.

Following receipt of the completed form, the State Agency reviews the laboratory's responses and supplemental documentation. On the basis of this information, the laboratory may receive a telephone call requesting more information or may receive an on-site visit. If no problems are identified, the laboratory receives recertification for a 2-year period, provided that all relevant fees are paid. The certificate is forwarded to the laboratory. No laboratory will go longer than 4 years without an on-site survey. Approximately 5% of the laboratories are visited on-site to verify the effectiveness of this self-survey process.

The performance-based survey is a reward for exceptional performance and an incentive for improvement for those laboratories that have not yet been granted permission to use this self-survey approach. General information regarding the survey process can be obtained by calling Judith Yost (Director, Center for Laboratories, Health Standards and Quality Bureau) at HCFA [(410) 786-3531] (44).

New Quality Guidelines

Currently, there are ongoing efforts at both the national and international levels to provide guidelines for clinical laboratories in order to upgrade their QC and quality assurance programs to a broader definition—that of quality systems. Where QC and quality assurance programs monitor performance aspects of very specific operations, a quality system applies universal quality elements throughout the entire operation of the laboratory.

ISO Guidelines

ISO (International Organization for Standardization) is the world's largest developer of standards. Since 2000, the worldwide standard for a quality system in business and industry has been the ISO 9001 guidelines (the third edition is published by the International Organization for Standardization). Countries trading products across international boundaries have found the standardized requirements very beneficial in improving quality; this approach has also reduced the time and cost of multiple inspections due to the international nature of their business. In the future, there will be a universal standard for quality management in medical laboratories: ISO 15189 (29, 39).

When the large majority of products or services in a particular business or industry sector conform to International Standards, a state of industry-wide standardization can be said to exist. This standardization is achieved through consensus agreements between national delegations representing all the economic stakeholders concerned: suppliers, users, government regulators, and other interest groups, such as consumers. They agree on specifications and criteria to be applied consistently in the classification of materials, in the manufacture and supply of products, in testing and analysis, in terminology, and in the provision of services.

According to their objectives, laboratories will choose a recognition of their quality management system with an ISO 9001 certification or a recognition extended to the technical skills with an ISO 17025 or ISO 15189 accreditation. The contents of these last two documents are very similar, and both integrate requirements of the standard ISO 9001. The standard ISO 17025 is somewhat distant from clinical laboratory needs, requiring many efforts of adaptation, just like the ISO 9001 standard. The standard ISO 15189 seems to be well adapted but more constraining, considering the detailed requirements required. It necessitates a perfect control of the preanalytical phase, which is difficult to acquire in a clinical framework where the clinical specimens are not taken by the laboratory staff.

A number of advantages are associated with the use of ISO. The focus on patients has been reestablished, all processes are identified and subject to continuous

improvement, and performance measurements provide an integrated picture of results. Measurements subsequently lead to improvement of quality of care and to quality system improvements. The documentation system can serve the organization's needs without leading to bureaucracy. Given the need for adequate quality management tools in health care and the need to demonstrate quality, the positive effects suggest that ISO will become more prevalent in health care organizations (67).

ISO provides technical and quality management, which results in benefits observed in daily laboratory practices. Technical requirements can include the addition of formal personnel training plans and detailed records, method development and validation procedures, measurement of method uncertainty, and a defined equipment calibration and maintenance program. Also, an expanded definition of the sample preparation process can be implemented and documented to maintain consistency in sampling. Management quality improvements often emphasize document control to maintain consistent analytical processes, improved monitoring of supplier performance, a periodic contract review process for documenting customer requirements, and a system for handling customer comments and complaints. Continuous improvement is monitored and improved through corrective and preventive action procedures and audits. Quarterly management review of corrective actions, non-conforming testing, and proficiency testing results also identifies more long-term trends. The practical benefits of these technical and management quality improvements can be seen on a daily basis in the laboratory. Faster identification and resolution of issues regarding methods, personnel or equipment, improved customer satisfaction, and overall increased laboratory business are all the result of implementing an effective quality system. Certainly, the ISO system provides one option among various quality improvement approaches (32).

CLSI (NCCLS) Model

In the 1990s, blood centers and transfusion services within the United States began adopting the concepts of quality systems into their routine operations, primarily based on direction provided by a 1993 FDAQA guideline (24). After a series of revisions, the American Association of Blood Banks (AABB) published their 10 Quality System Essentials (QSEs) (1). These have been incorporated into the most recent edition of the AABB *Standards for Blood Banks and Transfusion Services* (2).

It became very obvious that the QSEs proposed for the blood bank were applicable to the entire laboratory operation. These essentials also incorporated many of the

quality requirements developed by CLIA '88, JCAHO, and the College of American Pathologists (CAP).

Recognizing that standardization would be not only valuable, but also essential for high-quality laboratory operations as a whole, the Clinical Laboratory Standards Institute (CLSI) (formerly known as the National Committee for Clinical Laboratory Standards [NCCLS]) developed a subcommittee to prepare a guideline encompassing a complete quality system for the clinical laboratory. This document was recently published as GP26-A, *A Quality System Model for Health Care*, a proposed guideline (45). A comparison of the CLSI and ISO/DIS 15189 quality system models is given in Table 35.11. It is also important to realize that the 10 rules (QSEs) apply to all stages of the work within the laboratory (Table 35.12).

The QSEs form a composite of requirements that have come from various sources, including CLIA '88, the JCAHO standards, and the CAP checklist. By placing all the similar requirements under the headings in Table 35.12, it becomes clear that they are applicable to any and all health care organizations.

Factors Influencing Future Laboratory Practice

As consolidation among payers continues through mergers, acquisitions, and other arrangements, providers of care find themselves with fewer buyers of care with whom to negotiate. This requires the development of strategies through which provider leverage can be maintained. Consolidation on the provider side has been one response. Price reductions and exclusive arrangements have been others. Response to these changes also includes affiliation with community providers to increase bargaining strength and aggressive cost reduction to allow more competitive bidding. However, many institutions are now facing the acceptance of marked reductions in reimbursement rates or terminating contracts. As additional changes occur and negotiations continue on these issues, each institution must achieve a balance between the market share realized from each contract, the revenue per service unit, and the total revenue.

Marketplace trends include continued growth in managed care, particularly in the Health Maintenance Organization sector; integration of payers, providers, suppliers, and buyers; mergers and alliances; integration between hospitals and physicians; continued pressure for provider consolidation to address excess bed capacity; continued shift from inpatient to outpatient procedures; and provider alliances based on complementing services (linkage of primary-care facility with the tertiary or quaternary expertise of another institution).

Table 35.11 NCCLS and ISO/DIS 15189 quality system models^a

NCCLS QSEs ^b	ISO/DIS 15189 ^b	Comments
1. Organization	4.1 Organization and management 4.2 Quality management system 4.4 Referral of examinations to other laboratories 4.12 Management review	Executive management, directors, managers, and supervisors must support and participate in the quality system; develop policies for QSEs, provide resources for processes required for implementation; conduct periodic reviews of the quality system, review findings, take corrective action, and plan for improvements
2. Personnel	5.1 Personnel	Personnel need clearly defined job descriptions and qualifications; uniform processes for orientation, training, competency assessment, performance review; training must be adequate and appropriate for the situation
3. Equipment	5.3 Laboratory equipment	All equipment must be installed, calibrated, maintained, used, and stored as specified by manufacturer guidelines; all accreditation/regulatory requirements must be followed and documented; consistent processes for installing, calibrating, using, maintaining, troubleshooting, servicing, etc., as required
4. Purchasing and inventory	4.5 External services and supplies	Processes should be in place for supplies and services used, vendor criteria, ordering, receiving, logging, inspecting, testing, and managing inventory
5. Process control	5.2 Accommodation and environmental conditions 5.4 Preexamination procedures 5.5 Examination procedures 5.6 Assuring the quality of examination procedures 5.7 Postexamination procedures 5.8 Reporting results 5.9 Alterations and amendments of reports	Identification of all processes involved in workflow, need to be validated to ensure they work as expected; clearly written protocols for all laboratory levels of personnel; QC and proficiency-testing programs must be in place according to regulatory and accreditation requirements
6. Documents and records	4.3 Document control 4.10 Quality records and technical records	Written policies, protocols, etc., must be uniform in appearance and content; records include worksheets, forms, computer printouts, labels, tags, etc.; documents must be prepared, reviewed, managed, and archived
7. Occurrence management	4.6 Control of nonconformities	Variance recognition, documentation, analysis, identification of underlying problems, corrective action, review; large part of risk management program
8. Internal assessment	4.11 Internal audits	Quality assurance indicators must be identified and measured for all major processes in laboratory operations; action is required when performance falls outside acceptable limits; periodic audits of operations and systems can document differences between process documentation/protocols and actual practice
9. Process improvement	4.8 Preventive actions 4.9 Corrective actions	Identification of processes for improvement as a result of complaints, internal and external inspections, internal audits, benchmarking, customer feedback, and personnel recommendations for change; use of problem resolution process that includes problem identification, prioritization, analysis, root cause determination, development, implementation, and review of solution
10. Service and satisfaction	4.7 Consultative services and resolution of complaints	Feedback sought from both internal and external customers; when problems are identified, resolution and review stems from process improvement and problem-solving initiatives

Specimen receipt			

Strategies for survival will include (i) increased ability to capture market share, preferably related to covered lives rather than patient days; (ii) improved information systems to accurately identify costs (fixed, variable by service, procedure) and track the profitability of contracts; and (iii) recognition of the importance of these issues and implementation of proactive measures to structure the organization for survival in the coming years.

Managed Care

With the increase in health care contracts and overall health care reform, a number of potential issues will affect the laboratory of the future. Each institution is actively seeking new markets, with the overall objective being to increase the patient base served by that particular institution. As these contracts increase in number, the reimbursement approach becomes one of capitated payment; the provider takes on the risk previously assumed by the third-party payer. The provider receives a certain amount for each patient per year, the assumption being that the care can be delivered at less than the reimbursement capitated amount; thus, a profit is realized. As these changes

occur, there continue to be mergers and the development of large care networks. However, as more large networks are developed, there are fewer contracts on which to bid. Each institution may be forced to consider contracts that pay less than the current costs of service. Obviously, these changes serve as a tremendous incentive to deliver care at continued reduced costs. Once contracts are lost to other bidders, it may be more difficult to recapture that lost market.

Managed care is changing from a cost containment environment to a value purchasing environment. Considerations include careful examination of what is being received for the money spent, increases in requests for outcome data, and case management options. As competitiveness in the managed-care arena increases, long-standing partnerships between institutions and Health Maintenance Organizations will have no inherent merit in guaranteeing continued partnerships. More focused medical management, lower costs, and higher efficiency will determine the continuation or elimination of present agreements. The new environment will demand increased cohesiveness, cooperation, and creativity on the part of all employees within an institution.

Table 35.13 Evolution of the health care delivery system and the impact on clinical laboratory testing^a

Cause or development	Changes
Failure to slow exponential growth of total health care expenditures	Rapid and progressive penetration of MCOs in early 1990s; diagnostic testing viewed as a "commodity" rather than medical service
Growth of managed care	Hospital-based laboratories in a financial downward spiral
Shorter LOS; reduction in admissions	Reduction in in-house testing
Managed-care-associated businesses, consolidation and networking; outreach test market, point-of-care and satellite testing	Major strategies developed for restoring tests eliminated by massive changes
Regulatory restrictions imposed by CLIA '88; expanded penetration of MCOs (reimbursement limited to a few in-house procedures)	POLs closing
Reference labs gaining more tests through contracting with MCOs	Continued reduction of test volumes in POLs and hospital laboratories

^a CLIA '88, Clinical Laboratory Improvement Amendments of 1988; LOS, length of stay; MCO, managed-care organization; POL, physician office laboratory.

An insurance, payment, and delivery system for health care, loosely described as “managed care,” is increasingly viewed as dysfunctional by consumers (i.e., patients), providers, and employers, the last of which constitute the primary source of funding for health insurance for the employed sector of the population. In the current environment of managed-care dominance within the United States, clinical laboratories continue to change their focus of operations and mission in response to the continually changing landscape. Traditional laboratories that are unwilling to change and adapt to this environment will probably not survive. A synopsis of changes since the early 1990s is provided in Table 35.13.

There appears to be a climate of blame in which the various players in the health care arena reproach each other and advance conflicting solutions. Although the “demise” or significant modification of the managed-care system is widely predicted, there is a distinct absence of any consensus about the parameters of politically or economically viable alternatives. Nonetheless, it appears that “something else” will emerge—a return of the “managed-competition” plan proposed in the early years of the Clinton presidency, a national health model resembling the Canadian system, implicit and explicit rationing of resources, or other combinations and approaches.

Financial Considerations

Capitated reimbursement has already been mentioned as one of the driving forces behind the necessity to deliver health care at continuing reduced rates. Each year, reimbursement rates decline; currently, leverage lies with the payer, not the provider. Competitive bidding has become an absolute necessity. Also, institutions continue to review their costs in much greater detail than at any time in the past. To survive, each institution must know exact costs so that it can bid appropriately and remain financially viable. Complicating this approach are the various regulatory requirements and the fact that each contract is somewhat different in terms of services and costs. Laboratories are continually reviewing their test menus, methodologies, etc., for the most clinically relevant, cost-effective approach to diagnostic testing.

Current problems related to health care costs include a growing federal deficit and concerns about the future viability of Medicare, the increasing inability of state budgets to fund rising Medicaid expenditures, an aging population that will generate increasing demands on health care resources, the proliferation of costly technological and pharmacological advances in the ability to diagnose and treat disease, and a health care insurance and delivery system unable to provide insurance and

predictable access to care for approximately 40 million Americans (3).

Decentralized Testing

In the last few years, many inpatient procedures have been shifted to the outpatient setting in response to payer per diem cost containment initiatives. Most institutions are actively involved in developing or expanding outreach programs, including laboratory services, teaching, and consultations. Another area that will continue to expand is point-of-care (POC) testing, or testing at the site of the patient (bedside, emergency room, or clinic), or alternative-site testing (home or shopping mall). With this expansion comes new technology that is advertised as “fail-safe and foolproof,” some of which may be true and some of which may be exaggerated. Obviously, this approach is directly linked to patient and overall customer satisfaction related to a short turnaround time for test results. Since more and more patient care is being delivered on an outpatient basis as decentralized care, reductions in length of hospital stay and in cost continue to be issues for review.

In some institutions that service very specific patient groups, POC testing may offer distinct advantages; however, in institutions with highly efficient specimen transport systems and rapid response capabilities within the main clinical laboratory, advantages of POC testing may be minimal to none. Continued review of regulatory requirements, QC issues, proper and consistent documentation, proficiency testing, performance enhancement, and cost-effectiveness is mandatory for success. As technology moves toward microcomputerization, microchemistry, chip technology, and enhanced test menus, the use of POC will require ongoing scrutiny (18, 30, 37, 38, 43, 61).

Although the push for decentralized testing may be coming from a variety of sources, it is generally thought that the central laboratory has become more involved in managing the new testing technologies and trying to circumvent anticipated problems with testing quality and patient care.

There are real, continued concerns about test accuracy, precision, training, and QC issues; personnel training and experience; and proficiency testing by those actually performing the testing. To date, there is little scientific evidence for cost reduction and/or reduction in length of stay. There appears to be mounting evidence that in some settings, the cost is higher than that of central-laboratory testing.

Laboratory Services

Large, integrated testing laboratories may become “the laboratory of the future,” particularly considering the issue of economy of scale; i.e., the more we perform large numbers of the same test, theoretically the lower the cost. Although

this approach is more applicable to some areas of the laboratory (chemistry), it is being carefully evaluated even in labor-intensive areas with less automation (microbiology). As technology continues to change, the departmental limits within any laboratory (chemistry, hematology, microbiology, or blood bank) continue to become less well defined. Many laboratory operations are now structured around automated and manual methods rather than specific clinical disciplines. This approach will continue and will also affect personnel training and utilization. Review of in-house versus send-out tests will continue, particularly regarding cost containment parameters.

With continued development and implementation of computerized history algorithms, clinical pathways, and case management, more structured support for clinical decision making will also dramatically affect the laboratory. Inappropriate test-ordering patterns and overutilization will become less and less significant. The use of algorithms may also become much more common within the laboratory itself. All of these changes will be developed through the use of multidisciplinary teams, including all members of the health care delivery system (ancillary departments, nursing staff, and physicians).

New technology will continue to be evaluated for a number of parameters, including type of data, technical characteristics, diagnostic characteristics, clinical utility, and cost-benefit analysis. Laboratory design will be another key issue and will be influenced by a number of factors, including consolidation of health care facilities; continued shift to outpatient care and POC and alternative-site testing; development and use of clinical paths; and development and evaluation of new technologies. Physical plant design should consider a number of factors, such as analysis of institution mission, scope of the project, and specific objectives; written statements of needs; mechanisms for keeping people informed; careful analysis of operational needs (work flow, traffic patterns, etc.); detailed review of current and future space requirements (consolidation of instrumentation, workstations, storage capacity, and equipment location); flexibility of design (modular furniture and utilities); and safety issues.

Technological Trends

Currently, hospitals and clinics are not able to meet their expenses without continued decreases in labor costs. During the next few years, the greatest savings in laboratory costs will come from technology that leads to labor reductions. Laboratory automation has the potential to be a highly successful, cost-saving measure and has been implemented in Japan, where many laboratories employ 5 to 10 times fewer full-time equivalents than European and North American laboratories while still achieving similar

productivity results. Future expectations include the performance of all but a few esoteric tests by automated systems, the use of mass spectrometry, and performance of most routine testing on a single automated analyzer. It is very likely that specimens will arrive in the laboratory ready for testing, with all processing having been done prior to receipt by the laboratory. The specimen may contain information chips carrying patient medical history and physiologic data at the time of sampling. These chips may also allow wireless encoding and reading of specimen information. Thus, the old specimen-processing area can concentrate on customer service, provision of medical information, and client education.

As an adjunct to the highly automated core laboratory, miniature analyzers and POC testing will play a major role in testing. Multianalyte, spectroscopy-based, noninvasive sensors will provide a wide range of tests at the bedside; there is even the possibility of a wireless invasive analyzer that would reside in a device that could be injected or implanted under the skin or elsewhere in the body.

New molecular tools have been developed rapidly, especially with the excitement over the completion of the human genome project. Synthetic antibody-like molecules with high affinity and specificity have been developed from both DNA and RNA. These molecules may replace antibodies in molecular diagnostics, achieving tremendous levels of sensitivity.

Biometrics is the use of sensors to measure natural body features for positive identification. In the future, biometrics will be extremely helpful in confirming that patients and their body fluids or other specimens are correctly identified. A patient's complete medical history may be available on the Web when the patient simply places a finger into the sensor mechanism.

Nonlaboratory systems, such as robots, will be used much more commonly for delivery functions, saving a significant amount of money as well as improving service. Surgery robots that can perform complex procedures through very small incisions are currently under development, and some have been implemented.

Clinical Decision Support

A number of approaches are being developed and used to serve as "practice guidelines"—more structured approaches for both information gathering and clinical decision making related to the patient. A clinical pathway is defined as a set of interventions or actions that is used to help a patient move progressively through a clinical experience to an expected, positive outcome. One of the main reasons for developing clinical pathways is to provide a tool to evaluate clinical patient management and outcomes. Once defined sets of expectations are developed, data can be used

to monitor variances. The cost of care and utilization of resources can then be monitored more closely.

By using clinical pathways for predictable clinical outcomes (conditions, diseases, and procedures selected are generally very well established and patient outcomes are consistent), many also believe that patient care is more consistent. These clinical pathways can also be used as a teaching tool for all health care personnel. The development of clinical paths must be a multidisciplinary effort, with input from all relevant members of the health care team. Many institutions are also using the process of clinical path development to foster team building and continuous quality improvement initiatives.

Regardless of names or titles, the following are becoming more widely used and accepted. They are listed from the most well-defined and predictable medical situations (clinical pathway) to very complex cases with many underlying factors and complications (case management).

1. Clinical pathways (care maps) (used for conditions, diseases, and procedures for which the patient outcome is very predictable)
2. Clinical guidelines (used for care situations in which the outcome may have a few more variables)
3. Clinical algorithms (used for patient outcome situations in which more options may be required)
4. Case management (generally used for very complex cases, for which it is very difficult to establish a predetermined pathway; the patient may have multiple medical problems and/or complications)

Personnel Issues

Many personnel issues will continue to be relevant and important. Particular emphasis will probably include (i) the use of unlicensed individuals in relationship to CLIA '88 and various states developing, implementing, and revising personnel regulations; (ii) cross-training and the use of multi-skilled laboratory personnel; (iii) tremendous flexibility in covering fluctuations in workload; (iv) expansion of the use of multidisciplinary teams; (v) continued emphasis on horizontal rather than vertical management structures; and (vi) development and utilization of personnel competency assessment programs (now mandated by regulations).

Changing Demographics

The aging of the population will have a profound effect on many health care issues. Laboratory testing and monitoring will be no exception. Patient access, alternative-site testing, and clinical decision support options will play a large role in helping manage this expanding population.

Emerging Diseases

Not only do we have to deal with expanding diseases and conditions in the elderly, but also we now are faced with some serious problems related to infectious-disease threats. There is explosive population growth worldwide with expanding poverty and urban migration; international travel is increasing; and technology is rapidly changing. All of these factors affect our risk of exposure to the infectious agents in our environment. In recent years, our antimicrobial drugs have become less effective against many infectious agents, and experts in infectious diseases are concerned about the possibility of a "post-antibiotic era." As a result, our ability to detect, contain, and prevent emerging infectious diseases is in jeopardy.

Medical Parasitology: Case Histories

Protozoal infections

Helminth infections

Blood parasite infections

Diagnostic methods

The case histories in this chapter are taken from actual practice and provide an excellent method of review for the reader. Each case includes the history, laboratory findings, and clinical course. Self-assessment questions and a comprehensive discussion supplement each history. Also, parasite images photographed from actual bench work microscopy accompany each case. The cases illustrate many kinds of potential diagnostic problems encountered within the parasitology section of the laboratory and emphasize clinical relevance and recommended approaches for specimen ordering, collection, processing, testing, and reporting. Although not every parasite known to be a human pathogen is included, a wide spectrum of organisms and diseases is presented to illustrate particular points.

Protozoal Infections

Case 1

A 30-year-old patient complained that he had had diarrhea for about a week, and specimens were submitted to the laboratory. He had previously been in excellent health with no complaints, although he did report an unexplained weight loss of several pounds. On examination of the permanent stained smears, the following images were seen (Figure 36.1). These protozoan trophozoites measured approximately 17 μm long. The permanent stained smears have been stained using Wheatley's trichrome stain modification. The test result is reported as follows: "*Entamoeba histolytica* trophozoites present."

Questions

1. Based on the diagnosis of diarrhea and the laboratory findings, how would you identify the objects seen in the permanent stained smears?
2. Was the report correct as submitted to the physician? Why or why not?
3. Is diarrhea a normal finding in an infection caused by this organism?
4. Why is it important to report the presence of this organism correctly?

Figure 36.1 Case 1. Microscopic images (oil immersion 100× objective); permanent stained smear.

Correct Identification

The images presented in this case history are trophozoites of *Entamoeba histolytica/E. dispar*; therefore, the physician's report ("*Entamoeba histolytica* trophozoites present") was incorrect. You will notice that the amebic trophozoites in Figure 36.1 did not contain any ingested red blood cells (RBCs) within the cytoplasm. If no RBCs are seen in the cytoplasm and the trophozoites measure greater than or equal to 12 μm, the true pathogen, *E. histolytica*, cannot be differentiated from the nonpathogenic *E. dispar*. Currently, there are immunoassays available that can confirm the presence of organisms in the *E. histolytica/E. dispar* group, as well as one immunoassay that can confirm the presence of the pathogen *E. histolytica* (3, 4, 7, 8).

The correct laboratory report for the organisms seen in the case history would have been "*Entamoeba histolytica/E. dispar* trophozoites present." A computer comment could be added as follows: "Based on organism morphology, the presence of the true pathogen, *Entamoeba histolytica* (cause of amebiasis), could not be confirmed." Trophozoites of *E. histolytica*, the true pathogen, can be seen in Figure 36.2; the correct identification is confirmed by the presence of ingested RBCs within the organism cytoplasm.

If your laboratory offers the immunoassay specific for *E. histolytica*, the computer comment could be: "If

Figure 36.2 Case 1. *Entamoeba histolytica* trophozoites containing ingested RBCs.

you want confirmation of the presence of *Entamoeba histolytica*, submit a fresh stool sample." The immunoassays for *E. histolytica* or the *E. histolytica/E. dispar* group require fresh or frozen stools; formalinized specimens are not acceptable for testing.

Prior to the separation of *E. histolytica* into two distinct species (*E. histolytica* and *E. dispar*), there were suggestions that some *E. histolytica* strains were pathogenic and some were not. Now that *E. dispar* has been classified as a nonpathogenic organism, totally separated from the pathogenic *E. histolytica*, treatment of *E. dispar* infection is usually not recommended. However, this recommendation is based on the separation of the two species by molecular means, not by morphology alone. Since few laboratories will be routinely identifying the two *Entamoeba* species to the level of *E. histolytica* or *E. dispar*, the clinician will have to decide on the basis of clinical findings whether the patient has true pathogenic *E. histolytica* or nonpathogenic *E. dispar* infection. The laboratory report will merely indicate the presence of the "*Entamoeba histolytica/E. dispar*" group.

Infection with *E. dispar* cannot be diagnosed on the basis of morphologic criteria alone, even from the permanent stained smear. When the organism is seen in the routine ova and parasite examination, it cannot be differentiated from *E. histolytica* unless trophozoites are seen to contain RBCs in the cytoplasm, a finding that is diagnostic for *E. histolytica*. When routine diagnostic methods and not immunoassay procedures specific for *E. histolytica* are used, morphologic criteria would provide characteristics of both; the laboratory report would indicate "*Entamoeba histolytica/E. dispar*."

Key Points for Laboratory Identification

1. When routine ova and parasite (O&P) examinations are ordered, three specimens (stool) should be submitted for the diagnosis of intestinal amebiasis.
2. Any examination for parasites in stool specimens must include the use of a permanent stained smear (even on formed stool).
3. Presumptive identification on a wet preparation must be confirmed by using the permanent stained smear. Without using *E. histolytica*-specific antigen detection tests, the presence of the organism(s) should be reported as follows. Trophozoites containing ingested RBCs within the cytoplasm should be reported as the true pathogen ("*Entamoeba histolytica* trophozoites present"). However, if cysts or trophozoites containing no ingested RBCs are seen, the report should indicate that the *Entamoeba* group is present ("*Entamoeba histolytica/E. dispar* group trophozoites and cysts present").

- The six smears should be prepared at sigmoidoscopy but should not take the place of the O&P examination.
- Immunoassay procedures can be performed to confirm the presence of the *E. histolytica*/*E. dispar* group or can be used to differentiate pathogenic *E. histolytica* from nonpathogenic *E. dispar*. Remember that some of these reagent kits may require fresh or frozen stools only; formalin-preserved stool or stool containing polyvinyl alcohol are not acceptable.
- The serologic test for antibody may *or may not* be positive in intestinal disease and is much more likely to be positive in extraintestinal disease.
- What morphologic characteristics support your identification?
- What impact would AIDS have on this opportunistic infection?

Correct Identification

Assuming the possibility of infection with free-living amoebae, diagnostic procedures could include agar plate cultures for the recovery of trophozoites and cysts of *Acanthamoeba*. Nonnutrient agar plates are routinely used with a bacterial overlay. The organisms are *Acanthamoeba* spp. Note the spiky acanthopodia in the trophozoite stage and the presence of the characteristic double-walled cyst form.

The protracted course in this case is characteristic of severe illness caused by *Acanthamoeba* and distinguishes this disease from primary amebic meningoencephalitis (PAM), caused by *Naegleria*, which has a much more acute presentation. Additional features that helped to distinguish the patient's *Acanthamoeba* infection from that caused by *Naegleria* include the typical trophozoite and cyst morphology obtained from the culture system.

Although this patient was diagnosed as having a squamous cell carcinoma of the nasal septum, this was an incorrect diagnosis. Once the diagnosis of AIDS was made, the workup was expanded to include possible parasitic pathogens, particularly organisms in the free-living amoebae group. The final diagnosis was AIDS along with disseminated acanthamoebiasis. This case points up the importance of considering all possibilities, particularly in a patient who appears to be immunocompetent but who may actually be immunocompromised for one or more reasons.

An early diagnosis can be made if amebic infection is considered in patients with various presentations. *Acanthamoeba* spp. are now well accepted as opportunistic pathogens in immunocompromised patients with AIDS, generally those with a low CD4⁺ cell count. Unfortunately, diagnosis of this infection requires a high index of suspicion, since both clinical and histologic findings may mimic those of disseminated fungal or algal disease or noninfectious causes such as carcinoma. Patients with AIDS and *Acanthamoeba* infection may experience general symptoms such as fever and chills, nasal congestion or lesions, neurologic symptoms, and musculoskeletal and cutaneous lesions. Some patients, especially those with AIDS, develop erythematous nodules, chronic ulcerative skin lesions, or abscesses.

The primary site of infection is thought to be the sinuses and lungs. The skin is also thought to be a possible portal of entry. In patients with disseminated disease, the duration of infection from onset to death can

Case 2

A 28-year-old man presented with rhinosinusitis and was diagnosed as having a squamous cell carcinoma of the nasal septum. He was presumed to be a healthy and immunocompetent individual; however, he was later diagnosed with AIDS. As the diagnostic workup was expanded and other possible etiologic agents were considered, the following images were seen from agar culture plates (Figure 36.3).

These organisms have spine-like pseudopods, with the average diameter of the trophozoites being 30 μm . The nucleus has the typical large karyosome, and morphology can be seen on a wet preparation. The cysts are round with a single nucleus, which also has the large karyosome seen in the trophozoite nucleus. The double wall is usually visible, with the slightly wrinkled outer cyst wall and what has been described as a polyhedral inner cyst wall (4, 7, 12).

Questions

- Can you describe the type of culture system that was used to support the growth of these organisms?
- What do you think these organisms are (genus)? Why?

Figure 36.3 Case 2. Protozoan. (Left) Trophozoite with “spiky” acanthopodia; (right) cyst with hexagonal double wall.

range from 7 days to 5 months. Since early therapy can alter the clinical outcome, recognition of this disease is critical. It is important to initiate appropriate diagnostic testing for confirmation of the causative agent as soon as possible.

Acanthamoeba spp. have been found in the upper respiratory tract in humans with and without symptoms. In cases of disseminated disease, the portal of entry remains unknown but is suspected to be the respiratory tract. However, in patients with skin lesions, the skin may be the site of primary inoculation. Although many of the reported cases have been seen in compromised patients, cases have also occurred in immunocompetent hosts.

Although *Naegleria* dissemination outside the central nervous system (CNS) may occur, it is apparently rare and is unlike the protracted situation seen in this patient. The morphology of *Naegleria* trophozoites is quite different from that of *Acanthamoeba* trophozoites, and an image can be seen below (Figure 36.4). Note the lobular pseudopodia as compared with the “spiky” pseudopodia seen in *Acanthamoeba* trophozoites (Figure 36.3).

The nonnutrient agar plates are made using Page’s saline. Before use, the plates should be removed from the refrigerator and placed at 37°C for 30 min. Add about 0.5 ml of saline to a slant culture of *Escherichia coli*. Gently scrape the surface, and suspend bacteria uniformly. Add 2 or 3 drops of this suspension to the middle of the warmed agar plate. Using a loop, spread the bacteria on the surface of the agar. Depending on the specimen, cerebrospinal fluid (CSF) or other nervous system material should be incubated at 37°C; other tissues should be incubated at 30°C. After the fluid/specimen has been absorbed, seal the plates with a 5- to 6-in. strip of Parafilm; incubate the plate inverted in room air.

Figure 36.4 Case 3. Protozoan. (Left) Trophozoites growing on a nonnutrient agar plate seeded with *Escherichia coli* bacteria; (right) stained trophozoite (note the more globular pseudopods compared with the organism in case 2).

Using the low-power objective (10×), examine the plates for amebic cysts or trophozoites every day for 10 days. Thin, linear tracks, which represent areas where amebae have ingested the bacteria, might also be seen.

Current therapy for *Acanthamoeba* infection includes amphotericin B and sulfadiazine or sulfisoxazole or pentamidine isethionate. Treatment is somewhat problematic, and amphotericin B may be ineffective. Skin ulcers have been treated by combination therapy involving systemic intravenous pentamidine isethionate for 1 month and oral itraconazole for 8 months. The skin ulcers can also be cleaned twice daily with chlorhexidine gluconate solution and treated by topical application of 2% ketoconazole cream.

Key Points for Laboratory Identification

1. As with *N. fowleri*, beware of a false-positive Gram stain (the leukocyte count in CSF may be elevated).
2. Examine clinical material on a slide with a coverslip; do not use a counting chamber (organisms in CSF look like leukocytes).
3. Nonnutrient agar with Page’s saline and an *E. coli* overlay can be tried for culture recovery.
4. Various other media containing different agar bases, some of which contain horse, sheep, or rabbit blood, are also available.
5. Tissue stains are also effective, and the use of calcofluor white to visualize the double-walled cyst is recommended.
6. Refer to chapter 32 for specific methods and recommendations.

Case 3

A 6-year-old girl was admitted to the hospital in a coma. The patient was normally a healthy child with no significant medical history. Several days prior to admission, the family had been vacationing at a lake in the southern United States. Everyone had been swimming and boating during the vacation. Several days before admission, the patient had complained of some vague upper respiratory distress and a sore throat. On the day prior to admission, her mother indicated that she had complained of a stiff neck and headache; she also had a fever. On the day of admission, she became very confused and lapsed into a coma.

On physical examination, her neck was stiff and her pupils reacted sluggishly; her temperature was 104°F. The CSF was hemorrhagic and contained many neutrophils.

Although there was some debris on the smear, the Gram stain was read as negative. The following images were seen from culture and stained preparations (Figure 36.4) (4, 7).

Questions

1. What laboratory procedure should be performed immediately and why?
2. If the procedure was positive, what would you expect to see?
3. Treatment should be started immediately with what and why?
4. What is there about the history that should alert everyone to this disease possibility?

Correct Identification

The CSF should be examined as a wet mount (not in a counting chamber), looking for motile amebic trophozoites. The specimen can be centrifuged or examined as unspun fluid; it should not be refrigerated prior to examination. Amebic trophozoites can mimic neutrophils in a counting chamber, but characteristic motility can be seen on a slide with a coverslip. In a positive wet mount, motile trophozoites of free-living amebae, *Naegleria fowleri*, would be seen. The pseudopodia are rounded and nonspiky, and motility is visible unless the organisms are cold or dead. The only drug that appears to be effective is amphotericin B. Very few patients have survived this infection; two patients responded to amphotericin B and did survive. Rare cases have also responded to miconazole and, in one case, rifampin.

Central nervous system (CNS) infections caused by free-living amebae have been recognized only since the mid-1960s, and our understanding of this disease process is still incomplete. One type of meningoencephalitis (PAM) is a fulminant and rapidly fatal disease that mainly affects children and young adults. The disease closely resembles bacterial meningitis but is caused by *N. fowleri*, an organism found in moist soil and freshwater habitats.

There are trophozoite and cyst stages in the life cycle; the stage depends primarily on environmental conditions. Trophozoites can be found in water or moist soil and can be maintained in tissue culture or other artificial media. The trophozoites can occur in two forms, ameboid and flagellate. Motility can be observed in hanging-drop preparations from cultures of CSF; the ameboid form (the only form recognized in humans) is elongate with a broad anterior end and tapered posterior end. The size ranges from 7 to 20 μm . The diameter of the rounded forms is usually 15 μm . There is a large, central karyosome and no peripheral nuclear chromatin. The cytoplasm is

somewhat granular and contains vacuoles. The ameboid-form organisms change to the flagellate form when they are transferred from culture or teased from tissue into water and maintained at a temperature of 27 to 37°C. The change may occur within a few hours or may take as long as 20 h. The flagellate form is pear shaped, with two flagella at the broad end. Motility is typical, with either spinning or jerky movements. These flagellate forms do not divide, but when the flagella are lost, the ameboid forms resume reproduction. Cysts from nature and from agar cultures look the same and have a single nucleus almost identical to that seen in the trophozoite. The shape is generally round, measuring from 7 to 10 μm , and there is a thick double wall.

PAM caused by *N. fowleri* is an acute, suppurative infection of the brain and meninges. In humans, with extremely rare exceptions, the disease is rapidly fatal. The period between contact with the organism and onset of clinical symptoms such as fever, headache, and rhinitis may vary from 2 to 3 days to as long as 7 to 15 days. The amebae may enter the nasal cavity by inhalation or aspiration of water, dust, or aerosols containing the trophozoites or cysts. The organisms then penetrate the nasal mucosa, probably through phagocytosis of the olfactory epithelium cells, and migrate via the olfactory nerves to the brain. Early symptoms include vague upper respiratory distress, headache, lethargy, and occasionally olfactory problems. The acute phase includes sore throat, stuffy blocked or discharging nose, and severe headache. Progressive symptoms include pyrexia, vomiting, and stiffness of the neck. Mental confusion and coma usually occur approximately 3 to 5 days prior to death. The cause of death is usually cardiorespiratory arrest and pulmonary edema. PAM can resemble acute purulent bacterial meningitis, and the conditions may be difficult to differentiate, particularly in the early stages. Unfortunately, if the CSF Gram stain is interpreted incorrectly, with the identification of bacteria representing a false-positive result, the antibacterial therapy has no impact on the amebae and the patient will usually die within several days. Extensive tissue damage occurs along the path of amebic invasion; the nasopharyngeal mucosa shows ulceration, and the olfactory nerves are inflamed and necrotic. Hemorrhagic necrosis is concentrated in the region of the olfactory bulbs and the base of the brain. Organisms can be found in the meninges, perivascular spaces, and sanguinopurulent exudates.

Clinical and laboratory data usually cannot be used to differentiate pyogenic meningitis from PAM, so the diagnosis may have to be reached by a process of elimination. A high index of suspicion is often mandatory for early diagnosis. Although most cases are associated with exposure to contaminated water through swimming or

bathing, this is not always the case. The rapidly fatal course of 4 to 6 days after the beginning of symptoms, with an incubation period of 1 day to 2 weeks, requires early diagnosis and immediate chemotherapy if the patient is to survive. Analysis of the CSF shows decreased glucose and increased protein concentrations. Leukocytes may range from several hundred to $>20,000$ cells/mm³. Gram stains and bacterial cultures of CSF are negative.

A definite diagnosis could be made by demonstration of the amebae in the CSF or in biopsy specimens. Either CSF or sedimented CSF should be placed on a slide, under a coverslip, and observed for motile trophozoites; smears can also be stained with Wright's or Giemsa stain. CSF, exudate, or tissue fragments can be examined by light microscopy or phase-contrast microscopy. Care must be taken not to mistake leukocytes for actual organisms or vice versa. It is very easy to confuse leukocytes and amebae, particularly when one is examining CSF by using a counting chamber, hence the recommendation to use just a regular slide and coverslip. Motility may vary, so the main differential characteristic is the spherical nucleus with a large karyosome.

Specimens should never be refrigerated prior to examination. When centrifuging the CSF, low speeds ($250 \times g$) should be used so that the trophozoites are not damaged; however, centrifugation at $500 \times g$ is not detrimental to the morphology. Although bright-field microscopy with reduced light is acceptable, phase microscopy, if available, is recommended. Use of smears stained with Giemsa or Wright's stain or a Giemsa-Wright's stain combination can also be helpful. If *Naegleria* is the causative agent, trophozoites only are normally seen. If the infecting organism is *Acanthamoeba*, cysts may also be seen in specimens from the CNS. Unfortunately, most cases of PAM are diagnosed at autopsy; confirmation of these tissue findings must include culture and/or special staining using monoclonal reagents in indirect fluorescent-antibody procedures. Organisms can also be cultured on nonnutrient agar plated with *Escherichia coli*.

Over 175 presumptive or proven cases of PAM have been reported in the literature, including cases from the United States (86 cases as of January 1998), Ireland, England, Belgium, Czechoslovakia, Australia, New Zealand, Brazil, and Zambia. Clinical patient histories indicate exposure to the organism via freshwater lakes or swimming pools shortly before onset; patients had been previously healthy with no specific underlying problems. Pathogenic *Naegleria* organisms have also been isolated from nasal passages of individuals with no history of water exposure, suggesting the possibility of airborne exposure.

The first isolations of environmental strains of pathogenic *N. fowleri* were reported from water and soil in Australia and from sewage sludge samples in India. Detection of *N. fowleri* in heated discharge water has been reported in Belgium and Poland. Since then, there have been additional reports describing isolations of virulent or avirulent strains of *N. fowleri* from the environment. Studies in Belgium have clearly indicated that *N. fowleri* strains are present in artificially heated waters (power plant warm discharge), and studies in the United States have indicated that virulent strains are also found in lakes at geographic latitudes with water temperatures of 14 to 35°C that are totally isolated from any source of thermal discharge. These data suggest that the presence of pathogenic or potentially pathogenic amebic strains may depend on both climate and modification of the natural environment. The ability of the cysts to survive under various environmental conditions has been investigated by several workers. These findings suggest that *N. fowleri* cysts produced in the warm summer months may survive the winter and are capable of growth during the following summer.

General preventive measures include public awareness of potential hazards of contaminated water. It has been recommended that warm discharge water not be used for sports and recreational purposes, particularly since DNA restriction fragment profiles of environmental strains and human isolates were homogeneous.

Only 3 patients of more than 175 with presumptive or parasitologically proven cases of PAM had survived this infection outside of the United States by the 1970s. One case within California was documented in which the patient was successfully treated with amphotericin B, miconazole, and rifampin. There was a synergistic effect with miconazole and amphotericin B in vitro; however, rifampin was ineffective. The patient received intrathecal and intravenous injections of the drug. Dexamethasone and phenytoin were also given to this patient to decrease intracranial pressure and seizure, respectively. *Naegleria* infections have also been treated successfully with amphotericin B, rifampin, and chloramphenicol; amphotericin B, oral rifampin, and oral ketoconazole; and amphotericin B alone.

Key Points for Laboratory Identification

1. Never refrigerate the specimen(s) prior to examination.
2. Beware of the false-positive Gram stain, especially since PAM commonly mimics pyogenic meningitis with the CSF containing increased numbers of leukocytes.
3. *Naegleria* trophozoites mimic leukocytes if put in a counting chamber. Motility is more likely to be

seen if a drop of CSF is placed directly on a slide and a coverglass is added.

- Organisms can be cultured on nonnutrient agar plated with *E. coli*.

Case 4

An immunocompetent 5-year-old girl was diagnosed with diarrhea off and on for about 10 days, and two stool specimens were submitted to the laboratory for examination. After examination of the concentration sediment from both specimens, nothing was seen and the results were reported as “No parasites seen” (Figure 36.5, left). No permanent stained smears were prepared or examined. The child continued to be symptomatic with vague gastrointestinal problems and diarrhea. Another stool specimen was submitted, and both concentration sediment and permanent stained smears were examined. The parasite identified is seen in Figure 36.5 (right). This protozoan trophozoite measures approximately 13 to 16 μm long (3, 4, 7, 8, 12).

Questions

- Would you agree or disagree with the original diagnostic approach used for the first two stool samples?
- If one considers all the intestinal protozoa, which organisms might have been missed without the permanent stained smear examination?
- Identification of which organism requires the permanent stained smear? Why is this true?
- What references might be helpful in reviewing guidelines for a complete O&P examination?

Figure 36.5 Case 4. (Left) Stool fecal concentration sediment examined as a wet mount (appears to be negative); (right) protozoan trophozoite containing two nuclei, which are fragmented into several nuclear granules.

Correct Identification

The organism image presented is a trophozoite of the flagellate *Dientamoeba fragilis*; thus, the physician’s report (“No parasites seen”) was incorrect. The first report was based on examination of the concentration sediment wet preparation (Fig. 36.5, left), in which no organisms were seen.

D. fragilis was first seen in 1909 but not described until 1918. On the basis of electron microscopy studies, it has been reclassified as an ameba-flagellate rather than an ameba and is closely related to *Histomonas* and *Trichomonas* spp. It has a cosmopolitan distribution, and past surveys showed incidence rates of 1.4 to 19%. Much higher incidence rates have been reported for mental-institution inmates, missionaries, and Native Americans in Arizona. *D. fragilis* tends to be common in some pediatric populations, and in some studies the incidence figures are higher for patients younger than 20 years. Trophozoites can contain one or two nuclei, but no cyst form has been identified for this organism.

Although its pathogenic status is still not well defined, *D. fragilis* has been associated with a wide range of symptoms. Case reports of children infected with *D. fragilis* reveal a number of symptoms including intermittent diarrhea, abdominal pain, nausea, anorexia, malaise, fatigue, poor weight gain, and unexplained eosinophilia. The most common symptoms in patients infected with this parasite appear to be intermittent diarrhea and fatigue. In some patients, both the organism and the symptoms persist or reappear until appropriate treatment is initiated.

Diagnosis of *D. fragilis* infections depends on proper collection and processing techniques (a minimum of three fecal specimens). Although survival time for this parasite has been reported as 24 to 48 h, the survival time in terms of morphology is limited, and stool specimens must be examined immediately or preserved in a suitable fixative soon after defecation. It is particularly important that permanent stained smears of stool material be examined with an oil immersion lens (1,000 \times). These organisms have been recovered in formed stool; therefore, a permanent stained smear must be prepared for every stool submitted for a parasite examination.

If preserved specimens are submitted to the laboratory, it may be more cost-effective to delete the direct smear and begin the stool examination with the concentration procedure, particularly since motile protozoa are not viable because of the prior addition of preservative. Even if parasites are seen on a direct mount of preserved stool, they would almost certainly be seen on the concentration examination as well as on the permanent stained smear (protozoa in particular). With few exceptions, intestinal protozoa should never be identified on the basis of a wet mount alone; permanent stained smears should

be examined to confirm the specific identification of suspected organisms.

Every stool submitted for an O&P examination must be examined using the concentration and permanent stained smear procedures. This guideline is consistent with the College of American Pathologists laboratory inspection checklist.

Key Points for Laboratory Diagnosis

1. O&P examination (fresh stool specimen, liquid and/or very soft): direct wet smear, concentration, permanent stained smear.
2. O&P examination (fresh stool specimen, formed stool): concentration, permanent stained smear.
3. O&P examination (preserved stool specimen): concentration, permanent stained smear.

All intestinal protozoan infections can be missed if the concentration is the only test to be performed. The permanent stained smear is much more sensitive than the concentration alone. To date, there are no commercial immunoassay products available for the confirmation of infection with *D. fragilis*, although they are under development.

Case 5

A 3-year-old boy was first seen in the clinic because of failure to thrive and vague symptoms such as poor appetite and failure to gain weight. There was one other child in the family, a 6-year-old brother who was in good health. The patient was apparently fine for the first couple of years. He began to have diarrhea with light-colored stools; however, this condition was not always present. Although stool examinations were performed, it was unclear exactly what diagnostic methods were used and the test results were reported as negative. The child was placed on a high-protein, high-calorie diet with vitamins and supplements. However, he showed very little improvement over a 4-month period. Based on these and other findings (barium exam showed “large dilated loops of hypotonic bowel”), the child was admitted to the hospital with a diagnosis of celiac disease.

Complete stool examinations were performed (O&P examination: direct wet mount, concentration, and permanent stained slide). The following image is a wet preparation of stool (Figure 36.6); the organism was seen using the high dry objective of the microscope. Motility was seen, but it was very limited and the organism identification could not be confirmed without completion of the O&P examination (3, 4, 7, 8). The images in Figure 36.6 were photographed at a high magnification.

Figure 36.6 Case 5. (Left) Protozoan trophozoite seen in a wet mount; (right) protozoan cyst seen in a wet mount (note how round, distorted, and three-dimensional the cyst appears).

Questions

1. What parasites should be considered based on the patient’s history?
2. What factors might be responsible for the “negative” laboratory reports?
3. After seeing the organisms in the wet mounts, could these parasites be responsible for the patient’s symptoms?
4. What other diagnostic tests might be available? Would they be more or less sensitive than the O&P examination? Please explain.

Correct Identification

Figure 36.6 shows a *Giardia lamblia* trophozoite (left) and a *G. lamblia* cyst (right). The trophozoite measured approximately 8 by 12 μm , and there appeared to be minimal motility related to the flagella; the cyst measured approximately 10 μm and appeared to be somewhat round. Although this organism was seen in the wet mount, additional morphology could be seen from the concentration and permanent stained slide examinations. While the presumptive identification could be made from the concentration wet mount, confirmation of the diagnosis usually depends on examination of the permanent stained smear.

The incubation time for giardiasis is approximately 12 to 20 days. Because the acute stage usually lasts only a few days, giardiasis may not be recognized as the infection but may mimic acute viral enteritis, bacillary dysentery, bacterial or other food poisonings, acute intestinal amebiasis, or “traveler’s diarrhea” (caused by toxigenic *E. coli*). However, the type of diarrhea plus the lack of blood, mucus, and cellular exudate is consistent with giardiasis. Although the organisms in the crypts of the duodenal mucosa may reach very high densities, they may not cause any pathology. The organisms feed on the mucous secretions and do not penetrate the mucosa. For some reason,

in symptomatic cases there may be irritation of the mucosal lining, increased mucus secretion, and dehydration.

The acute phase is often followed by a subacute or chronic phase. Symptoms in these patients include recurrent, brief episodes of loose, foul-smelling stools; there may be increased distention and foul flatus. Between the episodes of passing mushy stools, the patient may have normal stools or may be constipated. Abdominal discomfort continues to include marked distention and belching with a rotten-egg taste. Chronic disease must be differentiated from amebiasis and other intestinal parasites such as *Dientamoeba fragilis*, *Cryptosporidium* spp., *Cyclospora cayetanensis*, *Isospora belli*, and *Strongyloides stercoralis* and from inflammatory bowel disease and irritable colon. Based on symptoms such as upper intestinal discomfort, heartburn, and belching, giardiasis must also be differentiated from duodenal ulcer, hiatal hernia, and gallbladder and pancreatic disease. Because giardiasis may not cause any symptoms at all, demonstration of the organism in symptomatic patients may not rule out other possibilities such as peptic ulcer, celiac disease, strongyloidiasis, and possibly carcinoma.

Giardiasis is one of the more common causes of traveler's diarrhea and has been recorded from all parts of the world. It has also been speculated that visitors to areas where *Giardia* is endemic are more likely to present with symptoms than are individuals who live in the area; this difference is most probably due to the development of immunity from prior, and possible continued, exposure of residents to the organism.

Both the trophozoite and the cyst are included in the life cycle of *G. lamblia*. Trophozoites divide by means of longitudinal binary fission, thus producing two daughter trophozoites. The most common location of the organisms is in the crypts within the duodenum. The trophozoites are the intestinal dwelling stage and attach to the epithelium of the host villi by means of the ventral disk. The attachment is substantial and results in disk "impression prints" when the organism detaches from the surface of the epithelium. Trophozoites may remain attached or may detach from the mucosal surface. Since the epithelial surface sloughs off the tip of the villus every 72 h, apparently the trophozoites detach at that time. For reasons which are not totally known, cyst formation takes place as the organisms move down through the colon. The trophozoites retract the flagella into the axonemes, the cytoplasm becomes condensed, and the cyst wall is secreted. As the cyst matures, the internal structures are doubled, so that when excystation occurs, the cytoplasm divides, thus producing two trophozoites. Excystation would normally occur in the duodenum.

Routine stool examinations are normally recommended for the recovery and identification of intestinal

protozoa. However, in the case of *G. lamblia*, because the organisms are attached so securely to the mucosa by means of the sucking disk, a series of even five or six stool specimens may be examined without recovering the organisms. The organisms also tend to be passed in the stool on a cyclical basis. The Entero-Test capsule can be helpful in recovering the organisms, as can the duodenal aspirate. Although cysts can often be identified on the wet stool preparation, many infections may be missed without the examination of a permanent stained smear. If material from the string test (Entero-Test) or mucus from a duodenal aspirate is submitted, it should be examined as a wet preparation for motility; however, motility may be represented by nothing more than a slight flutter of the flagella because the organism is caught up in the mucus. After diagnosis, the rest of the positive material can be preserved as a permanent stain.

Procedures using immunoassays (enzyme immunoassay, fluorescent-antibody assay, cartridge formats) have also been developed to detect *Giardia* antigen in feces. The immunoassays are more sensitive than the O&P examination. Many of these newer methods are being used to diagnose patients suspected of having giardiasis or those who may be involved in an outbreak situation, particularly if the patient history is suggestive.

Transmission is by ingestion of viable cysts. Although contaminated food or drink may be the source, transmission may occur via intimate contact with an infected individual. This organism tends to be found more frequently in children or in groups that live in close quarters. Often there are outbreaks due to poor sanitation facilities or breakdowns as evidenced by infections in travelers and campers. There may also be an increase in the prevalence of giardiasis in the male homosexual population, probably due to anal and/or oral sexual practices. Because of the potential for a wild-animal reservoir and possibly other domestic-animal reservoir hosts, measures in addition to personal hygiene and improved sanitary measures have to be considered. Iodine has been recommended as an effective disinfectant for drinking water, but it must be used according to directions. Filtration systems have also been recommended, although they have certain drawbacks such as clogging.

Most experts agree that the single most effective practice that prevents the spread of infection in the child care setting is good handwashing by the children, staff, and visitors. Rubbing hands together under running water is the most important part of washing away infectious organisms. Premoistened towelettes or wipes and waterless hand cleaners should not be used as a substitute for washing hands with soap and running water. These guidelines are not limited to giardiasis but include all potentially infectious organisms.

Key Points for Laboratory Diagnosis

1. Even if a series of three stool specimens is submitted and examined correctly, the organisms may not be recovered and identified. The organisms are shed on a sporadic basis.
2. Motility on wet preparations may be difficult to see because the organisms may be caught up in mucus.
3. Any examination for parasites in stool specimens must include the use of a permanent stained smear (even on formed stool) (Figure 36.7).
4. Duodenal drainage and/or the use of the Entero-Test capsule may be very helpful in organism recovery. However, this technique does not take the place of the ova and parasite examination. Fecal immunoassays for antigen detection are now widely used and include the enzyme immunoassay, fluorescent-antibody assay, and cartridge formats. Based on the patient's history, a fecal immunoassay performed on two separate stool specimens is more appropriate and sensitive than the O&P. However, it is important to remember that patients who are carriers and do not present with acute symptoms may have insufficient numbers of organisms for a positive fecal immunoassay result, even though the immunoassays are more sensitive than the O&P.

If giardiasis is diagnosed, the patient should be treated. In the majority of cases, metronidazole is the drug of choice, but it is still considered investigational. Metronidazole is not recommended for pregnant women; paromomycin may be used to treat giardiasis in pregnancy, although it is not absorbed and not highly effective. Tinidazole has also been used and has proven to be more effective than metronidazole as a single dose. Furazolidone is another option but has been reported to be mutagenic and carcinogenic.

Figure 36.7 Case 5. (Left) *Giardia lamblia* trophozoite seen in a permanent stained smear; (right) *G. lamblia* cyst seen in a permanent stained smear (note how much more detail is seen compared to the wet mounts in Figure 36.6).

In the absence of a parasitologic diagnosis, the treatment of suspected giardiasis is a common question with no clear-cut answer. The approach depends on the alternatives and the degree of suspicion of giardiasis, both of which vary among patients and physicians. However, it is not recommended that treatment be given without a good parasitologic workup, particularly since relief of symptoms does not allow a retrospective diagnosis of giardiasis; the most commonly used drug, metronidazole, targets other organisms besides *G. lamblia*.

Should asymptomatic patients be treated? Generally, it is recommended that all cases of proven giardiasis be treated because the infection may cause subclinical malabsorption, symptoms are often periodic and may appear later, and a carrier is a potential source of infection for others. Certainly in areas of the world where infection rates, as well as the prospect of reinfection, are extremely high, the benefit-per-cost ratio would also have to be examined.

Helminth Infections

Case 6

A 28-year-old postdoctoral student presented to his physician with complaints of recurrent abdominal cramps. He had grown up in Italy, come to the United States for graduate studies, and returned home each year for the holidays. Over a period of several years he had complained of recurrent abdominal cramps; however, the causes were thought to be changes in diet, as well as the usual stress associated with graduate school. During the past few months, the symptoms had become worse and he occasionally had diarrhea as well. There was some speculation that he might have an ulcer.

On presentation, the patient appeared in no particular distress, and the examination was unremarkable. The one exception was some slight discomfort on palpation of the abdomen. A gastrointestinal series was normal; however, stool examinations revealed the following objects (Figure 36.8). These objects measured about 30 by 47 μm and were easily seen in the saline wet preparation examination. Note the suggestion of filaments that lie between the egg shell and the embryo (3, 4, 7, 8).

Questions

1. Which group of parasites includes these objects?
2. Is there anything about the object morphology that suggests the identification?
3. If you know what is causing the infection, do patients usually present with symptoms?
4. What key characteristic of the life cycle plays a role in transmission?

Figure 36.8 Case 6. Helminth eggs (wet mounts of concentration sediment). Note the polar filaments that lie between the oncosphere and the egg shell.

Correct Identification

These images are *Hymenolepis nana* eggs; these eggs generally measure 30 to 47 μm in diameter. They are round to oval, contain a six-hooked oncosphere (embryo), and have polar filaments that lie between the egg shell and the developing embryo.

Since the adult worms or proglottids are rarely seen in the stool, the diagnosis is based on recovery and identification of the characteristic eggs. They are most easily seen and identified from fresh specimens or those preserved in formalin-based fixatives. The thin-shelled eggs also tend to collapse on the permanent stained smear and may be difficult to identify in this type of preparation. Eggs with the characteristic thin shell, six-hooked oncosphere, and polar filaments are diagnostic. Remember, the eggs are infectious, and unpreserved stool specimens should be handled with caution.

An infection with *H. nana* may cause no symptoms, even with a heavy worm burden. Some patients complain of headache, dizziness, anorexia, abdominal pain, diarrhea, or possibly irritability. Some patients have a low-grade eosinophilia of 5% or more. When young children have heavy infections, they may have loose stools or even diarrhea containing mucus. Persistent, diffuse abdominal pain seems to be the most common symptom.

Infection is usually acquired by the ingestion of *H. nana* eggs, primarily from human stool. The eggs hatch in the stomach or small intestine, and the liberated larvae (oncospheres) penetrate the villi in the upper small intestine. The larvae develop into the cysticercoid stage in the tissue and migrate back into the lumen of the small intestine, where they attach to the mucosa. The adult worms mature within several weeks; they measure up to 40 mm long. Adult worms are rarely seen in the stool. This life cycle involves transition from the egg to the adult worm within the human; no intermediate host is required. Although accidental ingestion of the insect intermediate host can result in development of the adult worms, this

mode of infection is probably rare. There is evidence that auto- or hyperinfection occurs when eggs spontaneously hatch in the small intestine and initiate a new life cycle. Although adult worms live for only about a year, some patients carry a large worm burden for many years, probably due to the autoinfection capability within the life cycle.

H. nana is the only human tapeworm in which an intermediate host is not required and transmission is from person to person. Children are usually infected more often than adults. Since infection is from person to person via the eggs, good personal hygiene is an important preventive measure.

Niclosamide has been widely used for years. However, the use of praziquantel in a single oral dose is apparently more effective and kills the cysticercoid as well as the adult worm. The recommended dose for adults and children is 25 mg/kg in a single dose (see chapter 25).

Key Points for Laboratory Diagnosis

1. Adult worms or proglottids are rarely seen in the stool.
2. Eggs with the characteristic thin shell, six-hooked oncosphere, and polar filaments are diagnostic.
3. Egg morphology is more easily seen in fresh specimens or those preserved in formalin-based fixatives (Figure 36.9).
4. The eggs are infectious, and unpreserved stool specimens should be handled with caution.

Case 7

A 47-year-old man was admitted to the hospital with complaints of severe mid-epigastric pain that had become worse over a period of about a week. This patient had

Figure 36.9 Case 6. *Hymenolepis nana* eggs or artifacts (permanent stained smear). The image on the left is probably just an artifact that resembles a helminth egg. The image on the right may or may not be an actual *H. nana* egg. On permanent stained smears, helminth egg morphology often appears distorted with very dark staining.

received prednisone over the course of several years, and the dose had been increased 2 months before. Previous diagnostic testing included an O&P examination, whose results were reported as “No parasites seen.”

He was treated with supportive care for epigastric pain and developing pneumonia, but his condition failed to improve. He became comatose and died 3 days later. Autopsy findings included the following image (of his colon) (Figure 36.10).

Questions

1. What infection most probably matches this image?
2. Based on the history, why might there be no evidence of eosinophilia?
3. What was there about his history that could lead to complications with this parasite?
4. Does the negative O&P examination in this case make sense? Why or why not? Should a repeat O&P examination have been ordered?
5. Which other test could have been ordered? Is this test more or less sensitive than the routine O&P examination?

Correct Identification

The autopsy image shows a *Strongyloides stercoralis* rhabditiform larva in a crypt of the colon. Remember, high eosinophilia may or may not be present. In this case, no eosinophils were noted (eosinopenia can occur in the hyperinfection syndrome and is a poor prognostic sign). Additional images can be seen in Figure 36.11.

This case represents a generalized infection with *S. stercoralis*, involving the lungs, liver, peritoneum, small intestine, colon, respiratory diaphragm, heart, lymph nodes, skeletal muscle, and periadrenal and peripancreatic

Figure 36.10 Case 7. Image from autopsy (colon). (Armed Forces Institute of Pathology photograph.)

Figure 36.11 Case 7. *Strongyloides stercoralis*. (Top) Larvae in sputum; (second from top) slit in the tail of filariform (infective) larva obtained using the Baermann concentration apparatus; (third from top) short buccal capsule and genital primordium packet of cells in a rhabditiform (noninfective) larva; (bottom) clear image of the genital primordium packet of cells in a rhabditiform larva.

fat. There was generalized peritonitis. Intact rhabditiform and filariform larvae of *S. stercoralis* were seen in the tissues and in stool specimens. It is unfortunate that additional O&P examinations or the agar plate culture were not performed during this hospital admission.

Strongyloidiasis is most often found in warm climates but can also occur in temperate and cold climates. It overlaps the same geographic range as hookworm infections. The disease is contracted by penetration of the filariform larvae into the skin by contact with infected soil, by autoinfection, or by fecal-oral contamination. Generalized disease may present in many ways: paralytic ileus, an acute surgical abdomen, asthma, and as a protein-losing enteropathy with malabsorption. It should be considered in the differential diagnosis of patients with bronchopneumonia and accompanying abdominal symptoms.

Findings of bilateral pulmonary disease were due to extensive intra-alveolar hemorrhage and interstitial pneumonia; numerous larval forms were present in the lungs. When young worms break out of the pulmonary capillary into the alveoli, hemorrhage and cellular infiltration into the air sacs and bronchioles result.

Malnutrition, lymphoma, treatment with immunosuppressive agents, and corticosteroid therapy are predisposing factors for strongyloidiasis. It is also very important to consider this infection in military personnel and travelers who may have been in an area of endemic infection many years earlier. More than 30 to 40 years after acquisition of the original infection, persistent, undiagnosed disease can be found in these individuals. If, for any reason, they become immunocompromised, the result can be disseminated disease leading to the hyperinfection syndrome and death.

In situations in which autoinfection occurs, some of the rhabditiform larvae that are within the intestine develop into the filariform larvae while passing through the bowel. These larvae can then reinfect the host by (i) invading the intestinal mucosa, traveling via the portal system to the lungs, and returning to the intestine, or (ii) being passed out in the feces and penetrating the host on reaching the perianal or perineal skin.

Pathology present in strongyloidiasis can vary both in severity and in the areas of the body involved. Some individuals may remain totally asymptomatic, with the only abnormal clinical finding being a peripheral eosinophilia.

Cutaneous Infection. Initial skin penetration usually causes very little reaction, although there may be some pruritus and erythema if there are large numbers of penetrating larvae. With repeated infections, the patient may mount an allergic response that prevents the parasite from

completing the life cycle. The larvae may be limited to skin migration or larva migrans. The term larva currens (“racing larvae”) was proposed in 1958 and is now generally accepted for cases of strongyloidiasis in which one or more rapidly progressing linear urticarial tracks starting near the anus are found. There is speculation that some of these cases may involve larvae of other species of *Strongyloides*. These tracks may progress as fast as 10 cm/h, with intermittent movement, usually on the thighs. Onset is sudden, and the lesions may disappear within 12 to 18 h.

Pulmonary Infection. Larval migration through the lungs may stimulate symptoms, depending on how many larvae are present and the intensity of the host immune response. Some patients are asymptomatic, while others present with pneumonia. With a heavy infective dose or in the hyperinfection syndrome, individuals often develop cough, shortness of breath, wheezing, fever, and transient pulmonary infiltrates (Loeffler’s syndrome). Cases have also been reported where the larvae can be found in the sputum.

Intestinal Infection. In heavy infections, the intestinal mucosa may be severely damaged with sloughing of tissue, although this type of damage is unusual. Symptoms may mimic peptic ulcer with abdominal pain, which may be localized in the right upper quadrant. Radiographic findings may mimic Crohn’s disease of the proximal small intestine. In immunocompetent patients there is a leukocytosis with a peripheral eosinophilia of 50 to 75%, while in chronic cases the eosinophilia may be much lower. Some of these chronic infections have lasted for over 30 years as a result of the autoinfective capability of the larvae. One case of chronic strongyloidiasis persisted for approximately 65 years.

Hyperinfection Syndrome. Autoinfection is probably the mechanism responsible for long-term infections that persist for years after the person has left the area of endemic infection. The parasite and host reach a status quo so that neither suffers any serious damage. If for any reason this equilibrium is disturbed and the individual becomes immunosuppressed, then the infection proliferates, with large numbers of larvae being produced and found in every tissue of the body. Several conditions, including the use of immunosuppressive therapy, predispose an individual to the hyperinfection syndrome. In addition to the actual tissue damage from the migrating larvae, the patient may die from sepsis, primarily as a result of the intestinal flora. Other causes of death include peritonitis, brain damage, and respiratory failure.

Reactive Arthritis. Few cases of reactive arthritis have been reported, and the number of cases may be underestimated. A case of reactive arthritis combined with uveitis associated with a long-standing, heavy *Strongyloides* infection has been found in a 32-year-old patient infected with human T-cell leukemia virus. Treatment with thiabendazole and ivermectin resulted in rapid improvement.

Debilitated or compromised patients should always be suspected of having strongyloidiasis, particularly if there are unexplained bouts of diarrhea and abdominal pain, repeated episodes of sepsis and/or meningitis with intestinal bacteria, or unexplained eosinophilia. However, a recent comparative study of the occurrence of *Strongyloides* in 554 AIDS and 142 non-AIDS patients demonstrated a similar prevalence of infection in the two groups, indicating that there are no significant statistical differences.

Key Points for Laboratory Identification

1. The rhabditiform (noninfective) larvae are normally recovered from the stool concentrate. However, it is important to remember that filariform (infective) larvae can also be recovered in the stool.
2. If the stool specimens are negative, examination of duodenal contents is recommended (duodenal aspirates, Entero-Test capsule).
3. Various concentrates (Baermann) and cultures (Harada-Mori, petri dish, or agar plate) can also be used for larval recovery.
4. Eggs are rarely seen in the stool but may be recovered from duodenal contents.
5. In very heavy infections, eggs (less common), larvae (both types), and adult worms may be recovered in the stool.
6. Remember that if agar plates are used, they must be dried at room temperature for 4 to 5 days to eliminate free water on the agar prior to use. The agar plate culture method is thought to be the most sensitive diagnostic procedure available (4, 7).

Thiabendazole has been used in the past; in some cases, repeated or extended (1 week) therapy may be necessary, and the cure rates range from 55 to 100%. Patients with the hyperinfection syndrome should be hospitalized during therapy for proper monitoring. Ivermectin has become more widely used in the last few years.

Contact with contaminated infective soil, feces, or surface water should be avoided. Individuals found to have the infection should be treated. All patients who are going to receive immunosuppressive drugs should be screened for strongyloidiasis before therapy.

Strongyloidiasis is endemic at least as far north as New York City. It is very likely that endemic foci also exist in other metropolitan areas within the United States, and cases similar to the one presented here could occur anywhere within the country. This was a case of disseminated strongyloidiasis presenting as acute abdominal distress in an adult who had been receiving immunosuppressive therapy.

Case 8

A 34-year-old man from Mexico went to the clinic because he found some white, rectangular objects in his stool. These objects were about an inch long and appeared to be “moving” very slowly. He had always been healthy and had come to the United States 2 years earlier. He denied experiencing gastrointestinal or other symptoms. He had lived in a rural area of Mexico, and he reported no unusual dietary habits or significant contact with animals. During the last few days, he complained of anorexia, some nausea, and abdominal cramps; however, he had no diarrhea. Laboratory findings were normal; however, the routine O&P examination revealed the following images (Figure 36.12) (3, 4, 7, 8).

Questions

1. What do you think the structures are as seen in Figure 36.12?
2. Are there any key morphologic characteristics that could help you identify this parasite?
3. What laboratory tests might be appropriate at this point?
4. Are there any standard precautions that should be

Figure 36.12 Case 8. (Upper) Structure obtained from stool specimen; (lower) objects seen in the concentration sediment wet mount (using high dry 40× objective).

taken? If so, what are they and why might they be important? If not, why not?

Correct Identification

The helminth eggs are those of *Taenia* spp. From the egg morphology, it is impossible to identify the cestode to the species level as *T. saginata* (beef tapeworm) or *T. solium* (pork tapeworm). This structure recovered from the patient's stool specimen is a *Taenia* sp. proglottid. To more fully visualize the internal structure of the proglottid, an India ink injection procedure could be performed. Results of this procedure can be seen in Figure 36.13.

The life cycle of *T. saginata* is very similar to that of *T. solium*. Infection with the adult worm is initiated by the ingestion of raw or poorly cooked beef containing encysted *T. saginata* larvae. As with *T. solium*, the larva is digested out of the meat in the stomach and the tapeworm evaginates in the upper small intestine and attaches to the intestinal mucosa, where the adult worm matures within 5 to 12 weeks. The adult worm can reach a length of 25 m but often measures only about half this length. Although a single worm is usually found, multiple worms can be present (personal observation).

The scolex is “unarmed” and has four suckers with no hooks. The proglottids usually number 1,000 to 2,000, with the mature proglottids being broader than long and the gravid proglottids being narrower and longer. Identification to the species level is usually based on the number of main lateral uterine branches, which are counted on one side of the gravid proglottid. There are between 15 and 20 branches, with an average of 18.

Gravid proglottids often crawl from the anus during the day, when the host is most active. These proglottids may crawl under the stool when a specimen is submitted unpreserved in the stool collection carton. The eggs cannot be distinguished from those of *T. solium*. They are round to slightly oval, measure 31 to 43 μm , have a thick, striated shell, and contain the six-hooked embryo (oncosphere).

Figure 36.13 Case 8. *Taenia saginata* gravid proglottid; note the large number of lateral uterine branches when counted on one side.

The eggs can remain viable in the soil for days to weeks. On ingestion by cattle, the oncospheres hatch in the duodenum, penetrate the intestinal wall, and are carried via the lymphatics or bloodstream, where they are filtered out in the striated muscle. They then develop into the bladder worm or cysticercus within approximately 70 days. The mature cysticercus measures 7.5 to 10 mm wide by 4 to 6 mm long and contains the immature scolex, which has no hooks (unarmed). Other animals found to harbor cysticerci include buffalo, giraffe, llama, and possibly reindeer. Actual cases of human cysticercosis with *T. saginata* are rare in the literature, and there is speculation that some reported cases have been inaccurately diagnosed.

There are usually few symptoms associated with the presence of the adult worm in the intestine. Although rare symptoms (obstruction, diarrhea, hunger pains, weight loss, and appendicitis) have been reported, the most common complaint is the discomfort and embarrassment caused by the proglottids crawling from the anus. This occurrence may be the first clue that the patient has a tapeworm infection. Occasionally, the proglottids are also seen on the surface of the stool after it is passed.

Key Points for Laboratory Identification

1. Preliminary examination of the gravid proglottid may not allow identification without clearing or injection of the uterine branches with India ink. Since there is always the possible danger that the proglottid is *T. solium*, with the inherent problem of egg ingestion and cysticercosis, all specimens should be handled with extreme caution.
2. The eggs look identical to those of *T. solium*, so that identification to the species level cannot be performed with eggs alone.
3. Although gravid proglottids of *T. saginata* are often somewhat larger than those of *T. solium*, this difference may be very minimal or impossible to detect.
4. Any patient with *Taenia* eggs recovered in the stool should be cautioned to use good hygiene. These patients should be treated as soon as possible to avoid the potential danger of accidental infection with the eggs, which may lead to cysticercosis (*T. solium*).

For therapy, the use of praziquantel or niclosamide has been recommended. The same general approach as used for *T. solium* is used to eradicate the adult worm. Therapy is usually very effective; however, if the proglottids begin to reappear in the stool or crawl from the anus, retreatment is necessary.

Case 9

A 45-year-old engineer presented to his physician with jaundice. He reported that a few days earlier he had developed a fever and also had experienced diarrhea, nausea, and vomiting. He also indicated that he had had a cough about a week earlier. A few days later, he experienced right upper quadrant pain. On the day he presented to the physician, he had noticed that his eyes were somewhat yellow. The patient works for an American-based engineering firm that has multiple contracts throughout South America; their main responsibilities include drilling for water and construction of irrigation canals in recently cleared land areas of several South American countries, including Bolivia, Argentina, Chile, and Peru. Periodically he spends time in these areas, usually eating whatever is available. Often the engineering job is adjacent to sheep- and/or cattle-raising regions.

On presentation, the patient appeared in no particular distress; however, he was jaundiced. The lungs and heart were normal. There was guarding and tenderness in the right upper quadrant. The liver was enlarged and tended down to 3 cm below the costal margin, with a span of 15 cm. There was no peripheral edema. The white blood cell count was 18,500, with 35 polymorphonuclear leukocytes, 10 lymphocytes, 3 monocytes, and 52 eosinophils. Stool examinations for parasites revealed the following image (Figure 36.14). These objects measured about 140 by 70 μm and were easily seen in the saline wet preparation examination.

Questions

1. Based on the size of the objects in Figure 36.14, what are the possibilities regarding identification?
2. What key morphologic features are helpful in making the diagnosis?
3. Are these key characteristics visible? If yes, what are they? If not, why not?

Figure 36.14 Case 9. Objects seen in the wet mount microscopic examination of concentration sediment. These objects measured about 140 by 70 μm and were easily seen in the saline wet preparation examination.

4. Are there any additional laboratory tests that might be helpful?

Correct Identification

The object in Figure 35.14 is a *Fasciola hepatica* egg; these eggs generally measure 130–150 by 63–90 μm . They are unembryonated, operculated, large, ovoid, and usually brownish yellow (3, 4, 8). However, based on morphology alone, the egg could also be *Fasciolopsis buski* or *Fasciola gigantica*.

The patient's symptoms reflect the phase of the infection, as well as the number of parasites present in the host. In the acute phase, symptoms may be present over a period of weeks to months. Metacercarial larvae do not produce significant pathologic damage until they begin to migrate through the liver parenchyma. The amount of damage depends on the worm burden of the host. Linear lesions of 1 cm or greater can be found. Hyperplasia of the bile ducts occurs, possibly as a result of toxins produced by the larvae. Symptoms associated with this migratory phase can include fever, epigastric and right upper quadrant pain, and urticaria. Asymptomatic infections appear to be more common in Peru.

In the more chronic phases of the disease, the patient generally has few to no symptoms once the flukes have lodged in the biliary passages. However, there may be some epigastric and right upper quadrant pain, diarrhea, nausea, vomiting, hepatomegaly, and jaundice. If the flukes are found in the extrahepatic biliary ducts, symptoms may mimic those seen in cholelithiasis. In the chronic phase, there tend to be some liver function abnormalities, as well as eosinophilia.

Once the worms have established themselves in the bile ducts and matured, they cause considerable damage from mechanical obstruction and metabolic by-products. The degree of pathologic change depends on the number of flukes penetrating the liver. The infection produces hyperplasia of the biliary epithelium and fibrosis of the ducts, with portal or total biliary obstruction. The gallbladder undergoes similar pathologic changes and may even harbor adult worms.

Symptoms and signs of infection during the late stages after egg production has begun are those associated with biliary obstruction and cholangitis. Acute epigastric pain, fever, pruritus, jaundice, hepatomegaly, and eosinophilia are common.

Adult worms, which may live for 9 years in the bile ducts, produce eggs that are carried by the bile fluid into the intestinal lumen and passed into the environment with the feces. The eggs are unembryonated, operculated, large, ovoid, and brownish yellow. The miracidium develops within 1 to 2 weeks and escapes from the egg to

infect the snail intermediate host, *Lymnaea* sp. Cercariae are liberated from the snail after the production of a sporocyst generation and two or three rediae generations. Cercariae encyst on water vegetation, e.g., watercress. Humans are infected by ingestion of uncooked aquatic vegetation on which metacercariae are encysted. Metacercariae excyst in the duodenum and migrate through the intestinal wall into the peritoneal cavity. The larvae enter the liver by penetrating the capsule (Glisson's capsule) and wander through the liver parenchyma for up to 9 weeks. They finally enter the bile ducts, where they mature and produce eggs, which are passed out in feces. The adult worms can attain a length of >1 in. (1 in. = 2.54 cm) and a width of about 0.5 in.

Fascioliasis is a cosmopolitan disease found where there is close association of livestock, humans, and snails. The largest numbers of infections have been found in Bolivia, Ecuador, Egypt, France, Iran, Peru, and Portugal. Although animal fascioliasis is endemic throughout the Americas, human infections are rare in most countries. Reservoir hosts include herbivores such as cattle, goats, and sheep. Animal fascioliasis is a major veterinary problem in Europe. Watercress is the main source of human infection, and in many countries wild watercress is touted as a healthy natural food. In many areas of the world, animal manure is used as the primary fertilizer for cultivation of watercress.

Prevention may be accomplished by public health education in areas where infections are endemic, stressing the dangers of eating watercress grown in the wild where animals and snails are abundant. Other measures have included mollusciciding, treatment of infected animals, and draining of pasture lands.

Key Points for Laboratory Identification

- Multiple stool specimens may be required to find the trematode eggs. In a very light infection, eggs may not be recovered; however, the patient might be asymptomatic.
- The sedimentation concentration method should be used; because the eggs are operculated, they do not float in the zinc sulfate flotation concentration method.
- When adding iodine to the wet preparation, do not add too much or the eggs will stain very darkly and resemble debris.
- The wet preparation can be examined using the 10× (low-power) objective; these eggs are large enough that they can usually be seen using this magnification.
- Eggs of *F. hepatica* can resemble those *Fasciola gigantica* (liver fluke) and *Fasciolopsis buski* (intestinal fluke).
- Do not make the wet preparation too thick; if it is too thick, the eggs can be obscured by normal stool debris.
- If available, antigen or antibody detection may be helpful in confirming the infection.

Although treatment with praziquantel at a dose of 25 mg/kg taken after each meal for 2 days is sometimes effective, it does not appear to be effective in treating cases of infection in Egypt. Treatment with 30 to 50 mg of biothionol/kg on alternate days for 10 to 15 doses is recommended. Triclabendazole at 10 mg/kg as a single dose is also recommended but may not be as easily obtained. The drug is given orally in single or multiple doses and has few side effects. The drug acts by inhibiting protein synthesis in *F. hepatica* and will probably become the drug of choice.

Case 10

A 14-month-old boy was admitted to the hospital with complaints of irritability, ataxia, and weakness that had developed over a period of several weeks. Just prior to admission, he was unable to sit up or walk. A complete blood count showed 35% eosinophilia; lumbar puncture revealed an elevated eosinophilia. His neurologic status did not improve. Several weeks after admission, his magnetic resonance imaging scan revealed severe cortical atrophic changes and severe diffuse white-matter degeneration. He remained in a vegetative state and died several months after his initial symptoms. He was not seropositive for *Toxocara canis*, and he had not lived in or traveled to areas where other causes of eosinophilic meningoencephalitis would be suspected. At autopsy, the following image was seen from brain tissue (Figure 36.15) (6).

Figure 36.15 Case 10. Image from autopsy (brain tissue).

Questions

1. What are some of the other causes of eosinophilic meningoencephalitis?
2. What questions would you ask regarding possible patient history details (animal contact, play practices, etc.)?
3. Does the patient's age suggest any possible diagnostic options?
4. What preventive measures could be taken to avoid this particular infection?

Correct Identification

The image seen in Figure 36.15 reveals a histologic section of larvae consistent with the raccoon roundworm, *Baylisascaris procyonis*. On further questioning, it became clear that the child had been exposed to feral raccoons and soil contaminated with raccoon feces in his backyard. Raccoons were seen in the surrounding area, and typical *B. procyonis* eggs were found in the soil. Adult worms were also found in the raccoons (Figure 36.16); the adult worms look very much like *Ascaris lumbricoides*.

The diagnosis of *B. procyonis* encephalitis was confirmed. This patient presented with the typical clinical syndrome, including peripheral and CSF eosinophilia. On further testing, the patient demonstrated positive antibody results in indirect-immunofluorescence testing of both serum and CSF to *B. procyonis*. Both the intensity and titers increased with time. Other infections causing eosinophilic meningoencephalitis include *Toxocara* spp. larval migrans.

Key Points for Laboratory Diagnosis

1. Definitive diagnosis requires identification of the larvae in tissues; however, this can be difficult depending on the body site. Cross sections of larvae tend to measure 60 to 70 μm , and the larvae have

- prominent, single lateral alae and paired, conical excretory columns (smaller than central intestine).
2. Ocular examinations may reveal retinal lesions, larval tracks, or migrating larvae; these findings may provide the tentative diagnosis involving a helminth infection.
3. Using indirect fluorescent-antibody testing, enzyme-linked immunosorbent assay, and Western blotting, anti-*Baylisascaris* antibodies can be detected in CSF. Currently, the only source for serologic testing is the Department of Veterinary Pathobiology at Purdue University, West Lafayette, Ind. [K. Kazacos; phone (765) 494-7558]. Acute- and convalescent-phase titers demonstrate several-fold increases in both serum and CSF antibody levels; there is no cross-reactivity with *Toxocara*. With the availability of a reliable serologic test, there is less need to perform a brain biopsy.
4. *In most cases, the clinical history provides the main clues.*

Feral raccoons were found in the area around the house; both dirt and plant debris were contaminated with viable *B. procyonis* eggs. Ingestion of infective *B. procyonis* eggs probably occurred through ingestion of contaminated soil or other hand-to-mouth transfer from areas or articles contaminated with raccoon feces. This roundworm is a common parasite of raccoons, especially in the Midwest and the Northeast and on the west coast of the United States. Infection rates can range as high as 82% in raccoons. In many metropolitan areas, the raccoon population is quite high, and people tend to lure the animals close to homes through intentional feeding or through dog food left in the surrounding areas. Thus, contamination of the surrounding environment with raccoon feces is common. The infected animals shed an average of >25,000 eggs/g of feces; millions of eggs can be shed each day. These infective eggs are very environmentally resistant and can survive for years in the soil.

Raccoons tend to defecate in the same areas, which are called latrines (often in barns, decks, patios, etc.). These sites remain sources of eggs that are infective for both humans and other animals for long periods. Young children with a history of ingesting soil and/or feces are at greatest risk for infection; most confirmed cases have been in this age group. Individuals with developmental impairment tend to be at special risk due to a greater tendency to exhibit behaviors that lead to egg ingestion.

Unfortunately, neural larval migrans caused by *B. procyonis* carries a poor prognosis. However, high-dose albendazole given early in the infection may prevent or halt the progression of CNS disease. Treatment before larvae

Figure 36.16 Case 10. *Baylisascaris procyonis*. (Left) Typical eggs isolated from raccoons; (right) adult worms isolated from raccoons.

reach the CNS is beneficial. Because they diminish inflammatory reactions, steroids may be beneficial unless the CNS damage is too advanced. Although ivermectin has been used, this drug does not cross the blood-brain barrier.

In addition to direct damage caused by the migrating larvae, it is likely that eosinophil-derived neurotoxin contributes to the manifestations of encephalitis. Two features distinguish this infection from other nematode infections that cause larval migrans: the somatic migration and invasion of the CNS and the continued growth of the larvae to a large size within the CNS. Despite therapy, to date there are no documented cases of neurologically intact survivors.

Although reports of cases of eosinophilic meningoencephalitis caused by *B. procyonis* infections are rare, large populations of raccoons with high rates of *B. procyonis* infections live in close proximity to humans in many areas. Widespread contamination of the domestic environment suggests that the risk of exposure and human infection may be substantial. Prevention of infection is the most important public health measure; educating the public is essential for disease prevention.

There is no effective cure for *B. procyonis* infection; treatment is symptomatic and involves systemic corticosteroids and anthelmintic agents. Unfortunately, neural larva migrans is usually not responsive to anthelmintic therapy; by the time the diagnosis is made, extensive damage has already taken place. Drugs that can be tried include albendazole, mebendazole, thiabendazole, levamisole, diethylcarbamazine, and ivermectin. Experimental data from animal studies indicate that albendazole and diethylcarbamazine may have the best CSF penetration and larvicidal activity. Unfortunately, since the diagnosis does not take place until symptoms have begun, larval invasion of the CNS has already taken place. Therefore, treatment is usually started too late in the course of the infection.

Considering the potential outcomes associated with delay of treatment until symptoms begin, prophylactic treatment for asymptomatic children exposed to raccoons or contaminated environments is now being considered. Since the anthelmintics do not appear to be problematic, prophylaxis seems appropriate for specific individuals. Albendazole has been used in these cases; treatment has been discontinued when environmental testing has proven to be negative.

Blood Parasite Infections

Case 11

The patient was a 52-year-old man from California who had just returned from a trip to Africa. About a week after he returned, he began complaining of

fever, headache, and general malaise. The first blood specimens examined using automated instrumentation revealed nothing significant. He continued to have high fevers and severe headaches, and eventually several additional blood specimens were submitted to the microbiology laboratory for examination as thick and thin blood films (4, 5, 7–9, 14). The following images were seen (Figure 36.17).

Questions

1. What parasitic infections should be considered in the diagnosis?
2. Do the images in Figure 36.17 provide a diagnosis?
3. Why do you think automation failed to indicate anything significant?
4. Does your presumptive diagnosis match the patient's history? Why or why not?

Correct Identification

At first glance, the fact that the man had just returned from a trip to Africa might suggest a parasitic infection as a possibility. The patient's symptoms were caused by a mixed infection with *Plasmodium falciparum* and *Plasmodium vivax* that he had acquired in Africa. Although he had

Figure 36.17 Case 11. Blood films stained with Giemsa stain. (Upper left) Thick blood film; (upper right) thin blood film; (lower left) thick blood film; (lower right) thin blood film.

taken prophylaxis for malaria, he had not taken the medication on a regular basis and did not continue to take the medication after returning to the United States. Because he had never had any contact with malaria before (i.e., he was immunologically naive), he began to have symptoms with a very low parasitemia ($>0.01\%$) that was undetectable by automated instrumentation. By the time his symptoms became more severe (about 2 weeks), he had numerous parasites in the peripheral blood. By the time the infection was diagnosed, the man was severely ill. Organisms seen on the blood films were

1. *Plasmodium falciparum* ring form (thick blood film)
2. *Plasmodium falciparum* ring forms (thin blood film) (note the typical “headphone” appearance of some of the ring forms)
3. *Plasmodium vivax* (thick blood film) (note the developing rings and one developing schizont)
4. *Plasmodium vivax* (thin blood film) (note the mature schizont with about 18 merozoites)

Comments on *P. falciparum*. *P. falciparum* tends to invade all ages of RBCs, and the proportion of infected cells may exceed 50%. Schizogony occurs in the internal organs (spleen, liver, bone marrow, etc.) rather than in the circulating blood. Ischemia caused by the plugging of vessels within these organs by masses of parasitized RBCs produces various symptoms, depending on the organ involved. It has been suggested that a decrease in the ability of the RBCs to change shape when passing through capillaries or the splenic filter may lead to the plugging of the vessels.

Onset of a *P. falciparum* malaria attack occurs 8 to 12 days after infection and is preceded by 3 to 4 days of vague symptoms such as aches, pains, headache, fatigue, anorexia, or nausea. The onset is characterized by fever, a more severe headache, and nausea and vomiting, with occasional severe epigastric pain. There may be only a feeling of chilliness at the onset of fever. The periodicity of the cycle is not established during the early stages, and the presumptive diagnosis may be totally unrelated to a possible malaria infection. If the fever does develop a synchronous cycle, it is usually a cycle of somewhat less than 48 h. True relapses from the liver do not occur, and recrudescences are rare after a year.

Severe or fatal complications of *P. falciparum* malaria can occur at any time during the infection and are related to the plugging of vessels in the internal organs; the symptoms depend on the organ(s) involved. The severity of the complications in a malaria infection may not correlate with the parasitemia seen in the peripheral blood, particularly in *P. falciparum* infections.

Disseminated intravascular coagulation is a rare complication of malaria; it is associated with high parasite burden, pulmonary edema, rapidly developing anemia, and cerebral and renal complications. Vascular endothelial damage from endotoxins and bound parasitized blood cells may lead to clot formation in small vessels. Cerebral malaria is most often seen in *P. falciparum* malaria, although it can occur in the other types as well. If the onset is gradual, the patient may become disoriented or violent or may develop severe headaches and pass into a coma. Some patients, even those who exhibit no prior symptoms, may suddenly become comatose. Physical signs of CNS involvement are quite variable, and there is no real correlation between the severity of the symptoms and the peripheral-blood parasitemia.

Although malaria is no longer endemic within the United States, this infection is considered to be life-threatening, and laboratory requests for blood smear examination and organism identification should be treated as STAT requests. Malaria is usually associated with patients having a history of travel within an area where malaria is endemic, although other routes of infection are well documented. During 2002 (the most recent data available), $>45\%$ of the malaria cases reported in the United States were caused by *P. falciparum*, the most pathogenic of the four species infecting humans.

Comments on *P. vivax*. The primary clinical attack usually occurs 7 to 10 days after infection, although there are strain differences, and a much longer incubation period is possible. In some patients, symptoms such as headache, photophobia, muscle aches, anorexia, nausea, and sometimes vomiting occur before organisms can be detected in the bloodstream. In other patients, the parasites can be found in the bloodstream several days before symptoms appear.

During the first few days, the patient may not exhibit a typical paroxysm pattern but, rather, may have a steady low-grade fever or an irregular remittent fever pattern. Once the typical paroxysms begin, after an irregular periodicity, a regular 48-h cycle is established. An untreated primary attack may last from 3 weeks to 2 months or longer. The paroxysms become less severe and more irregular in frequency and then stop altogether. In 50% of patients, relapses occur after weeks, months, or up to 5 years (or more).

Severe complications are rare in *P. vivax* infections, although coma and sudden death or other symptoms of cerebral involvement have been reported. These patients can exhibit cerebral malaria, renal failure, circulatory collapse, severe anemia, hemoglobinuria, abnormal bleeding, acute respiratory distress syndrome, and jaundice. Studies have confirmed that these were not mixed infections with

P. falciparum but single-species infections with *P. vivax*. However, of the two infections, *P. falciparum* causes the most severe complications.

Since *P. vivax* infects only the reticulocytes, the parasitemia is usually limited to around 2 to 5% of the available RBCs. Splenomegaly occurs during the first few weeks of infection, and the spleen progresses from being soft and palpable to hard, with continued enlargement during a chronic infection. If the infection is treated during the early phases, the spleen will return to its normal size.

Leukopenia is usually present; however, leukocytosis may be present during the febrile episodes. Concentrations of total proteins in plasma are unchanged, although the albumin level may be low and the globulin fraction may be elevated. The increase in the concentration of gamma globulins is caused by the development of antibodies. The level of potassium in serum may also be increased as a result of RBC lysis.

Diagnosis. Frequently, for a number of reasons, organism recovery and subsequent identification are more difficult than the textbooks imply. It is very important that this fact be recognized, particularly when one is dealing with a possibly fatal infection with *P. falciparum*. When requests for malarial smears are received in the laboratory, some patient history information should be made available to the laboratorian. This information should include the following:

1. Where has the patient been, and what was the date of return to the United States? (“Where do you live?”)
2. Has malaria ever been diagnosed in the patient before? If so, which species was identified?
3. What medication (prophylaxis or otherwise) has the patient received, and how often? When was the last dose taken?
4. Has the patient ever received a blood transfusion? Is there a possibility of other needle transmission (drug user)?
5. When was the blood specimen drawn, and was the patient symptomatic at the time? Is there any evidence of a fever periodicity? Answers to such questions may help eliminate the possibility of infection with *P. falciparum*, usually the only species that can rapidly lead to death.

Often the diagnosis of malaria is considered, and a single blood specimen is submitted to the laboratory for examination; however, single films or specimens cannot be relied on to exclude the diagnosis, especially when incomplete prophylactic medication or therapy is used.

Incomplete use of antimalarial agents may be responsible for reducing the numbers of organisms in the peripheral blood, thus leading to a blood smear that contains few organisms, which then reflects a low parasitemia when in fact serious disease is present. Patients with a relapse case or an early primary case may also have few organisms in the blood smear.

It is recommended that both thick and thin blood films be prepared on admission of the patient, and at least 200 to 300 oil immersion fields should be examined on the thin film before a negative report is issued. Since one set of negative films does not rule out malaria, additional blood specimens should be examined over a 36-h time frame. Although Giemsa stain is recommended for all parasitic blood work, the organisms can also be seen with other blood stains such as Wright’s stain or the rapid stains. Blood collected with EDTA anticoagulant is acceptable; however, if the blood remains in the tube for any length of time, true stippling may not be visible within the infected RBCs (*P. vivax*, as an example). Also, when using anticoagulants, it is important to remember that use of the proper ratio between blood and anticoagulant is necessary for good organism morphology. If the blood stands for >2 h prior to blood film preparation, organism distortion is very likely, with the morphology beginning to mimic that seen with *P. malariae*. If the blood stands for >6 h prior to blood film preparation, the organisms will disintegrate.

Malaria is one of the few parasitic infections considered to be immediately life-threatening, and a diagnosis of *P. falciparum* malaria should be considered a medical emergency because the disease can be rapidly fatal. Any laboratory providing the expertise to identify malarial parasites should do so on a 24-h basis, 7 days/week.

Characteristics of *P. falciparum* (malignant tertian malaria) include the following:

1. 36- to 48-h cycle
2. Tends to infect any cell regardless of age; thus, very heavy infection may result
3. All sizes of RBCs
4. No Schüffner’s dots (Maurer’s dots: may be larger, single dots, bluish)
5. Multiple rings per cell (only young rings, gametocytes, and occasional mature schizonts are seen in peripheral blood)
6. Delicate rings; may have two dots of chromatin per ring, appliqué or accolé forms
7. Crescent-shaped gametocytes

Note Without the appliqué form, Schüffner’s dots, multiple rings per cell, and other developing stages, differentiation among the species can be very difficult. It is obvious that the early rings of all four species can mimic one another

very easily. Remember that one set of negative blood films cannot rule out a malaria infection, and this information must be conveyed to the physician.

Characteristics of *P. vivax* (benign tertian malaria) include the following:

1. 48-h cycle
2. Tends to infect young cells
3. Enlarged RBCs
4. Schüffner's dots after 8 to 10 h
5. Delicate ring
6. Very ameboid trophozoite
7. Mature schizont contains 12 to 24 merozoites

Reporting Parasitemia. It is important to report the level of parasitemia when blood films are reviewed and found to be positive for malaria parasites. Because of the potential for drug resistance in some of the *Plasmodium* species, particularly *P. falciparum*, it is important that every positive smear be assessed and the parasitemia reported using the exact same method on follow-up specimens as on the initial specimen. This allows the parasitemia to be monitored after therapy has been initiated. In cases where the patient is hospitalized, monitoring should be performed at 24, 48, and 72 h after initiation of therapy. Generally, the parasitemia will drop very quickly within the first 24 h; however, in cases of drug resistance, the level may appear to drop and then begin to rise again or the level may not decrease but actually increase over time.

Case 12

A 37-year-old private contractor returning from Iraq presented to his physician with a lesion on his arm. About 6 weeks earlier, he had noticed a small, red area on his arm. There was some itching, and over the next few weeks, the area ulcerated and measured about an inch in diameter. There was no drainage. He indicated that he was feeling well and had not had any fever, chills, anorexia, or weight loss. His medical history was unremarkable. The ulcer had a moist base and raised borders as seen in Figure 36.18 (1, 2, 4, 7, 9).

Questions

1. Based on the patient's history, what presumptive diagnosis might be appropriate?
2. What other diagnostic tests might be suggested at this point?
3. Based on additional diagnostic testing, what would you expect to find in order to support the presumptive diagnosis?
4. Should any special precautions be taken when

Figure 36.18 Case 12. (Upper) Lesion on patient's arm; (lower) skin biopsy specimen from margin of lesion.

processing and examining the clinical material? Why or why not?

Correct Identification

The lesion in Figure 36.18 could have been caused by a number of agents; however, some options became much more likely after the patient's travel and work history were reviewed. The patient had traveled and worked in Iraq. He did not remember being bitten at any specific

Figure 36.19 Case 12. Cutaneous leishmaniasis. (Left) Skin macrophage containing Leishman-Donovan bodies (note the nucleus and bar-shaped kinetoplast); (right) sand fly vector of leishmaniasis.

Figure 36.20 Case 12. (Left) Wet mount of organisms from culture; (right) Giemsa-stained smear of culture sediment.

time, but he did indicate that there were lots of flies (sand flies) present. The following images were obtained from a skin biopsy specimen that was examined in pathology, and the organisms were isolated in culture (Figures 36.19 and 36.20). This patient had cutaneous leishmaniasis.

It is important to remember that with cutaneous and/or mucocutaneous lesions, the only area where the parasites are generally found is the lesion itself. Unless the infection is the visceral type (*Leishmania donovani*), no organisms are found in the spleen, bone marrow, and/or liver. There may be exceptions in cutaneous or mucocutaneous types of disease in which the amastigotes are found in other parts of the reticuloendothelial system; however, this tends to be unusual.

Leishmania major, *L. tropica*, *L. aethiopica*, and, rarely, *L. infantum* cause cutaneous disease in the Old World; disease manifestations include nodular and ulcerative skin lesions. Local geographic names for cutaneous leishmaniasis include Oriental sore, Baghdad boil, Delhi boil, Biskra button, and Aleppo evil.

The lesions of Old World cutaneous leishmaniasis are very similar to those seen with New World cutaneous disease. Weeks to months after infection, an erythematous, often pruritic papule develops at the bite site. This papule may become scaly and enlarged, developing a central ulcer surrounded by a raised margin. Disease progression at this point will vary, depending on the species involved. Lesions may be single or multiple and usually occur on exposed areas of the body such as the face, hands, feet, arms, and legs. In general, all lesions on a patient have a similar appearance and progress at the same speed.

The original lesion may remain as a flattened plaque or may progress, with the surface becoming covered with fine, papery scales. These scales are dry at first but later become moist and adherent, covering a shallow ulcer. As the ulcer enlarges, it produces an exudate and may develop a crust. The edge of the lesion is usually raised.

Depending on the species, satellite lesions are common and merge with the original lesion.

In areas of the world where physicians are very familiar with leishmaniasis, the diagnosis may be made on clinical grounds. However, in other areas of the world, where the disease is rare, the condition may not be recognized as leishmaniasis. Definitive diagnosis depends on demonstrating the amastigotes in tissue specimens or the promastigotes in culture. Newer results suggest that PCR is a valuable tool for the diagnosis of leishmaniasis on a routine basis and can provide valuable epidemiologic information in areas of endemic infection. Cutaneous leishmaniasis may have to be differentiated from a number of other lesions and diseases, including basal cell carcinoma, tuberculosis, various mycoses, cheloid, and lepromatous leprosy.

The ability to detect parasites in aspirates, scrapings, or biopsy specimens depends on the number of amastigotes present, the level of the host immune response, the absence or presence of bacterial and/or fungal contamination within the lesion, and whether the specimen is collected from an active or healing lesion. If the patient has multiple lesions, specimens should be collected from the more recent or active lesions. These lesions should be thoroughly cleaned with 70% alcohol, and necrotic debris should be removed to prevent the risk of bacterial and/or fungal contamination of the specimen. Also, the specimen should be taken from the advancing margin of the lesion; the central portion of the ulcer contains nothing but necrotic debris.

Appropriate specimens would include scrapings of the lesions, as well as a collection of several punch biopsy specimens, taken from the most active lesion areas. However, fine-needle aspiration cytology has also been recommended. Biopsy specimens can be divided and used for cultures and touch preparations; some material should always be saved and submitted for routine histologic examination. The biopsy specimen can be used to make impression smears (touch preparations); these smears should be prepared after portions of the specimen have been placed in culture media by using sterile techniques. After cleaning off any excess blood, a horizontal cut is made through the core of the specimen and the cut surface is gently touched to glass slides; multiple slides should be prepared. Once material has been set up for culture and touch preparations have been made, the remainder of the tissue can be sent to the Pathology Department for routine processing.

Culture media that have been used for the recovery and growth of the leishmaniae include Novy-MacNeal-Nicolle medium and Schneider's *Drosophila* medium supplemented with 30% fetal bovine serum. Patient cultures should not be set unless the laboratory maintains

specific organism strains for quality control checks. Both the control and patient cultures should be examined twice weekly for the first 2 weeks and once a week thereafter for up to 4 weeks before they are called negative. Promastigote stages can be detected microscopically in wet mounts taken from centrifuged culture fluid. This material can also be stained with Giemsa stain to facilitate observation at a higher magnification.

A sensitive microcapillary culture method (MCM) was developed for the rapid diagnosis of cutaneous leishmaniasis (1). The MCM is superior to the traditional culture method (TCM) as determined by the smaller inoculum size, the higher sensitivity for detection of promastigotes, and the shorter time to the emergence of promastigotes. With lesion amastigote loads from grade III to 0, the positive rates and the periods for promastigote emergence were three- to fourfold higher and faster with the MCM than with the TCM, e.g., 83 to 97% positive in 4 to 7 days versus 20 to 40% positive in 15 to 30 days ($p = 0.0001$). This MCM has the advantage of simplicity and may be suitable for diagnostic use and for parasite retrieval in many other areas of endemic infection where parasites are known to be difficult to grow.

Key Points for Laboratory Identification

1. For a complete laboratory diagnosis, microscopic examination of Giemsa-stained touch preparations and cultures is recommended.
2. Aspirates or biopsy specimens should be taken from the margin or base of the most active lesion (papule or ulcer). The lesion should be cleaned before the sample is collected, to reduce the chances of contamination with fungi or bacteria.
3. Multiple slides should be prepared for examination.
4. Tissue imprints or smears should be stained with Giemsa stain (or one of the stains commonly used for blood smears) (see chapter 31).
5. Amastigote stages should be found within macrophages or close to disrupted cells.
6. If cultures are to be performed, specimens must be taken aseptically and control organism cultures should be set up at the same time (see chapter 32).
7. Cultures should be checked weekly for 4 weeks before they are declared negative.

Most Old World cutaneous leishmaniasis lesions are self-healing over a period of a few months to several years. This healing process confers immunity to individuals living within the immediate area of endemic infection; therefore, treatment is not recommended unless disfiguring scarring is a possibility. Local care of

the lesion and treatment of secondary bacterial infection are essential for healing. Antileishmanial therapy is indicated in immunocompromised hosts and patients with progressive, multiple, or critically located lesions. Pentavalent antimony compounds remain the main therapeutic option for all species. They are given intravenously, intramuscularly, or intralesionally. Cryotherapy and some systemic antifungal agents have been used successfully. Oral azoles are promising new treatments for lesions caused by *L. major*.

Case 13

A 61-year-old man presented to his physician with a history of symptoms, beginning about 3 weeks after he returned from a trip. Symptoms included general malaise followed by fever, chills, headaches, and back pain. The man lived in southern Texas and had returned from a photographic safari to Africa, including Kenya, Tanzania, Uganda, and South Africa. He had seen a physician before returning to the United States and had received some anti-malarial medication. He was an active wildlife photographer and was often exposed to a number of life zones and resident plants, animals, insects, etc., both at home and on trips outside of the United States.

Although both the patient and several others in the group remembered being bitten by insects, he was the only one who was symptomatic. On examination, he was found to have several swollen areas, including a lymph node on his neck and a draining lesion on his upper arm.

Blood was drawn for routine hematology procedures, and a specimen was also drawn to be sent to the microbiology laboratory for examination as blood films stained with Giemsa stain (Figure 36.21) (4, 7, 9, 12). Based on his travel history, additional laboratory work revealed a slightly elevated white blood cell count with a relative lymphocytosis. His gamma globulin level was elevated, with a marked elevation of the immunoglobulin M (IgM) level.

Figure 36.21 Case 13. Objects seen in Giemsa-stained thin blood films. (Left) Patient smear.

Questions

1. In Figure 36.21, what are the major differences between the two parasites seen?
2. Is there anything in the patient's history that would help you with the diagnosis? What and why?
3. How do you explain the marked elevation in the IgM level?
4. Is there anything in the life cycle that would explain the laboratory findings?

Correct Identification

The patient was suffering from African trypanosomiasis, probably caused by *Trypanosoma brucei rhodesiense* (East African trypanosomiasis) based on travel history (Kenya and Uganda), the severity of symptoms, and the overall description of the case. Although the man lived in southern Texas, where *Trypanosoma cruzi* (the cause of Chagas' disease, or American trypanosomiasis) is found, the African trypomastigotes and the American trypomastigotes look quite different.

The African trypomastigotes (both East and West African trypomastigotes) (Figure 36.21, left) have a very small kinetoplast (the dot at one end of the organism), while *T. cruzi* tends to have a very large kinetoplast that appears to go beyond the body of the organism (Figure 36.21, right). Although both organisms can actually be found in a C shape, this finding alone does not indicate infection with *T. cruzi*.

The course of infection in African trypanosomiasis occurs in three stages. Soon after inoculation of the metacyclic trypanosomes by an infected tsetse fly, an inflammatory lesion, called the trypanosomal chancre, develops at the site of inoculation. Trypomastigotes then invade the local lymphatics and later the bloodstream. After a time, the organisms invade the choroid plexus and enter the brain and CSF. There is quite a bit of variation between East African and West African trypanosomiasis. In the East African disease (caused by *T. brucei rhodesiense*), chancres are common and the hemolymphatic stage is severe, rapidly progressing to a fatal meningoencephalitis, often within months of infection. With the West African form of the disease (caused by *T. brucei gambiense*), chancres are uncommon, the hemolymphatic stage may even be inapparent, and meningoencephalitis progresses very slowly, often over several years: hence the "sleeping sickness" syndrome.

During the course of the infection, the number of trypomastigotes in the blood fluctuates. This relapsing parasitemia is due to the host immune response to the parasites. Each decline in parasite number results from the antibody-mediated destruction of trypomastigotes bearing

a particular variant surface glycoprotein (VSG). Each new wave of parasitemia represents the growth of a trypomastigote population expressing an antigenically different VSG. This process of antigenic variation is a feature of all African trypomastigotes. Since each trypomastigote expresses only one VSG at a time and has as many as 1,000 different VSG genes, the number of different variable antigen types that can be expressed during an infection is quite large. The continued response of the host to the new/different variable antigen types leads to elevated gamma globulin levels, particularly the IgM levels, including in the CSF. Generally, if an individual does not have an elevated IgM level, he almost certainly does not have African trypanosomiasis.

Key Points for Laboratory Identification

1. Trypomastigotes are highly infectious, and health care workers must use blood-borne pathogen precautions.
2. Trypomastigotes may be detected in aspirates of the chancre and enlarged lymph nodes in addition to blood and CSF.
3. Concentration techniques, such as centrifugation of CSF and blood, should be used in addition to thin and thick smears (Giemsa, Wright's, or rapid stains).
4. Trypomastigotes are present in largest numbers in the blood during febrile periods.
5. Multiple daily blood examinations may be necessary to detect the parasite.
6. Blood and CSF specimens should be examined during therapy and 1 to 2 months posttherapy.

All drugs currently used in the therapy of African trypanosomiasis are toxic and require prolonged administration. Treatment should be started as soon as possible and is based on the patient's symptoms and laboratory findings. The choice of antiparasitic drug depends on whether the CNS is infected. Specific details can be found in chapters 9 and 25.

Case 14

The patient was a 9-month-old male infant living in the United States, with multiple medical problems, who was admitted to the hospital with the complaint of irregular recurrent fever of 3 months' duration. He had received several blood transfusions over a period of several months, primarily for low hemoglobin levels. He became feverish with a temperature of 102 to 104°F, which did not respond to antimicrobials. His fever appeared to peak about every 4 days. Just prior to admission, the fever

Figure 36.22 Case 14. Blood films stained with Giemsa stain. (Left) Thick blood film; (right) thin blood film.

began to occur daily. On examination of both thick and thin blood films prepared from blood collected in EDTA tube (purple top), the following images were seen (Figure 36.22). Both the thick and thin blood films were stained using Giemsa stain (4, 7, 9, 14).

Questions

1. Based on the patient's history, what parasitic infections might be suspected? Why?
2. Considering the organism morphology, is there enough detail to allow identification to the genus and species levels?
3. What differences might be seen if the blood films had been stained with Wright-Giemsa or rapid stains? Would this approach have been acceptable? Why or why not?
4. Would the request for blood films be considered a STAT request? Why or why not?

Figure 36.23 Case 14. Thin blood films stained with Giemsa stain. *Plasmodium malariae* “band” forms are evident where the developing trophozoites spread across the RBC. Note that the infected RBCs are normal to smaller than normal size compared with the uninfected RBCs.

Correct Identification

The images (Figure 36.22) obtained after the first blood specimen was drawn represent *Plasmodium malariae* developing and mature schizonts in a thick blood film (left) and a mature schizont (containing merozoites) in the thin blood film (right). Note the small size of the infected RBC (typical of *P. malariae*). The number of merozoites in the mature schizont is always a clue to the species identification; in this case there appear to be about eight merozoites.

The images obtained after the second blood draw (Figure 36.23) represent developing trophozoites, which are spread across the infected RBC as “band” forms (again *P. malariae*). This configuration is not always seen but is very suggestive of *P. malariae*.

Key Characteristics of *P. malariae*

1. There is a 72-h cycle.
2. The parasite tends to infect old cells.
3. It infects small to normal-sized RBCs.
4. No Schüffner's dots are present; small dots (Ziemann's dots) may be present, but they are not considered true stippling.
5. There is a thick ring and a heavy chromatin dot.
6. “Band” form trophozoites are often present.
7. The mature schizont contains about eight merozoites, often arranged around the remaining clump of malarial pigment. This configuration of the merozoites is often called the “daisy” form.

Since this patient had received several blood transfusions, it is logical to assume that one of the transfusions was the source of the infection. Individuals can harbor *P. malariae* in the blood for many years at very low levels of parasitemia; these individuals are asymptomatic. Often, even with a complete blood donor history, the possibility of malaria infection with this organism is not suspected. Individuals have been known to harbor this parasite for up to 42 years. In spite of the patient's severe splenomegaly and splenectomy, he was considered cured after therapy with chloroquine and remained asymptomatic.

It is very important to realize that a single set of thick and thin blood films can be negative, even though the patient may be infected. In this case, both thick and thin blood films were positive. A second draw was taken to examine the thick and thin blood films for additional stages and/or evidence of a mixed infection. Venipunctures were performed for both blood draws, with the recommended EDTA anticoagulant in the lavender (purple)-top tube. It is important that the slides be prepared as quickly as possible after the blood draw to prevent the organism distortion and possible loss that can occur if the blood is

allowed to stand for several hours prior to slide preparation. Remember, every request for malaria blood films should always be considered a STAT request and the laboratory coverage should be 24 h/day, 7 days/week.

Examination of the thin blood film is relatively simple when the parasitemia is high, as in this slide. However, a returning traveler with his or her first malaria infection may experience the typical clinical symptoms of high fever, chills, myalgia, and headache with a much lower parasitemia. Also, these patients may present to the emergency room with vague symptoms that do not represent the typical textbook description; they may have malaise, a steady low-grade fever, and even diarrhea. These low levels of parasitemia are often impossible to detect using thin blood film examination only. For this reason, the key to successful detection of malaria parasites in the peripheral blood is the examination of both thick and thin blood films from every patient suspected of having malaria (or any patient from whom blood is submitted to the laboratory for blood film examination).

Thick films allow a larger amount of blood to be examined, which increases the possibility of detecting light infections. Species identification from the thick-film examination, particularly in the case of malaria, may be difficult for workers with little experience examining thick blood films. The morphologic characteristics of blood parasites are best seen in thin films, particularly the relationship between the sizes of infected and uninfected RBCs. However, in cases with a low parasitemia, the identification to the species level may have to be accomplished by thick-film examination.

The accurate examination of thick and thin blood films and identification of parasites depends on the use of absolutely clean, grease-free slides for preparation of all blood films. Old (unscratched) slides should be cleaned first in detergent and then with 70% ethyl alcohol; new slides should also be cleaned with alcohol before use.

Blood films are usually prepared when the patient is admitted; in instances in which malaria is a possible diagnosis, samples should be taken at intervals of 6 to 8 h for at least three successive days after the first set of negative smears, particularly if *P. falciparum* has not been excluded as a diagnosis. Extensive therapy information is available in chapter 25.

Diagnostic Methods

Case 15

The patient was a 54-year-old man from the United States, who had received a liver transplant 14 months earlier. He had traveled throughout the world as a

Figure 36.24 Case 15. Objects seen in a wet mount (left) and a permanent stained smear (right). The structure on the right measures approximately 16 μm , and the structures on the left measure approximately 65 μm .

professional consultant (Europe, Asia, Central and South America, Australia, New Zealand, etc.). He was diagnosed as having diarrhea, cough, and general malaise. He had a history of vague health problems since the transplant but did not seek medical attention for several weeks. The first stool specimen was submitted to the laboratory. After examination of the concentration sediment and permanent stained smears from all three specimens, the following objects were seen (Figure 36.24) (3, 4, 7, 10, 11, 13).

The structure on the right measures approximately 16 μm , and the structures on the left measure approximately 65 μm . The structure on the right is stained with the standard Wheatley's modification of the Gomori trichrome, while the structure on the left is a wet preparation of the sedimentation concentration.

After submission of the other two stool specimens, it was also decided to perform special stains for the coccidia and microsporidia. The following things were seen on the stained smears. Structures on the left measure ca. 4 to 6 μm , while those on the right measure ca. 1.5 μm (Figure 36.25).

Figure 36.25 Case 15. (Left) Objects in a concentrated fecal sediment stained with modified acid-fast stain. (Right) Objects in a concentrated fecal sediment stained with modified trichrome stain (note the diagonal or horizontal lines in some of the objects).

Questions

1. Based on Figure 36.24, what do you think the objects are?
2. Considering the patient's history, what types of parasites would you suspect? Why?
3. What additional laboratory tests might have been performed prior to the routine O&P examination? Do you think other laboratory tests would have been more appropriate? Why or why not?
4. Why should special stains or other testing options be considered for a patient with this type of history? What would you be looking for?

Correct Identification

The images presented after the first stool specimen represent artifact material (Figure 36.24). The structure on the right mimics an *Entamoeba coli* cyst; however, this structure is not an organism but an artifact. The structure on the left tends to resemble helminth eggs, but they are vegetable cells and not parasites. Unfortunately, even when structures are within the correct size range, the morphology may not be correct or accurate enough to identify the structure as a true parasite.

The two images obtained when special stains were performed provide excellent examples of *Cryptosporidium* spp. oocysts (Figure 36.25, left) and microsporidial spores (Figure 36.25, right), probably *Enterocytozoon bieneusi* or *Encephalitozoon intestinalis*.

Because this patient is a posttransplant (liver) patient, who has been and continues to be immunosuppressed, continuous diarrhea with negative O&P examinations should suggest the use of special stains for the coccidia (modified acid-fast stains) or microsporidia (modified trichrome stains). These diagnostic options are important, particularly if the patient is immunosuppressed and continues to be symptomatic with diarrhea.

Although there are immunoassays available for the diagnosis of cryptosporidiosis (enzyme immunoassay, fluorescent-antibody assay, cartridge formats), many laboratories continue to use the modified acid-fast stain. It is important to remember that the destaining (acid) step should be performed quickly and the acid content should not be too high. If the percentage is above 3% acid, too much color may be removed from the oocysts. Color loss can be a definite problem for the identification of *Cyclospora cayentanensis* (modified acid-fast variable) but is less of a problem with *Cryptosporidium* spp. Many laboratories are using this stain with a 1% acid destain step. Both *Cryptosporidium* and *Cyclospora* look fine when this approach is used. However, regardless of the destain step, some of the *C. cayentanensis* oocysts may appear pale

pink or even colorless. It is also recommended that these special stains (for both coccidia and microsporidia) be performed on concentration sediment to enhance sensitivity (centrifuge for 10 min at 500 × g).

Currently, there are no commercially available immunoassays for detection of the microsporidial spores in clinical specimens. There are a number of different modified trichrome stain methods, some hot and some cold; they all work well, so selection of a particular method often depends on personal preferences among laboratory personnel. Again, it is important to perform these stains on concentrated fecal sediment. Remember that other clinical specimens can also be stained (sputum, urine, etc.) and may contain less debris than that seen in a fecal specimen.

Appendixes

Although common names are frequently used to describe parasitic organisms, these names may represent different parasites in different parts of the world. To eliminate these problems, a binomial system of nomenclature is used in which the scientific name consists of the genus and species. On the basis of life histories and morphology, systems of classification have been developed to indicate the relationship among the various parasite species.

Parasites of humans are classified in five major subdivisions: Protozoa (amebae, flagellates, ciliates, sporozoans, and coccidia); Platyhelminthes, or flatworms (cestodes and trematodes); Acanthocephala, or thorny-headed worms; Nematoda, or roundworms; and Arthropoda (insects, spiders, mites, ticks, etc.). Information on Protozoa, Nematoda, Platyhelminthes, and Arthropoda is presented in appendix 1, Table A1.1. This classification scheme is designed to provide some order and meaning to a widely divergent group of organisms. No attempt has been made to include every possible organism, only those that are considered to be clinically relevant in the context of human parasitology. This information provides some insight into the parasite groupings, thus leading to a better understanding of organism morphology, parasitic infections, and the appropriate clinical diagnostic approach.

Data on the distribution of various parasites are presented in Tables A1.2 through A1.7; these tables are from E. K. Markell, M. Voge, and D. T. John, *Medical Parasitology*, 6th ed., The W. B. Saunders Co., Philadelphia, 1986. Diagnostic clinical review information and parasite prevalence estimations are presented in Tables A1.8 through A1.21.

Flowcharts for various diagnostic kits and staining tables are given in appendix 2. Common problems in parasite identification are discussed in appendix 3. Appendix 4 contains examples of quality control recording sheets. Information on sources of diagnostic products and teaching materials is provided in appendix 5. General references, a list of relevant journals and periodicals, and abstracts and bibliographic sources are provided in appendix 6. Appendix 7 contains a number of color plates, including relevant human parasites and arthropods.

Appendix 8 is one of the most important sections in this edition. This section contains information that has been published just months prior to final publication of the book. This “late-breaking” synopsis of very recent publications will assist readers in obtaining the latest information available. I encourage all readers to review this section as they read the various chapters throughout the book.

APPENDIX I

Information Tables

Table AI.1 Classification of human parasites

I. Protozoa

1. Intestinal amebae

Entamoeba histolytica
Entamoeba dispar^a
Entamoeba hartmanni
Entamoeba coli
Entamoeba polecki
Endolimax nana
Iodamoeba bütschlii
Blastocystis hominis

2. Intestinal flagellates

Giardia lamblia^b
Chilomastix mesnili
Dientamoeba fragilis
Pentatrichomonas hominis
Enteromonas hominis
Retortamonas intestinalis

3. Intestinal ciliates

Balantidium coli

4. Intestinal coccidia and microsporidia

Cryptosporidium parvum
Cryptosporidium hominis
Cryptosporidium spp.
Cyclospora cayetanensis
Isospora belli
Sarcocystis hominis
Sarcocystis suihominis
Sarcocystis "lindemanni"^c
Microsporidia
Enterocytozoon bieneusi
Encephalitozoon (Septata) intestinalis

5. Sporozoa and flagellates from blood and tissue

Sporozoa (causing malaria and babesiosis)

Plasmodium vivax
Plasmodium ovale
Plasmodium malariae
Plasmodium falciparum
Babesia spp.

Flagellates (leishmaniae and trypanosomes)

Old World *Leishmania* species

Leishmania (Leishmania) tropica
Leishmania (Leishmania) major
Leishmania (Leishmania) aethiopica
Leishmania (Leishmania) donovani
Leishmania (Leishmania) archibaldi
Leishmania (Leishmania) infantum

New World *Leishmania* species

Leishmania (Leishmania) mexicana
Leishmania (Leishmania) amazonensis
Leishmania (Leishmania) pifanoi
Leishmania (Leishmania) garnhami
Leishmania (Leishmania) venezuelensis
Leishmania (Leishmania) chagasi
Leishmania (Viannia) braziliensis
Leishmania (Viannia) colombiense
Leishmania (Viannia) guyanensis
Leishmania (Viannia) lainsoni
Leishmania (Viannia) naiffi
Leishmania (Viannia) panamensis
Leishmania (Viannia) peruviana
Leishmania (Viannia) shawi

Old World *Trypanosoma* species

Trypanosoma brucei gambiense

Table A1.1 (continued)

<i>Trypanosoma brucei rhodesiense</i>	<i>Trichinella</i> spp. (<i>T. britovi</i> , <i>T. murrelli</i> , <i>T. nativa</i> ,
New World <i>Trypanosoma</i> species	<i>T. nelsoni</i> , <i>T. papuae</i> , <i>T. pseudospiralis</i> ,
<i>Trypanosoma cruzi</i>	<i>T. zimbabwensis</i>)
<i>Trypanosoma rangeli</i>	<i>Toxocara canis</i> and <i>Toxocara cati</i> (visceral and
6. Amebae and flagellates from other body sites	ocular larva migrans)
Amebae	<i>Ancylostoma braziliense</i> and <i>Ancylostoma</i>
<i>Naegleria fowleri</i>	<i>caninum</i> (cutaneous larva migrans)
<i>Sappinia diploidea</i>	<i>Dracunculus medinensis</i>
<i>Acanthamoeba</i> spp.	<i>Angiostrongylus cantonensis</i>
<i>Hartmanella</i> spp.	<i>Angiostrongylus costaricensis</i>
<i>Balamuthia mandrillaris</i>	<i>Gnathostoma spinigerum</i>
<i>Entamoeba gingivalis</i>	<i>Anisakis</i> spp. (larvae from saltwater fish)
Flagellates	<i>Phocanema</i> spp. (larvae from saltwater fish)
<i>Trichomonas vaginalis</i>	<i>Contraecum</i> spp. (larvae from saltwater fish)
<i>Trichomonas tenax</i>	<i>Hysterothylacium</i>
7. Coccidia, sporozoa, and microsporidia from other	<i>Porrocaecum</i> spp.
body sites	<i>Capillaria hepatica</i>
Coccidia	<i>Thelazia</i> spp.
<i>Toxoplasma gondii</i>	<i>Ternidens diminutus</i>
Sporozoa	3. Blood and tissues (filarial worms)
<i>Pneumocystis jirovecii</i> ^d	<i>Wuchereria bancrofti</i>
Microsporidia	<i>Brugia malayi</i>
<i>Nosema ocularum</i>	<i>Brugia timori</i>
<i>Pleistophora</i> spp.	<i>Loa loa</i>
<i>Pleistophora ronniaefiei</i>	<i>Onchocerca volvulus</i>
<i>Trachipleistophora hominis</i>	<i>Mansonella ozzardi</i>
<i>Trachipleistophora anthropophthera</i>	<i>Mansonella streptocerca</i>
<i>Brachiola vesicularum</i>	<i>Mansonella perstans</i>
<i>Brachiola (Nosema) algerae</i>	<i>Dirofilaria immitis</i> (usually found in lung lesions;
<i>Brachiola (Nosema) connori</i>	in dogs, heartworm)
<i>Encephalitozoon cuniculi</i>	<i>Dirofilaria</i> spp. (may be found in subcutaneous
<i>Encephalitozoon (Septata) intestinalis</i>	nodules)
<i>Encephalitozoon hellem</i>	
<i>Vittaforma corneae (Nosema corneum)</i>	
“ <i>Microsporidium</i> ” ^e	
II. Nematodes (roundworms)	III. Cestodes (tapeworms)
1. Intestinal	1. Intestinal
<i>Ascaris lumbricoides</i>	<i>Diphyllobothrium latum</i>
<i>Enterobius vermicularis</i>	<i>Diplogonoporus</i> spp.
<i>Ancylostoma duodenale</i>	<i>Dipylidium caninum</i>
<i>Necator americanus</i>	<i>Hymenolepis nana</i>
<i>Strongyloides stercoralis</i>	<i>Hymenolepis diminuta</i>
<i>Strongyloides fuelleborni</i>	<i>Taenia solium</i>
<i>Trichostrongylus colubriformis</i>	<i>Taenia saginata</i>
<i>Trichostrongylus orientalis</i>	2. Tissue (larval forms)
<i>Trichostrongylus</i> spp.	<i>Taenia solium</i>
<i>Trichuris trichiura</i>	<i>Echinococcus granulosus</i>
<i>Capillaria philippinensis</i>	<i>Echinococcus multilocularis</i>
2. Tissue	<i>Echinococcus vogeli</i>
<i>Trichinella spiralis</i>	<i>Echinococcus oligarthrus</i>
	<i>Multiceps multiceps</i>
	<i>Spirometra mansonoides</i>
	<i>Diphyllobothrium</i> spp.

--	--

^a The name *Entamoeba histolytica* is used to designate the true pathogen, while the name *E. dispar* is now being used to designate the nonpathogen. However, unless trophozoites containing ingested red blood cells (*E. histolytica*) are seen, the two organisms cannot be differentiated on the basis of morphology seen in permanent stained smears of fecal specimens. Fecal immunoassays are available for identification of the *Entamoeba histolytica/E. dispar* group and for differentiating between the two species.

^b Although some individuals have changed the species designation for the genus *Giardia* to *G. intestinalis* or *G. duodenalis*, there is no general agreement. Therefore, for this listing, the name *Giardia lamblia* is retained.

^c When humans are intermediate hosts, preventive measures involve careful disposal of animal feces that may contain the infective sporocysts. This may be impossible in the wilderness areas, where wild animals may serve as reservoir hosts for many of the different types of organisms that have been grouped under the term *Sarcocystis* “*lindemanni*.” However, this name is no longer used.

^d *Pneumocystis jiroveci* has now been reclassified with the fungi.

^e This designation is not a true genus, but a “catch-all” for organisms that have not been (or may never be) identified to the genus and/or species levels (*Microsporidium ceylonensis*, *Microsporidium africanum*). In the future, *Microsporidium* may be accepted as an official genus within the microsporidia.

Table AI.8 Body sites and specimen collection^a

Site	Specimen options	Collection method ^b
Blood	Smears of whole blood	Thick and thin films, fresh blood
	Anticoagulated blood	Anticoagulant EDTA (1st choice) Heparin (2nd choice)
Bone marrow	Aspirate	Sterile
Central nervous system	Spinal fluid	Sterile
Cutaneous ulcers	Aspirates from below surface	Sterile plus air-dried smears
	Biopsy specimen	Sterile, nonsterile to histopathology (formalin acceptable)
Eyes	Biopsy specimen	Sterile (in saline), nonsterile to histopathology
	Scrapings	Sterile (in saline)
	Contact lens	Sterile (in saline)
	Lens solution	Sterile (unopened commercial solutions not acceptable)
Intestinal tract	Fresh stool	0.5-pt (ca. 0.237-liter) waxed container
	Preserved stool ^c	5 or 10% formalin, MIF, SAF, Schaudinn's, PVA, single-vial collection systems
	Sigmoidoscopy material	Fresh, PVA, or Schaudinn's smears
	Duodenal contents	Entero-Test or aspirates
	Anal impression smear	Cellulose tape (pinworm examination)
	Adult worm or worm segments	Saline, 70% alcohol
Liver, spleen	Aspirates	Sterile, collected in 4 separate aliquots (liver)
	Biopsy specimen	Sterile, nonsterile to histopathology
Lungs	Sputum	True sputum (not saliva)
	Induced sputum	No preservative (10% formalin if time delay)
	Bronchoalveolar lavage fluid	Sterile
	Transbronchial aspirate	Air-dried smears
	Tracheobronchial aspirate	Air-dried smears
	Brush biopsy specimen	Air-dried smears
	Open-lung biopsy specimen	Air-dried smears
	Aspirate	Sterile
Muscle	Biopsy specimen	Fresh, squash preparation, nonsterile to histopathology
Skin	Scrapings	Aseptic, smear or vial
	Skin snip	No preservative
	Biopsy specimen	Sterile (in saline), nonsterile to histopathology
Urogenital system	Vaginal discharge	Saline swab, transport swab (no charcoal), culture medium, plastic-envelope culture Air-dried smear for FA
	Urethral discharge	Same as above
	Prostatic secretions	Same as above
	Urine	Single unpreserved specimen, 24-h unpreserved specimen, early morning

^a Modified from H. D. Isenberg, ed., *Clinical Microbiology Procedures Handbook*, 2nd ed., ASM Press, Washington, D.C., 2004.^b MIF, Merthiolate-iodine-formalin; SAF, sodium acetate-acetic acid-formalin; PVA, polyvinyl alcohol; FA, fluorescent antibody.^c A number of new stool fixatives are now available; some use a zinc sulfate base rather than mercuric chloride. Some collection vials can be used as a single-vial system; both the concentration and permanent stained smear can be performed from the preserved stool. However, not all single-vial systems provide material that can be used for fecal immunoassay procedures.

Table AI.9 Body sites and possible parasites recovered (trophozoites, cysts, oocysts, spores, adults, larvae, eggs, amastigotes, and trypomastigotes)^a

Site	Parasites	Site	Parasites
Blood		Intestinal tract (<i>cont.</i>)	<i>Enterocytozoon bieneusi</i>
Red cells	<i>Plasmodium</i> spp. <i>Babesia</i> spp.		<i>Encephalitozoon</i> spp. Microsporidia
White cells	<i>Leishmania</i> spp. <i>Toxoplasma gondii</i>		<i>Ascaris lumbricoides</i> <i>Enterobius vermicularis</i>
Whole blood or plasma	<i>Trypanosoma</i> spp. Microfilariae		Hookworm <i>Strongyloides stercoralis</i>
Bone marrow	<i>Leishmania</i> spp. <i>Trypanosoma cruzi</i> <i>Plasmodium</i> spp.		<i>Trichuris trichiura</i> <i>Hymenolepis nana</i> <i>Hymenolepis diminuta</i>
Central nervous system	<i>Taenia solium</i> (cysticerci) <i>Echinococcus</i> spp. <i>Naegleria fowleri</i> <i>Acanthamoeba</i> and <i>Hartmanella</i> spp. <i>Balamuthia mandrillaris</i> <i>Sappinia diploidea</i> <i>Toxoplasma gondii</i> Microsporidia <i>Trypanosoma</i> spp.		<i>Taenia saginata</i> <i>Taenia solium</i> <i>Diphyllobothrium latum</i> <i>Clonorchis</i> (<i>Opisthorchis</i>) <i>sinensis</i> <i>Paragonimus</i> spp. <i>Schistosoma</i> spp. <i>Fasciolopsis buski</i> <i>Fasciola hepatica</i> <i>Metagonimus yokogawai</i> <i>Heterophyes heterophyes</i>
Cutaneous ulcers	<i>Leishmania</i> spp. <i>Acanthamoeba</i> spp. <i>Entamoeba histolytica</i>	Liver and spleen	<i>Echinococcus</i> spp. <i>Entamoeba histolytica</i> <i>Leishmania</i> spp. Microsporidia
Eyes	<i>Acanthamoeba</i> spp. <i>Toxoplasma gondii</i> <i>Loa loa</i> Microsporidia	Lungs	<i>Pneumocystis jiroveci</i> ^b <i>Cryptosporidium</i> spp. ^c <i>Echinococcus</i> spp. <i>Paragonimus</i> spp.
Intestinal tract	<i>Entamoeba histolytica</i> <i>Entamoeba dispar</i> <i>Entamoeba coli</i> <i>Entamoeba hartmanni</i> <i>Endolimax nana</i> <i>Iodamoeba bütschlii</i> <i>Blastocystis hominis</i> <i>Giardia lamblia</i> <i>Chilomastix mesnili</i> <i>Dientamoeba fragilis</i> <i>Pentatrichomonas hominis</i> <i>Balantidium coli</i> <i>Cryptosporidium</i> spp. <i>Cyclospora cayatanensis</i> <i>Isospora belli</i>	Muscles	<i>Taenia solium</i> (cysticerci) <i>Trichinella</i> spp. <i>Onchocerca volvulus</i> (nodules) <i>Trypanosoma cruzi</i> Microsporidia
		Skin	<i>Leishmania</i> spp. <i>Onchocerca volvulus</i> Microfilariae
		Urogenital system	<i>Trichomonas vaginalis</i> <i>Schistosoma</i> spp. Microsporidia Microfilariae

^a Modified from H. D. Isenberg, ed., *Clinical Microbiology Procedures Handbook*, 2nd ed., ASM Press, Washington, D.C., 2004. This table does not include every possible parasite that could be found in a particular body site. However, the most likely organisms have been listed.

^b Now classified with the fungi.

^c Disseminated in severely immunosuppressed individuals.

Table A1.10 Body site, specimen and procedures, recommended methods, relevant parasites, and comments

Body site	Procedures ^a and specimens	Recommended methods and relevant parasites ^a	Comments
Amniotic fluid	PCR (and/or culture): fresh material	PCR based on the detection of highly repetitive gene sequences is the method of choice	Only applicable to confirm suspected prenatal <i>Toxoplasma</i> infections.
	Animal inoculation (toxoplasmosis)		
Blood	Microscopy ^b : thin and thick blood films; fresh blood (preferred) or EDTA-blood (fill EDTA tube completely with blood, then mix)	Giemsa stain (all blood parasites); hematoxylin-based stain (sheathed microfilariae); for malaria, thick and thin blood films are definitely recommended and should be prepared within 30–60 min of blood collection via venipuncture (other tests may be used as well); Wright-Giemsa stain or Diff-Quik (rapid stains) can also be used	Most drawings and descriptions of blood parasites are based on Giemsa-stained blood films. Although Wright's stain (or Wright-Giemsa combination stain) will work, stippling in malaria may not be visible and the organisms' colors will not match the descriptions. However, with other stains (those listed above, in addition to some of the "rapid" blood stains), the organisms should be detectable on the blood films. The use of blood collected with anticoagulant (rather than fresh) has direct relevance to the morphology of malaria organisms seen in peripheral blood films. If the blood smears are prepared after more than 1 h, stippling may not be visible, even if the correct pH buffers are used. Also, if blood is kept at room temperature (with the stopper removed), the male microgametocyte may exflagellate and fertilize the female macrogametocyte, and development continues within the tube of blood (as it would in the mosquito host). The ookinete may actually resemble a <i>Plasmodium falciparum</i> gametocyte. The microgamete may resemble spirochetes.
	Concentration methods: EDTA-blood	Buffy coat, fresh blood films for detection of moving microfilariae or trypanosomes; QBC, a screening method for blood parasites (hematocrit tube contains acridine orange), has been used for malaria, <i>Babesia</i> , trypanosomes, and microfilariae; it is usually impossible to identify malaria organisms to the species level; this requires high levels of training	
	Antigen detection: EDTA-blood for malaria, serum or plasma for circulating antigens (hemolyzed blood can interact in some tests)	Commercial test kits for malaria and some microfilariae	
	PCR: EDTA-blood, ethanol-fixed or -unfixed thin and thick blood films, coagulated blood, possible with hemolyzed or frozen blood samples	Sensitivity not higher than thick films for <i>Plasmodium</i> spp., much more sensitive for <i>Leishmania</i> (peripheral blood is used from immunodeficient patients only). Sequencing of PCR product is often used for species or genotype identification	So far no commercial tests available; high laboratory standards needed (may work with frozen, coagulated, or hemolyzed blood samples).
	Specific antibody detection: serum or plasma, anticoagulated or coagulated blood (hemolyzed blood can cause problems in some tests)	Most commonly used are EIA (many test kits commercially available), EITB (commercially available for some parasites), and IFA	Many labs are using in-house tests; only a few fully defined antigens are available; sensitivities and specificities of the tests should be documented by the lab.
Bone marrow	Biopsy specimens or aspirates		<i>Leishmania</i> amastigotes are recovered in cells of the reticuloendothelial system; if films are not prepared directly after sample collection, infected cells may disintegrate. Sensitivity of microscopy low, so it should be used only in combination with other methods.
	Microscopy: thin and thick films with aspirate collected in EDTA	Giemsa stain (all blood parasites)	
	Cultures: sterile material in EDTA or culture medium	Culture for <i>Leishmania</i> (or <i>Trypanosoma cruzi</i>)	
	PCR: aspirate in EDTA	PCR for blood parasites including <i>Leishmania</i> and <i>Toxoplasma</i> and rare other parasites	

(continued)

Table A1.10 Body site, specimen and procedures, recommended methods, relevant parasites, and comments (*continued*)

Body site	Procedures ^a and specimens	Recommended methods and relevant parasites ^a	Comments
Central nervous system	Microscopy: spinal fluid and CSF (wet examination, stained smears), brain biopsy specimen (touch or squash preparations, stained)	Stains: Giemsa (trypanosomes, <i>Toxoplasma</i>); Giemsa, trichrome, or calcofluor (amebae [<i>Naegleria</i> or <i>Sappinia</i> —PAM, <i>Acanthamoeba</i> or <i>Balamuthia</i> —GAE]); Giemsa, acid-fast, PAS, modified trichrome, silver methenamine (microsporidia) (tissue Gram stains also recommended for microsporidia in routine histologic preparations); H&E, routine histology (larval cestodes, <i>Taenia solium</i> cysticerci, <i>Echinococcus</i> spp.)	If CSF is received (with no suspect organism suggested), Giemsa would be the best choice; however, modified trichrome or calcofluor is also recommended as a second stain (amebic cysts, microsporidia). If brain biopsy material is received (particularly from an immunocompromised patient), cultivation is recommended for microsporidial isolation and PCR for identification to the species or genotype level. A small amount of the sample should always be stored frozen for PCR analyses in case the results of the other methods are inconclusive.
	Culture: sterile aspirate or biopsy material (in physiologic NaCl)	Free-living amebae (exception: <i>Balamuthia</i> does not grow in the routine agar/bacterial overlay method), microsporidia, and <i>Toxoplasma</i>	
	PCR: aspirate or biopsy material fresh, frozen, or fixed in ethanol	Protozoa and helminths, species and genotype characterization	
Cutaneous ulcers	Microscopy: aspirate, biopsy (smears, touch or squash preparations, histologic sections)	Giemsa (<i>Leishmania</i>); H&E, routine histology (<i>Acanthamoeba</i> spp., <i>Entamoeba histolytica</i>)	The most likely causative parasites would be <i>Leishmania</i> , which would stain with Giemsa. PAS could be used to differentiate <i>Histoplasma capsulatum</i> from <i>Leishmania</i> in tissue. In immunocompromised patients, skin ulcers have been documented with amebae as causative agents.
	Cultures (less common)	<i>Leishmania</i> , free-living amebae (often bacterial contaminations)	
	PCR: aspirate, biopsy material fresh, frozen, or fixed in ethanol	<i>Leishmania</i> (species identification), free-living amebae	
Eyes	Microscopy: smears, touch or squash preparations; biopsy specimens, scrapings, contact lens, sediment of lens solution	Calcofluor for cyst only (amebae [<i>Acanthamoeba</i>]); Giemsa for trophozoites and cysts (amebae); modified trichrome (preferred) or silver methenamine stain, PAS, acid-fast, (microsporidial spores), H&E, routine histology (cysticerci, <i>Loa loa</i> , <i>Toxoplasma</i>)	Some free-living amebae (most commonly <i>Acanthamoeba</i>) have been implicated as a cause of keratitis. Although calcofluor stains the cyst walls, it does not stain the trophozoites. Therefore, in suspect cases of amebic keratitis, both stains should be used. H&E (routine histology) can be used to detect and confirm cysticercosis. The adult worm of <i>Loa loa</i> , when removed from the eye, can be stained with a hematoxylin-based stain (Delafield's) or can be stained and examined by routine histology.
	Culture: fresh material (see above) in PBS supplemented with antibiotics if possible to avoid bacterial growth	Cultures: free-living amebae, <i>Toxoplasma</i> , microsporidia	
	PCR: fresh material in physiologic NaCl or PBS, ethanol or frozen	Free-living amebae, <i>Toxoplasma</i> , microsporidian species and genotype identification	Microsporidia: confirmation to the species or genotype levels can be done by PCR and sequence analyses; however, the spores could be found by routine light microscopy with modified trichrome, calcofluor, and/or tissue Gram stains.
Intestine	(i) Stool and other intestinal material		Stool fixation with formalin or formalin-containing fixatives preserves parasite morphology, allows prolonged storage (room temperature) and long transportation, and prevents hatching of <i>Schistosoma</i> eggs, but makes <i>Strongyloides</i> larval concentration difficult and impedes further PCR analyses.

	Microscopy: stool, sigmoidoscopy material, duodenal contents (all fresh or preserved), direct wet smear, concentration methods	Concentration methods: ethyl acetate sedimentation of SAF-fixed stool samples (most protozoa); flotation or combined sedimentation flotation methods (helminth ova); agar or Baermann concentration (larvae of <i>Strongyloides</i> spp., fresh stool required) Direct wet smear (direct examination of unpreserved fresh material is also used (motile protozoan trophozoites; helminth eggs, protozoan cysts may also be detected) Stains: trichrome or iron hematoxylin (intestinal protozoa); modified trichrome (microsporidia); modified acid-fast (<i>Cryptosporidium</i> , <i>Cyclospora</i> , <i>Isospora</i>)	
	Anal impression smear	Adhesive cellulose tape, no stain (<i>Enterobius vermicularis</i>)	Taeniid eggs cannot be identified to the species level.
	Adult worms or tapeworm segments (proglottids)	Carmine stains (rarely used for adult worms or cestode segments). Proglottids can usually be identified to the genus level (<i>Taenia</i> , <i>Diphyllobothrium</i> , <i>Hymenolepis</i>) without using tissue stains	Microsporidia: confirmation to the species or genotype levels requires PCR; however, modified trichrome and/or calcofluor stains can be used to confirm the presence of spores.
	Antigen detection (fresh or frozen material, suitability of fixation is test dependent)	Commercial immunoassays, e.g., EIA, FA, cartridge formats (<i>Entamoeba histolytica</i> , the <i>Entamoeba histolytica</i> /E. <i>dispar</i> group, <i>Giardia lamblia</i> , <i>Cryptosporidium</i> spp.); in-house tests for <i>T. solium</i> and <i>T. saginata</i>	Four to six consecutive negative tapes are required to rule out infection with pinworm (<i>Enterobius vermicularis</i>). Worm segments can be stained with special stains. However, after dehydration through alcohols and xylenes (or xylene substitutes) without prior staining, the sexual organs and the branched uterine structure will be visible, allowing identification of the proglottid to the species level.
	PCR: fresh, frozen, or ethanol-fixed material	No commercial tests available; primers for genus or species identification of most helminths and protozoa are published	Coproantigens can be detected in the prepatent period and independently from egg excretion.
	(ii) Biopsy specimens Microscopy: fixed for histology or touch or squash preparations for staining	H&E, routine histology (<i>Entamoeba histolytica</i> , <i>Cryptosporidium</i> , <i>Cyclospora</i> , <i>Isospora belli</i> , <i>Giardia</i> , microsporidia); less common findings would include <i>Schistosoma</i> spp., hookworm, or <i>Trichuris</i>	Due to potential inhibition after DNA extraction from stool samples, concentration or isolation methods may be required prior to DNA extraction. However, new DNA isolation kits facilitate isolation of high-quality DNA from stool. Sequence analyses may be required for species or genotype identification.
	PCR: see above		Special stains may be helpful for the identification of microsporidia: tissue Gram stains, silver stains, PAS, and Giemsa or modified acid-fast stains for the coccidia
Liver and spleen	Biopsy specimens or aspirates Microscopy: unfixed material in physiologic NaCl; fixed for histology Culture: sterile preparation of fresh material	Examination of wet smears for <i>Entamoeba histolytica</i> (trophozoites), protoscolices of <i>Echinococcus</i> spp. or eggs of <i>Capillaria hepatica</i> ; Giemsa (<i>Leishmania</i> , other protozoa and microsporidia); H&E (routine histology) For <i>Leishmania</i> (not common)	There are definite risks associated with punctures (aspirates and/or biopsy) of spleen or liver lesions (<i>Echinococcus</i>). Always keep a small amount of material frozen for PCR.

(continued)

Table AI.10 Body site, specimen and procedures, recommended methods, relevant parasites, and comments (*continued*)

Body site	Procedures ^a and specimens	Recommended methods and relevant parasites ^a	Comments
	Animal inoculation: sterile preparation of fresh material	Intraperitoneal inoculation of <i>E. multilocularis</i> cyst material for viability test after long-term chemotherapy	
	PCR: fresh, frozen, or ethanol fixed	Species or genotype identification (e.g., <i>Echinococcus</i> spp.)	
Lungs	Sputum, induced sputum, nasal and sinus discharge, bronchoalveolar lavage fluid, transbronchial aspirate, tracheobronchial aspirate, brush biopsy specimen, open-lung biopsy specimen Microscopy: unfixed material, treated for smear preparation PCR: fresh, frozen, or fixed in ethanol	Helminth larvae (<i>Ascaris</i> , <i>Strongyloides</i>), eggs (<i>Paragonimus</i> , <i>Capillaria</i>), or hooklets (<i>Echinococcus</i>) can be recovered in unstained respiratory specimens; stains include Giemsa for many protozoa including <i>Toxoplasma</i> tachyzoites, modified acid-fast stains (<i>Cryptosporidium</i>), and modified trichrome (microsporidia); routine histology was H&E; silver methenamine stain, PAS, acid-fast, and tissue Gram stains for helminths, protozoa, and microsporidia	Immunoassay reagents (FA) are available for the diagnosis of pulmonary cryptosporidiosis. Routine histologic procedures allow the identification of any of the helminths or helminth eggs present in the lungs. Disseminated toxoplasmosis and microsporidiosis are well documented, with organisms being found in many different respiratory specimens.
Muscles	Biopsy material Microscopy: unfixed, touch and squash preparations or fixed for histology and EM PCR: fresh, frozen, or ethanol fixed	Larvae of <i>Trichinella</i> spp. can be identified unstained (species identification with single larvae by PCR); H&E, routine histology (<i>Trichinella</i> spp., cysticerci); silver methenamine stain, PAS, acid-fast, tissue Gram stains, EM (rare microsporidia) Microsporidian identification to the species level requires subsequent sequencing	If <i>Trypanosoma cruzi</i> is present in the striated muscle, the organisms could be identified in routine histology preparations. Modified trichrome and/or calcofluor stains can be used to confirm the presence of microsporidial spores.
Skin	Aspirates, skin snips, scrapings, biopsy specimens Microscopy: wet examination, stained smear (or fixed for histology or EM) PCR: fresh, frozen, or fixed in ethanol	See cutaneous ulcer (above) Wet preparations (microfilariae), Giemsa-stained smears or H&E, routine histology (<i>Onchocerca volvulus</i> , <i>Dipetalonema streptocerca</i> , <i>Dirofilaria repens</i> , other larvae causing cutaneous larva migrans [zoonotic <i>Strongyloides</i> spp.], hookworms), <i>Leishmania</i> , <i>Acanthamoeba</i> spp., <i>Entamoeba histolytica</i> , microsporidia, and arthropods (<i>Sarcoptes</i> and other mites) Primers for most parasite species available	Any of the potential parasites present can be identified by routine histology procedures.

Urogenital system	Vaginal discharge, saline swab, transport swab (no charcoal), air-dried smear for FA, urethral discharge, prostatic secretions, urine (single unpreserved, 24-h unpreserved, or early-morning specimens)	Giemsa, immunoassay reagents (FA) (<i>Trichomonas vaginalis</i>); Delafield's hematoxylin (microfilariae); modified trichrome (microsporidia); H&E, routine histology PAS, acid-fast, tissue Gram stains (microsporidia); direct examination of urine sediment for <i>Schistosoma haematobium</i> eggs or microfilariae	Although <i>T. vaginalis</i> is probably the most common parasite identified, there are others to consider, the most recently implicated organisms being in the microsporidian group. Microfilariae could also be recovered and stained. Fixation of urine with formalin prevents hatching of <i>Schistosoma</i> eggs. Material must be put into culture medium immediately after collection; do not cool or freeze.
	Microscopy: wet smears, smears of urine sediment, stained smears	Identification and propagation of <i>T. vaginalis</i> (commercialized plastic-envelope culture systems available); moving trophozoites can be detected using microscopy (or in Giemsa-stained smears)	
	Cultivation: vaginal or urethral discharge or swab preparations		
	Antigen detection (vaginal swab)	Commercial immunoassay (rapid formal), <i>T. vaginalis</i>	
	Probe	Commercial instrumentation, <i>T. vaginalis</i>	
	PCR: fresh, frozen, or fixed in ethanol		

^a CSF, cerebrospinal fluid; EIA, enzyme immunoassay; EITB, enzyme-linked immunoelectrotransfer blot (Western blot); EM, electron microscopy; FA, fluorescent antibody; GAE, granulomatous amebic encephalitis; GI, gastrointestinal; H&E, hematoxylin and eosin; IFA, indirect fluorescent-antibody assay; PAM, primary amebic encephalitis; PAS, periodic acid-Schiff stain; PBS, phosphate-buffered saline; QBC, quantitative buffy coat; SAF, sodium acetate-acetic acid-formalin.

^b Many parasites or parasite stages may be detected in standard histologic sections of tissue material. However, species identification is difficult and additional examinations may be required. Usually, these techniques are not considered first-line methods. Additional methods like EM (electron microscopy) are carried out only by specialized laboratories and are not available for standard diagnostic purposes. EM examination for species identification has largely been replaced by PCR assays.

Table AI.11 Examination of tissue and body fluids^a

Suspected causative agent	Disease(s)	Appropriate test(s) ^b	Positive result
Protozoa			
<i>Naegleria fowleri</i>	Primary amebic meningoencephalitis (PAM)	1. Wet examination of CSF (not in counting chamber) 2. Stained preparation of CSF sediment	Trophozoites present and identified
<i>Acanthamoeba</i> spp.	Amebic keratitis, chronic meningoencephalitis (granulomatous amebic encephalitis [GAE])	1. Culture or stained smears 2. Calcofluor (cysts only) 3. Biopsy for routine histology	Trophozoites and/or cysts present and identified
<i>Balamuthia mandrillaris</i>	Chronic meningoencephalitis (GAE)	1. Calcofluor (cysts only) 2. Biopsy for routine histology	Trophozoites and/or cysts present and identified
<i>Entamoeba histolytica</i>	Amebiasis	1. Biopsy for routine histology 2. Immunoassays	Trophozoites present and identified
<i>Giardia lamblia</i>	Giardiasis	1. Duodenal aspirate 2. Duodenal biopsy or routine histology 3. Entero-Test capsule 4. Immunoassays	Trophozoites and/or cysts present and identified
<i>Leishmania</i> spp.			
Cutaneous lesions	Cutaneous leishmaniasis	1. Material from under bed of ulcer A. Smear B. Culture C. Animal inoculation 2. Punch biopsy A. Routine histology B. Squash preparation C. Culture D. Animal inoculation	Amastigotes recovered in macrophages of skin or from animal inoculation; other stages recovered in culture
Mucocutaneous lesions	Mucocutaneous leishmaniasis	As for cutaneous leishmaniasis	Amastigotes recovered in macrophages of skin and mucous membranes or from inoculation of animals; other stages recovered in culture
Visceral	Visceral leishmaniasis (kala azar)	1. Buffy coat A. Stain B. Culture C. Animal inoculation 2. Bone marrow A. Stain B. Culture C. Animal inoculation 3. Liver or spleen biopsy A. Routine histology B. Stain C. Culture D. Animal inoculation	Amastigotes recovered in cells of reticuloendothelial system; other stages recovered in culture

<i>Pneumocystis jirovecii</i> ^c	Pneumocystosis	<ol style="list-style-type: none"> 1. Open lung biopsy for histology 2. Lung needle aspirate 3. Bronchial brush 4. Transtracheal aspirate 5. Bronchoalveolar lavage 6. Induced sputum (AIDS patients) 7. Calcofluor 8. Immunoassays 	Trophozoites or cysts present and identified; trophozoite- and cyst-specific stains available; immunoassay reagents available Cysts present and identified
<i>Toxoplasma gondii</i>	Toxoplasmosis	<ol style="list-style-type: none"> 1. Lymph node biopsy <ol style="list-style-type: none"> A. Routine histology B. Tissue culture isolation C. Animal inoculation 2. Serology 	Identification of organisms plus appropriate serologic test results
<i>Cryptosporidium</i> spp.	Cryptosporidiosis	<ol style="list-style-type: none"> 1. Duodenal scraping 2. Duodenal biopsy <ol style="list-style-type: none"> A. Stain B. Routine histology 3. Other tissue biopsy <ol style="list-style-type: none"> A. Routine histology B. Squash preparation 4. Sputum (modified AFB stains) 5. Immunoassays 	Identification of organisms in microvillus border or in other tissues (lung and gallbladder have also been involved)
Microsporidia <i>Nosema</i> spp. <i>Encephalitozoon</i> spp. <i>Enterocytozoon</i> spp. <i>Pleistophora</i> spp. <i>Trachipleistophora</i> spp. <i>Brachiola</i> sp. “ <i>Microsporidium</i> ” spp. <i>Vittaforma corneae</i>	Microsporidiosis	Routine histology (fair); acid-fast, PAS, modified trichrome, Giemsa, and tissue Gram stains recommended (spores); animal inoculation not recommended (latent infections); EM or PCR may be necessary to confirm genus	These organisms (spores) have been found as insect or other animal parasites; the most common route of infection is probably ingestion. Human cases involve gastrointestinal tract, muscle, and CSF (AIDS); other body sites have also been documented; not limited to compromised patients
Helminths			
Larvae (<i>Ascaris lumbricoides</i> , <i>Strongyloides stercoralis</i>)	“Pneumonia”	Sputum, wet preparation	This is an incidental finding but has been reported in severe infections
Eggs (<i>Paragonimus</i> spp.)	Paragonimiasis	Sputum, wet preparation	Eggs will be coughed up and will appear as “iron filings”; eggs can also be found in stool
Hooklets (<i>Echinococcus</i> spp.)	Hydatid disease	Sputum, wet preparation	Rare finding, but hooklets can be found when the hydatid cyst is in the lungs
<i>Onchocerca volvulus</i> <i>Mansonella streptocerca</i>	Onchocerciasis	Skin	Skin snips examined in saline; microfilariae may be present
<i>Schistosoma</i> spp.	Schistosomiasis	<ol style="list-style-type: none"> 1. Rectal valve biopsy 2. Bladder biopsy 	Eggs present and identified

^a Modified from H. D. Isenberg, ed., *Clinical Microbiology Procedures Handbook*, 2nd ed. ASM Press, Washington, D.C., 2004. CSF, cerebrospinal fluid; AFB, acid-fast bacillus; PAS, periodic acid-Schiff; EM, electron microscopy.

^b PCR is now being used for the identification of a number of human parasites; however, these tests are generally limited to academic or reference centers. Routine laboratory use is not common.

^c Now classified with the fungi.

Table AI.12 Key characteristics of protozoa of the intestinal tract and urogenital system^a

Organism	Trophozoite or tissue stage	Cyst or other stage in specimen	Comments
Amebae			
<i>Entamoeba histolytica</i> (pathogenic)	Cytoplasm is clean; presence of RBCs is diagnostic, but cytoplasm may also contain some ingested bacteria; peripheral nuclear chromatin is evenly distributed with central, compact karyosome.	Mature cyst contains 4 nuclei; chromatoidal bars have smooth, rounded ends; cannot be differentiated from <i>E. dispar</i> .	Considered pathogenic; should be reported to Public Health; trophozoites can be confused with macrophages and cysts can be confused with WBCs in the stool.
<i>Entamoeba dispar</i> (nonpathogenic)	Morphology identical to that of <i>E. histolytica</i> (confirmed by presence of RBCs in cytoplasm). If no RBCs, molecular testing or fecal immunoassays are necessary to confirm species designation.	Mature cyst has morphology identical to that of <i>E. histolytica</i> .	Nonpathogenic; morphology resembles <i>E. histolytica</i> ; these organisms should be reported as <i>Entamoeba histolytica/E. dispar</i> and reported to Public Health; immunoassay reagents are now available to identify the <i>Entamoeba histolytica/E. dispar</i> group and to differentiate pathogenic <i>E. histolytica</i> and nonpathogenic <i>E. dispar</i> ; some laboratories may decide to use these reagents on a routine basis, depending on positivity rate and cost.
<i>Entamoeba histolytica/E. dispar</i>			Correct way to report, unless immunoassay is used to identify <i>E. histolytica</i> or trophozoites are seen with ingested RBCs (<i>E. histolytica</i>).
<i>Entamoeba hartmanni</i> (nonpathogenic)	Looks identical to <i>E. histolytica/E. dispar</i> but is smaller (<12 µm); RBCs are not ingested.	Mature cyst contains 4 nuclei but often has only 2; chromatoidal bars are often present and look like those of <i>E. histolytica/E. dispar</i> (size, <10 µm).	Shrinkage occurs on the permanent stain (especially in the cyst form). <i>E. histolytica/E. dispar</i> may actually be below the 12- and 10-µm cutoff limits and can be as much as 1.5 µm below the limits quoted for wet preparation measurements.
<i>Entamoeba coli</i> (nonpathogenic)	Cytoplasm is dirty and may contain ingested bacteria or debris; peripheral nuclear chromatin is unevenly distributed, with a large, eccentric karyosome.	Mature cyst contains 8 nuclei; more may be seen; chromatoidal bars (if present) tend to have sharp, pointed ends.	If a smear is too thick or thin and if stain is too dark or light, <i>E. histolytica/E. dispar</i> and <i>E. coli</i> can often be confused, since there is much overlap in morphology.
<i>Endolimax nana</i> (nonpathogenic)	Cytoplasm is clean, not diagnostic, with a great deal of nuclear variation; there may even be some peripheral nuclear chromatin. Normally only karyosomes are visible.	Cyst is round to oval, with the 4 nuclear karyosomes being visible.	There is more nuclear variation in this ameba than any others. The organisms can be confused with <i>Dientamoeba fragilis</i> and/or <i>E. hartmanni</i> .
<i>Iodamoeba bütschlii</i> (nonpathogenic)	Cytoplasm contains much debris; organisms are usually larger than <i>E. nana</i> but may look similar; large karyosome.	Cyst contains single nucleus (may be “basket nucleus”) with bits of nuclear chromatin arranged on the nuclear membrane (the karyosome is the basket, bits of chromatin are the handle); large glycogen vacuole.	Glycogen vacuole stains brown with the addition of iodine in the wet preparation; “basket nucleus” is more common in cyst but can be seen in trophozoite; vacuole may be so large that the cyst collapses on itself.

Flagellates

<i>Giardia lamblia</i> (pathogenic)	Trophozoites are teardrop shaped from the front and like a curved spoon from the side; contain nuclei, linear axonemes, and curved median bodies.	Cysts are round to oval, containing multiple nuclei, axonemes, and median bodies.	Organisms live in the duodenum, and multiple stool specimens may be negative; additional sampling techniques (aspiration, Entero-Test) may be needed.
<i>Chilomastix mesnili</i> (nonpathogenic)	Trophozoites are teardrop shaped; cytostome must be visible for identification.	Cyst is lemon shaped with 1 nucleus and a curved fibril called a shepherd's crook.	The cyst can be identified much more easily than the trophozoite form. The trophozoite looks like some of the other small flagellates.
<i>Dientamoeba fragilis</i> (pathogenic)	Cytoplasm contains debris; may contain 1 or 2 nuclei (chromatin often fragmented into 4 dots).	No known cyst form.	Tremendous size and shape range on a single smear; trophozoites with 1 nucleus can resemble <i>E. nana</i> .
<i>Trichomonas vaginalis</i> (pathogenic)	Supporting rod (axostyle) is present; undulating membrane comes halfway down the organism; small dots may be seen in the cytoplasm along the axostyle.	No known cyst form.	Recovered from genitourinary system; often diagnosed at bedside with wet preparation (motility).
<i>Pentatrichomonas hominis</i> (nonpathogenic)	Supporting rod (axostyle) is present; undulating membrane comes all the way down the organism; small dots may be seen in the cytoplasm along the axostyle.	No known cyst form.	Recovered in stool; trophozoites may resemble other small flagellate trophozoites.

Ciliates

<i>Balantidium coli</i> (pathogenic)	Very large trophozoites (50–100 µm long) covered with cilia; large bean-shaped nucleus present.	Morphology not significant with exception of large, bean-shaped nucleus.	Rarely seen in the United States; causes severe diarrhea with large fluid loss; will be seen in proficiency-testing specimens.
--------------------------------------	---	--	--

Coccidia

<i>Cryptosporidium</i> spp. (pathogenic)	Seen in intestinal mucosa (edge of brush border), gallbladder, and lungs; present in biopsy specimens.	Oocysts seen in stool and/or sputum; organisms acid fast, measure 4–6 µm; hard to find if only a few are present.	Chronic infection in the compromised host (internal autoinfective cycle), self-cure in the immunocompetent host; numbers of oocysts correlate with stool consistency; can cause severe, watery diarrhea; oocysts are immediately infective when passed.
<i>Cyclospora cayatanensis</i> (pathogenic)	Experience with this organism is not extensive; may be difficult to identify in tissue; since patients are immunocompetent, biopsy specimens will probably rarely be required or requested.	Oocysts seen in stool; approximately 8–10 µm in size; are unsporulated and thus difficult to recognize as coccidia; mimic <i>Cryptosporidium</i> on modified acid-fast-stained smears.	Most infections are associated with the immunocompetent individual but may also be seen in the immunosuppressed patient; may be associated with traveler's diarrhea; oocysts are not immediately infective when passed. Within the United States, infections have been associated with contaminated food, including raspberries, basil, snow peas, and mesclun (baby lettuce leaves). PCR can detect 40 or fewer oocysts per 100 g of raspberries or basil but has a detection limit of around 1,000 per 100 g in mesclun lettuce.

(continued)

Table AI.12 Key characteristics of protozoa of the intestinal tract and urogenital system^a (*continued*)

Organism	Trophozoite or tissue stage	Cyst or other stage in specimen	Comments
<i>Isospora belli</i> (pathogenic)	Seen in intestinal mucosal cells; seen in biopsy specimens; does not seem to be as common as <i>Cryptosporidium</i> .	Oocysts seen in stool; organisms are acid fast; best technique is concentration, not permanent stained smear.	Thought to be the only <i>Isospora</i> sp. that infects humans; oocysts are not immediately infective when passed.
Microsporidia	Developing stages sometimes difficult to identify; spores can be identified by size, shape, and presence of polar tubules.	Depending on the genus involved, spores could be identified in stool or urine using the modified trichrome stain, calcofluor, or immunoassay reagents.	Spores are generally quite small (1–2.0 µm for <i>Enterocytozoon</i> spp.) and can easily be confused with other organisms or artifacts (particularly in stool). Infections tend to be present in immunosuppressed patients; however, they are not limited to this patient group.
<i>Nosema</i> spp.			
<i>Encephalitozoon</i> spp.			
<i>Pleistophora</i> spp.			
<i>Trachipleistophora</i> spp.			
<i>Brachiola</i> sp.			
<i>Enterocytozoon</i> spp.			
“ <i>Microsporidium</i> ” spp.			
<i>Vittaforma corneae</i>			

^a Modified from H. D. Isenberg, ed., *Clinical Microbiology Procedures Handbook*, 2nd ed. ASM Press, Washington, D.C., 2004. RBC, red blood cells; WBC, white blood cells.

Table AI.13 Key characteristics of tissue protozoa^a

Species	Shape and size	Other features ^b
<i>Toxoplasma gondii</i>		
Trophozoites (tachyzoites)	Crescent shaped; 4–6 µm long by 2–3 µm wide	Found in peritoneal fluid of experimentally infected mice; intracellular forms somewhat smaller and not usually seen in humans. May be isolated in tissue culture, particularly from CSF. Diagnosis is most frequently based on clinical history and serologic evidence (acute- and convalescent-phase sera).
Cysts (bradyzoites)	Generally spherical; 200 µm to 1 mm in diameter	Occur in many tissues (approximately 25% of the U.S. population have these organisms in the tissues, indicating past infection). Many infections are asymptomatic. Infections in the compromised host are very serious and involve the CNS. In these patients, particularly those with AIDS, diagnostic serologic titers may be very difficult to demonstrate and/or interpret. Note Organisms identified in histologic preparations or isolated in animals or tissue culture systems may or may not be the causative agent of the symptoms.
<i>Pneumocystis jiroveci</i> ^c		
Trophozoites	Ameboid in shape; measure about 5 µm; nucleus is visible with Giemsa or hematoxylin stain	Patients with AIDS may have a longer incubation period (mean, around 40 days, but can be up to 1 yr). As many as 28% of these patients show normal chest X rays, and physical signs are absent or ill defined. Rales may or may not be detected. Serologic studies indicate that by age 4, ca. 80% of those tested are positive. Diagnosis is based on actual demonstration of the organism.
Cysts	Usually round; when mature contain 8 trophozoites; often measure 5 µm and contain very small trophozoites (1 µm)	Before the AIDS epidemic, the recommended procedure of choice was the open-lung biopsy. Currently, BAL, transbronchial biopsy, and collection of induced sputum specimens have been more widely used. No commercial reagents are available for serologic diagnosis. Immunoassay reagents for direct organism detection are commercially available.
<i>Cryptosporidium</i> spp.		
	Oocyst usually round, 4–6 µm; each mature oocyst contains sporozoites (infective on passage)	Oocyst is usually the diagnostic stage in stool, sputum, and possibly other body specimens. Various other stages in the life cycle can be seen in biopsy specimens taken from the gastrointestinal tract (brush border of epithelial cells and intestinal tract) and other tissues (lung and gallbladder). A number of modified acid-fast stains have been used successfully. Detection methods using immunoassay reagents are also available. Note Infection in immunocompetent hosts is self-limiting; however, in immunodeficient patients (AIDS), the infection is chronic owing to an autoinfective capability in the life cycle. The number of oocysts usually correlates with the symptoms (watery diarrhea indicates many oocysts in the specimen). The more normal the stool, the more difficult it is to find the oocysts. Clinicians should be aware that risk groups include animal handlers, travelers, immunocompromised individuals, children in day care centers, and anyone who comes in contact with these individuals. Since the oocysts are immediately infective, nosocomial transmission has been documented.
<i>Cyclospora cayetanensis</i>		
	Oocyst usually round, 8–10 µm; each oocyst is immature on passage; no internal morphology visible; oocysts appear as “wrinkled” cellophane	The oocyst is the diagnostic stage in stool. Various other stages in the life cycle can be seen in biopsy specimens taken from the gastrointestinal tract (within epithelial cells and intestinal tract); oocysts are not immediately infectious when passed. The morphology is similar to that of <i>Isospora belli</i> . A number of modified acid-fast stains have been used successfully to demonstrate the oocysts (quite acid-fast variable). Detection methods involving immunoassay reagents are under development.

(continued)

Table AI.13 Key characteristics of tissue protozoa^a (continued)

Species	Shape and size	Other features ^b
<i>Isospora belli</i>	Ellipsoidal oocyst; usual range, 20–30 µm long by 10–19 µm wide; sporocysts rarely seen broken out of oocysts but measure 9–11 µm	Mature oocyst contains 2 sporocysts with 4 sporozoites each; the usual diagnostic stage in feces is the immature oocyst, containing a spherical mass of protoplasm (diarrhetic stool). Developing stages can be recovered from intestinal biopsy specimens. Oocysts are also acid fast and could be detected during acid-fast staining of stool for <i>Cryptosporidium</i> . Oocysts are often detected in the concentration sediment (wet preparation); they are not immediately infectious when passed.
Microsporidia <i>Nosema</i> spp. <i>Encephalitozoon</i> spp. <i>Enterocytozoon</i> spp. <i>Pleistophora</i> spp. <i>Trachipleistophora</i> spp. <i>Brachiola</i> sp. “ <i>Microsporidium</i> ” spp. <i>Vittaforma corneae</i>	Spores are extremely small and have been recovered in all body organs, including the eye	These organisms have been found as insect or other animal parasites; the route of infection may be ingestion, inhalation, or direct inoculation (eyes). Histology results vary (spores are acid fast); PAS, silver, tissue Gram, and Giemsa stains are recommended for spores. Animal inoculation is not recommended; laboratory animals may carry occult infection. Electron microscopy or molecular methods may be necessary for confirmation and identification to the genus and species levels. Although difficult to diagnose, infections have been found in a large number of AIDS patients (<i>Enterocytozoon bienersi</i> , <i>Encephalitozoon [Septata] intestinalis</i> in the intestinal tract, <i>Pleistophora</i> spp. in muscle, and various other microsporidia in other tissues). To date, it is still somewhat difficult to diagnose this infection by examining stool specimens prepared with optical brightening agents (calcofluor) or routine stains (modified trichrome stains). Diagnostic immunoassay reagents are under development.
<i>Sarcocystis hominis</i> , <i>S. suihominis</i> , <i>S. bovisominis</i>	Oocyst is thin walled and contains 2 mature sporocysts, each containing 4 sporozoites; the thin oocyst wall frequently ruptures; ovoidal sporocysts measure 9–16 µm long by 7.5–12 µm wide	Thin-walled oocyst or ovoidal sporocysts are found in stool. There have been reports of fever, severe diarrhea, abdominal pain, and weight loss in the compromised host, although the number of patients has been small. Infections occur from the ingestion of uncooked pork or beef. The life cycle occurs within the intestinal cells, with the eventual production of sporocysts in stool.
<i>Sarcocystis</i> “ <i>lindemanni</i> ”	Shapes and sizes of skeletal and cardiac muscle sarcocysts vary considerably	When humans accidentally ingest oocysts from other animal stool sources, sarcocysts that develop in human muscle apparently do little if any harm. These could be identified by routine histologic methods. When humans are intermediate hosts, preventive measures involve careful disposal of animal feces that may contain the infective sporocysts. This may be impossible in the wilderness areas, where wild animals may serve as reservoir hosts for many of the different types of organisms that have been grouped under the term <i>Sarcocystis</i> “ <i>lindemanni</i> .” However, this name is no longer used.

^a Modified from H. D. Isenberg, ed., *Clinical Microbiology Procedures Handbook*, 2nd ed. ASM Press, Washington, D.C., 2004.^b CNS, central nervous system; CSE, cerebrospinal fluid; BAL, bronchoalveolar lavage; PAS, periodic acid-Schiff.^c Now classified with the fungi.

Table AI.14 Key characteristics of helminths^a

Helminths	Diagnostic stage ^b	Comments
Nematodes (roundworms)		
<i>Ascaris lumbricoides</i> (pathogenic)	Egg: both fertilized (oval to round with thick, mammilated/tuberculated shell) and unfertilized (tend to be more oval or elongate, with bumpy shell exaggerated) eggs can be found in stool; adult worms: 10–12 in. found in stool; rarely (in severe infections), migrating larvae can be found in sputum	Unfertilized eggs do not float in flotation concentration method; adult worms tend to migrate when irritated (by anesthesia or high fever); hence, patients from areas of endemic infection should be checked for infection prior to elective surgery.
<i>Trichuris trichiura</i> (whipworm) (pathogenic)	Egg: barrel shaped with 2 clear, polar plugs; adult worm: rarely seen; eggs should be quantitated (rare, few, etc.), since light infections may not be treated	Dual infections with <i>A. lumbricoides</i> may be seen (both infections are acquired from ingestion of eggs from contaminated soil); in severe infections, rectal prolapse may occur in children or bloody diarrhea can be mistaken for amebiasis (these clinical manifestations are usually not seen in the United States).
<i>Enterobius vermicularis</i> (pinworm)	Egg: football shaped with one flattened side; adult worm: about 3/8 in. long, white with pointed tail; female migrates from the anus and deposits eggs on the perianal skin	Causes itching in some patients. Test of choice is Scotch tape preparation; 4–6 consecutive tapes necessary to rule out infection; symptomatic patients often treated without actual confirmation of infection; eggs become infective within a few hours.
<i>Ancylostoma duodenale</i> (Old World hookworm), <i>Necator americanus</i> (New World hookworm) (pathogenic)	Egg: eggs of both species are identical, oval with broadly rounded ends, thin shell, clear space between shell and developing embryo (8–16-cell stage); adult worms: rarely seen in clinical specimens	Causes blood-loss anemia on the differential smear in heavy infections in some patients. If stool remains unpreserved for several hours or days, the eggs may continue to develop and hatch; rhabditiform larvae may resemble those of <i>Strongyloides stercoralis</i> .
<i>Strongyloides stercoralis</i> (pathogenic)	Rhabditiform larvae (noninfective) usually found in the stool; short buccal cavity or capsule with large genital primordial packet of cells (“short and sexy”); in very heavy infections, larvae occasionally found in sputum and/or filariform (infective) larvae can be found in stool (slit in the tail)	May cause unexplained eosinophilia, abdominal pain, unexplained episodes of sepsis and/or meningitis, and pneumonia (migrating larvae) in the compromised patient. Potential for internal autoinfection can maintain low-level infections for many years (patient is asymptomatic or has eosinophilia); hyperinfection can occur in the compromised patient (leading to disseminated strongyloidiasis and death); agar plate culture is the most sensitive diagnostic method; many infections are low-level, and larvae are difficult to recover.
<i>Ancylostoma braziliensis</i> (dog or cat hookworm) (pathogenic)	Humans are accidental hosts; larvae wander through the outer layer of skin, creating tracks (causing severe itching and eosinophilia); no practical microbiological diagnostic tests	Cause of cutaneous larva migrans; typical setup for infection is when dogs and cats defecate in sand boxes and hookworm eggs hatch and penetrate human skin when in contact with infected sand or soil (children playing in sand box).
<i>Toxocara cati</i> and <i>T. canis</i> (dog and cat ascarid) (pathogenic)	Humans are accidental hosts; infection is by ingestion of dog or cat ascarid eggs in contaminated soil; larvae wander through deep tissues (including the eye); can be mistaken for cancer of the eye; serologic tests helpful for confirmation; infection causes eosinophilia	Cause of visceral larva migrans and ocular larva migrans; requests for laboratory services often originate in the ophthalmology clinic.

(continued)

Table AI.14 Key characteristics of helminths^a (continued)

Helminths	Diagnostic stage ^b	Comments
Cestodes (tapeworms)		
<i>Taenia saginata</i> (beef tapeworm)	Scolex (4 suckers, no hooklets) and gravid proglottid (>12 branches on a single side) are diagnostic; eggs indicate <i>Taenia</i> spp. only (thick, striated shell containing a 6-hooked embryo or oncosphere); worm usually about 12–15 ft long	Adult worm causes symptoms in some individuals. Infection occurs via ingestion of raw or poorly cooked beef; usually only a single worm per patient; individual proglottids may crawl from the anus; India ink can be injected into proglottids to visualize the uterine branches for identification.
<i>Taenia solium</i> (pork tapeworm)	Scolex (4 suckers with hooklets) and gravid proglottid (<12 branches on a single side) are diagnostic; eggs indicate <i>Taenia</i> spp. only (thick, striated shell containing a 6-hooked embryo or oncosphere); worm is usually about 6–20 ft long	Adult worm causes gastrointestinal complaints in some individuals; cysticercosis (accidental ingestion of eggs) can cause severe central nervous system symptoms. Infection is via ingestion of raw or poorly cooked pork; usually only a single worm per patient; occasionally 2 or 3 proglottids (hooked together) are passed. India ink can be injected into proglottids to visualize the uterine branches for identification. Cysticerci are normally small and contained within an enclosing membrane; they occasionally develop as the “racemose” type in which the worm tissue grows in the body like a metastatic cancer.
<i>Diphyllobothrium latum</i> (broad fish tapeworm)	Scolex (lateral sucking grooves), gravid proglottid (wider than long, reproductive structures in the center “rosette”); eggs are operculated	Causes gastrointestinal complaints in some individuals. Infection is via ingestion of raw or poorly cooked freshwater fish; life cycle has 2 intermediate hosts (copepod and fish); worm may reach 30 ft long. Associated with vitamin B ₁₂ deficiency in genetically susceptible groups (e.g., Scandinavians).
<i>Hymenolepis nana</i> (dwarf tapeworm)	Adult worm not normally seen; egg round to oval, thin shell, containing a 6-hooked embryo or oncosphere with polar filaments lying between the embryo and egg shell	Causes gastrointestinal complaints in some individuals. Infection is via ingestion of eggs (the only life cycle in which the intermediate host [grain beetle] can be bypassed); life cycle of egg to larval form to adult can be completed in the human. May be the most common tapeworm in the world.
<i>Hymenolepis diminuta</i> (rat tapeworm)	Adult worm not normally seen; egg round to oval, thin shell, containing a 6-hooked embryo or oncosphere without polar filaments lying between the embryo and egg shell	Uncommon; egg can be confused with <i>H. nana</i> . Eggs will be submitted in proficiency-testing specimens and must be differentiated from those of <i>H. nana</i> .
<i>Echinococcus granulosus</i> (pathogenic)	Adult worm found only in the carnivore (dog); hydatid cysts develop (primarily in the liver) when humans accidentally ingest eggs of the dog tapeworms; cyst contains daughter cysts and many scolices; laboratory should examine fluid aspirated from cyst at surgery	Humans are accidental intermediate hosts; the normal life cycle is dog to sheep, with the hydatid cysts developing in the liver, lung, etc., of the sheep. Human hosts may be unaware of their infection unless fluid leaks from the cyst (can trigger an anaphylactic reaction) or pain is felt at the cyst location.
<i>Echinococcus multilocularis</i> (pathogenic)	Adult worm found only in the carnivore (fox or wolf); hydatid cysts develop (primarily in the liver) when humans accidentally ingest eggs of the carnivore tapeworms; cyst grows like a metastatic cancer with no limiting membrane	Humans are accidental intermediate hosts. Prognosis is poor; surgical removal of the tapeworm tissue is very difficult. Found in Canada, Alaska, and less frequently in the northern United States but is becoming more common in the United States, where the geographic range is moving further south.

Trematodes (flukes)

<i>Fasciolopsis buski</i> (giant intestinal fluke)	Eggs found in stool; very large and operculated (morphology like that of <i>F. hepatica</i> eggs)	Symptoms depend on worm burden; acquired from ingestion of plant material on which metacercariae have encysted (e.g., water chestnuts); worms are hermaphroditic.
<i>Fasciola hepatica</i> (sheep liver fluke)	Eggs found in stool; cannot be differentiated from those of <i>F. buski</i>	Symptoms depend on worm burden; acquired from ingestion of plant material on which metacercariae have encysted (e.g., watercress); worms are hermaphroditic.
<i>Clonorchis (Opisthorchis) sinensis</i> (Chinese liver fluke)	Eggs found in stool; very small (<35 µm); are operculated with shoulders into which the operculum fits	Symptoms depend on worm burden; acquired from ingestion of raw fish. Eggs can be missed unless ×400 power is used for examination; eggs can resemble those of <i>Metagonimus yokogawai</i> and <i>Heterophyes heterophyes</i> (small intestinal flukes). Worms are hermaphroditic.
<i>Paragonimus</i> spp. (lung fluke)	Eggs coughed up in sputum (brownish “iron filings” are egg packets); can be recovered in sputum or stool (if swallowed); are operculated with shoulders into which operculum fits	Symptoms depend on worm burden and egg deposition. Infection acquired from ingestion of raw crabs. Eggs can be confused with those of <i>D. latum</i> . Infections seen in the Orient (infections with <i>P. mexicanus</i> found in Central and South America). <i>P. kellicotti</i> infections (rare) are seen in the United States. Worms are hermaphroditic but often cross-fertilize with another worm if present.
<i>Schistosoma mansoni</i> (blood fluke)	Eggs recovered in stool (large lateral spine); specimens should be collected with no preservatives (to allow demonstration of egg viability); worms in veins of large intestine	Acquired from skin penetration by a single cercaria from the freshwater snail. Pathologic findings are caused by host immune response to the presence of eggs in tissues; adult worms in veins cause no problems. Adult worms are separate sexes.
<i>Schistosoma haematobium</i> (blood fluke)	Eggs recovered in urine (large terminal spine); specimens should be collected with no preservatives (to allow demonstration of egg viability); worms in veins of bladder	Acquired from skin penetration by single cercaria from the freshwater snail; pathologic findings as with <i>S. mansoni</i> ; 24-h and spot urine samples should be collected. Chronic infection has association with bladder cancer. Adult worms are separate sexes.
<i>Schistosoma japonicum</i> (blood fluke)	Eggs recovered in stool (very small lateral spine); specimens should be collected with no preservatives (to allow demonstration of egg viability); worms in veins of small intestine	Acquired from skin penetration by multiple cercariae from the freshwater snail; pathologic findings as with <i>S. mansoni</i> ; infection usually the most severe of the 3 species because of original loading dose of infective cercariae from the freshwater snail (multiple cercariae stick together). Symptoms are associated with egg production, which is greatest in <i>S. japonicum</i> infections.

^a Modified from H. D. Isenberg, ed., *Clinical Microbiology Procedures Handbook*, 2nd ed. ASM Press, Washington, D.C., 2004.

^b 1 in. = 2.54 cm; 1 ft = 30.48 cm.

Table AI.15 Key characteristics of parasites found in blood^a

Organism	Diagnostic stage	Comments
Protozoa		
Malaria parasites		
<i>Plasmodium vivax</i> (benign tertian malaria)	Ameboid rings; presence of Schüffner's dots, beginning in older rings (appear later than those in <i>P. ovale</i>); all stages seen in peripheral blood; mature schizont contains 16–18 merozoites	Infects young cells; 48-h cycle; large geographic range; tends to have true relapse from the residual liver stages (hypnozoites); enlarged red blood cells
<i>Plasmodium ovale</i> (ovale malaria)	Nonameboid rings; presence of Schüffner's dots, beginning in young rings (appear earlier than those in <i>P. vivax</i>); all stages seen in peripheral blood; mature schizont contains 8–10 merozoites; red blood cells may be oval and have fimbriated edges	Infects young cells; 48-h cycle; narrow geographic range; tends to have true relapse from residual liver stages (hypnozoites); enlarged red blood cells
<i>Plasmodium malariae</i> (quartan malaria)	Thick rings; no stippling; all stages seen in peripheral blood; presence of band forms and rosette-shaped mature schizont; abundant malarial pigment	Infects old cells; 72-h cycle; narrow geographic range; associated with recrudescence and nephrotic syndrome; no true relapse; normal or small red blood cells
<i>Plasmodium falciparum</i> (malignant tertian malaria)	Multiple rings; appliqué/accolé forms; no stippling (rare Maurer's clefts); rings and crescent-shaped gametocytes seen in peripheral blood (no other developing stages, with rare exception of mature schizont)	Infects all cells; 36–48-h cycle; large geographic range; no true relapse; most pathogenic of the 4 species; plugged capillaries can cause severe symptoms and sequelae (cerebral malaria, lysis of red blood cells, etc.)
<i>Babesia</i> spp.	Ring forms only (resemble <i>P. falciparum</i> rings); seen in splenectomized patients; endemic in the United States (no travel history necessary); if present, “Maltese cross” configuration is diagnostic but not always seen	Tick-borne infection; associated with Nantucket Island; infection mimics malaria; ring forms more pleomorphic than malaria; usually more rings/cell than in malaria; endemic in several areas in the United States (East and West Coasts); organisms occasionally seen outside red blood cells (unlike malaria merozoites)
Trypanosomes		
<i>Trypanosoma brucei gambiense</i> (West African sleeping sickness)	Trypomastigotes long, slender, with typical undulating membrane; lymph nodes and blood can be sampled; microhematocrit tube concentration helpful; examine spinal fluid in later stages of the infection	Tsetse fly vector; tends to be chronic infection, causing the real symptoms of sleeping sickness
<i>Trypanosoma brucei rhodesiense</i> (East African sleeping sickness)	Trypomastigotes long, slender, with typical undulating membrane; small kinetoplast; lymph nodes and blood can be sampled; microhematocrit tube concentration helpful; examine spinal fluid in later stages of the infection	Tsetse fly vector; tends to be more severe, short-lived infection (particularly in children); patient may die before progressive symptoms of sleeping sickness appear
<i>Trypanosoma cruzi</i> (Chagas' disease) (American trypanosomiasis)	Trypomastigotes short, stumpy, often curved in C shape; large kinetoplast; blood sampled early in infection; trypomastigotes enter striated muscle (heart, gastrointestinal tract) and transform into the amastigote form	Reduviid bug vector (kissing bug); chronic in adults but severe in young children; great morbidity associated with cardiac failure and loss of muscle contractility in heart and gastrointestinal tract

Leishmaniae

Leishmania spp. (cutaneous); not actually a blood parasite but presented for comparison with *L. donovani*)

Amastigotes found in macrophages of skin; presence of intracellular forms containing nucleus and kinetoplast diagnostic

Sand fly vector; organisms recovered from site of lesion only; specimens can be stained or cultured in NNN^b and/or Schneider's medium; animal (hamster) inoculation rarely used

Leishmania braziliensis and other *Leishmania* spp. (mucocutaneous; not actually a blood parasite but presented for comparison with *L. donovani*)

Amastigotes found in macrophages of skin and mucous membranes; presence of intracellular forms containing nucleus and kinetoplast diagnostic

Sand fly vector; organisms recovered from site of lesion only; specimens can be stained or cultured in NNN and/or Schneider's medium; animal (hamster) inoculation rarely used

Leishmania donovani and other *Leishmania* spp. (visceral)

Amastigotes found throughout the reticuloendothelial system (spleen, liver, bone marrow, etc.); presence of intracellular forms containing nucleus and kinetoplast diagnostic

Sand fly vector; organisms recovered from buffy coat (rarely found), bone marrow aspirate, spleen or liver puncture (rarely performed); specimens can be stained or cultured in NNN and/or Schneider's medium; animal (hamster) inoculation rarely used; cause of kala azar

Helminths

Wuchereria bancrofti

Microfilariae sheathed, clear space at end of tail; nocturnal periodicity seen; elephantiasis seen in chronic infections

Pathogenicity due to presence of adult worms; mosquito vector; microfilariae recovered in blood (membrane filtration, Knott concentrate, thick films); hematoxylin stains the sheath; Giemsa stain does not stain the sheath

Brugia malayi

Microfilariae sheathed, subterminal and terminal nuclei at end of tail; nocturnal periodicity seen; elephantiasis seen in chronic infections

Pathogenicity due to presence of adult worms; mosquito vector; microfilariae recovered in blood (membrane filtration, Knott concentrate, thick films); hematoxylin stains the sheath; Giemsa stains the sheath pink; sheath of *B. timori* does not stain with Giemsa

Loa loa (African eye worm)

Microfilariae sheathed, nuclei continuous to tip of tail; diurnal periodicity; adult worm may cross the conjunctiva of the eye

Pathogenicity due to presence of adult worms; mango fly vector; history of calabar swellings, worms in the eye; microfilariae difficult to recover from blood; hematoxylin stains the sheath; Giemsa stain does not stain the sheath

Mansonella spp.

Microfilariae unsheathed, nuclei may or may not extend to tip of tail (depending on species); nonperiodic; symptoms usually absent or mild

Pathogenicity mild and due to presence of adult worms; midge or blackfly vector; microfilariae recovered in blood (membrane filtration, Knott concentrate, thick films); hematoxylin and Giemsa stain characteristics identical

Mansonella streptocerca

Microfilariae unsheathed, nuclei extend to tip of tail; when immobile, curved like shepherd's crook; adults in dermal tissues

Pathogenicity mild and due to presence of adult worms and/or microfilariae; midge vector; microfilariae found in skin snips; microfilarial tails are split rather than blunt; hematoxylin and Giemsa stain characteristics identical

Onchocerca volvulus

Microfilariae unsheathed, nuclei do not extend to tip of tail; adults in nodules

Pathogenicity due to presence of microfilariae; blackfly vector; microfilariae found in skin snips; microfilariae migrate to optic nerve; cause of river blindness

^b May require numbers of infected cells, eggs, etc. (either as specific count or as rare, few, moderate, or many).

^c NA, not applicable.

^d If *Trichuris trichiura* eggs are rare or few, the infection may not be treated.

^e The specimen must be fresh and should be examined immediately; alternatively, it should be freshly preserved in a stool collection kit *by the patient* (no lag time between stool passage and preservation); if these requirements are not met, the report (presence of budding yeasts and/or pseudohyphae or hyphae) may be misleading and should not be reported to the physician. Report budding yeast cells and/or the presence of pseudohyphae or hyphae.

Table AI.17 Pros and cons of stool specimen collection and testing options^a

Option ^b	Pros	Cons
Rejection of stools from inpatients who have been in-house for >3 days	Data suggest that patients who begin to have diarrhea after they have been inpatients for a few days are not symptomatic from parasitic infections, but generally from other causes.	There is always the chance that the problem is related to a health care-associated (nosocomial) parasitic infection (rare), but <i>Cryptosporidium</i> and microsporidia are possible considerations.
Examination of 1 stool (O&P examination)	Data suggest that 40–50% of organisms present will be found with only 1 stool exam. Some feel that most intestinal parasitic infections can be diagnosed from examination of a single stool. If the patient becomes asymptomatic after collection of the first stool, subsequent specimens may not be necessary.	Diagnosis from examination of a single specimen depends on the experience of the microscopist, proper collection, and the parasite load in the specimen. In a series of 3 stool specimens, frequently not all 3 specimens are positive and/or may be positive for different organisms.
Use of 2 O&P exams (concentration, permanent stained smear)	The examination of 2 specimens is more sensitive than 1 examination; different organisms may be found in the 2 specimens; 1 might be negative while 1 is positive.	May not be as cost-effective as examination of 1 specimen. Not always as good as examination of 3 specimens (may be a relatively cost-effective approach); any patient remaining symptomatic would require additional testing.
Examination of a second stool specimen only after the first is negative and the patient is still symptomatic	With additional examinations, the yield of protozoa increases (<i>Entamoeba histolytica</i> , 22.7%; <i>Giardia lamblia</i> , 11.3%; <i>Dientamoeba fragilis</i> , 31.1%)	Assumes that the second (or third) stool is collected within the recommended 10-day time frame for a series of stools; protozoa are shed periodically. May be inconvenient for patient.
Examination of 1 stool specimen and an immunoassay (EIA, FA, lateral- or vertical-flow cartridge)	If the examinations are negative and the patient's symptoms subside, probably no further testing is required.	This approach is a mix: 1 immunoassay may be acceptable; however, immunoassay testing of 2 separate specimens may be required to confirm the presence of <i>Giardia</i> antigen. One O&P exam is not the best approach (review the last option below). Patients may exhibit symptoms (off and on), so it may be difficult to rule out parasitic infections. If the patient remains symptomatic, even if 2 <i>Giardia</i> immunoassays are negative, other protozoa may be missed (the <i>Entamoeba histolytica</i> / <i>E. dispar</i> group, <i>E. histolytica</i> , <i>Dientamoeba fragilis</i> , <i>Cryptosporidium</i> spp., the microsporidia). Normally, there are specific situations where fecal immunoassays or O&P exams should be ordered. It is not recommended to automatically perform both the O&P and fecal immunoassay as a stool exam for parasites (see Table A1.18). Depending on the patient's history and clinical symptoms, EITHER the O&P exam OR a fecal immunoassay may be recommended, BUT GENERALLY NOT BOTH.
Pool 3 specimens for examination; perform 1 concentration and 1 permanent stain	Three specimens are collected by the patient (3 separate collection vials) over 7–10 days; pooling by the laboratory may save time and expense.	Organisms present in small numbers may be missed due to the dilution factor once the specimens are pooled.
Pool 3 specimens for examination; perform 1 concentration and 3 permanent stained smears	Three specimens are collected by the patient (3 separate collection vials) over 7–10 days; pooling by the laboratory for the concentration would probably be sufficient for the identification of helminth eggs. Examination of the 3 separate permanent stained smears (1 from each vial) would maximize recovery of intestinal protozoa in areas of the country where these organisms are most common.	Might miss light helminth infection (eggs, larvae) due to the pooling of the 3 specimens for the concentration; however, with a permanent stain performed on each of the 3 specimens, this approach would probably be the next best option to the standard approach (concentration and permanent stained smear performed on every stool). Coding and billing would have to match the work performed; this may present some problems where work performed does not match existing codes.

(continued)

Table A1.17 Pros and cons of stool specimen collection and testing options^a (continued)

Option ^b	Pros	Cons
Collection of 3 stools by the patient, with all 3 samples put into a single vial (patient given a single vial only)	Pooling of the specimens would require only a single vial.	This would complicate patient collection and very likely result in poorly preserved specimens, especially regarding the recommended ratio of stool to preservative and the lack of proper mixing of specimen and fixative.
<i>Immunoassays performed for selected patients,^c using methods for G. lamblia, Cryptosporidium spp., and/or the E. histolytica/E. dispar group or E. histolytica</i>	Would be more cost-effective than performing immunoassay procedures on all specimens; however, information required to group patients is often not received with specimens. <i>This approach assumes that the physicians have guidance in terms of correct ordering options (see Table A1.18).</i>	Labs rarely receive information that would allow them to place a patient in a particular risk group: children <5 yr old, children from day care centers (may or may not be symptomatic), patients with immunodeficiencies, and patients from outbreaks. Performance of immunoassay procedures on every stool sample is not cost-effective, and the positive rate will be low unless an outbreak situation is involved
<i>Immunoassays and O&P exams performed on request using methods for G. lamblia, Cryptosporidium spp., and/or E. histolytica/E. dispar group or E. histolytica (a number of variables will determine the approach to immunoassay testing and the O&P exam [geography, parasites recovered, positive rate, physician requests]; immunoassays and/or O&P exams should be separately ordered, reported, and billed)</i>	This approach limits the number of stools on which immunoassay procedures are performed for parasites. Immunoassay results do not have to be confirmed by any other tests (such as O&P exams or modified acid-fast stains). If specific kit performance problems have been identified, individual laboratories may prefer to do additional testing. <i>However, the fecal immunoassays are more sensitive than the O&P exam and special stains (modified acid-fast stains).</i> Also, this may be considered duplicate testing and may not be approved for reimbursement unless specifically ordered by the physician.	Requires education of the physician clients regarding appropriate times and patients for whom fecal immunoassays should be ordered. Educational initiatives must also include information on the test report indicating the pathogenic parasites that will not be detected by these methods. It is critical to ensure that clients know that if patients have become asymptomatic, further testing may not be required. <i>However, if the patient remains symptomatic, further testing (O&P exams) is required.</i> Remember, a single O&P exam may not reveal all organisms present. Present plan to physicians for approval: immunoassays or O&P exams, procedure discussion, report formats, clinical relevance, and limitations on each approach.

^a For further information, see the following papers. R. A. Hiatt, E. K. Markell, and E. Ng, How many stool examinations are necessary to detect pathogenic intestinal protozoa? *Am. J. Trop. Med. Hyg.* 53:36–39, 1995; K. S. C. Kehl, Screening stools for *Giardia* and *Cryptosporidium*: are antigen tests enough? *Clin. Microbiol. Newsl.* 18:133–135; 1996; A. J. Morris, M. L. Wilson, and L. B. Reller, Application of rejection criteria for stool ovum and parasite examinations, *J. Clin. Microbiol.* 30:3213–3216, 1992; D. L. Siegel, P. H. Edelstein, and I. Nachamkin, Inappropriate testing for diarrheal diseases in the hospital, *JAMA* 263:979–982, 1990.

^b O&P exam, ova and parasite examination; EIA, enzyme-linked immunoassay; FA, fluorescent-antibody immunoassay.

^c It is difficult to know when you may be in an early-outbreak situation where testing of all specimens for either *Giardia lamblia* or *Cryptosporidium* spp., or both, may be relevant. Extensive efforts are under way to encourage communication among laboratories, water companies, pharmacies, and public health officials regarding the identification of potential or actual outbreaks. If it appears that an outbreak is in the early stages, then performing the immunoassays on request can be changed to screening all stools.

Table AI.18 Approaches to stool parasitology: test ordering

Patient and/or situation	Test ordered ^a	Follow-up test ordered
Patient with diarrhea and AIDS or other cause of immune deficiency or Patient with diarrhea involved in a potential waterborne outbreak (municipal water supply)	<i>Cryptosporidium</i> or <i>Giardia/Cryptosporidium</i> immunoassay	If immunoassays are negative and symptoms continue, special tests for microsporidia (modified trichrome stain) and other coccidia (modified acid-fast stain) and O&P exam should be performed
Patient with diarrhea (nursery school, day care center, camper, backpacker) or Patient with diarrhea involved in a potential waterborne outbreak (resort setting)	<i>Giardia</i> or <i>Giardia/Cryptosporidium</i> immunoassay	If immunoassays are negative and symptoms continue, special tests for microsporidia and other coccidia (see above) and O&P exam should be performed
Patient with diarrhea and relevant travel history outside of the United States or Patient with diarrhea who is a past or present resident of a developing country or Patient in an area of the United States where parasites other than <i>Giardia</i> are found (large metropolitan centers such as New York, Los Angeles, Washington D.C., Miami, etc.)	O&P exam, ^b <i>Entamoeba histolytica/E. dispar</i> immunoassay; immunoassay for confirmation of <i>E. histolytica</i> ; various tests for <i>Strongyloides</i> may be relevant (even in the absence of eosinophilia), particularly if there is any history of pneumonia (migrating larvae in lungs), sepsis, or meningitis (fecal bacteria carried by migrating larvae); agar culture plate is the most sensitive diagnostic approach for <i>Strongyloides</i>	The O&P exam is designed to detect and identify a broad range of parasites (amebae, flagellates, ciliates, <i>Isospora belli</i> , helminths); if exams are negative and symptoms continue, special tests for coccidia (fecal immunoassays, modified acid-fast stains, autofluorescence) and microsporidia (modified trichrome stains, calcofluor white stains) should be performed; fluorescent stains are also options
Patient with unexplained eosinophilia	Although the O&P exam is recommended, the agar plate culture for <i>Strongyloides stercoralis</i> (more sensitive than the O&P exam) is also recommended, particularly if there is any history of pneumonia (migrating larvae in lungs), sepsis, or meningitis (fecal bacteria carried by migrating larvae)	If tests are negative and symptoms continue, additional O&P exams and special tests for microsporidia (modified trichrome stains, calcofluor white stains, fluorescent stains) and other coccidia (modified acid-fast stains, autofluorescence, fluorescent stains) should be performed
Patient with diarrhea (suspected food-borne outbreak)	Test for <i>Cyclospora cayetanensis</i> (modified acid-fast stain, autofluorescence, fluorescent stains)	If tests are negative and symptoms continue, special procedures for microsporidia and other coccidia and O&P exam should be performed

^a Depending on the particular immunoassay kit used, various single or multiple organisms may be included. Selection of a particular kit depends on many variables: clinical relevance, cost, ease of performance, training, personnel availability, number of test orders, training of physician clients, sensitivity, specificity, equipment, time to result, etc. Very few laboratories will handle this type of testing exactly the same. Many options are clinically relevant and acceptable for good patient care. It is critical that the laboratory report indicate specifically which organisms could be identified using the kit; a negative report should list the organisms relevant to that particular kit. It is important to remember that sensitivity and specificity data for all of these fecal immunoassay kits (fluorescent-antibody assay, enzyme immunoassay, cartridge formats) are comparable.

^b O&P exam, ova and parasite examination.

Table A1.19 Pros and cons of ova and parasite examination options^a

Testing option ^b	Pros	Cons
<i>Stools from patients who have been inpatients for at least 3 days should not be submitted for routine examinations without consulting the laboratory</i>	Normally, only very few parasitic infections can be acquired by an inpatient. Although rare, one of these infections is cryptosporidiosis, which has been documented in nosocomial transmission.	Etiologic agents other than parasites, as well as other causes such as therapy, are more likely to cause diarrhea in patients who have been hospitalized for 3 days or more. There are always exceptions, but this is a reasonable guideline to follow (see Table A1.17).
3 separate stools collected within 10 days; concentration and permanent stained smear on all specimens; if specimen is fresh (unpreserved), direct wet smear can be performed (soft, liquid specimens) for the detection of organism motility	Maximize recovery of all organisms, including those in small numbers; concentration for recovery of protozoan cysts, helminth eggs, and larvae; permanent stain for confirmation of protozoa and finding protozoa missed on concentration wet examination. Special stains or immunoassay reagents may be used for the recovery of coccidia and microsporidia.	Although this approach is the most labor intensive, the results are the most complete. ^c
3 separate stools collected within 10 days; concentration on pooled specimen, permanent stained smear on all specimens (performed as 3 separate examinations)	By pooling 3 specimens and performing one concentration and examination, time is saved. Since intestinal protozoa tend to be the most common parasites found in many areas of the United States, it is important to perform permanent stained smears on the 3 individual specimens.	If helminth eggs or larvae are present in small numbers, they may be missed. Protozoa that may be missed in small numbers will probably be identified on the individual permanent stained smears.
1 stool; concentration and permanent stained smear; additional specimens may be examined after results of the first specimen are reported	Saves time.	Organisms present in small numbers may be missed; the collection of specimens 2 or 3 may be outside the 10-day recommended time frame. The series of 3 specimens now becomes 3 series of a single specimen (depending on collection time frames). ^c
1 stool; <i>Giardia</i> and <i>Cryptosporidium</i> immunoassay ^d	This can be ordered after complete discussion with physicians so that they recognize what the results (negative) mean in terms of limitations; if negative with a patient who continues to be symptomatic, ova and parasite examinations can be ordered. In areas where <i>Giardia lamblia</i> is commonly found or in a suspect waterborne outbreak (<i>Cryptosporidium</i> or other organisms), this is an acceptable option. However, it is now clear that 2 specimens may have to be examined to confirm the presence of giardiasis.	If complete information on the relevance of a negative report is not given to the physician, this approach can be used incorrectly. It is very important that immunoassay procedures be thoroughly discussed in terms of the clinical relevance of results and the specificity and sensitivity of the methods (more sensitive than the routine ova and parasite examination).
1 stool; concentration performed; permanent stained smear performed <i>only</i> if something suspicious is seen on the concentration examination	This approach is thought to save time; however, it is unacceptable both technically and in terms of quality patient care.	Numerous studies have confirmed the importance of the permanent stain, not only in confirming the identification of intestinal protozoa <i>but also in finding organisms that were missed in the concentration examination</i> . Use of this technical approach leads to very misleading reported results and should be discouraged. If a laboratory is using this approach, the specimens for parasitology testing should be sent to another laboratory.

Examination approach

Direct wet smear: unpreserved soft or liquid stools; total 22- by 22-mm coverslip with 10× objective (low power); 1/4–1/3 of area with 40× objective (high dry power)

Concentration: total 22- by 22-mm coverslip with 10× objective (low power); 1/4–1/3 of area with 40× objective (high dry power)

Permanent stained smear: minimum of 300 fields with 100× objective (oil immersion); a 50× or 60× oil immersion lens can also be used in the examination process, but some small organisms will be missed without the use of the 100× oil immersion lens

This represents the most complete approach; however, the important point is to understand the pros and cons of any modifications to this approach. The most common change is the transition from fresh, unpreserved specimens being submitted to the laboratory to fecal specimens that are transported in fixatives. Once received by the laboratory, the direct wet smear is eliminated from the standard ova and parasite procedure (no motility is visible in preserved specimens) and only the concentration and permanent stained smear is performed.

Any modification(s) from the recommended procedures *must* be discussed thoroughly with your physician clients. It is critical that they understand the advantages and disadvantages of each approach. Information can be transmitted through various communication channels: telephone, newsletters, information updates, in-service presentations, verbal and written reminders, information via computer system, etc.

^a It is mandatory that the physicians know exactly what procedures are performed for the diagnosis of parasitic infections in your specific laboratory and how the results should be interpreted in terms of clinical relevance. It is mandatory that they be given information regarding the pros and cons (limitations) of any diagnostic approach. The complete ova and parasite examination includes direct wet smear, concentration, and permanent stained smear (fresh specimen) or concentration and permanent stained smear (preserved specimen).

^b A direct wet smear of fresh specimens (soft or liquid) should be examined for motile trophozoites. If the specimen is formed or is received in preservative, eliminate the direct wet smear examination and proceed directly to the concentration and permanent stained smear.

^c An excellent reference is R. A. Hiatt, E. K. Markell, and E. Ng, 1995, How many stool examinations are necessary to detect pathogenic intestinal protozoa? *Am. J. Trop. Med. Hyg.* 53:36–39, 1995. The sensitivity of one stool examination was compared with that of three examinations. The additional examinations increased the percent positive results as follows: 22.7% increase for *Entamoeba histolytica*, 11.3% increase for *Giardia lamblia*, and 31.1% increase for *Dientamoeba fragilis*. Even in symptomatic patients, these data indicate that examination of a single stool specimen will miss a large number of infections by pathogenic protozoa.

^d The ova and parasite examination and specific immunoassays should be separate, orderable, billable tests.

Table AI.20 Laboratory test reports: optional comments^{a,b}**1. *Entamoeba histolytica*/*E. dispar* group**

Unless you see trophozoites containing ingested RBCs (true pathogen: *E. histolytica*), you cannot tell from the organism morphology whether you have actual pathogenic *E. histolytica* organisms or nonpathogenic *E. dispar* present. Report as seen above.

Additional computer comments:

- A. Unable to determine pathogenicity from organism morphology.
- B. Unable to rule out true pathogen, *Entamoeba histolytica*.
- C. Depending on patient's clinical condition, treatment may be appropriate.

If you have the kit reagents to differentiate the two organisms,^c comments could also be added:

- A. If you wish to determine which of the two organisms is present, please submit a fresh stool specimen.
- B. To determine the presence or absence of pathogenic *E. histolytica*, submit a fresh stool specimen.

2. Identification of nonpathogens

Comments that can be used for reporting nonpathogens include the following. However, *these statements assume that a complete stool exam was performed on multiple stools*; you may detect nonpathogens in the first examination or an incomplete examination but miss a pathogen (example: *Dientamoeba fragilis* requires the permanent stained smear for identification)

Additional computer comments:

- A. Considered nonpathogenic; treatment not recommended.
- B. Nonpathogen; however, indication that patient has ingested something contaminated with fecal material.

3. Reporting *Blastocystis hominis*

Several comments are optional for reporting *Blastocystis hominis*.

- A. Clinical significance is controversial.
- B. Status as a pathogen is controversial.

You may want to add a second comment:

- A. Other organisms capable of causing diarrhea should first be ruled out.

4. Reporting *Plasmodium* spp.

If *Plasmodium* spp. are detected but you are unable to identify to the species level, report as follows.

- A. *Plasmodium* spp. seen.
- B. Unable to "rule out" *Plasmodium falciparum*.
- C. Send additional blood samples approximately every 6 h for 3 days (unless malaria is no longer a consideration).

^a It is important to remember that educational information for your clients is critical to the success of your test-reporting formats. The information in the table should be shared with your clients prior to changing your actual reporting formats. Your physician group may have a preference regarding additional comments. Information updates or newsletters are appropriate for this purpose.

^b All of the comments in the table are optional, and wording can be changed to fit your circumstances. However, it is recommended that you select specific comments and try not to use "free text," so that everyone reports test results in the same way each time.

^c It is important to remember that current fecal immunoassay kits for the detection of the *Entamoeba histolytica*/*E. dispar* group or differentiation between the true pathogen (*E. histolytica*) and the nonpathogen (*E. dispar*) require fresh or frozen fecal specimens; although preserved specimens (generally formalin base or some of the single-vial fixatives) can be used for the fecal immunoassays for *Giardia lamblia* or *Cryptosporidium* spp., they cannot be used for *Entamoeba* spp. testing.

Table AI.21 Estimated prevalence of parasitic diseases worldwide

Disease	Estimated prevalence figures
Protozoa	
Amebiasis	1% of population; annual deaths, 40,000–110,000
Giardiasis	200 million infected
Helminths (nematodes)	
Ascariasis	1.3 billion infected; annual deaths, 1,550; 320 million (35%) school-age children
Hookworm	1.3 billion infected; 233 million (25%) school-age children
Trichuriasis	900 million infected; 239 million (26%) school-age children
Strongyloidiasis	35 million infected
Trichostrongylosis	5.5 million infected
Dracunculiasis	<100,000 infected
Helminths (cestodes)	65 million infected
Helminths (trematodes)	
Schistosomiasis	200 million infected; 500 million–600 million at risk
<i>S. haematobium</i>	100 million; 56 million (Africa only)
<i>S. mansoni</i>	60 million; 25 million (Africa only)
<i>S. japonicum</i>	1.5 million; annual deaths for all species, 500,000–1 million
Clonorchiasis and opisthorchiasis	13.5 million infected
Paragonimiasis	2.1 million infected
Fasciolopsiasis	10 million infected
Helminths (filarial infections)	
Lymphatic filariasis	128 million infected; >40 million seriously incapacitated or disfigured; one-third of the people infected with the disease live in India, one-third are in Africa, and most of the remainder are in South Asia, the Pacific, and the Americas
Onchocerciasis	17.7 million infected
Blood parasites	
Malaria	400 million–490 million; annual deaths, 2.2 million–2.5 million; 40% of world's population at risk (3.2 billion); 853,000 deaths/yr in children <5 yr old (fifth leading cause of death in this age group)
Leishmaniasis	12 million infected; 1.5 million–2 million new cases each year; 90% are in 5 countries (Bangladesh, Brazil, India, Nepal, and Sudan); 90% of all cases of mucocutaneous leishmaniasis occur in Bolivia, Brazil, and Peru; 90% of all cases of cutaneous leishmaniasis occur in Afghanistan, Brazil, Iran, Peru, Saudi Arabia, and Syria, with 1 million–1.5 million new cases reported annually worldwide
African trypanosomiasis	300,000–500,000; 100,000 new cases each year; annual deaths, 5,000
American trypanosomiasis	24 million infected; 60,000 annual deaths

APPENDIX 2

Flowcharts and Staining Tables for Diagnostic Procedures

Special stains will be necessary for *Cryptosporidium* and *Cyclospora* (modified acid-fast) and the microsporidia (modified trichrome, Calcofluor). Immunoassay kits are now available for some of these organisms. If the permanent staining method (iron hematoxylin) contains a carbol fuchsin step, the coccidia will stain pink.

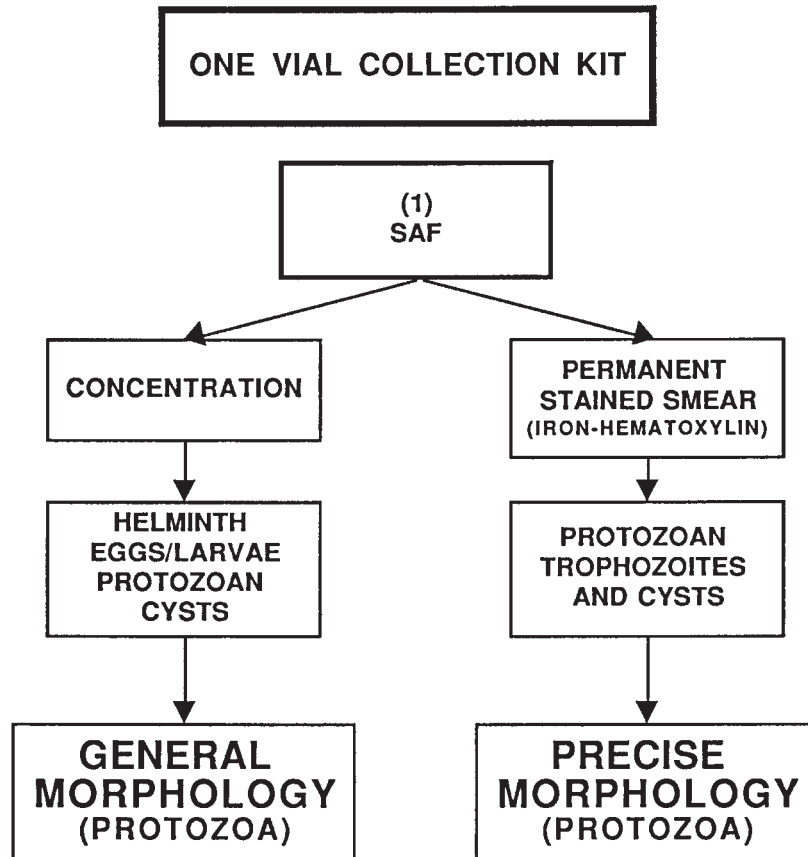

Flowchart A2.1 Procedure for processing fresh stool for the ova and parasite examination. Schaudinn's fixative can be prepared using the mercuric chloride base or the zinc sulfate base; the copper sulfate base does not produce organism morphologic quality equal to that seen with the mercuric chloride or zinc sulfate bases. The permanent stained smear can be stained using iron hematoxylin or trichrome stains. This approach includes the direct wet smear, concentration, and the permanent stained smear (complete ova and parasite examination for fresh specimen that is liquid or very soft).

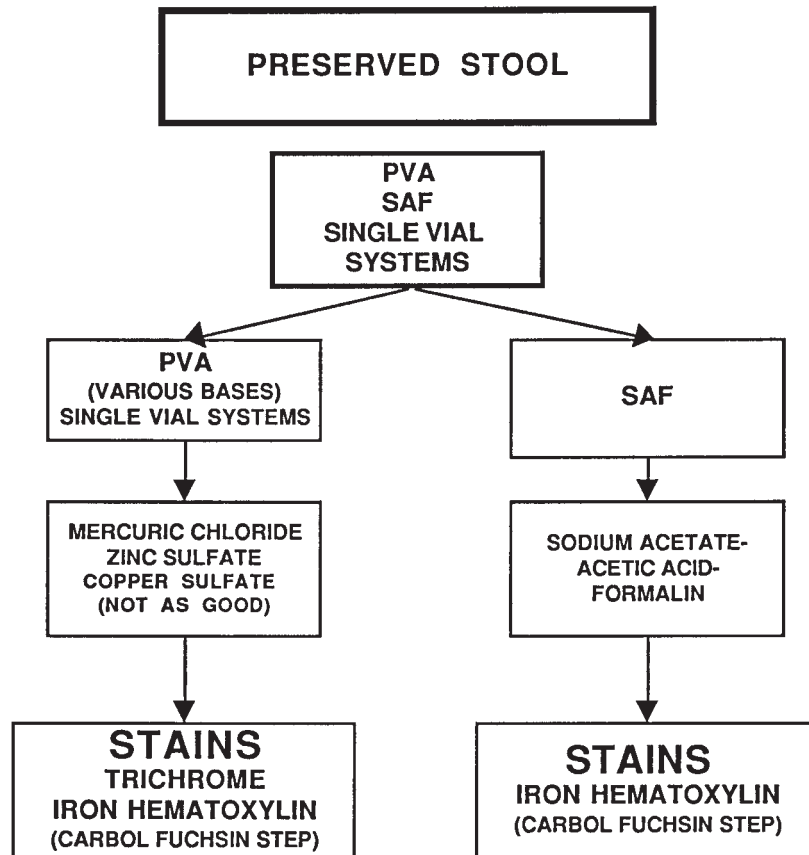

Flowchart A2.2 Procedure for processing liquid specimens for the ova and parasite examination. If the volume of the liquid stool is quite small, mixing some of the specimen with polyvinyl alcohol (PVA) fixative (Schaudinn’s fixative or other fixative containing PVA plastic powder that serves as the adhesive to “glue” the fecal material onto the glass slide) directly on the slide is recommended. Make sure that the slide is thoroughly dry before staining. NOTE: PVA FIXATIVE REFERS TO ANY LIQUID FIXATIVE INTO WHICH PVA PLASTIC POWDER HAS BEEN ADDED AS AN ADHESIVE TO “GLUE” THE FECAL MATERIAL ONTO THE SLIDE.

Flowchart A2.3 Procedure for processing preserved stool for the ova and parasite examination by using the traditional two-vial collection kit. This collection kit has been in use for many years. If the fecal specimen arrives in the laboratory in preservative, the direct wet mount for motility should not be performed. The complete ova and parasite examination consists of the concentration and permanent stained smear. PVA, polyvinyl alcohol; SAF, sodium acetate-acetic acid-formalin.

Flowchart A2.4 Procedure for processing sodium acetate-acetic acid-formalin (SAF)-preserved stool for the ova and parasite examination. SAF-preserved stool can be used with the fecal immunoassay kits (fluorescent-antibody assay, enzyme immunoassay, and cartridge formats for *Giardia lamblia* and *Cryptosporidium* spp.; kits for the true pathogen *Entamoeba histolytica* or the *Entamoeba histolytica*/*E. dispar* group require fresh or frozen stools); modified acid-fast stains for coccidia and modified trichrome stains can also be performed from SAF-preserved stool.

Flowchart A2.5 Use of various fixatives and their recommended stains. Fecal specimens preserved using polyvinyl alcohol (PVA) fixative (liquid fixative into which PVA plastic powder has been added) can be stained using either the iron hematoxylin or trichrome stains. However, fecal specimens preserved using sodium acetate-acetic acid-formalin appear to stain better using the iron hematoxylin approach. The single-vial preservatives (proprietary formulas) can be stained with iron hematoxylin, trichrome, or a manufacturer's stain prepared to accompany a particular fixative. *It is important to remember that parasite morphology (particularly intestinal protozoa) may not be as precise or clear as that seen when stool specimens are preserved in Schaudinn's fixative prepared with the mercuric chloride base (gold standard).*

Table A2.1 Steps in the trichrome staining procedure (mercuric chloride-based PVA-preserved stool specimens)

Steps in the procedure	Time	Comments
Prepare slide for staining		Can be prepared from Schaudinn's liquid fixative or from mercuric chloride-based polyvinyl alcohol (PVA)
70% ethanol	5 min	Rinses off excess Schaudinn's fixative
70% ethanol + iodine	5 min	Color should look like strong tea; iodine will remove mercury from fecal smears; 10 min may be better if staining a full rack of slides ^a
70% ethanol	5 min	Rinses off excess iodine
70% ethanol	5 min	Completes removal of iodine
Trichrome stain ^b	10 min	Both mercury and iodine have been removed prior to placing the smears in stain
90% ethanol + acetic acid	Several dips	This begins the destaining process; it is important to move the smears rapidly from this dish to the next so that the destaining does not continue too long
95 or 100% ethanol	Several dips	This step removes the acidified alcohol, preventing the decolorizing step from continuing
100% ethanol	3–5 min	This step begins the dehydration process, in which all moisture is removed from the smear
100% ethanol	3–5 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process completed
Permout slides or allow them to air dry with no coverslip (see Table A2.6)		Permouted slides should be allowed to dry; they can be placed on trays and put in the incubator for 30 min or overnight; room temperature overnight is also sufficient

^a The iodine-alcohol does not require an exact concentration. The color should not be too dark or the iodine will stain the protozoa, interfering with the subsequent trichrome staining; however, the color should not be too light or the mercuric chloride in the fixative will not be removed and mercuric chloride residue in the stained fecal smear will interfere with examination. Again, a strong-tea color is preferred (do not use "port wine" as a potential color intensity guide; this color is too dark).

^b The trichrome staining procedure is a "regressive staining method" in which the fecal smears are overstained and then destained to provide better color and contrast.

Table A2.2 Steps in the trichrome staining procedure (non-mercuric chloride-based PVA-preserved stool specimens)

Steps in the procedure	Time	Comments
Prepare slide for staining		Can be prepared from non-mercuric chloride-based Schaudinn's fixative, with polyvinyl alcohol (PVA); examples would be Schaudinn's fixative prepared with the zinc sulfate or copper sulfate bases
70% ethanol	5 min	This dish is optional; a rinse can be used for dry smears (PVA) or from liquid Schaudinn's liquid fixative
Trichrome stain ^a	10 min	Since no mercury was present on the smear, there was no need to use the iodine dish; however, when staining proficiency-testing specimens that have been preserved in mercuric chloride-based fixatives, the iodine dish and subsequent rinse steps must be added back into your staining protocol; some proficiency-testing agencies are now using fecal specimens preserved in fixatives containing no mercury; it is important to know what type of fixative was used prior to staining
90% ethanol + acetic acid	Several dips	This begins the destaining process; it is important to move the smears rapidly from this dish to the next so that the destaining does not continue too long
95 or 100% ethanol	Several dips	This step removes the acidified alcohol, preventing the decolorizing step from continuing
100% ethanol	3–5 min	This step begins the dehydration process, in which all moisture is removed from the smear
100% ethanol	3–5 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process completed
Permout slides or allow them to air dry with no coverslip (see Table A2.6)		Permouted slides should be allowed to dry; they can be placed on trays and put in the incubator for 30 min or overnight; room temperature overnight is also sufficient

^a The trichrome staining procedure is a "regressive staining method" in which the fecal smears are overstained and then destained to provide better color and contrast.

Table A2.3 Steps in the iron hematoxylin staining procedure (mercuric chloride-based PVA-preserved stool specimens) (Spencer-Monroe method)

Steps in the procedure	Time	Comments
Prepare slide for staining		Can be prepared from Schaudinn's liquid fixative or mercuric chloride-based polyvinyl alcohol (PVA); sodium acetate-acetic acid-formalin (SAF)-preserved specimens are also recommended
70% ethanol	5 min	Rinses off excess Schaudinn's fixative
70% ethanol + iodine	5 min	Color should look like strong tea; iodine will remove mercury from fecal smears; 10 min may be better if staining a full rack of slides ^a
70% ethanol (begin the process for SAF-preserved smears or non-mercuric chloride-preserved specimens at this point)	5 min	Rinses off excess iodine
Rinse in running tap water	10 min	Use a constant stream of water running into the container
Place in iron hematoxylin working solution	4–5 min	This step is the staining process
Rinse in running tap water	10 min	Use a constant stream of water running into the container
70% ethanol	5 min	This step begins the dehydration process in which all moisture is removed from the smear
95% ethanol	5 min	Dehydration process continues
100% ethanol	3–5 min	Dehydration process continues
100% ethanol	3–5 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process completed
Permunt slides or allow them to air dry with no coverslip (see Table A2.6)		Permunt slides should be allowed to dry; they can be placed on trays and put in the incubator for 30 min or overnight; room temperature overnight is also sufficient

^a The iodine-alcohol does not require an exact concentration. The color should not be too dark, or the iodine will stain the protozoa, interfering with the subsequent trichrome staining; however, the color should not be too light or the mercuric chloride in the fixative will not be removed and mercuric chloride residue in the stained fecal smear will interfere with examination. Again, a strong-tea color is preferred (do not use "port wine" as a potential color intensity guide; this color is too dark).

Table A2.4 Steps in the iron hematoxylin staining procedure (mercuric chloride-based PVA-preserved stool specimens) (Tompkins-Miller method)

Steps in the procedure	Time	Comments
Prepare slide for staining		Can be prepared from Schaudinn's liquid fixative or mercuric chloride-based polyvinyl alcohol (PVA); sodium acetate-acetic acid-formalin (SAF)-preserved specimens are also recommended
70% ethanol	5 min	Rinses off excess Schaudinn's fixative
70% ethanol + iodine	5 min	Color should look like strong tea; iodine will remove mercury from fecal smears; 10 min may be better if staining a full rack of slides ^a
50% ethanol (begin the process for SAF-preserved smears or non-mercuric chloride-preserved specimens at this point)	5 min	Rinses off excess iodine
Rinse in running tap water	3 min	Use a constant stream of water running into the container
Place in 4% ferric ammonium sulfate mordant	5 min	This prepares the smear to take up the stain
Rinse in running tap water	1 min	Use a constant stream of water running into the container
Place in 0.5% aqueous hematoxylin	2 min	This begins the staining process
Rinse in running tap water	1 min	Use a constant stream of water running into the container
Place in 2% phosphotungstic acid	2–5 min	This provides the destaining process ^b
Rinse in running tap water	10 min	Use a constant stream of water running into the container
70% ethanol + a few drops of saturated aqueous lithium carbonate	3 min	The purpose of this step is to “blue up” the color
95% ethanol	5 min	This step begins the dehydration process in which all moisture is removed from the smear
100% ethanol	3–5 min	Dehydration process continues
100% ethanol	3–5 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process completed
Permount slides or allow them to air dry with no coverslip (see Table A2.6)		Permounted slides should be allowed to dry; they can be placed on trays and put in the incubator for 30 min or overnight; room temperature overnight is also sufficient

^a The iodine-alcohol does not require an exact concentration. The color should not be too dark or the iodine will stain the protozoa, interfering with the subsequent trichrome staining; however, the color should not be too light or the mercuric chloride in the fixative will not be removed and mercuric chloride residue in the stained fecal smear will interfere with examination. Again, a strong-tea color is preferred (do not use “port wine” as a potential color intensity guide; this color is too dark).

^b Like the trichrome stain, this iron hematoxylin staining procedure is a “regressive staining method” in which the fecal smears are overstained and then destained to provide better color and contrast.

Table A2.5 Steps in the iron hematoxylin staining procedure (incorporating the carbol fuchsin step)^a

Steps in the procedure	Time	Comments
Prepare slide for staining		Can be prepared from SAF-preserved specimens (SAF sediment placed on albumin-coated slides); specimens preserved in Schaudinn's fixative and/or PVA are not recommended (any preservative containing mercuric chloride or PVA powder is not recommended)
70% ethanol	5 min	Helps "glue" the material onto the slide
Rinse in container of tap water	2 min	Do not use running water
Place in Kinyoun's stain	5 min	Stains for modified acid-fast characteristics
Rinse in running tap water	1 min	Use a constant stream of water running into the container
Acid-alcohol decolorizer (0.5% acid-alcohol)	4 min	This must not be too strong or <i>Cyclospora cayetanensis</i> will decolorize too much ^b
Rinse in running tap water	1 min	Use a constant stream of water running into the container
Place in iron hematoxylin working solution	8 min	This begins the staining process
Rinse in container of tap water	1 min	Do not use running water
Place in picric acid solution	3–5 min	This step differentiates the hematoxylin stain
Rinse in running tap water	10 min	Use a constant stream of water running into the container
70% ethanol + some ammonia to bring pH to 8.0	3 min	The purpose of this step is to "blue up" the color
95% ethanol	5 min	This step begins the dehydration process
100% ethanol	3–5 min	Dehydration process continues
100% ethanol	3–5 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process continues
Xylene or xylene substitute	5–10 min	Dehydration process completed
Permunt slides or allow them to air dry with no coverslip (see Table A2.6)		Permunt slides should be allowed to dry; they can be placed on trays and put in the incubator for 30 min or overnight; room temperature overnight is also sufficient

^a This staining approach not only stains the intestinal protozoa (iron hematoxylin) but also stains the coccidia (*Cryptosporidium* spp., *Cyclospora cayetanensis*, and *Isospora belli*), which are modified acid-fast positive.

^b This iron hematoxylin staining procedure is a "regressive staining method" in which the fecal smears are overstained and then destained to provide better color and contrast.

Table A2.6 Oil-mounted permanent stained smears (no Permout is used)

Steps in the procedure	Time	Comments
Remove stained smears from last dehydration step (xylene or xylene substitute) and place them flat on paper towels to dry	Allow to dry for 10 min	If using a xylene substitute, the smears will take longer to dry; leave on paper towels for 15–20 min
Once the fecal smears are dry, place 1 to 2 drops of immersion oil onto the dry fecal smear	3–5 min	Allow the oil to “sink into” the dry fecal smear; if the smears are somewhat thick, wait 10–15 min before microscopic examination
Place a no. 1 coverslip onto the fecal smear/oil combination	No waiting time required	A 22- by 22-mm coverslip is recommended; the addition of the coverslip will prevent damage to the oil lens when microscopic examination begins; when fecal material on the smear has been thoroughly dehydrated, the material may be hard/brittle and could scratch the oil lens if not protected
Add 1 drop of immersion oil to the top of the coverslip ^a	No waiting time required	The fecal smear is now ready to examine using the oil immersion objective (100× lens for a total magnification of ×1,000)

^a The layers are as follows: glass slide, fecal smear, immersion oil, coverslip, immersion oil; this approach works quite well and is a substitute for the use of Permout or other mounting fluids. If a positive smear is found, the oil can be removed in xylene or xylene substitute and mounted with Permout and a coverslip in the normal way. The negative slides can be stored in a slide box that is recycled every month or so, and the old slides can then be discarded.

Table A2.7 Tips on stool processing and staining

Processing or staining step	Commentary and tips
Direct wet mount, water or saline	In general, organisms do not like distilled water; even in saline, trophozoites may not maintain adequate morphology very long; even with viable organisms, motility may be difficult to see (lower microscope light intensity); direct wet mounts should be prepared on liquid or very soft stools only (more formed stools usually do not contain any trophozoites)
Direct wet mount, iodine	If the iodine is too dark, it may interfere with helminth egg detection; eggs resemble debris and/or artifacts; internal protozoan morphology may be too dark; iodine should be the color of strong tea; iodine kills the organisms, so that no motility will be seen
Concentration-sedimentation	Rinse solutions can be water, saline, or formalin (regular 5% or 10% solution); do not rinse too many times (the supernatant fluid does <i>not</i> have to be clear); although a cleaner sediment may be easier to read, too much rinsing results in loss of organisms; a dirtier sediment is preferred to maximize organism detection; do not make coverslip preparations too thick (thinner is preferable); every centrifugation step should be at $500 \times g$ for 10 min
Concentration-flotation	Rinse solutions can be water, saline, or formalin (regular 5% or 10% solution); do not rinse too many times (the supernatant fluid does <i>not</i> have to be clear); the more you rinse, the more likely you are to lose organisms each time; many labs use a single rinse or two at the most; it is important to use zinc sulfate of the correct specific gravity (1.18 for non-formalin-fixed material, 1.20 for specimens received in formalin); both the surface film and sediment must be examined (not all parasites float in the zinc sulfate method)
Permanent stained smear-smear preparation	The smear should be neither too thick nor too thin (you should be able to read newsprint through the fecal smear); if using polyvinyl alcohol (PVA)-preserved specimens, make sure that the excess PVA is removed from the stool prior to smear preparation (absorb excess PVA from specimen by placing a bit of specimen onto paper towels, wait a few minutes, and then prepare smears); smears should be thoroughly dry prior to staining (with the exception of using liquid Schaudinn's fixative); formalin-fixed stool is not appropriate for permanent staining
Permanent stained smear-staining	If specimen is preserved in a fixative containing mercuric chloride, it is mandatory that all mercury be removed prior to staining (iodine and subsequent alcohol steps); dehydration (moisture removal) must be complete or protozoan morphology will be difficult to see; the best dehydration is obtained with absolute ethanol; if the "commercial" absolute alcohol is used (ethanol plus other alcohols), the dehydration is not as complete, so dishes containing this solution must be changed more often (at least weekly and every few days if staining more than a few slides at a time); xylene substitutes do not dehydrate as well as xylene (dishes must be changed more often); xylene substitutes take longer to dry; however, slides must be thoroughly dry prior to mounting with immersion oil (see Table A2.6); formalin-fixed stool is not appropriate for permanent staining

APPENDIX 3

Common Problems in Parasite Identification

The drawings (except Figure A3.26) are reprinted from H. D. Isenberg, ed., *Clinical Microbiology Procedures*

Handbook, 2nd ed., ASM Press, Washington, D.C., 2004. Other confusing artifacts can be seen in chapter 34.

Figure A3.1 (a) *Entamoeba histolytica/E. dispar* trophozoite. Note the evenly arranged nuclear chromatin, central compact karyosome, and relatively clean cytoplasm. (b) *Entamoeba coli* trophozoite. Note the unevenly arranged nuclear chromatin, eccentric karyosome, and messy cytoplasm. These characteristics are very representative of the two organisms. (Illustration by Sharon Belkin.)

Figure A3.2 (a) *Entamoeba histolytica/E. dispar* trophozoite. Note the evenly arranged nuclear chromatin, central compact karyosome, and clean cytoplasm. (b) *Entamoeba coli* trophozoite. Note that the nuclear chromatin appears to be evenly arranged, the karyosome is central (but more diffuse), and the cytoplasm is messy, with numerous vacuoles and ingested debris. The nuclei of these two organisms tend to resemble one another (a very common finding in routine clinical specimens). (Illustration by Sharon Belkin.)

Figure A3.3 (a) *Entamoeba histolytica/E. dispar* trophozoite. Again, note the typical morphology (evenly arranged nuclear chromatin, central compact karyosome, and relatively clean cytoplasm). (b) *Entamoeba coli* trophozoite. Although the nuclear chromatin is eccentric, note that the karyosome seems to be compact and central. However, note the various vacuoles containing ingested debris. These organisms show some characteristics that are very similar (very common in clinical specimens). (Illustration by Sharon Belkin.)

Figure A3.4 (Top row) *Entamoeba histolytica/E. dispar* trophozoites shown in a wet preparation (left) and a permanent stained smear (right). (Middle row) *Entamoeba histolytica/E. dispar* trophozoite in permanent stained smear (left); *Entamoeba coli* trophozoite in permanent stained smear (right). (Bottom row) *Entamoeba histolytica/E. dispar* trophozoite in permanent stained smear (left); *Entamoeba coli* trophozoite in permanent stained smear (right). Note the differences in the nucleus and cytoplasm: *Entamoeba histolytica/E. dispar* has even nuclear chromatin, central karyosome, and clean cytoplasm, whereas *Entamoeba coli* has uneven nuclear chromatin, eccentric karyosome, and messy/dirty cytoplasm. However, often there are nuclear and cytoplasmic characteristics that are not specific for one species or another; too many characteristics are seen that resemble either or both species.

Figure A3.5 (a) *Entamoeba histolytica* trophozoite. Note the evenly arranged nuclear chromatin, central compact karyosome, and red blood cells (RBCs) in the cytoplasm. (b) Human macrophage. The key difference between the macrophage nucleus and that of *E. histolytica* is the size. Usually the ratio of nucleus to cytoplasm in a macrophage is approximately 1:6 or 1:8, while the true organism has a nucleus-to-cytoplasm ratio of approximately 1:10 or 1:12. The macrophage also contains ingested RBCs. In patients with diarrhea or dysentery, trophozoites of *E. histolytica* and macrophages are often confused, occasionally leading to a false-positive diagnosis of amebiasis when no parasites are present. Both the actual trophozoite and the macrophage may also be seen without ingested RBCs and can mimic one another. (Illustration by Sharon Belkin.)

Figure A3.6 *Entamoeba histolytica* trophozoites on permanent stained smears; note the evenly arranged nuclear chromatin, central karyosome, and ingested RBCs. The presence of the ingested RBCs indicates the presence of the true pathogen, *E. histolytica*. Without the presence of ingested RBCs, the organism would have been identified as *Entamoeba histolytica/E. dispar* (it is impossible to determine pathogenicity from the morphology on the permanent stained smear).

Figure A3.7 (a) *Entamoeba histolytica*/*E. dispar* precyst. Note the enlarged nucleus (prior to division) with evenly arranged nuclear chromatin and central compact karyosome. Chromatoidal bars (rounded ends with smooth edges) are also present in the cytoplasm. (b) Polymorphonuclear leukocyte (PMN). The nucleus is somewhat lobed (normal morphology) and represents a PMN that has not been in the gut very long. Occasionally, the positioning of the chromatoidal bars and the lobed nucleus of the PMN will mimic one another. The chromatoidal bars stain more intensely, but the shapes can overlap, as seen here. (Illustration by Sharon Belkin.)

Figure A3.8 (a) *Entamoeba histolytica*/*E. dispar* mature cyst. Note that the four nuclei are very consistent in size and shape. (b) PMN. Note that the normal lobed nucleus has now broken into four fragments, which mimic four nuclei with peripheral chromatin and central karyosomes. When PMNs have been in the gut for some time and have begun to disintegrate, the nuclear morphology can mimic that seen in an *E. histolytica*/*E. dispar* cyst. However, human cells are often seen in the stool in patients with diarrhea; with rapid passage of the gastrointestinal tract contents, there will not be time for amebic cysts to form. Therefore, for patients with diarrhea and/or dysentery, if “organisms” that resemble the cell in panel b are seen, think first of PMNs, not *E. histolytica*/*E. dispar* cysts. (Illustration by Sharon Belkin.)

Figure A3.9 *Entamoeba histolytica*/*E. dispar* cysts in permanent stained smears. Note the four nuclei and chromatoidal bar with smooth, rounded ends. From the cyst morphology, it is impossible to differentiate between the true pathogen *E. histolytica* and the nonpathogen *E. dispar*.

Figure A3.10 Human cells in permanent stained smears. (Left) Macrophage. Note the large size of the nucleus (the ratio of nucleus to cytoplasm is much larger than in the amebae in the genus *Entamoeba*). (Right) PMN. Note the lobed nucleus; when the lobes break apart, the “individual nuclei” can mimic those seen in amebae.

Figure A3.11 (a) *Endolimax nana* trophozoite. This organism is characterized by a large karyosome with no peripheral chromatin, although many nuclear variations are normally seen in any positive specimen. (b) *Dientamoeba fragilis* trophozoite. Normally, the nuclear chromatin is fragmented into several dots (often a “tetrad” arrangement). The cytoplasm is normally more “junky” than that seen in *E. nana*. If the morphology is typical, as in these two illustrations, differentiating between these two organisms is not very difficult. However, the morphologies of the two are often very similar. (Illustration by Sharon Belkin.)

Figure A3.12 (a) *Endolimax nana* trophozoite. Note that the karyosome is large and surrounded by a “halo,” with very little chromatin on the nuclear membrane. (b) *Dientamoeba fragilis* trophozoite. In this organism, the karyosome is beginning to fragment and there is a slight clearing in the center of the nuclear chromatin. If the nuclear chromatin has not become fragmented, *D. fragilis* trophozoites can very easily mimic *E. nana* trophozoites. This could lead to a report indicating that no pathogens were present when, in fact, *D. fragilis* is now considered a definite cause of symptoms. (Illustration by Sharon Belkin.)

Figure A3.13 (Left) *Endolimax nana* trophozoite (note the large karyosome and no peripheral chromatin). (Right) *Dientamoeba fragilis* with a single nucleus (note the clearing within the karyosome, indicating that the chromatin is beginning to fragment into the chromatin dots).

Figure A3.14 *Dientamoeba fragilis* trophozoites. (Left) Trophozoite with single nucleus fragmented into four chromatin dots. (Right) Trophozoite with two nuclei, each of which is fragmented into chromatin dots.

Figure A3.15 (a) *Endolimax nana* trophozoite. Note the large karyosome surrounded by a clear space. The cytoplasm is relatively clean. (b) *Iodamoeba bütschlii* trophozoite. Although the karyosome is similar to that of *E. nana*, note that the cytoplasm in *I. bütschlii* is much more heavily vacuolated and contains ingested debris. Often, these two trophozoites cannot be differentiated. However, the differences in the cytoplasm are often helpful. There is a definite size overlap between the two genera. (Illustration by Sharon Belkin.)

Figure A3.16 (Left) *Endolimax nana* trophozoite (as seen in Figure A3.13) (note the large single karyosome without any peripheral chromatin). (Right) *Iodamoeba bütschlii* trophozoite (note the large karyosome, some light peripheral nuclear chromatin, and the messy/dirty cytoplasm containing many vacuoles).

Figure A3.17 (a) RBCs on a stained fecal smear. Note that the cells are very pleomorphic but tend to be positioned in the direction in which the stool was spread onto the slide. (b) Yeast cells on a stained fecal smear. These cells tend to remain oval and are not aligned in any particular way on the smear. These differences are important when the differential identification is between *Entamoeba histolytica* containing RBCs and *Entamoeba coli* containing ingested yeast cells. If RBCs or yeast cells are identified in the cytoplasm of an organism, they must also be visible in the background of the stained fecal smear. (Illustration by Sharon Belkin.)

Figure A3.18 (a) *Entamoeba histolytica*/*E. dispar* cyst. Note the shrinkage due to dehydrating agents in the staining process. (b) *E. histolytica*/*E. dispar* cyst. In this case, the cyst exhibits no shrinkage. Only three of the four nuclei are in focus. Normally, this type of shrinkage is seen with protozoan cysts and is particularly important when a species is measured and identified as either *E. histolytica*/*E. dispar* or *Entamoeba hartmanni*. The whole area, including the halo, must be measured prior to species identification. If just the cyst is measured, the organism would be identified as *E. hartmanni* (nonpathogenic) rather than *E. histolytica*/*E. dispar* (possibly pathogenic). (Illustration by Sharon Belkin.)

Figure A3.19 (a) *Plasmodium falciparum* rings. Note the two rings in the RBC. Multiple rings per cell are more typical of *P. falciparum* than of the other species causing human malaria. (b) *Babesia* rings. One of the RBCs contains four small *Babesia* rings. This particular arrangement is called the Maltese cross and is diagnostic for *Babesia* spp. (although this configuration is not always seen). *Babesia* infections can be confused with cases of *P. falciparum* malaria, primarily because multiple rings can be seen in the RBCs. Another difference involves ring morphology. *Babesia* rings are often of various sizes and tend to be very pleomorphic, while those of *P. falciparum* tend to be more consistent in size and shape. (Illustration by Sharon Belkin.)

Figure A3.20 (Left) *Plasmodium falciparum* rings. Note the “clean” morphology and headphone appearance of some of the rings; also note the appliqué forms. (Right) *Babesia* spp. Note the “messy/pleomorphic” rings and the presence of the Maltese cross configuration of four rings within a single RBC; this does not occur in every species of *Babesia*.

Figure A3.21 (a) *Strongyloides stercoralis* rhabditiform larva. Note the short buccal capsule (mouth opening) and the internal structure, including the genital primordial packet of cells. (b) Root hair (plant material). Note that there is no specific internal structure and the end is ragged (where it was broken off from the main plant). Plant material often mimics some of the human parasites. This comparison is one of the best examples. These artifacts are occasionally submitted as proficiency-testing specimens. (Illustration by Sharon Belkin.)

Figure A3.24 (Left) *Taenia* egg, showing the striated shell and six-hooked embryo (oncosphere) within the egg shell. (Right) Pollen grain that can resemble an actual *Taenia* egg. Note that the shape may vary, especially depending on the way the pollen grain is lying in the wet preparation.

Figure A3.22 (Left) Root hair artifact that resembles actual nematode larva. (Right) *Strongyloides stercoralis* rhabditiform larva. Note the internal structures, especially the large, genital primordium packet of cells.

Figure A3.25 (a) *Trichuris trichiura* egg. This egg is typical and is characterized by the barrel shape with thick shell and two polar plugs. (b) Bee pollen. This artifact certainly mimics the *T. trichiura* egg. However, note that the shape is somewhat distorted. This is an excellent example of a parasite look-alike that could be confusing. (Illustration by Sharon Belkin.)

Figure A3.23 (a) *Taenia* egg. This egg has been described as having a thick, radially striated shell containing a six-hooked embryo (oncosphere). (b) Pollen grain. Note that this trilobed pollen grain has a similar type of “shell” and, if turned the right way, could resemble a *Taenia* egg. This similarity represents another source of confusion between a helminth egg and a plant material artifact. When examining fecal specimens in a wet preparation, you can tap on the coverslip to get objects to move around. As they move, you can see more morphologic detail. (Illustration by Sharon Belkin.)

Figure A3.26 Relative sizes of helminth eggs.

Table A3.1 Adult nematodes and/or larvae found in stool specimens: size comparisons

Nematodes	Size
<i>Ascaris lumbricoides</i>	
Adult female	200–350 by 4–6 mm
Adult male	150–200 by 2–4 mm
<i>Trichuris trichiura</i>	
Adult female	35–50 mm
Adult male	30–45 mm
<i>Enterobius vermicularis</i>	
Adult female	8–13 mm
Adult male	2–5 mm
Hookworms (<i>Ancylostoma duodenale</i> and <i>Necator americanus</i>)	
Adult female	8–11 by 0.45 mm
Adult male	10–13 by 0.6 mm
Filariform larva	700 by 20 μ m
Rhabditiform larva	250 by 20 μ m
<i>Strongyloides stercoralis</i>	
Filariform larva	600 by 20 μ m
Rhabditiform larva	250 by 20 μ m
<i>Trichinella spiralis</i>	
Adult female	3–4 by 0.6 mm
Adult male	1.5 by 0.045 mm
Larva	90–100 by 6 μ m
Microfilariae	
<i>Wuchereria bancrofti</i>	230–320 by 10 μ m
<i>Brugia malayi</i>	170–260 by 5–6 μ m
<i>Loa loa</i>	250–300 by 6–8.5 μ m
Adult female	70 by 0.5 mm
Adult male	30–36 by 0.6 mm
<i>Onchocerca volvulus</i>	150–368 by 5–9 μ m
Adult female	34–50 cm by 270–400 μ m
Adult male	19–42 cm by 130–210 μ m
<i>Mansonella perstans</i>	200 by 4.5 μ m
<i>Mansonella streptocerca</i>	180–240 by 3 μ m
<i>Mansonella ozzardi</i>	175–240 by 4.5 μ m
<i>Dracunculus medinensis</i>	
Adult female	500–1,200 by 0.9–1.7 mm
Adult male	12–29 by 0.4 mm
Larva	500–750 by 15–25 μ m
<i>Gnathostoma spinigerum</i>	
Adult female	25–54 mm
Adult male	11–25 mm

^a Tests for the *Entamoeba histolytica*/*E. dispar* group or *E. histolytica* require the use of fresh or fresh, frozen stools. All other tests (with the exception of DFA for the *Cryptosporidium*-*Giardia* combination) can be used with fresh or preserved stools (formalinized base, not polyvinyl alcohol; some single-vial systems may be acceptable, so consult the manufacturer). Since the combination *Cryptosporidium*-*Giardia* tests (DFA) are based on visual recognition of the fluorescing oocysts and/or cysts, the specimens must not be frozen if fresh stools are used for testing. DFA, direct fluorescent-antibody assay; EIA, enzyme immunoassay.

---	---

^a Modified from H. D. Isenberg, ed., *Clinical Microbiology Procedures Handbook*, 2nd ed. ASM Press, Washington, D.C., 2004. Much of the updated immunology testing information was provided by Marianna Wilson (CDC). Abbreviations: DFA, direct fluorescent-antibody assay; EIA, enzyme immunoassay; IB, immunoblot; IFA, indirect fluorescent-antibody assay; IgG, immunoglobulin G; LA, latex agglutination; PVA, polyvinyl alcohol; QC, quality control; Rapid, rapid immunochromatographic.

^b Not cleared by the Food and Drug Administration for in vitro diagnostic use.

APPENDIX 7

Color Plates of Diagnostic Stages of Human Parasites

Plate 1 (see p. 1108) Unless so noted, the protozoa in this plate were photographed using the oil immersion lens from trichrome-stained smears. (A) *Entamoeba histolytica* trophozoite. Note the ingested red blood cells (RBCs) within the cytoplasm and in the background. (B) *Entamoeba histolytica*/*E. dispar* trophozoite Merthiolate-iodine-formalin [MIF], polychrome stain). Note the evenly distributed nuclear chromatin and central karyosome. Trophozoites containing no RBCs are very typical; the presence of RBCs in the cytoplasm is the exception. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (C) *Entamoeba histolytica*/*E. dispar* precyst. Note the enlarged nucleus (prior to division) and presence of chromatoidal bars. (D) *Entamoeba histolytica*/*E. dispar* cyst. Note the multiple nuclei and the chromatoidal bars with smooth, rounded edges. Also note the “halo” due to shrinkage. (E) *Entamoeba hartmanni* trophozoites. Note the absence of RBCs. The nucleus mimics that seen with *E. histolytica* (evenly distributed nuclear chromatin and central karyosome). (F) *Entamoeba hartmanni* cyst. Although the mature cyst contains four nuclei, cysts are often seen with one (precyst) or two. Note the numerous chromatoidal bars; these are similar to those seen with *E. histolytica*/*E. dispar* (smooth, rounded edges). (G) *Entamoeba coli* trophozoite. Note the uneven nuclear chromatin and eccentric karyosome. (Courtesy of Parasitology Training Branch, Centers for Disease Control and Prevention.) (H) *Entamoeba coli* cyst (iodine stain, wet mount). The presence of five or more nuclei allows the identification to be made. These cysts are usually seen more clearly in wet preparations; they may be shrunk or distorted in the permanent stained smear (see panel I). (I) *Entamoeba coli* cyst. Note the shrinkage and pink color; this is typical on the permanent stained smear. (From L. S. Garcia, in S. M. Finegold and E. J. Baron, *Diagnostic Microbiology*, 7th ed., The C. V. Mosby Co., St. Louis, Mo., 1986.) (J) *Entamoeba coli* cyst. This is an excellent example of an *E. coli* cyst on the permanent stained smear; the presence of five or more nuclei allows this identification. (K) *Endolimax nana* trophozoites. Note the large karyosome and lack of peripheral chromatin. The organism on the right is an excellent example of “nuclear variation,” where the nuclear chromatin displays unusual shapes. Nuclear variation is more common in *E. nana* than any of the other protozoa. (L) *Endolimax nana* cyst. Note the typical oval shape (they can also be round) and the presence of four karyosomes. (M) *Iodamoeba bütschlii* trophozoites. Note the large karyosome,

vacuolated cytoplasm, and size (compared with *E. nana*). (N) *Iodamoeba bütschlii* cysts. Note the large glycogen vacuole and “basket nucleus” (chromatin granules at one edge of the nuclear membrane; karyosome appears to be the basket, with the chromatin granules being the handle [use your imagination!]). (O) *Blastocystis hominis*. The “central body form” of this protozoan appears in an iodine preparation, and the frame on the right contains organisms on the permanent stained smear (photographed at a lower magnification; organisms overlap sizes of other protozoa). (P) *Dientamoeba fragilis* trophozoites. These organisms are characterized by having either one or two nuclei (nuclear chromatin frequently fragmented). There is no known cyst form. (Q) *Giardia lamblia* trophozoite. Note the two nuclei, curved median bodies, and linear axonemes. (R) *Giardia lamblia* cysts. Although these cysts are oval, some *G. lamblia* cysts appear more round (iron hematoxylin stain). (S) *Giardia lamblia* cyst. The nuclei, median bodies, and axonemes are clearly visible in this cyst. Frequently, the internal structures are not this clearly seen (iron hematoxylin stain). (T) *Chilomastix mesnili* trophozoites and cyst. The three trophozoites are characterized by the clear “oral groove” (feeding groove) seen coming down from the nucleus at the left side of the trophozoites. Without being able to see this oral groove, the identification of this trophozoite is very difficult. In the cyst (right frame) the “shepherd’s crook,” the curved fibril to the right of the nucleus, can be seen. (U) *Trichomonas vaginalis* trophozoites (Giemsa stain). Note the undulating membrane, flagella, and linear axostyle (penetrates the end of the organism). (V) *Trichomonas vaginalis* trophozoite (Giemsa stain). Note the undulating membrane, flagella, and axostyle. (W) *Balantidium coli* trophozoite. Note the large macronucleus and cilia; this organism is from an iodine preparation and is photographed at a lower magnification. (From L. S. Garcia, in E. J. Baron and S. M. Finegold, *Diagnostic Microbiology*, 8th ed., The C. V. Mosby Co., St. Louis, Mo., 1990.) (X) *Balantidium coli* in tissue (routine histologic preparation). Note the macronucleus that is partially visible in one of the trophozoites.

Plate 2 (see p. 1109) (A) Charcot-Leyden crystals (trichrome stain, oil immersion). Note the characteristic shape; various sizes are present in a single specimen. The presence of these crystals indicates an immune response, not necessarily directed against parasites. (B) Budding yeast cells and pseudohyphae (trichrome

stain, oil immersion). (C) White blood cells (polymorphonuclear leukocytes [PMNs], eosinophils; trichrome stain, oil immersion). These cells can easily be confused with actual intestinal protozoa (PMN = *E. histolytica*/*E. dispar* cyst; macrophage = *E. histolytica*/*E. dispar* trophozoite). (D) White blood cells (PMNs; trichrome stain, oil immersion). Notice how the normally lobed nucleus begins to disintegrate and break into separate pieces. When this occurs, these human cells can be confused with *E. histolytica*/*E. dispar* cysts (the PMN may even contain four nuclear fragments, each having a “protozoan-like” nucleus). Human white blood cells have more nuclear material per cell than do the true protozoa. (E) Macrophage (trichrome stain, oil immersion). Note the large nucleus with a karyosome. These cells can often mimic *E. histolytica*/*E. dispar* trophozoites. However, the ratio of nuclear material to cytoplasm in these cells is large (1/6) compared with an *E. histolytica*/*E. dispar* trophozoite (1/10 to 1/12). (F) *Pneumocystis jiroveci* trophozoites (Giemsa stain). With this stain, the cyst wall does not stain; however, the trophozoites within the cyst wall can be seen. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (G) *Pneumocystis jiroveci* cysts (Gomori methenamine silver stain). Note the “parentheses” within the cyst (two commas facing one another). (H) *Pneumocystis jiroveci* cysts (calcofluor white fluorescent stain). (Courtesy of Susan Novak.) (I) *Pneumocystis jiroveci* cysts and trophozoites (monoclonal antibody fluorescent stain). (Courtesy of Meridian Diagnostics, Inc., Cincinnati, Ohio.) (J) *Toxoplasma gondii* bradyzoites in tissue. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (K) *Toxoplasma gondii* tachyzoites from mouse peritoneal cavity (Giemsa stain). (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (L) *Cryptosporidium* oocysts (modified acid-fast stain). Occasionally, the four sporozoites within the oocyst are visible. These oocysts are immediately infective when they are passed in the stool. (M) *Giardia lamblia* cyst and *Cryptosporidium* oocysts (monoclonal antibody fluorescent stain-combination product). (Courtesy of Meridian Diagnostics, Inc.) (N) *Isospora belli* oocyst (iodine stain, wet mount). These organisms can be seen in the concentration sediment from formalin preservative; morphology of this particular organism will be very poor when concentrated from polyvinyl alcohol fixative. (O) *Isospora belli* oocyst (modified acid-fast stain). If the modified acid-fast stain for *Cryptosporidium* spp. is used, *I. belli* is also visible in the stained smear. (P) *Cyclospora* oocysts (saline, wet preparation). These organisms were formerly called CLBs (cyanobacterium-like or coccidian-like organisms). (Courtesy of Earl G. Long, Centers for Disease Control and Prevention.) (Q) *Cyclospora* oocysts (autofluorescence). Note the fluorescence around the oocysts (lower magnification than that in panel P). (Courtesy of Earl G. Long.) (R) *Cyclospora* oocysts (trichrome stain). Note that the oocysts do not stain with trichrome; they appear as “ghost cells” and are approximately twice the size of *Cryptosporidium* oocysts. (Courtesy of Earl G. Long.) (S) *Cyclospora* oocysts (modified acid-fast stain). Note the variability in staining; this is common and demonstrates the difference between these organisms and *Cryptosporidium* oocysts, which stain more consistently with this stain. (Courtesy of Earl G. Long.) (T) Concentrated duodenal aspirate with pinkish-red microsporidian spores (Weber’s chromotrope stain, $\times 1,150$). (Courtesy of Rainer Weber and Ralph T. Bryan, Division of Parasitic Diseases, National Center for Infectious Diseases, Centers for Disease Control and Prevention.) (U) Microsporidian spores (polyclonal fluorescent stain [reagent courtesy of Charles

Zierdt]). In some spores, horizontal or diagonal lines (polar tubule) can be seen. In rare cases the extruded polar tubule is visible (not in this particular picture). (V) Microsporidian spores (acid-fast stain). Note the variability in staining. (Armed Forces Institute of Pathology photograph.) (W) Microsporidian spores in corneal tissue (Gomori methenamine silver stain). Note the spore outline within the tissue. (X) Microsporidian spores in corneal tissue (periodic acid-Schiff [PAS] stain). Note the spore outline within the tissue; also note the PAS-positive granule at the end of each spore.

Plate 3 (see p. 1110) (A) *Ascaris lumbricoides* unfertilized egg. Note the thick, bumpy shell. (B) *Ascaris lumbricoides* fertilized egg (iodine stain, wet mount). Note the thick, bumpy shell (more rounded off than those seen in the unfertilized egg) and more rounded shape. (C) *Enterobius vermicularis* (pinworm) eggs on tape preparation. Note the shape (football shaped with one flattened side). (D) *Trichuris trichiura* (whipworm) egg (iodine stain, wet mount). Note the barrel-shaped thick shell and polar plugs at each end of the egg. (E) Hookworm egg (iodine stain, wet mount). Note the developing embryo (usually 4- to 16-ball stage of development) and the clear space between the egg shell and developing embryo. (From L. S. Garcia, in E. J. Baron and S. M. Finegold, *Diagnostic Microbiology*, 8th ed., The C. V. Mosby Co., St. Louis, Mo., 1990.) (F) *Strongyloides stercoralis* rhabditiform larva (iodine stain, wet mount). Note the short mouth opening and packet of genital primordial cells. (From L. S. Garcia, in E. J. Baron and J. M. Finegold, *Diagnostic Microbiology*, 8th ed., The C. V. Mosby Co., St. Louis, Mo., 1990.) The right frame shows *Strongyloides stercoralis* rhabditiform larva (trichrome stain). The internal morphology is rarely seen on the permanent stained smear; the wet mount examination is recommended. (G) *Trichinella spiralis* larvae in muscle (routine histologic preparation). (From L. S. Garcia, in E. J. Baron and S. M. Finegold, *Diagnostic Microbiology*, 8th ed., The C. V. Mosby Co., St. Louis, Mo., 1990.) (H) Hydatid sand from hydatid cyst (immature scolices). Note the row of hooklets (dark area). (I) *Taenia solium* (pork tapeworm) scolex. Note the suckers and hooklets (“armed rostellum”). (J) *Taenia solium* (pork tapeworm) gravid proglottid (India ink injection). The number of side branches on one side (counted where they come off the main uterine stem) is normally fewer than 12 (ca. 8). The proglottids are passed singly or in small numbers attached to each other. (K) *Taenia saginata* (beef tapeworm) scolex. Note the four suckers and no hooklets. (L) *Taenia saginata* (beef tapeworm) gravid proglottid (India ink injection). The number of side branches on one side (counted where they come off the main uterine stem) is normally more than 12 (ca. 16). The proglottids are usually passed singly. (M) *Taenia* egg. Note the thick, striated shell with a six-hooked embryo within the egg shell. (N) *Diphyllobothrium latum* (broad fish tapeworm or freshwater tapeworm) scolex. Note the lateral “sucking groove.” (O) *Diphyllobothrium latum* (broad fish tapeworm or freshwater tapeworm) gravid proglottid. Note that the proglottids are wider than long (opposite of *Taenia* proglottids [longer than wide]). Also note that the reproductive structures are in the middle of the proglottid (“rosette formation”). A number of attached proglottids are usually passed together. (P) *Diphyllobothrium latum* (broad fish tapeworm or freshwater tapeworm) eggs. Note that they are operculated (this is the only operculated tapeworm egg). (Q) *Hymenolepis nana* egg. These eggs are characterized by their thin shell, the presence of a six-hooked embryo within the egg shell, and the long, thin threads (polar filaments) that lie between the embryo and shell (found at the ends of the egg).

(R) *Hymenolepis diminuta* egg. These eggs are characterized by their thin shell, the presence of a six-hooked embryo within the egg shell, and no polar filaments. Unlike the magnification in the photograph, these eggs are somewhat larger than *H. nana* eggs. (S) *Clonorchis (Opisthorchis) sinensis* egg. This is one of the smallest helminth eggs (~30 µm) and is operculated. They have a small knob at the end opposite the operculum, but it may be difficult to see. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (T) *Paragonimus westermani* (lung fluke) egg. These eggs have an operculum which fits into the shell where the opercular “shoulders” are located (mimics a teapot rim and lid). Remember that these eggs can be found in both sputum and stool. (U) *Fasciola hepatica/Fasciolopsis buski* egg. These two eggs are difficult to differentiate. Both are operculated and are not embryonated when passed. This egg is photographed at a lower magnification (it is the largest of the helminth eggs). (V) *Schistosoma mansoni* egg (iodine stain, wet mount). Note the large, lateral spine. (W) *Schistosoma haematobium* egg (iodine stain, wet mount). Note the terminal spine. (X) *Schistosoma japonicum* egg (wet mount, blue filter). Note the small, lateral spine.

Plate 4 (see p. 1111) These slides are stained with Giemsa stain and are photographed using an oil immersion lens, unless stated otherwise. (A) *Plasmodium falciparum* ring forms. Note the cell with two ring forms (young trophozoites) and the appliqué or accolé form at the edge of the RBC. (B) *Plasmodium falciparum* ring forms. Note the “headphone” appearance of the ring forms (young trophozoites). (C) *Plasmodium falciparum* mature schizont and ring forms. The mature schizont is infrequently seen in the peripheral blood, but it does occur. (D) *Plasmodium falciparum* gametocytes. Note the typical crescent shape. Also, note that although the gametocytes are intracellular, the RBC membrane may not always be visible. (E) *Plasmodium vivax* early trophozoite. Note the ameboid trophozoite and the enlarged RBC. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (F) *Plasmodium vivax* developing trophozoites. Note the ameboid trophozoites and enlarged RBCs. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (G) *Plasmodium vivax* trophozoite. Note the Schüffner’s dots (true stippling). (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (H) *Plasmodium vivax* mature schizont. Note the merozoites within the mature schizont. The number of merozoites helps determine the correct malaria species. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (I) *Plasmodium malariae* “band” forms (developing trophozoites). The band form is typical of *P. malariae*; also note that the infected RBCs are normal size. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (J) *Plasmodium malariae* mature schizonts. Note the merozoites clustered around the excess malarial pigment (brownish color) (described as a “daisy” or “rosette”). (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (K) *Plasmodium ovale* early trophozoites. Note the Schüffner’s dots (true stippling) and the nonameboid trophozoite. (Parasite in left frame from A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (L) *Plasmodium ovale* early trophozoites. Note the Schüffner’s dots and fimbriated edges of the infected RBCs. (Parasite in left frame from A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H.

Zaiman.) (M) *Babesia* spp. ring forms. Note the small, multiple rings in the RBC at the top of the frame. These rings tend to be smaller and have more per cell than the ring forms in *P. falciparum* infections. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (N) *Babesia* spp., “Maltese cross” form. Here four elongated rings can be seen. This appearance is diagnostic for *Babesia* spp. but is not always seen. (Photograph by Zane Price.) (O) *Leishmania donovani* amastigotes (Leishman-Donovan bodies [L-D bodies]). Note the nucleus and bar (primitive flagella) in each one of the small organisms. This is a bone marrow specimen. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (P) *Leishmania* spp. in culture. As the organisms grow in culture, they form these “rosette” formations. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (Q) *Trypanosoma cruzi* trypomastigote. Note the C shape, undulating membrane, and large nucleus. (Photograph by Zane Price.) (R) *Trypanosoma cruzi* amastigotes in cardiac muscle (routine histologic preparation). Note the amastigotes clustered together. The individual amastigote looks identical to those found in leishmaniasis; however, the body site is different (reticuloendothelial system for leishmaniasis, striated muscle for Chagas’ disease). (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (S) *Trypanosoma brucei* trypomastigote. Note the slender body, no particular arrangement (unlike the typical C or U shape seen with *T. cruzi*), and small nucleus. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (T) *Trypanosoma brucei* trypomastigote. Note the slender body, no particular arrangement (unlike the typical C or U shape seen with *T. cruzi*), and small nucleus. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.) (U) *Wuchereria bancrofti* microfilaria (Delafield’s hematoxylin stain). Note the presence of the sheath (normally not visible using Giemsa stain) and the empty tail space beyond the last nucleus. (V) *Wuchereria bancrofti* microfilaria (anterior end) (Delafield’s hematoxylin stain). Note the sheath and the space between the anterior end and beginning of nuclei. (W) Microfilaria (nonsheathed). This is an example of one of the smaller microfilariae seen in a blood film; note that there is no sheath and that the nuclei are not seen as distinct dots like those seen in *W. bancrofti*. (X) *Onchocerca volvulus* nodule (routine histologic preparation, special trichrome stain). Note the cross section through the uterus of the adult worm (microfilariae visible as small curves within the uterus).

Plate 5 (see p. 1112) Trichrome stain was used for panels A through S; iron hematoxylin stain was used for panel T. (A) *Entamoeba histolytica* trophozoites (note ingested RBCs undergoing digestion). (B) *Entamoeba histolytica/E. dispar* trophozoite (note debris [the red object]). (C and D) *Entamoeba histolytica/E. dispar* cysts with chromatoidal bars (rounded ends). (E and F) Macrophages that can mimic *Entamoeba histolytica/E. dispar* trophozoites. (G and H) PMNs that can mimic *Entamoeba histolytica/E. dispar* cysts. (I) *Entamoeba coli* trophozoite with large karyosome and highly vacuolated cytoplasm. (J) *Entamoeba coli* trophozoite with uneven nuclear chromatin and eccentric karyosome. (K) *Entamoeba coli* cyst (iodine wet preparation). (L) *Entamoeba coli* cyst. (M and N) *Endolimax nana* trophozoites (large karyosome with little to no peripheral nuclear chromatin). (O) *Endolimax nana* cyst (vacuole is sometimes present, can be confused with cyst of *Iodamoeba bütschlii*). (P) *Endolimax nana* cyst with four karyosomes (the

typical number) visible (also note the round rather than oval shape). (Q) *Iodamoeba bütschlii* trophozoite and cyst (cyst somewhat out of focus). (R and S) *Iodamoeba bütschlii* cysts with large glycogen vacuoles. (T) *Iodamoeba bütschlii* cyst with large glycogen vacuole and “basket” nucleus.

Plate 6 (see p. 1113) (A) *Giardia lamblia* trophozoites in mucus (note the teardrop shape). (B) *Giardia lamblia* trophozoite. (C and D) *Giardia lamblia* cysts. (E) *Chilomastix mesnili* trophozoite (note the cytostomal groove). (F) *Chilomastix mesnili* cyst (lemon shape with “shepherd’s crook”). (G) *Pentatrachomonas hominis* trophozoite in stool (note the axostyle and typical large granules). (H) *Trichomonas vaginalis* trophozoite from the urogenital system (Giemsa stain). (I through L) *Dientamoeba fragilis* trophozoites (one- and two-nucleated trophozoites; note the nuclear chromatin fragmented into “dots”). (M) Charcot-Leyden crystals. (N) Macrophages, PMNs, and RBCs (no parasites are present, high dry power). (O and P) Artifacts (pollen and other plant material that can mimic helminth eggs). (Q through T) *Prototheca wickerhamii* (from culture).

Plate 7 (see p. 1114) (A) *Cyclospora cayetanensis* (modified acid-fast stain; courtesy of Earl Long, Centers for Disease Control and Prevention). (B and C) *Isospora belli* (modified acid-fast stain; the organism in panel B is less mature than that in panel C). (D) Microsporidian spores in muscle (*Pleistophora* spp.; high dry power). (E and F) Microsporidian spores in stool (modified trichrome stain; probably *Enterocytozoon bieneusi*; note the horizontal line through the spore [polar tubule] [arrow in panel E]). (G) Microsporidian spores in urine sediment (modified trichrome stain; probably *Encephalitozoon [Septata] intestinalis*). (H) Microsporidian spores in urine sediment (experimental indirect fluorescent-antibody method; probably *Encephalitozoon [Septata] intestinalis*). (I) Microsporidian spores in urine sediment (calcofluor white; probably *Encephalitozoon [Septata] intestinalis*). (J and K) Microsporidian spores in enterocytes (Giemsa stain). (L) Microsporidian spores in enterocytes (silver stain).

Plate 8 (see p. 1115) (A through K) *Plasmodium vivax* (note the presence of two rings per cell [not always limited to *Plasmodium falciparum*], enlarged RBCs, ameboid trophozoites and rings, and presence of stippling in some parasitized RBCs [Schüffner’s dots]). (L through S) *Plasmodium vivax*, developing and mature schizonts. (T) *Plasmodium vivax*, thick blood film containing mature schizont.

Plate 9 (see p. 1116) (A through J) *Plasmodium ovale* developing trophozoites with rings (note the nonameboid growing rings, the oval shape of some RBCs, RBCs with Schüffner’s dots, and RBCs with fimbriated edges). (K through M) *Plasmodium malariae* rings (note the normal-size RBCs). (N through P) *Plasmodium malariae* “band” forms. (Q and R) *Plasmodium malariae* developing schizonts. (S and T) *Plasmodium malariae* mature schizonts (note the rosette appearance of the merozoites clustered around the excess pigment).

Plate 10 (see p. 1117) (A) *Babesia* spp., “Maltese cross” configuration of small rings seen in some species of *Babesia*. (B) *Babesia* spp. (note the “band” form, which can be confused with *Plasmodium malariae*). (C and D) *Babesia* spp. with multiple rings per cell. (E through I) *Plasmodium falciparum* rings. (J) *Plasmodium falciparum* appliqué or accolé form. (K) *Plasmodium falciparum* (note the two chromatin dots and the “headphone” appearance of the ring). (L) *Plasmodium falciparum*, two rings per RBC. (M through P) *Plasmodium falciparum* thick blood films showing ring forms. (Q through S) *Plasmodium falciparum* micro- and macrogametocytes. (T) *Plasmodium falciparum*, section of capillary containing parasitized RBCs.

Plate 11 (see p. 1118) (A) *Dermacentor variabilis*, adult male on skin. (B) *Dermacentor andersoni*, male on left, female on right. (C) *Dermacentor variabilis*, adult females on skin. (D) *Argas* sp., soft tick; dorsal and ventral views. (E) Nit of louse on fiber. (F) *Phthirus pubis* (crab louse). (G) *Sarcoptes scabiei* (itch mite, the cause of scabies). (H) Human hand showing evidence of mite infestation. (Photographs from A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

Plate 12 (see p. 1119) (A) *Cimex lectularius* (bedbug). (B) *Tunga penetrans* (chigoe flea), lesion on the medial aspect of a medical missionary’s foot. (C) *Pulex irritans* (human flea). (D) Myiasis, ocular (species of fly unknown). (E) Ulcer from which a maggot was removed in a patient in Liberia. (F) *Dermatobia hominis* fly larva, a common cause of myiasis. (G) Fly larvae in a sacral decubitus ulcer in a Mexican patient confined to bed with a fractured femur. (H) Caterpillar rash induced by migration of caterpillar over the skin of a missionary physician in Liberia. The caterpillars usually fall from trees. (Photographs from A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman.)

APPENDIX 8

“Late-Breaking” Published Information

The following information was published in the last couple of months of 2005 and the first six months of 2006 and contains relevant information for the field of diagnostic medical parasitology. This is “late-breaking” published information that may be helpful for the reader.

Intestinal Protozoa (Amebae)

Entamoeba spp.

MacFarlane, R. C., and U. Singh. 2006. Identification of differentially expressed genes in virulent and nonvirulent *Entamoeba* species: potential implications for amebic pathogenesis. *Infect. Immun.* 74:340–351.

Several *Entamoeba* species and strains with differing levels of virulence have been identified. *E. histolytica* HM-1:IMSS is a virulent strain, *E. histolytica* Rahman is a nonvirulent strain, and *Entamoeba dispar* is a nonvirulent species. The authors used an *E. histolytica* DNA microarray consisting of 2,110 genes to assess the transcriptional differences between these species and strains with the goal of identifying genes whose expression correlated with a virulence phenotype. They found 415 genes expressed at lower levels in *E. dispar* and 32 genes with lower expression in *E. histolytica* Rahman than in *E. histolytica* HM-1:IMSS. Overall, 29 genes had decreased expression in both the nonvirulent species and strains than in the virulent *E. histolytica* HM-1:IMSS. Also, a number of genes with potential roles in stress response and virulence had decreased expression in either one or both nonvirulent *Entamoeba* species and strains. A number of the non-long-terminal-repeat retrotransposons (EhLINEs and EhSINEs), which modulate gene expression and genomic evolution, had lower expression in the nonvirulent species and strains than in *E. histolytica* HM-1:IMSS. **These results, identifying expression profiles and patterns indicative of a virulence phenotype, may be useful in characterizing the transcriptional framework of virulence.**

Moncada, D., K. Keller, S. Ankri, D. Mirelman, and K. Chadee. 2006. Antisense inhibition of *Entamoeba histolytica* cysteine

proteases inhibits colonic mucus degradation. *Gastroenterology* 130:721–730.

The exact role of *Entamoeba histolytica* cysteine proteases in overcoming the colonic mucus barrier, as a prerequisite to epithelial cell disruption, is not known. The authors determined whether *E. histolytica* trophozoites expressing the antisense transcript to cysteine protease 5 (EhCP5) could degrade colonic mucin and destroy epithelial cells. Cysteine protease-deficient amebae were generated by antisense inhibition of EhCP5 and assayed for proteolytic activity against [³⁵S]cysteine-labeled mucin from LS 174T and HT-29F Cl.16E cells. Recombinant EhCP5 mucinase activity was also assessed. Disruption of an intact mucus barrier and epithelial cell invasion by amebae were measured using high-mucin-producing LS 174T and HT-29F Cl.16E monolayers or Chinese hamster ovary (CHO) cells devoid of a mucus barrier. Trophozoites with reduced cysteine protease activity were >60% more ineffective at degrading [³⁵S]cysteine-labeled colonic mucin than were wild-type amebae. However, bioactive recombinant EhCP5 degraded >45% of purified native mucin, which was specifically inhibited by the cysteine proteinase (CP) inhibitor E-64. Cysteine protease-deficient trophozoites could not overcome a protective intact mucus barrier and disrupt LS 174T or HT-29F Cl.16 cell monolayers; however, they readily adhered to and disrupted CHO monolayers devoid of a mucus barrier. **These results unravel a central role for *E. histolytica* CPs as key virulence factors in disrupting an intact mucus barrier in the pathogenesis of intestinal amebiasis.**

Pelosof, L. C., P. H. Davis, Z. Zhang, X. Zhang, and S. L. Stanley, Jr. 2006. Co-ordinate but disproportionate activation of apoptotic, regenerative and inflammatory pathways characterizes the liver response to acute amebic infection. *Cell. Microbiol.* 8:508–522.

It is well known that the liver has the remarkable ability to respond to injury with repair and regeneration. The protozoan parasite *Entamoeba histolytica* is the most common

cause of liver abscess worldwide. The authors report a transcriptional analysis of the response of mouse liver to *E. histolytica* infection, the first study looking at acute liver infection by a nonviral pathogen. Focusing on early time points, they identified 764 genes with altered transcriptional levels in amebic liver abscess. The response to infection is rapid and complex, with concurrent increased expression of genes linked to host defense through interleukin-1 (IL-1), Toll-like receptor 2, or interferon (IFN)-induced pathways, liver regeneration via activation of IL-6 pathways, and genes associated with programmed cell death possibly through tumor necrosis factor alpha or Fas pathways. A comparison of amebic liver infection with the liver response to partial hepatectomy or toxins reveals striking similarities between amebic liver abscess and noninfectious injury in key components of the liver regeneration pathways. The response to amebic liver abscess is biased toward apoptosis compared with the response to acute liver injury from hepatectomy, toxins, or other forms of liver infection. ***E. histolytica* infection of the liver simultaneously activates inflammatory, regenerative, and apoptotic pathways, but the sum of these early responses is biased toward programmed cell death.**

Welter, B. H., R. R. Powell, R. C. Laughlin, G. C. McGugan, M. Bonner, A. King, and L. A. Temesvari. 2006. *Entamoeba histolytica*: comparison of the role of receptors and filamentous actin among various endocytic processes. *Exp. Parasitol.* 1 Feb. [Epub ahead of print.]

Uptake of iron is critical for *Entamoeba histolytica* growth, and iron-bound human transferrin (holo-transferrin) has been shown to serve as an iron source in vitro. Although a transferrin binding protein has been identified in *E. histolytica*, the mechanism by which this iron source is taken up by this pathogen is not well understood. The uptake of fluorescent dextran, holo-transferrin, and human red blood cells (hRBCs) was compared. Both dextran and transferrin were taken up in an apparent receptor-independent fashion, in contrast to hRBCs, which were taken up in a receptor-mediated fashion. The uptake of fluorescein isothiocyanate (FITC)-dextran and FITC-holo-transferrin differentially relied on an intact actin cytoskeleton, suggesting that their internalization routes may be regulated independently.

Blastocystis hominis

Sio, S. W., M. K. Puthia, A. S. Lee, J. Lu, and K. S. Tan. 2006. Protease activity of *Blastocystis hominis*. *Parasitol. Res.* 4 Mar. [Epub ahead of print.]

Proteases of the intestinal protozoan parasite *Blastocystis hominis* were studied for the first time by azocasein assays and gelatin sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) analysis. Parasitic lysates were found to have high protease activity, and nine protease bands of low (20 to 33 kDa) and high (44 to 75 kDa) molecular masses were reported. Proteases were found to be pH dependent, and the highest proteolytic activity was observed at neutral pH. **Inhibition studies showed that *B. hominis* isolate B, like many other protozoan parasites, contains mainly cysteine proteases.**

Tan, T. C., and K. G. Suresh. 2006. Predominance of ameboid forms of *Blastocystis hominis* in isolates from symptomatic patients. *Parasitol. Res.* 98:189–193.

Blastocystis hominis is one of the most common human parasites that inhabit the intestinal tract. Conflicting reports continue to exist regarding the existence and the functional role of the ameboid forms in the life cycle of the parasite. This study investigated the presence of these forms in 20 isolates obtained from 10 symptomatic and 10 asymptomatic patients. A total of 10,000 parasite cells/ml from each isolate were inoculated into three culture tubes each containing 3 ml of Jones' medium supplemented with 10% horse serum, incubated at 37°C. The contents were examined daily for 10 days. Irregular and polymorphic ameboid forms with multiple extended pseudopodia were observed in all isolates from symptomatic patients, while none of the isolates from asymptomatic patients showed the presence of the ameboid forms. The ameboid forms were first seen on day 2, and the percentages increased from 2% to 28%, with peak percentages from day 3 to day 6. Transmission electron microscopy revealed two types of ameboid forms, one containing a large central vacuole completely filled with tiny electron-dense granules and the other containing multiple small vacuoles within the central body. The cytoplasm contained strands of electron-dense granules resembling rough endoplasmic reticulum, which is suggestive of active protein synthesis. The surface coat of the ameboid form surrounding the parasite showed uneven thickness. Acridine orange stained the central body yellow and the periphery orange, indicating activity at the level of nucleic acids. **The ameboid form could be either an indicator of pathogenicity of *B. hominis* or the form most likely to contribute to pathogenicity and to be responsible for the symptoms seen in patients.**

Intestinal Protozoa (Flagellates and Ciliates)

Dientamoeba fragilis

Stark, D., N. Beebe, D. Marriott, J. Ellis, and J. Harkness. 2006. Evaluation of three diagnostic methods, including real-time PCR, for detection of *Dientamoeba fragilis* in stool specimens. *J. Clin. Microbiol.* 44:232–235.

The authors developed a 5' nuclease (TaqMan)-based real-time PCR assay, targeting the small-subunit rRNA gene, for the detection of *Dientamoeba fragilis* in human stool specimens and compared its sensitivity and specificity to those of conventional PCR and microscopic examination by a traditional modified iron hematoxylin-staining procedure. Real-time PCR exhibited 100% sensitivity and specificity.

Giardia lamblia

Hausen, M. A., J. C. Freitas, Jr., and L. H. Monteiro-Leal. 2006. The effects of metronidazole and furazolidone during *Giardia* differentiation into cysts. *Exp. Parasitol.* 10 Feb. [Epub ahead of print.]

The search for an effective anti-*Giardia* treatment has been intense, but recurrent infections, virulence factors, and drug resistance have created obstacles to the achievement

of an efficient medication. Most published reports about drug effects in *Giardia* are related to the trophozoite form, although infective cysts are continuously eliminated in the stools during the treatment. The authors analyzed the inhibitory effects of metronidazole and furazolidone on the differentiation of *Giardia* into cysts and their viability. The presence of cavities, lamellar bodies, and thread-like structures were the most frequent morphologic alterations. The results also showed that furazolidone was more effective by 50% than metronidazole in inhibiting in vitro cyst differentiation.

Intestinal Protozoa (Coccidia and Microsporidia)

Cryptosporidium spp.

Li, X., K. Guyot, E. Dei-Cas, J. P. Mallard, J. J. Ballet, and P. Brasseur. 2006. *Cryptosporidium* oocysts in mussels (*Mytilus edulis*) from Normandy (France). *Int. J. Food Microbiol.* 108:321–325.

Cultured mussels (*Mytilus edulis*) were collected seasonally during 1 year from three sites on the Northwestern coastal area of Normandy (France). Flesh, gills, and innerwater were examined for *Cryptosporidium* oocysts using immunomagnetic separation and the immunofluorescence assay. Oocysts were present in all samples for all sites and seasons, and flesh was the most contaminated part. Oocyst rates appeared to be related to variations in seasonal precipitation. Molecular analysis revealed that oocysts belonged to the species *Cryptosporidium parvum* (formerly genotype 2 or “bovine genotype”). Oocyst infectivity was assessed by oral administration to suckling NMRI mice, and developmental stages were observed in only one mouse infected with oocysts from one location. The detection of potentially infectious *C. parvum* oocysts of likely cattle-breeding origin in cultured edible mussels confirms their resistance to marine environments and underlines the potential risk of food-borne infection. This work reports for the first time the presence of infectious *Cryptosporidium* oocysts in shellfish from France.

Rossignol, J. F., S. M. Kabil, Y. el-Gohary, and A. M. Younis. 2006. Effect of nitazoxanide in diarrhea and enteritis caused by *Cryptosporidium* species. *Clin. Gastroenterol. Hepatol.* 4:320–324.

A multicenter, randomized, double-blind, placebo-controlled study was conducted with 90 outpatients aged 12 years and older from the Nile Delta region of Egypt. Patients were randomized to receive either one 500-mg nitazoxanide tablet or one matching placebo tablet, or 25 ml of nitazoxanide oral suspension (500 mg of nitazoxanide), each given twice daily for 3 days. Clinical and microbiological response rates were evaluated 4 days after completion of treatment. Of the 28 patients receiving nitazoxanide tablets, 27 (96%) responded clinically compared with 11 (41%) of 27 patients who received placebo ($P < 0.0001$). Of the 28 patients who received nitazoxanide, 26 (93%) were free of *Cryptosporidium* oocysts in each of two posttreatment stool samples compared with

only 10 (37%) of 27 patients who received placebo ($P < 0.0001$). Response rates in patients receiving the tablets and the suspension were comparable (clinical response rate for suspension, 27 [87%] of 31; microbiological response rate for suspension, 28 [90%] of 31). These results indicate that a 3-day course of nitazoxanide is effective in treating diarrhea and enteritis caused by *Cryptosporidium* in nonimmunodeficient patients 12 years of age and older.

Tanriverdi, S., A. Markovics, M. O. Arslan, A. Itik, V. Shkap, and G. Widner. 2006. Emergence of distinct genotypes of *Cryptosporidium parvum* in structured host populations. *Appl. Environ. Microbiol.* 72:2507–2513.

Cryptosporidium parvum isolated from cattle in northeastern Turkey and in Israel was genotyped using multiple polymorphic genetic markers, and the two populations were compared to assess the effect of cattle husbandry on the parasite's population structure. Dairy herds in Israel are permanently confined with essentially no opportunity for direct herd-to-herd transmission, whereas in Turkey there are more opportunities for transmission as animals range over wider areas and are often traded. A total of 76 *C. parvum* isolates from 16 locations in Israel and 7 farms in the Kars region in northeastern Turkey were genotyped using 16 mini- and microsatellite markers. In both countries, distinct multilocus genotypes confined to individual farms were detected; the number of genotypes per farm was larger and mixed isolates were more frequent in Turkey than in Israel. Based on the presence of distinct multilocus genotypes in individual herds, linkage disequilibrium among loci was detected in Israel. These observations show that genetically distinct populations of *C. parvum* can emerge within a group of hosts in a relatively short time. This may explain the frequent detection of host-specific genotypes with unknown taxonomic status in surface water and the existence of geographically restricted *C. hominis* genotypes in humans.

Microsporidia

Jordan, C. N., A. M. Zajac, K. S. Snowden, and D. S. Lindsay. 2006. Direct agglutination test for *Encephalitozoon cuniculi*. *Vet. Parasitol.* 135:235–240.

Currently, serologic diagnosis of infection with *Encephalitozoon cuniculi* is made using the indirect immunofluorescent-antibody assay (IFA) or enzyme-linked immunosorbent assay (ELISA). Although these methods are sensitive and reliable, cross-reactivity between other *Encephalitozoon* species is common, and specialized equipment is required to conduct these tests. The authors report the development of a direct agglutination test for detecting immunoglobulin G (IgG) antibodies to *E. cuniculi*. The utility of the agglutination test was examined by using CD-1 and C3H/He mice infected with *E. cuniculi* or one of two other *Encephalitozoon* species. Test sera were incubated overnight with eosin-stained microsporidial spores in round-bottom microtiter plates. In positive samples, agglutination of spores with antibodies in test sera resulted in an opaque mat spread across the well. The results indicate that the agglutination test is 86% sensitive and 98% specific for *E. cuniculi*, with

limited cross-reactivity with *Encephalitozoon intestinalis*. No cross-reactivity with *Encephalitozoon hellem* was observed. The test is fast and easy to conduct, and species-specific antibodies are not required.

Jordan, C. N., J. A. Dicristina, and D. S. Lindsay. 2006. Activity of bleach, ethanol and two commercial disinfectants against spores of *Encephalitozoon cuniculi*. *Vet. Parasitol.* 136:343–346.

Hosts are infected with *Encephalitozoon cuniculi* by ingestion or inhalation of spores passed in the urine or feces, and infection is usually asymptomatic, except in young or immunocompromised hosts. Spores of *E. cuniculi* were exposed to several dilutions of commercial bleach, 70% ethanol, and dilutions of commercial disinfectants HiTor and Roccal for 10 min and then loaded onto human fibroblast cells (Hs68 cells). A 10-min exposure to these disinfectants was lethal to *E. cuniculi* spores. Additional exposure time studies were done using 0.1, 1, and 10% dilutions of bleach and 70% ethanol. Exposure of *E. cuniculi* spores to 1 or 10% bleach for 30 s rendered them noninfectious for Hs68 cells. Growth of *E. cuniculi* was observed in Hs68 cells inoculated with spores treated with 0.1% bleach for 30 s or 1, 3, or 5 min but not with spores treated for 7 min or longer. Exposure of *E. cuniculi* spores to 70% ethanol for 30 s rendered them noninfectious for Hs68 cells. Spores of *E. cuniculi* are more sensitive to disinfectants than are coccidial oocysts and other parasite cysts. The relatively short contact time needed to kill spores indicates that disinfection of animal housing may be a viable means of reducing exposure of animals to *E. cuniculi* spores.

Joseph, J., S. Murthy, P. Garg, and S. Sharma. 2006. Use of different stains for microscopic evaluation of corneal scrapings for diagnosis of microsporidial keratitis. *J. Clin. Microbiol.* 44:283–285.

Retrospective evaluation of potassium hydroxide plus calcofluor white (KOH+CFW), Gram, Giemsa, and modified Ziehl-Neelsen (1% H₂SO₄, cold) stains for the detection of microsporidia in corneal scrapings from 30 patients showed KOH+CFW and acid-fast stains to be the most efficient (29 of 30 [96.7%] and 28 of 30 [93.3%], respectively) in the diagnosis of microsporidial keratitis.

Singh, I., A. S. Sheoran, Q. Zhang, A. Carville, and S. Tzipori. 2005. Sensitivity and specificity of a monoclonal antibody-based fluorescence assay for detecting *Enterocytozoon bieneusi* spores in feces of simian immunodeficiency virus-infected macaques. *Clin. Diagn. Lab. Immunol.* 12:1141–1144.

Enterocytozoon bieneusi is clinically the most significant among the microsporidia causing chronic diarrhea, wasting, and cholangitis in individuals with human immunodeficiency virus/AIDS. Microscopy with either calcofluor or modified trichrome stains is the standard diagnostic test for microsporidiosis but does not allow species identification. Detection of *E. bieneusi* infection based on PCR is limited to a few reference laboratories, so it is not the standard diagnostic

assay. The authors have recently reported the development and characterization of a panel of monoclonal antibodies (MAbs) against *E. bieneusi*, and in this study they evaluated the specificity and sensitivity of an IFA, compared with PCR, in detecting *E. bieneusi* infection in simian immunodeficiency virus-infected macaques. The IFA correlated with the primary PCR method, with a detection limit of 1.5×10^5 spores/g of feces, and will simplify the detection of *E. bieneusi* spores in clinical and environmental specimens and in laboratory and epidemiologic investigations.

Protozoa from Other Body Sites

Free-Living Amebae

Clarke, D. W., and J. Y. Niederkorn. 2006. The pathophysiology of *Acanthamoeba* keratitis. *Trends Parasitol.* 22:175–180.

Acanthamoeba keratitis is a sight-threatening infection of the ocular surface that is produced by several free-living amebae of the genus *Acanthamoeba*. Infection is usually initiated by *Acanthamoeba*-contaminated contact lenses and causes exquisite pain and ulceration of the ocular surface. The pathophysiology of this infection involves an intricate series of sequential events that includes the production of several pathogenic proteases that degrade basement membranes and induce cytolysis and apoptosis of the cellular elements of the cornea, culminating in dissolution of the collagenous corneal stroma. Targeting such proteases could lead to the development of vaccines that target the disease process rather than the pathogen itself.

Trichomonas vaginalis

Mundodi, V., A. S. Kucknoor, T. H. Chang, and J. F. Alderete. 2006. A novel surface protein of *Trichomonas vaginalis* is regulated independently by low iron and contact with vaginal epithelial cells. *BMC Microbiol.* 6:6.

Trichomoniasis caused by *Trichomonas vaginalis* is the most common nonviral sexually transmitted disease and affects more than 250 million people worldwide. IgA has been implicated in resistance to mucosal infections by pathogens. No reports are available of IgA-reactive proteins and the role, if any, of this class of antibody in the control of this sexually transmitted disease. The availability of an IgA MAb immunoreactive to trichomonads by whole-cell ELISA was used to characterize the IgA-reactive protein of *T. vaginalis*. An IgA MAb called 6B8 was isolated from a library of MAbs reactive with surface proteins of *T. vaginalis*, which recognized a 44-kDa protein (TV44) by immunoblot analysis, and a full-length cDNA clone encoded a protein of 438 amino acids. Southern analysis revealed the gene (*tv44*) of *T. vaginalis* to be a single-copy gene. The *tv44* gene was down regulated at both the transcriptional and translational levels in iron-depleted trichomonads as well as in parasites after contact with immortalized MS-74 vaginal epithelial cells (VECs). Immunofluorescence on nonpermeabilized organisms confirmed the surface localization of TV44, and the intensity of fluorescence was reduced after parasite adherence to VECs. Also, an identical protein and gene were present in

Tritrichomonas foetus and *Trichomonas tenax*. This is the first report of a *T. vaginalis* gene (*tv44*) encoding a surface protein (TV44) reactive with an IgA MAb, and both gene and protein were conserved in human and bovine trichomonads. Further, TV44 is independently down regulated in expression and surface placement by iron and contact with VECs. TV44 is another *T. vaginalis* gene that is regulated by at least two independent signaling mechanisms involving iron and contact with VECs.

Van Der Pol, B., C. S. Kraft, and J. A. Williams. 2006. Use of an adaptation of a commercially available PCR assay aimed at diagnosis of chlamydia and gonorrhea to detect *Trichomonas vaginalis* in urogenital specimens. *J. Clin. Microbiol.* **44**:366–373.

Using reagents from a commercially available assay for *Chlamydia trachomatis* and *Neisseria gonorrhoeae*, *Trichomonas vaginalis* PCR was evaluated for detection of infection in women and men attending a sexually transmitted disease clinic. Evaluations included three primer sets, endocervical swabs, vaginal swabs and urine, and various storage conditions. The TVK3-TVK7 primer set was optimal, with sensitivities ranging from 69.5 to 96.8%. In all comparisons, *T. vaginalis* PCR performed better than routine diagnostics involving microscopy for women and culture for men ($P > 0.05$). The assay performed well for all sample types tested, and vaginal swabs were stable for up to 7 days at ambient temperature. The use of samples prepared for, and reagents from, the *C. trachomatis*-*N. gonorrhoeae* PCR assay allowed the incorporation of *T. vaginalis* PCR diagnosis into routine clinical testing.

Tissue Protozoa

Toxoplasma gondii

Campbell, A. L., C. L. Goldberg, M. S. Magid, G. Gondolesi, C. Rumbo, and B. C. Herold. 2006. First case of toxoplasmosis following small bowel transplantation and systematic review of the tissue-invasive toxoplasmosis following noncardiac solid organ transplantation. *Transplantation* **81**:408–417.

Toxoplasmosis prophylaxis is standard following heart and heart-lung transplantation, when an increased risk of allograft-transmitted *Toxoplasma* is well recognized. In contrast, prophylaxis and routine serologic evaluation of donors and recipients for *Toxoplasma* in noncardiac solid-organ transplantation (SOT) is not recommended. The authors report the first case of disseminated toxoplasmosis following small bowel transplantation, presumably transmitted via the transplanted intestine, and systematically review reported cases of toxoplasmosis in noncardiac SOT recipients to determine if current guidelines should be reconsidered. Systematic MEDLINE review was performed for tissue-invasive toxoplasmosis in noncardiac SOT recipients and analysis of clinical features, serologic status, and treatment regimens with respect to mortality. **Fifty-two cases of toxoplasmosis in noncardiac SOT recipients were identified. Eighty-six percent developed disease within 90 days of transplantation. Presentation was nonspecific and consisted of fever (77%), respiratory distress (29%), neurologic manifestations (29%),**

and bone marrow suppression (26%). Multivariate analyses demonstrated that localized disease, treatment received, and donor and recipient serostatus were predictors of survival. High-risk recipients (seropositive donor, seronegative recipient) developed disease earlier (16 days versus 31 days) and were less likely to survive than standard-risk recipients. **Toxoplasmosis following noncardiac SOT is recognized. Reduction of morbidity and mortality necessitates knowledge of donor and recipient *Toxoplasma* serostatus, prophylaxis, early diagnosis, and treatment. The findings support a reconsideration of pretransplantation evaluation and prophylaxis strategies in SOT recipients.**

De Moura, L., L. M. Bahia-Oliveira, M. Y. Wada, J. L. Jones, S. H. Tuboi, E. H. Carmo, W. M. Ramalho, N. J. Camargo, R. Trevisdan, R. M. Graca, A. J. da Silva, I. Moura, J. P. Dubey, and D. O. Garrett. 2006. Waterborne toxoplasmosis, Brazil, from field to gene. *Emerg. Infect. Dis.* **12**:326–329.

Water was the suspected vehicle of *Toxoplasma gondii* dissemination in a toxoplasmosis outbreak in Brazil. A case-control study and geographic mapping of cases were performed. *T. gondii* was isolated directly from the implicated water and genotyped as SAG 2 type I.

Hu, K., J. Johnson, L. Florens, M. Fraunholz, S. Suravajjala, C. Dilullo, J. Yates, D. S. Roos, and J. M. Murray. 2006. Cytoskeletal components of an invasion machine—the apical complex of *Toxoplasma gondii*. *PLoS Pathog.* **2**:e13.

The apical complex of *Toxoplasma gondii* is thought to serve essential functions both in invasion of its host cells (including human cells) and in replication of the parasite. The understanding of apical complex function, the basis for its structure, and the mechanism for its motility are limited due to lack of knowledge of its molecular composition. The authors have partially purified the conoid-apical complex, identified ~200 proteins that represent 70% of its cytoskeletal protein components, characterized 7 novel proteins, and determined the sequence of recruitment of 5 of these proteins into the cytoskeleton during cell division. These results provide new markers for the different subcompartments within the apical complex and reveal previously unknown cellular compartments, which facilitate understanding the invasion process. **The extreme apical and extreme basal structures of this highly polarized cell originate in the same location and at the same time very early during parasite replication.**

Laibe, S., S. Ranque, C. Curtillet, F. Faraut, H. Dumon, and J. Franch. 2006. Timely diagnosis of disseminated toxoplasmosis by sputum examination. *J. Clin. Microbiol.* **44**:646–648.

The diagnosis of disseminated toxoplasmosis in a 14-year-old allogeneic bone marrow recipient with graft-versus-host disease was determined by the detection of *Toxoplasma gondii* tachyzoites in sputum smears. Sputum analysis is a valuable alternative in the clinical assessment of pulmonary toxoplasmosis, especially when conventional invasive techniques may not be practical.

Shrestha, S. P., T. Tomita, L. M. Weiss, and A. Orlofsky. 2006. Proliferation of *Toxoplasma gondii* in inflammatory macrophages in vivo is associated with diminished oxygen radical production in the host cell. *Int. J. Parasitol.* 17 Feb. [Epub ahead of print.]

While reactive oxygen species (ROS) can kill *Toxoplasma gondii* in vitro, the role played by these molecules in vivo is not known. The authors used a flow cytometry-based assay to investigate the relationship between intracellular infection and ROS production during acute peritoneal toxoplasmosis in mice. A distinct population of ROS⁺ inflammatory macrophages was observed to increase progressively in frequency during the course of infection and to be inversely correlated with the degree of cell parasitization. These data imply that either intracellular parasites inhibit ROS synthesis or ROS-producing cells contain anti-*Toxoplasma* activity. The latter interpretation was supported by the finding that uninfected ROS-producing inflammatory macrophages were resistant to infection in vivo. However, in the same animals, ROS-producing macrophages that had previously been parasitized could readily be infected with additional parasites, suggesting that the difference in ROS production between highly infected and less highly infected cells was not due to ROS-associated killing of parasites within these cells. Also, macrophages infected with *T. gondii* in vitro and then briefly transferred to acutely infected mice up regulated ROS production that was again inversely correlated with the degree of intracellular parasitization. **These findings suggest that both ROS-associated anti-*Toxoplasma* activity and parasite-driven inhibition of ROS production underlie the observed pattern of ROS production. ROS function and parasite evasion of this function may contribute to the balance between host defense and disease progression during acute infection.**

***Plasmodium* and *Babesia* spp.**

***Plasmodium* spp.**

Combes, V., N. Coltel, D. Faille, S. C. Wassmer, and G. E. Grau. 2006. Cerebral malaria: role of microparticles and platelets in alterations of the blood-brain barrier. *Int. J. Parasitol.* 10 Mar. [Epub ahead of print.]

Brain lesions of cerebral malaria (CM) are characterized by a sequestration of *Plasmodium falciparum*-parasitized RBCs (PRBCs), leukocytes, and platelets within brain microvessels, by an excessive release of proinflammatory cytokines, and by disruption of the blood-brain barrier. The authors evaluated the possibility that PRBCs and platelets interact and induce functional alterations in brain endothelium. Using an in vitro model of endothelial lesion, they demonstrated that platelets can act as bridges between PRBCs and endothelial cells allowing the binding of PRBCs to endothelium devoid of cytoadherence receptors. Furthermore, platelets enhanced the cytotoxicity of PRBCs for brain endothelial cells by inducing an alteration of their monolayer integrity and increasing their apoptosis. Another aspect of inflammatory and infectious diseases is that platelets often lead to activation of vascular and blood cells, which results in an enhanced release of circulating

microparticles (MP). The authors then investigated the levels of endothelial MP in plasma of Malawian children with malaria. Plasma MP numbers were markedly increased on admission only in patients with severe malaria complicated by coma. Using the experimental-mouse model of CM, the authors evaluated the pathogenic implications of MP by using genetically deficient mice in which the capacity to release circulating MP was impaired. Such mice, lacking the ABCA-1 gene, showed complete resistance to CM after infection by *Plasmodium berghei* ANKA. When purified from infected susceptible animals, MP were able to reduce the normal plasma-clotting time and to significantly enhance tumor necrosis factor release from naive macrophages. **The finding that ABCA-1 gene deletion confers complete protection against cerebral pathology, linked to impaired MP production, provides new potential targets for therapeutic amelioration of severe malaria.**

Gogtay, N. J., K. D. Kamtekar, S. S. Dalvi, S. S. Mehta, A. R. Chogle, U. Aigal, and N. A. Kshirsagar. 2006. A randomized, parallel study of the safety and efficacy of 45 mg primaquine versus 75 mg bulaquine as gametocytocidal agents in adults with blood schizonticide-responsive uncomplicated falciparum malaria [ISCRTN50134587]. *BMC Infect. Dis.* 6:16.

The World Health Organization recommends that adults with uncomplicated *Plasmodium falciparum* infection successfully treated with a blood schizonticide receive a single dose of 45 mg of primaquine (PQ) as a gametocytocidal agent. An earlier pilot study suggested that 75 mg of bulaquine (BQ), of which PQ is a major metabolite, may be a useful alternate to PQ. In a randomized, partial-blind study, 90 hospitalized adults with *P. falciparum* malaria that was blood schizonticide responsive and a gametocytemia of >55/ μ l within 3 days of diagnosis were randomized to receive single doses of either 45 mg of PQ or 75 mg of BQ on day 4. Gametocytemia was assessed on days 8, 15, 22, and 29, and gametocyte viability was determined by exflagellation on day 8. On day 8, 20 (65%) of 31 PQ recipients versus 19 (32%) of 59 BQ recipients showed persistence of gametocytes ($P = 0.002$). At day 15 and beyond, all patients were gametocyte free. On day 8, 16 of 31 PQ and 7 of 59 BQ volunteers showed gametocyte viability ($P = 0.000065$). **Based on these results, BQ is a safe, useful alternate to PQ as a *Plasmodium falciparum* gametocytocidal agent and may clear gametocytemia faster than PQ.**

Hill, A. V. 2006. Pre-erythrocytic malaria vaccines: towards greater efficacy. *Nat. Rev. Immunol.* 6:21–32.

Several new types of *Plasmodium falciparum* vaccine are now being evaluated in clinical trials. Recently, two vaccine candidates that target the pre-erythrocytic stages of the malaria life cycle—a protein particle vaccine with a powerful adjuvant and a prime-boost viral-vector vaccine—entered phase II clinical trials in the field, and the first has shown partial efficacy in preventing malarial disease in African children. The authors discuss the potential immunological basis for the encouraging partial protection induced by these

vaccines and consider ways to develop more effective malaria vaccines.

Johnston, S. P., N. J. Pieniazek, M. V. Xayavong, S. B. Slemenda, P. P. Wilkins, and A. J. da Silva. 2006. PCR as a confirmatory technique for laboratory diagnosis of malaria. *J. Clin. Microbiol.* 44:1087–1089.

The authors compared a nested PCR assay and microscopic examination of Giemsa-stained blood films for detection and identification of *Plasmodium* spp. in blood specimens. PCR was more sensitive than microscopy and was capable of identifying malaria parasites at the species level when the microscopy results were equivocal.

Magill, A. J. 2006. Malaria: diagnosis and treatment of falciparum malaria in travelers during and after travel. *Curr. Infect. Dis. Rep.* 8:35–42.

Plasmodium falciparum is responsible for most of the mortality in travelers with imported malaria. Problems that occur while abroad include the inaccuracy of the microscopic diagnosis of malaria, both false positives and false negatives, when ill travelers seek care. A false-positive diagnosis can result in unnecessary parenteral injections that carry a risk of transmission of blood-borne pathogens, receipt of potentially dangerous drugs such as halofantrine, or receipt of fake, counterfeit drugs. Increased morbidity and mortality are associated with delays in diagnosis and initiation of prompt treatment for falciparum malaria. The availability of expert microscopy to confirm the diagnosis of malaria is limited. The presence of splenomegaly and thrombocytopenia is strongly associated with malaria and would justify empiric treatment. The availability of atovaquone-proguanil, a safe and well-tolerated oral drug, should prompt a reconsideration of current treatment recommendations that discourage empiric treatment on clinical suspicion alone.

Lee, S. A., A. Yeka, S. L. Nsoyba, C. Dokomajilar, P. J. Rosenthal, A. Talisuna, and G. Dorsey. 2006. Complexity of *Plasmodium falciparum* infections and antimalarial drug efficacy at 7 sites in Uganda. *J. Infect. Dis.* 193:1160–1163.

Malaria infections in Africa frequently include multiple parasite strains. The authors examined the relationship between the number of infecting *Plasmodium falciparum* strains and the responses to three different combination therapies in 3,072 patients with uncomplicated malaria at seven sites in Uganda. Patients infected with at least three strains had almost three times the odds of treatment failure (odds ratio, 2.93 [95% confidence interval, 2.51 to 3.43]; $P < 0.001$) compared with those infected with one or two strains. **Data suggest that efforts to reduce the complexity of infection in areas of high endemicity through the use of intermittent presumptive therapy, improved case management, and reduction in transmission intensity may improve the efficacy of antimalarial therapies.**

Mita, T., A. Kaneko, I. Hwaihwanje, T. Tsukahara, N. Takahashi, H. Osawa, K. Tanabe, T. Kobayakawa, and A. Bjorkman. 2006.

Rapid selection of *dhfr* mutant allele in *Plasmodium falciparum* isolates after the introduction of sulfadoxine/pyrimethamine in combination with 4-aminoquinolines in Papua New Guinea. *Infect. Genet. Evol.* 4 Apr. [Epub ahead of print.]

To overcome the declining efficacy of the 4-aminoquinolines in Papua New Guinea, sulfadoxine-pyrimethamine (SP) has been combined with the 4-aminoquinolines as a first-line treatment for falciparum malaria since 2000. To assess how this change had affected SP-resistant gene polymorphisms, the authors determined allele frequencies of *dhfr* and *dhps* in 113 *Plasmodium falciparum* isolates from Wewak, East Sepik of Papua New Guinea, in 2002 and 2003. In *dhfr*, the double mutant (ACNRRNVI) was the predominant allele, with a prevalence of 91%. The authors found a significant decrease of wild *dhfr* allele prevalence (7%) compared with that reported in the adjacent area of East Sepik called the Wosera region (57%), before the drug policy changed in 1990 to 1993. Between 2002 and 2003, the prevalence of this allele decreased from 15% to 3% ($P = 0.02$). Two distinct microsatellite haplotypes flanking *dhfr* were found in isolates with the *dhfr* double mutant, suggesting the selection of preexisting SP-resistant parasites rather than a frequent occurrence of *dhfr* mutations. The *dhfr/dhps* quartet mutations (ACNRRNVI in *dhfr* and SGEAA in *dhps*) were identified in six (8%) of the isolates from 2003. This genotype, which is associated with in vivo resistance to SP, has not been reported before in Papua New Guinea. **The data suggest that isolates resistant to SP were rapidly selected despite the use of the SP combination therapy, probably because of their preexisting high level of resistance to the 4-aminoquinoline partner drug.**

Murthi, P., B. Kalionis, H. Ghabrial, M. E. Dunlop, R. A. Smallwood, and R. B. Sewell. 2006. Kupffer cell function during the erythrocytic stage of malaria. *J. Gastroenterol. Hepatol.* 21:313–318.

Previous studies using isolated perfused rat liver in vivo have suggested that during the erythrocytic phase of malaria infection, overall phagocytosis by Kupffer cells is enhanced. The aim of the present study was to further investigate the individual phagocytic capacity and prostaglandin E₂ secretion of isolated Kupffer cells in vitro and the immunohistochemical characteristics of Kupffer cells in vivo. Malaria was induced in male Sprague-Dawley rats ($n = 12$) by inoculation with parasitized RBCs containing *Plasmodium berghei*. Kupffer cells were isolated by centrifugal elutriation. **A significantly increased yield of Kupffer cells was obtained from malaria-infected livers compared to controls.** There was an increased internalization by phagocytosis of ³H-labeled bovine serum albumin-containing latex microspheres after 60 min in malaria-infected Kupffer cells compared to controls. Prostaglandin E₂ secretion into the cell culture medium was significantly suppressed in malaria-infected Kupffer cells compared to controls. Staining of ED1, ED2, and proliferating-cell nuclear antigen was greater in malaria-infected livers compared to controls. **These results indicate that the number of Kupffer cells is significantly increased and their phagocytic activity on a cell-by-cell basis is enhanced during the erythrocytic stage of malaria.**

Otieno, R. O., C. Ouma, J. M. Ong’echa, C. C. Keller, T. Were, E. N. Waindi, M. G. Michaels, R. D. Day, J. M. Vulule, and D. J. Perkins. 2006. Increased severe anemia in HIV-1-exposed and HIV-1-positive infants and children during acute malaria. *AIDS* 20:275–280.

Since the primary hematologic complication in both pediatric human immunodeficiency virus type 1 (HIV-1) infection and malaria is anemia, coinfection with these pathogens may promote life-threatening severe malarial anemia (SMA). The primary objective of the study was to determine if HIV-1 exposure and/or HIV-1 infection increased the prevalence of SMA in children with acute malaria. **The effect of HIV-1 exposure and HIV-1 infection on the prevalence of SMA (hemoglobin level, <6.0 g/dl), parasitemia (parasites per microliter), and high-density parasitemia ($\geq 10,000$ parasites/ μ l) in children aged 2 years or younger presenting at hospital with acute *Plasmodium falciparum* malaria in a rural holoendemic malaria transmission area of western Kenya was investigated.** On enrollment, a complete hematologic and clinical evaluation was performed on all children. Malaria parasitemia was determined, and children with acute *P. falciparum* malaria were evaluated for HIV-1 exposure and infection by two rapid serologic antibody tests and HIV-1 DNA PCR, respectively. Relative to an HIV-1-uninfected group ($n = 194$), the HIV-1-exposed ($n = 100$) and HIV-1-positive ($n = 23$) groups had lower hemoglobin concentrations ($P < 0.001$ and $P < 0.001$, respectively), while parasitemia and high-density parasitemia (HDP) were equivalent among the three groups. Multivariate analyses demonstrated that the risk of SMA was elevated in HIV-1-exposed and HIV-1-positive children. The multivariate model further revealed that HIV-1 exposure or infection was not significantly associated with HDP. **Results demonstrate that both HIV-1 exposure and HIV-1 infection are associated with increased prevalence of SMA during acute *P. falciparum* infection, independent of parasite density.**

Perez-Leal, O., A. Mongui, J. Cortez, G. Yepes, J. Leiton, and M. A. Patarroyo. 2006. The *Plasmodium vivax* rhoptry-associated protein 1. *Biochem. Biophys. Res. Commun.* 341:1053–1058.

Rhoptries are cellular organelles localized at the apical pole of apicomplexan parasites. Their content is rich in lipids and proteins that are released during target cell invasion. *Plasmodium falciparum* rhoptry-associated protein 1 (RAP1) has been the most widely studied among the rhoptry proteins of this species and is considered to be a good antimalarial vaccine candidate since it displays little polymorphism and induces antibodies in infected humans. MAbs directed against RAP1 are also able to inhibit target cell invasion in vitro, and protection against *P. falciparum* experimental challenge is induced when nonhuman primates are immunized with this protein expressed in its recombinant form. This study identifies and characterizes RAP1 in *Plasmodium vivax*, the most widespread parasite species causing malaria in humans, which produces more than 80 million infections yearly, mainly in Asia and Latin America. **This new protein is encoded by a two-exon gene and is proteolytically processed**

in a similar manner to its *falciparum* homologue, and the immunofluorescence pattern displayed is suggestive of its rhoptry localization. **Studies evaluating the protective efficacy of *P. vivax* RAP1 in nonhuman primates are recommended, taking into account the relevance of its *P. falciparum* homologue as an antimalarial vaccine candidate.**

Riley, E. M., S. Wahl, D. J. Perkins, and L. Schofield. 2006. Regulating immunity to malaria. *Parasite Immunol.* 28:35–49.

Much of the pathology of malaria infection can be immune mediated, which implies that immune responses have to be carefully regulated. The mechanisms by which antimalarial immune responses are thought to be regulated were discussed at the Malaria Immunology Workshop (Bloomberg School of Public Health, Johns Hopkins University, Baltimore, Md., February 2005). Potential regulatory mechanisms include regulatory T cells, which significantly modify cellular immune responses to various protozoan infections, including leishmaniasis and malaria; neutralizing antibodies to proinflammatory malarial toxins such as glycosylphosphatidylinositol and hemozoin; and self-regulating networks of effector molecules. Innate and adaptive immune responses are further moderated by the broader immunologic environment, which is influenced by both the genetic background of the host and coinfection with other pathogens. **A detailed understanding of the interplay between these different immunoregulatory processes may facilitate the rational design of vaccines and novel therapeutics.**

Sacci, J. B., Jr., U. Alam, D. Douglas, J. Lewis, D. L. Tyrrell, A. F. Azad, and N. M. Kneteman. 2006. *Plasmodium falciparum* infection and exoerythrocytic development in mice with chimeric human livers. *Int. J. Parasitol.* 36:353–360.

The exoerythrocytic stage of *Plasmodium falciparum* remains a difficult phase of the parasite life cycle to study. The host and tissue specificity of the parasite requires experimental infection of humans or nonhuman primates and subsequent surgical recovery of parasite-infected liver tissue to analyze this stage of the parasite’s development. This type of study is impossible with humans due to obvious ethical considerations, and the cost and complexity of working with primate models have precluded their use for extensive studies of the exoerythrocytic stage. In this study the authors assessed, for the first time, the use of transgenic, chimeric mice containing functioning human hepatocytes as an alternative for modeling the in vivo interaction of *P. falciparum* parasites and human hepatocytes. Infection of these mice with *P. falciparum* sporozoites produced morphologically and antigenically mature liver stage schizonts containing merozoites capable of invading human RBCs. Additionally, when microdissection was used, highly enriched *P. falciparum* liver stage parasites essentially free of hepatocyte contamination were recovered for molecular studies. **These results obtained using mice with chimeric human livers establish a stable murine model for *P. falciparum* that will have a wide utility for assessing the biology of the parasite, potential antimalarial chemotherapeutic agents, and vaccine design.**

Singh, S. K., R. Hora, H. Belrhali, C. E. Chitnis, and A. Sharma. 2006. Structural basis for Duffy recognition by the malaria parasite Duffy-binding-like domain. *Nature* 439:741–744.

Molecular processes that govern pathogenic features of erythrocyte invasion and cytoadherence in malaria are reliant on *Plasmodium*-specific Duffy-binding-like domains (DBLs). These cysteine-rich modules recognize diverse host cell surface receptors during pathogenesis. DBLs from parasite RBC binding proteins mediate invasion, and those from the antigenically variant *P. falciparum* erythrocyte membrane protein 1 (PfEMP1) have been implicated in cytoadherence. The simian (*P. knowlesi*) and human (*P. vivax*) malarial parasites invade human RBCs exclusively through the host DARC receptor (Duffy antigen receptor for chemokines). The authors present the crystal structure of the *P. knowlesi* DBL domain (Pk α -DBL), which binds to DARC during invasion of human erythrocytes. Pk α -DBL retains the overall fold observed in DBLs from *P. falciparum* erythrocyte binding antigen 175 (EBA-175). Mapping the residues that have previously been implicated in binding highlights a fairly flat but exposed site for DARC recognition in subdomain 2 of Pk α -DBL; this is in sharp contrast to receptor recognition by EBA-175. In Pk α -DBL, the residues that contact DARC and the clusters of residues under immune pressure map to opposite surfaces of the DBL, suggesting a possible mechanism for immune evasion by *P. vivax*. **The comparative structural analysis of Pk α -DBL and *P. falciparum* EBA-175 provides a framework for the understanding of malaria parasite DBLs and may affect the development of new prophylactic and therapeutic strategies.**

***Babesia* spp.**

Carcy, B., E. Precigout, T. Schetters, and A. Gorenflot. 2006. Genetic basis for GPI-anchor merozoite surface antigen polymorphism of *Babesia* and resulting antigenic diversity. *Vet. Parasitol.* 18 Mar. [Epub ahead of print.]

Glycosylphosphatidylinositol anchor merozoite surface antigens (GPI-anchor MSA) are proposed to act in the invasion process of infective merozoites of *Babesia* into host RBCs. Because of their essential function in the survival of *Babesia* parasites, they constitute good candidates for the development of vaccines against babesiosis, and they have been extensively analyzed. These antigens include *Babesia bovis* variable MSA and *Babesia bigemina* gp45/gp55 proteins of the agents of bovine babesiosis from tropical and subtropical countries and the *Babesia divergens* Bd37 and *Babesia canis* Bc28 proteins of the main agents of bovine and canine babesiosis in Europe, respectively. However, they are very polymorphic antigens, and *Babesia* parasites have evolved molecular mechanisms that enable these antigens to evade the host immune system as a survival strategy. This review focuses on the genetic basis of GPI-anchor MSA polymorphism and the antigenic diversity of B-cell epitopes that might be generated in each of these *Babesia* species. No *Babesia* genome sequence is available. However, the available sequences suggest that two distinct, non-cross-reactive GPI-anchor MSA (i.e., with unique B-cell epitopes) may be required by

all *Babesia* species for invasion and that these two distinct GPI-anchor MSA would be encoded by a multigene family. The data are consistent with the ability of biological clones from *Babesia* spp. to use these multigene families for the expression of GPI-anchor MSA, either conserved (*B. canis* and *B. bovis*) or polymorphic (*B. divergens* and *B. bigemina*) in their amino acid sequence. Moreover, as a consequence for successful parasitism, the data suggest that both conserved and polymorphic GPI-anchor MSA would present unique B-cell epitopes.

Fox, L. M., S. Wingerter, A. Ahmed, A. Arnold, J. Chou, L. Rhein, and O. Levy. 2006. Neonatal babesiosis: case report and review of the literature. *Pediatr. Infect. Dis. J.* 25:169–173.

Jaundice, hepatosplenomegaly, anemia, and conjugated hyperbilirubinemia developed in a preterm infant with transfusion-associated neonatal babesiosis. The diagnosis was eventually made by blood smear, serology, and PCR amplification. The patient was treated with clindamycin and quinine and made a favorable recovery. The authors review nine other cases of neonatal babesiosis reported in the literature, including six that were transfusion associated, two that were congenital, and two that were tick transmitted.

Kjemtrup, A. M., K. Wainwright, M. Miller, B. L. Penzhorn, and R. A. Carreno. 2006. *Babesia conradae*, sp. nov., a small *Babesia* identified in California. *Vet. Parasitol.* 6 Mar. [Epub ahead of print.]

Small piroplasms as a cause of canine babesiosis have usually been identified as *Babesia gibsoni*. Recent genetic studies suggested that small piroplasms are more likely to be composed of at least three genotypically distinct species. In southern California, canine babesiosis caused by a small piroplasm has been documented since 1990. Morphologic characteristics of this parasite include a small (0.3 to 3.0 μ m) intraerythrocytic merozoite stage with predominantly ring, pyriform, tetrad, ameboid, or anaplasmod forms. Transmission electron microscopic images of merozoites demonstrate the presence of an apical complex consisting of an inner subplasmalemmal membrane and rhoptries. **Based on phylogenetic analyses of the 18S rRNA and the ITS-2 genes, the Californian small piroplasm isolate is more closely related to piroplasm isolates from wildlife and humans in the western United States than it is to *B. gibsoni*. Molecular and morphologic evidence supports naming the small piroplasm from southern California as a distinct species, *Babesia conradae*.**

Leiby, D. A. 2006. Babesiosis and blood transfusion: flying under the radar. *Vox Sang.* 90:157–165.

Infectious agents impact transfusion medicine as an increasing number of pathogens are described that pose a potential blood safety risk. While the recent focus has been on newly emerging pathogens, several other pathogens remind us that other agents continue to pose threats, but fail to elicit adequate measures to prevent their transmission by blood transfusion. Perhaps foremost among this group of agents are

the *Babesia* spp., which have been known to cause human disease in the United States for close to 40 years. *B. microti*, *B. divergens*, and several *Babesia*-like agents are responsible for a growing number of human babesiosis infections. At the same time, in the United States there has been a sharp rise in the number of transfusion-transmitted infections by *Babesia* spp., attributable almost exclusively to *B. microti*. Despite the obvious public health issues posed by *Babesia* spp., options for preventing blood transfusion-related transmission remain limited. However, recognition that the *Babesia* spp. are indeed an ongoing and expanding blood safety threat will probably prove instrumental in the development of viable interventions to limit the transmission of these agents.

Vial, H. J., and A. Gorenflot. 2006. Chemotherapy against babesiosis. *Vet. Parasitol.* 24 Feb. [Epub ahead of print.]

Some *Babesia* spp., particularly *Babesia microti* and *Babesia divergens*, can infect humans, and human babesiosis is a significant emerging tick-borne zoonotic disease. Clinical manifestations differ markedly between European and North American diseases. In clinical cases, a combination of clindamycin and quinine is administered as the standard treatment, but administration of atovaquone-azithromycin is also effective. Supportive therapy such as intravenous fluids and blood transfusions are employed when necessary. More specific fast-acting new treatments for babesiosis remain to be developed. This should be facilitated by the sequencing of the *Babesia* spp. genome and increased interest for this malaria-like parasite.

Leishmania spp.

Alborzi, A., M. Rasouli, and A. Shamsizadeh. 2006. *Leishmania tropica*-isolated patient with visceral leishmaniasis in southern Iran. *Am. J. Trop. Med. Hyg.* 74:306–307.

Visceral leishmaniasis (VL) is caused by various strains of *Leishmania donovani*, *Leishmania infantum*, and *Leishmania chagasi* with different geographic distributions. Leishmanial DNA was extracted from the slides of bone marrow aspirates and spleen punctures, which were positive for Leishman bodies from patients who were referred to the hospitals affiliated with Shiraz University of Medical Sciences in southern Iran. Differences in strains were indicated by size difference determined by PCR amplification as visualized on agarose gels. PCR results and smears had 100% correlation. The dominant strain of *Leishmania* was *L. infantum* (63 of the 64 cases), but 1 case of *L. tropica* was also detected. VL mostly involves children younger than 2 years in Iran; therefore, infection with *L. infantum* was expected. However, this study is the first to report VL caused by *L. tropica* in Iran.

Bensoussan, E., A. Nasereddin, F. Jonas, L. F. Schnur, and C. L. Jaffe. 2006. Comparison of PCR assays for diagnosis of cutaneous leishmaniasis. *J. Clin. Microbiol.* 44:1435–1439.

Three PCR assays were compared and validated against parasite cultures and microscopic evaluation of stained tissue

smears, using 92 specimens from patients with imported and locally acquired suspected cases of cutaneous leishmaniasis (CL) in Israel and the West Bank. The kinetoplast DNA (kDNA) PCR showed the highest sensitivity (98.7%), correctly diagnosing 77 of 78 confirmed positive samples, followed by the rRNA gene internal transcribed spacer 1 (ITS1) PCR (71 of 78 positive; 91.0% sensitivity) and the spliced leader miniexon PCR (42 of 78 positive; 53.8% sensitivity). Parasite culture or microscopy alone detected 62.8% (49 of 78) or 74.4% (58 of 78) of the positive specimens, respectively, while culture and microscopy together improved the overall sensitivity to 83.3% (65 of 78). Except for the kDNA PCR that had six false positives, all other assays were 100% specific. Furthermore, restriction enzyme analysis of the ITS1 PCR product enabled identification of 74.6% of the positive samples, which included strains of *Leishmania major* (50.9%), *Leishmania tropica* (47.2%), and the *Leishmania braziliensis* complex (1.9%). The data suggest that PCR with kDNA should be used for the diagnosis of CL and that an ITS1 PCR can be reliably used for the diagnosis of CL when rapid species identification is needed.

Campanelli, A. P., A. M. Roselino, K. A. Cavassani, M. S. Pereira, R. A. Mortara, C. I. Brodskyn, H. S. Goncalves, Y. Belkaid, M. Barral-Netto, A. Barral, and J. S. Silva. 2006. CD4⁺CD25⁺ T cells in skin lesions of patients with cutaneous leishmaniasis exhibit phenotypic and functional characteristics of natural regulatory T cells. *J. Infect. Dis.* 193:1313–1322.

Endogenous regulatory T (T_{reg}) cells are involved in the control of infections, including *Leishmania* infection in mice. *Leishmania viannia braziliensis* is the main etiologic agent of CL in Brazil, and it is also responsible for the more severe mucocutaneous form. The authors investigated the possible involvement of T_{reg} cells in the control of the immune response in human skin lesions caused by *L. viannia braziliensis* infection. Data showed that functional T_{reg} cells can be found in skin lesions of patients with CL. These cells express phenotypic markers of T_{reg} cells (CD25, cytotoxic T-lymphocyte-associated antigen 4, Foxp3, and glucocorticoid-induced tumor necrosis factor receptor) and are able to produce large amounts of IL-10 and transforming growth factor β. Furthermore, CD4⁺CD25⁺ T cells derived from the skin lesions of four of six patients with CL significantly suppressed in vitro the phytohemagglutinin-induced proliferative T-cell responses of allogeneic peripheral-blood mononuclear cells from healthy control subjects at a ratio of 1 T_{reg} cell to 10 allogeneic peripheral-blood mononuclear cells. The data suggest that functional T_{reg} cells accumulate at sites of *Leishmania* infection in humans and possibly contribute to the local control of effector T-cell functions.

Croft, S. L., S. Sundar, and A. H. Fairlamb. 2006. Drug resistance in leishmaniasis. *Clin. Microbiol. Rev.* 19:111–126.

Leishmaniasis is a complex disease, with visceral and cutaneous manifestations, and is caused by over 15 different species of the protozoan parasite genus *Leishmania*. There are significant differences in the sensitivity of these species

both to the standard drugs, including pentavalent antimonials and miltefosine, and to those undergoing clinical trial, for example, paromomycin. Over 60% of patients with VL in Bihar State, India, do not respond to treatment with pentavalent antimonials. This is now considered to be due to acquired resistance. Although this class of drugs has been used for over 60 years for leishmaniasis treatment, it is only in the past 2 years that the mechanisms of action and resistance have been identified and related to drug metabolism, thiol metabolism, and drug efflux. With the introduction of new therapies, including miltefosine in 2002 and paromomycin in 2005 to 2006, the authors stress the importance of a strategy to prevent the emergence of resistance to new drugs; combination therapy, monitoring of therapy, and improved diagnostics could play an essential role in this strategy.

Genestra, M., W. J. Souza, D. Guedes-Silva, G. M. Machado, L. Cysne-Finkelstein, R. J. Bezerra, F. Monteiro, and L. L. Leon. 2006. Nitric oxide biosynthesis by *Leishmania amazonensis* promastigotes containing a high percentage of metacyclic forms. *Arch. Microbiol.* 31 Mar. [Epub ahead of print.]

Due to the diversity of its physiologic and pathophysiologic functions and general ubiquity, the study of nitric oxide (NO) has increased. The authors demonstrated that *Leishmania amazonensis* promastigotes produce NO, a free radical synthesized from L-arginine by nitric oxide synthase (NOS). A soluble NOS was purified from *L. amazonensis* promastigotes by affinity chromatography (2', 5'-ADP-agarose), and on SDS-PAGE the enzyme migrated as a single protein band of 116.2 ± 6 kDa. Furthermore, a constitutive NOS was detected through indirect immunofluorescence using anti-cNOS and in NADPH consumption assays. The data show that NO production, detected as nitrite in the culture supernatant, is prominent in promastigote preparations with large numbers of metacyclic forms, suggesting an association with the differentiation and infectivity of the parasite.

Rotureau, B., C. Ravel, C. Aznar, B. Carme, and J. P. Dedet. 2006. First report of *Leishmania infantum* in French Guiana: canine visceral leishmaniasis imported from the old world. *J. Clin. Microbiol.* 44:1120–1122.

The first two cases of canine VL in French Guiana are described. One infected dog was most probably imported from France. A second dog was then infected with *Leishmania infantum* in French Guiana. These observations support the intercontinental transportation theory for *L. infantum*.

Rotureau, B., C. Ravel, P. Couppie, F. Pralong, M. Nacher, J. P. Dedet, and B. Carme. 2006. Use of PCR-restriction fragment length polymorphism analysis to identify the main New World *Leishmania* species and analyze their taxonomic properties and polymorphism by application of the assay to clinical samples. *J. Clin. Microbiol.* 44:459–467

Approximately 13 characterized *Leishmania* species are known to infect humans in South America; 5 of these are transmitted in the sylvatic ecotopes of the whole French Guianan territory and are responsible for CL. Restriction

fragment length polymorphism analyses have given promising results in the diagnosis of CL. The end of the small subunit and ITS1 of the rRNA genes were sequenced and targeted by PCR/restriction fragment length polymorphism analysis in the 10 main New World *Leishmania* species from the two subgenera. The procedure was tested on 40 samples from patients with CL, and the results were compared with those of conventional methods. The results of this simple genus-specific method were in agreement with those of previous isoenzyme analyses. This method distinguished the most medically relevant *Leishmania* species with only one enzyme (RsaI) and could be performed directly on human biopsy specimens (sensitivity, 85.7%). Performing New World *Leishmania* species typing rapidly and easily in the field constitutes a very valuable improvement for detection of *Leishmania* spp. Revealing great diversity with several enzymes, this method could also be useful for taxonomic, ecological, and epidemiologic studies in space and time.

Rotureau, B., C. Ravel, M. Nacher, P. Couppie, I. Curtet, J. P. Dedet, and B. Carme. 2006. Molecular epidemiology of *Leishmania (Viannia) guyanensis* in French Guiana. *J. Clin. Microbiol.* 44:468–473.

Genetic polymorphism of a nuclear sequence encompassing the end of the ribosomal small subunit and ITS1 of 265 isolates from patients with CL was examined by restriction fragment length polymorphism analysis. Genotypes based on the fingerprinting phenetic integration were compared to epidemiologic, clinical, and geographic data. In agreement with previous reports, five different *Leishmania* species were identified, but *Leishmania (Viannia) guyanensis* represented 95.8% of the samples. Two distinct *L. (V.) guyanensis* populations were found to originate in two ecologically characterized regions. Higher lesional parasite densities and the need for additional treatments were significantly linked to genotype group I. Parasites of genotype group II were more likely to cause chronic and disseminated cutaneous forms in patients. Although *L. (V.) guyanensis* was previously said not to be very polymorphic, the data indicate a significant degree of discrimination among *L. (V.) guyanensis* isolates from diverse ecological areas and with different clinical implications.

Stark, D., S. Pett, D. Marriott, and J. Harkness. 2006. Post-kala-azar dermal leishmaniasis due to *Leishmania infantum* in a human immunodeficiency virus type 1-infected patient. *J. Clin. Microbiol.* 44:1178–1180.

The authors report the first case of post-kala azar dermal leishmaniasis due to *Leishmania infantum* in an HIV-1-infected patient in Australia. Molecular characterization of the isolate was performed using PCR/restriction fragment length polymorphism targeting both repetitive sequences from *Leishmania* nuclear DNA and repetitive kinetoplast DNA minicircles for species differentiation.

Zhang, W. W., C. Miranda-Verastegui, J. Arevalo, M. Ndao, B. Ward, A. Llanos-Cuentas, and G. Matlashewski. 2006.

Development of a genetic assay to distinguish between *Leishmania viannia* species on the basis of isoenzyme differences. *Clin. Infect. Dis.* 42:801–809.

Tegumentary leishmaniasis in Latin America is caused by *Leishmania viannia braziliensis* complex parasites. *L. braziliensis* and *Leishmania viannia peruviana* are the two predominant *Leishmania* species in Peru. *L. braziliensis* is more virulent, because it can cause mucocutaneous leishmaniasis, known as espundia, which results in severe facial destruction. Early identification of the species that causes the initial cutaneous infection would greatly help to prevent mucocutaneous leishmaniasis because it would allow more aggressive treatment and follow-up. However, because of the close genetic similarity of *L. braziliensis* and *L. peruviana*, there is no simple assay to distinguish between these species. The authors cloned the mannose phosphate isomerase gene from both *L. braziliensis* and *L. peruviana*. It is the only known isoenzyme capable of differentiating between *L. braziliensis* and *L. peruviana* in multilocus enzyme electrophoresis. Only a single nucleotide polymorphism was found between the mannose phosphate isomerase genes from *L. braziliensis* and *L. peruviana*, resulting in an amino acid change from threonine to arginine at amino acid 361. A PCR assay was developed to distinguish the single-nucleotide polymorphism of the mannose phosphate isomerase gene to allow for the specific identification of *L. braziliensis* or *L. peruviana*. This assay was validated with 31 reference strains that were previously typed by multilocus enzyme electrophoresis, successfully applied to patient biopsy samples, and adapted to a real-time PCR assay. This innovative approach combines new genetic knowledge with traditional biochemical fundamentals of multilocus enzyme electrophoresis to better manage leishmaniasis in Latin America.

Trypanosoma spp.

African Trypanosomiasis

Bisser, S., O. N. Ouwe-Missi-Oukem-Boyer, F. S. Toure, Z. Taoufig, B. Bouteille, A. Buguet, and D. Mazier. 2006. Harboring in the brain: a focus on immune evasion mechanisms and their deleterious effects in malaria and human African trypanosomiasis. *Int. J. Parasitol.* 9 Mar. [Epub ahead of print.]

Malaria and human African trypanosomiasis represent the two major tropical vector-transmitted protozoan infections, displaying different prevalence and epidemiologic patterns. Death occurs mainly due to neurologic complications which are initiated at the blood-brain barrier level. Adapted host immune responses present differences but also similarities in blood-brain barrier/parasite interactions for these diseases and are the focus of this review. The authors describe and compare parasite evasion mechanisms, the initiating mechanisms of central nervous system (CNS) pathology, and the major clinical and neuropathologic features. They also highlight the common immune-mediated mechanisms leading to brain involvement. **In both diseases, neurologic damage is caused mainly by cytokines (gamma interferon, tumor necrosis factor- α , and IL-10), NO, and endothelial cell apoptosis.**

Blum, J., C. Schmid, and C. Burri. 2006. Clinical aspects of 2541 patients with second stage human African trypanosomiasis. *Acta Trop.* 97:55–64.

The clinical symptoms and signs of patients with second-stage human African trypanosomiasis are described for a large cohort of patients treated in a prospective multicenter, multinational study. Special emphasis is given to the influence of the disease stage (duration, number of white blood cells [WBC] in cerebrospinal fluid [CSF]) and patient age on the clinical picture. **Even though the frequencies of the symptoms and signs are highly variable among centers, the clinical picture of the disease is similar for all countries.** Headache (78.7%), sleeping disorder (74.4%), and lymphadenopathy (56.1%) are the most frequent symptoms and signs, and they are similar for all stages of the disease. Lymphadenopathy tends to be highest in the advanced second stage (59.0%). The neurologic and psychiatric symptoms increase significantly with the number of WBC in the CSF, indicating the stage of progression of the disease. Pruritus is observed in all stages and increases with the number of WBC in CSF from 30 to 55%. In children younger than 7 years, lymphadenopathy is less frequently reported (11.8 to 37.3%) than in older children or adults (56.4 to 61.2%). Fever is most frequently reported in children between 2 and 14 years of age (26.1 to 28.7%), and malnutrition is significantly more frequently observed in children of all ages (43 to 56%) than in adults (23.5%).

Joshi, P. P., V. R. Shegokar, R. M. Powar, S. Herder, R. Katti, H. R. Salkar, V. S. Dani, A. Bhargava, J. Jannin, and P. Truc. 2005. Human trypanosomiasis caused by *Trypanosoma evansi* in India: the first case report. *Am. J. Trop. Med. Hyg.* 73:491–495.

The authors report an Indian farmer who had fluctuating trypanosome parasitemia associated with febrile episodes for 5 months. Morphologic examination of the parasites indicated the presence of large numbers of trypanosomes belonging to the species *Trypanosoma evansi*, which is normally a causative agent of animal trypanosomiasis known as surra. Basic clinical and biological examinations are described, using several assays including parasitological, serologic, and molecular biological tests, all of which confirmed the infecting species as *T. evansi*. Analysis of CSF indicated no invasion of the CNS by trypanosomes. Suramin, a drug used exclusively for treatment of early-stage human African trypanosomiasis with no CNS involvement, led to an apparent cure in the patient. **This is the first reported case of human infection due to *Trypanosoma evansi*, which was probably caused by transmission of blood from an infected animal.**

Kennedy, P. G. 2006. Diagnostic and neuropathogenesis issues in human African trypanosomiasis. *Int. J. Parasitol.* 3 Mar. [Epub ahead of print.]

Human African trypanosomiasis, also known as sleeping sickness, is caused by protozoan parasites of the genus *Trypanosoma* and is a major cause of human mortality and morbidity. The East African and West African variants, caused by *Trypanosoma brucei rhodesiense* and *Trypanosoma brucei*

gambiense, respectively, differ in their presentation, but the disease is fatal if untreated. **Accurate staging of the disease into the early hemolymphatic stage and the late encephalitic stage is critical because the treatment for the two stages is different. The only effective drug for late-stage disease, melarsoprol, which crosses the blood-brain barrier, is followed by a severe posttreatment reactive encephalopathy in 10% of patients, half of whom die.** There is no current consensus on the diagnostic criteria for CNS involvement, and the specific indications for melarsoprol therapy also differ. There is a pressing need for a quick, simple, cheap, and reliable diagnostic test to diagnose human African trypanosomiasis in the field and also to determine CNS invasion. **CSF and plasma analyses for patients with human African trypanosomiasis have indicated a role for both proinflammatory and counterinflammatory cytokines in determining the severity of the meningoencephalitis of late-stage disease; at least in *T. brucei rhodesiense* infection, the balance of these opposing cytokines may be critical.** Animal models have allowed a greater understanding of the more direct effect of trypanosome infection on CNS function, including the disruption of circadian rhythms, as well as the immunologic determinants of the passage of trypanosomes across the blood-brain barrier.

Kennedy, P. G. 2006. Human African trypanosomiasis—neurological aspects. *J. Neurol.* 20 Mar. [Epub ahead of print.]

Human African trypanosomiasis, also known as sleeping sickness, is a major cause of death and disability in 36 countries in sub-Saharan Africa. The disease is caused by the protozoan parasite of the *Trypanosoma* genus, which is transmitted by the bite of the tsetse fly. The two types of human African trypanosomiasis, the East African form due to *Trypanosoma brucei rhodesiense* and the West African form due to *T. brucei gambiense*, differ in their tempo of infection, but in both cases the disease is always fatal if untreated. As well as multiple systemic features seen in the early (hemolymphatic) stage of disease, the late (encephalitic) stage is associated with a wide range of neurologic features including neuropsychiatric, motor, and sensory abnormalities. **Accurate staging of the disease is absolutely essential because of the potentially fatal complications of melarsoprol treatment of late-stage disease, the most important of which is a severe posttreatment reactive encephalopathy, whose pathogenesis is not fully understood.** However, there is no universal consensus as to how late-stage disease should be diagnosed using CSF criteria, and this has been very problematic in human African trypanosomiasis. **A more recent alternative drug for late-stage gambiense disease is eflornithine.** There is a need for a nontoxic oral drug for both early- and late-stage disease that would eliminate many of the staging problems.

Kibona, S. N., L. Matemba, J. S. Kaboya, and G. W. Lubega. 2006. Drug-resistance of *Trypanosoma b. rhodesiense* isolates from Tanzania. *Trop. Med. Int. Health* 11:144–155.

The authors screened 35 *Trypanosoma brucei rhodesiense* strains in the mouse model for sensitivity to melarsoprol (1.8,

3.6, and 7.2 mg/kg), diminazene aceturate (3.5, 7, and 14 mg/kg), suramin (5, 10, and 20 mg/kg) and isometamidium (0.1, 1.0, and 2 mg/kg). Thirteen isolates suspected to be resistant were selected for further testing in vitro and in vivo. From the in vitro testing, 50% inhibitory concentrations (IC₅₀s) were determined by a short-term viability assay, and MICs were calculated by a long-term viability assay. For in vivo testing, doses higher than those in the initial screening test were used. Two *T. brucei rhodesiense* stocks expressed resistance in vivo to melarsoprol at 5 mg/kg and at 10 mg/kg. Melarsoprol had high IC₅₀s and MICs for these strains, consistent with those for the melarsoprol-resistant reference strain. Infection with another isolate relapsed after treatment with 5 mg of melarsoprol/kg although the isolate did not appear resistant in vitro. One isolate was resistant to diminazene at 14 mg/kg, and another was resistant at both 14 and 28 mg/kg. The IC₅₀s for these two isolates were consistent with the diminazene-resistant reference strain. Infections with two isolates relapsed at a suramin dose of 5 mg/kg, although no isolate appeared resistant in the in vitro tests. Two isolates were resistant to isometamidium at 1.0 mg/kg, and the IC₅₀s were higher. Two isolates were cross resistant to melarsoprol and diminazene, and one isolate was cross resistant to suramin and isometamidium. **The reduced susceptibility of *T. brucei rhodesiense* isolates to these drugs strongly indicates that drug resistance may be emerging in northwestern Tanzania.**

MacLean, L., M. Odiit, and J. M. Sternberg. 2006. Intrathecal cytokine responses in *Trypanosoma brucei rhodesiense* sleeping sickness patients. *Trans. R. Soc. Trop. Med. Hyg.* 100:270–275.

Intrathecal cytokine levels and blood-CSF barrier function in 91 *Trypanosoma brucei rhodesiense*-infected patients were studied. The concentrations of the cellular immune activation marker neopterin and the cytokines IL-6 and IL-10 in CSF were increased over control and posttreatment levels in all patients, with maximal levels observed in late-stage (meningoencephalitic) individuals. Analysis of concentration quotients in CSF and serum indicated that IL-10 and neopterin were derived from CNS in at least 25% of the patients. Blood-CSF barrier dysfunction occurred in 64% of late-stage patients but not in early-stage patients. **While the high level of neopterin observed in the CSF of late-stage patients is indicative of widespread cellular activation, the increased levels of IL-6 and IL-10 suggest that counter-inflammatory cellular responses may be important in the regulation of neuropathogenesis in late-stage human African trypanosomiasis.**

American Trypanosomiasis

Benchimol Barbosa, P. R. 2006. The oral transmission of Chagas' disease: an acute form of infection responsible for regional outbreaks. *Int. J. Cardiol.* 4 Apr. [Epub ahead of print.]

Orally transmitted Chagas' disease is an ordinarily rare form of *Trypanosoma cruzi* transmission and is responsible for regional outbreaks. Ingestion of contaminated material is generally associated with massive parasitic transmission,

ultimately leading to acute myocarditis, with more severe clinical presentation at younger ages and high death rates. Close monitoring of regional outbreaks by health agencies is mandatory to prevent recrudescence of the disease.

de Castro, A. M., A. O. Luquetti, A. Rassi, E. Chiari, and L. M. da Cunha Galvao. 2006. Detection of parasitemia profiles by blood culture after treatment of human *Trypanosoma cruzi* infection. *Parasitol. Res.* 29 Mar. [Epub ahead of print.]

The change in parasitemia profile, measured by sequential blood cultures of 27 benznidazole-treated patients compared with 13 untreated patients, during the chronic phase of Chagas' disease is described. All patients were adults (age limits, 23 to 88 years) with positive serology (three tests); 23 of them were females. All patients submitted six blood cultures, three before and three after the benznidazole treatment. The parasitemia was classified as nondetected (with three negative blood cultures), medium (one positive culture in three), or high (two or three positive cultures). Of the 8 patients with nondetected parasitemia before treatment, 7 still had the same profile and only 1 switched to medium; of the 8 with medium parasitemia, 7 shifted to nondetected and 1 shifted to high parasitemia; of the 11 patients with high parasitemia before treatment, 10 converted to nondetected and only 1 was positive. Of the 27 patients, 19 changed the parasitemia profile (70.4%), and the rate of therapeutic failure was 11.1% (3 of 27) during the first 24 months of follow-up after treatment. The shift to the nondetected parasitemia profile was from 8 of 27 to 24 of 27 patients for the first 2 years after benznidazole treatment. Only 46.2% (6 of 13) of the nontreated individuals changed their parasitemia profile. The authors concluded that benznidazole has a strong trypanocidal effect (88.8%) and that the rate of therapeutic failure during the first 2 years after trypanocidal treatment is 11.1%.

Mora, M. C., O. Sanchez Negrette, D. Marco, A. Barrio, M. Ciaccio, M. A. Segura, and M. A. Basombrio. 2005. Early diagnosis of congenital *Trypanosoma cruzi* infection using PCR, hemoculture, and capillary concentration, as compared with delayed serology. *J. Parasitol.* 91:1468–1473.

Congenital *Trypanosoma cruzi* infection is a highly pathogenic and underreported condition. Early recognition is essential for effective treatment. Umbilical cord blood from newborns ($n = 302$) born of infected mothers was analyzed by microhematocrit, hemoculture, and PCR methods. Each subject was then monitored serologically. In calibrated suspensions of *T. cruzi* in blood, the sensitivity of PCR was 27-fold higher than that of hemoculture. However, this advantage was not reflected during routine testing of samples from maternity wards, partly because of the uneven distribution of few parasites in small samples. Levels of detection of congenital infection were 2.9% (8 of 272) for microhematocrit, 6.3% (18 of 287) for hemoculture, 6.4% (15 of 235) for PCR, and 8.9% (27 of 302) for cumulated results. Evaluation against the standard of delayed serology indicates that the regular use of PCR, hemoculture, and microhematocrit with blood

samples allows rapid detection of about 90% of congenitally infected newborns from samples that can be obtained before the mother and child leave the maternity ward.

Intestinal Nematodes

Capillaria philippinensis

Intapan, P. M., W. Maleewong, W. Sukeepaisarnjaroen, and N. Morakote. 2006. Potential use of *Trichinella spiralis* antigen for serodiagnosis of human capillariasis philippinensis by immunoblot analysis. *Parasitol. Res.* 98:227–231.

Intestinal capillariasis is an emerging helminthic zoonosis caused by *Capillaria philippinensis* and is frequently fatal if not diagnosed correctly. The present study demonstrates cross-reactivity between *Trichinella spiralis* larval antigens and *C. philippinensis*-infected human sera by immunoblotting. Sera from 16 patients with proven intestinal capillariasis and 16 patients with proven trichinosis were tested. The antigenic patterns recognized by sera from patients with intestinal capillariasis varied with the molecular masses, ranging from less than 20.1 to more than 94 kDa. The immunoblotting profiles of the sera from patients with trichinosis were similar to those of the sera from patients with intestinal capillariasis. The antigenic bands with 100% reactivity were located at 36.5, 40.5, and 54 kDa, respectively. Sera from patients with trichuriasis, strongyloidiasis, opisthorchiasis, and healthy controls differed clearly from the previous two and produced very faint patterns of reactivity and attenuated bands. This assay is potentially useful for large-scale screenings of persons at risk for *C. philippinensis* infection. However, parasitologic stool examinations from the positive patients are necessary as second-tier laboratory tests for confirming the diagnosis.

Hookworm

Fleming, F. M., S. Brooker, S. M. Geiger, I. R. Caldas, R. Correa-Oliveira, P. J. Hotez, and J. M. Bethony. 2006. Synergistic associations between hookworm and other helminth species in a rural community in Brazil. *Trop. Med. Int. Health* 11:56–64.

The authors determined the prevalence and intensity of infections by single and multiple helminth species in an age-stratified sample of 1,332 individuals from 335 households. Hookworm was the most prevalent helminth (68.2%), followed by *Ascaris lumbricoides* (48.8%) and *Schistosoma mansoni* (45.3%). Overall, 60.6% of individuals had multiple-helminth infections. Multivariate analysis indicated significant positive associations for coinfection with hookworm and *S. mansoni* and for coinfection with hookworm and *A. lumbricoides*. Coinfections with hookworm and *A. lumbricoides* resulted in higher egg counts for both, suggesting a synergistic relationship between these species, although the authors found important age differences in this relationship. However, the intensity of *S. mansoni* or *A. lumbricoides* coinfection did not differ from that of monoinfection. These results have implications for the epidemiology, immunology, and control of multiple-helminth infections. More research is needed to examine the rates of reinfection and immune responses after chemotherapy and the extent to which the effects of polyparasitism are altered by chemotherapy.

Helde, M. R., R. D. Bungiro, L. M. Harrison, I. Hamza, and M. Capello. 2006. Dietary iron content mediates hookworm pathogenesis in vivo. *Infect. Immun.* 74:289–295.

Hookworm infection is associated with growth delay and iron deficiency anemia in developing countries. A series of experiments were designed to test the hypothesis that host dietary iron restriction mediates susceptibility to hookworm infection by using the hamster model of *Ancylostoma ceylanicum*. Animals were maintained on diets containing either 10 ppm iron (iron restricted) or 200 ppm iron (standard/high iron) and were then infected with *A. ceylanicum* third-stage larvae. Infected animals fed the standard diet exhibited statistically significant growth delay and reduced blood hemoglobin levels compared to uninfected controls on day 20 postinfection. In contrast, no statistically significant differences in weight or hemoglobin concentration were observed between infected and uninfected animals fed the iron-restricted diet. Moreover, iron-restricted animals were observed to have reduced intestinal worm burdens on days 10 and 20 postinfection compared to those of animals maintained on the standard/high-iron diet. In a subsequent study, animals equilibrated on diets containing a range of iron levels (10, 40, 100, or 200 ppm) were infected with *A. ceylanicum* and monitored for evidence of hookworm disease. Infected animals from the intermediate-dietary-iron (40- and 100-ppm) groups exhibited greater weight loss and anemia than did those in the low (10-ppm)- or high (200-ppm)-iron groups. Mortality was also significantly higher in the intermediate-dietary-iron groups. These data suggest that severe dietary iron restriction impairs hookworm development in vivo but that moderate iron restriction enhances host susceptibility to severe disease.

Ranjit, N., M. K. Jones, D. J. Stenzel, R. B. Gasser, and A. Loukas. 2006. A survey of the intestinal transcriptomes of the hookworms, *Necator americanus* and *Ancylostoma caninum*, using tissues isolated by laser microdissection microscopy. *Int. J. Parasitol.* 6 Mar. [Epub ahead of print.]

The gastrointestinal tracts of multicellular blood-feeding parasites are targets for vaccines and drugs. Recombinant vaccines that interrupt the digestion of blood in the hookworm gut have shown efficacy, and so the authors explored the intestinal transcriptomes of the human and canine hookworms, *Necator americanus* and *Ancylostoma caninum*, respectively. They used laser microdissection microscopy to dissect gut tissue from the parasites, extracted the RNA, and generated cDNA libraries. A total of 480 expressed sequence tags were sequenced from each library and assembled into contigs, accounting for 268 *N. americanus* genes and 276 *A. caninum* genes. Only 17% of *N. americanus* and 36% of *A. caninum* contigs were assigned gene ontology classifications. Twenty-six *N. americanus* (9.8%) and 18 *A. caninum* (6.5%) contigs did not have homologues in any databases, including dbEST. Of these novel clones, seven *N. americanus* and three *A. caninum* contigs had open reading frames with predicted secretory signal peptides. The most abundant transcripts corresponded to mRNAs encoding cholesterol and fatty acid binding proteins, C-type lectins, activation-associated secretory proteins, and prote-

ases of different mechanistic classes, particularly astacin-like metallopeptidases. Expressed sequence tags corresponding to known and potential recombinant vaccines were identified, and these included homologues of proteases, anti-clotting factors, defensins, and integral membrane proteins involved in cell adhesion.

Strongyloides stercoralis

Arsic-Arsenijevic, V., A. Dzamic, Z. Dzamic, D. Milobratovic, and D. Tomic. 2005. Fatal *Strongyloides stercoralis* infection in a young woman with lupus glomerulonephritis. *J. Nephrol.* 18:787–790.

The authors report a case of fatal *Strongyloides stercoralis* infection in a 35-year-old woman with lupus glomerulonephritis after prolonged steroid therapy. An epidemiologic evaluation revealed that the patient originated from a rural area in Bosnia and Herzegovina, which was an area of *S. stercoralis* endemicity in the former Yugoslavia. She had severe gastrointestinal and pulmonary symptoms and a history of a 13-kg weight loss in 3 months. Histopathologic examination of large-bowel mucosa showed nematode larvae. Microscopy of stool, sputum, and urine samples confirmed *S. stercoralis*. The diagnosis was delayed because of the low suspicion index, the absence of eosinophilia, and nonspecific signs of infection, which could be a result of the underlying disease or the effects of corticosteroids. This case highlights the importance of screening for *S. stercoralis* in patients starting immunosuppressive therapy, especially if they are from areas of endemic infection.

Ternidens deminutus

Hemsrichart, V. 2005. *Ternidens deminutus* infection: first pathological report of a human case in Asia. *J. Med. Assoc. Thai.* 88:1140–1143.

The authors report a case of *Ternidens deminutus* infection in a 33-year-old Thai woman who was admitted to the hospital because of abdominal pain and a right lower quadrant mass. Exploratory laparotomy revealed an omental mass with attached terminal ileum. Resection of the mass together with the terminal ileum and the right-sided colon was performed. Pathologically, the omental mass was an abscess containing an immature male *Ternidens deminutus*. The parasite usually is found in the intestine of primates in Africa and Asia. Human infection occurs when food contaminated with infective filariform larvae is ingested. The larvae molt in the intestinal wall and become adults. They pass eggs in feces. Eggs in contaminated soil hatch and become rhabditiform larvae and then infective filariform larvae. This is the first reported human case in Asia.

Tissue Nematodes

Angiostrongylus cantonensis

Kanpittaya, J., S. Jitpimolmard, S. Tiamkao, and E. Mairiang. 2000. MR findings of eosinophilic meningoencephalitis attributed to *Angiostrongylus cantonensis*. *Am. J. Neuroradiol.* 21:1090–1094.

Eosinophilic meningoencephalitis is prevalent and widely distributed in Thailand, especially in the northeastern and central parts of the country. *Angiostrongylus cantonensis* is one of the causative agents of fatal eosinophilic meningoencephalitis. The nematodes cause extensive tissue damage by moving through the brain and inducing an inflammatory reaction. In six patients with eosinophilic meningoencephalitis, the clinical presentation included severe headache, clouded consciousness, and meningeal irritation. Abnormal magnetic resonance imaging (MRI) findings included prominence of the Virchow-Robin spaces, subcortical enhancing lesions, and abnormal high-T₂ signal lesions in the periventricular regions. Proton brain MR spectroscopy was performed for three patients; the results were abnormal in one patient with a severe case, showing decreased choline levels in a lesion. Small hemorrhagic tracts were found in one patient. Lesions thought to be due to microcavities and migratory tracts were found in only one patient. MRI and MR spectroscopy findings are helpful in understanding the pathogenic mechanisms of the disease.

Anisakiasis

De Nicola, P., L. Napolitano, N. Di Bartolomeo, M. Waku, and P. Innocenti. 2005. Anisakiasis presenting as perforated ulcer of the cecum. *G. Chir.* 26:375–377.

Symptoms of cecal anisakiasis in this patient were compatible with appendicitis. Surgery was performed, and a perforated ulcer of the cecum was found. Ileocolic resection was performed. The histologic result showed the presence of *Anisakis simplex* larva in the muscle of the cecum. The patient was discharged on day 5 without complications and at present remains asymptomatic. He had eaten uncooked anchovies some days before the onset of the disease.

Chai, J. Y., K. Darwin Murrell, and A. J. Lymbery. 2005. Fish-borne parasitic zoonoses: status and issues. *Int. J. Parasitol.* 35:1233–1254.

The fish-borne parasitic zoonoses have been limited for the most part to populations living in low- and middle-income countries, but the geographic limits and populations at risk are expanding because of growing international markets, improved transportation systems, and demographic changes such as population movements. While many people in developed countries recognize meat-borne zoonoses such as trichinellosis and cysticercosis, far fewer are acquainted with the fish-borne parasitic zoonoses, which are mostly helminthic diseases caused by trematodes, cestodes, and nematodes. Yet these zoonoses are responsible for large numbers of human infections around the world. The list of potential fish-borne parasitic zoonoses is quite long. However, in this review, emphasis has been placed on liver fluke diseases such as clonorchiasis, opisthorchiasis, and metorchiasis, as well as on intestinal trematodiasis (the heterophyids and echinostomes), anisakiasis (due to *Anisakis simplex* larvae), and diphyllorhynchiasis. The life cycles, distributions, epidemiology, clinical aspects, and, importantly, the research needed for improved risk assessments, clinical management, and prevention and control of these important parasitic diseases are reviewed.

Angiostrongylus cantonensis

Liu, I. H., Y. M. Chung, S. J. Chen, and W. L. Cho. 2006. Necrotizing retinitis induced by *Angiostrongylus cantonensis*. *Am. J. Ophthalmol.* 141:577–579.

The authors report a case of bilateral necrotizing retinitis induced by *Angiostrongylus cantonensis*. A 52-year-old Asian woman developed eosinophilic meningitis after eating several undercooked snails. One week later, sudden onset of vision loss in both eyes was noted. Widespread yellow retinal exudates were accompanied by bullous retinal detachment in both eyes. *A. cantonensis* infection was confirmed by positive ELISA of the serum and CSF and a positive Western blot test of the subretinal fluid. After treatment with mebendazole, levamisole, and corticosteroid, these necrotizing patches regressed gradually. However, the final visual acuity was no light perception. Considering the possible outcome, *A. cantonensis* infection should be considered one of the causes of necrotizing retinitis.

Baylisascaris procyonis

Gavin, P. J., K. R. Kazacos, and S. T. Shulman. 2005. Baylisascariasis. *Clin. Microbiol. Rev.* 18:703–718.

The raccoon roundworm, *Baylisascaris procyonis*, is the most common and widespread cause of clinical larva migrans in animals. In addition, it is increasingly recognized as a cause of devastating or fatal neural larva migrans in infants and young children and ocular larva migrans in adults. Humans become infected by accidentally ingesting infective *B. procyonis* eggs from raccoon latrines or articles contaminated with their feces. Two features distinguish *B. procyonis* from other helminths that cause larva migrans: (i) its aggressive somatic migration and invasion of the CNS and (ii) the continued growth of larvae to a large size within the CNS. Typically, *B. procyonis* neural larva migrans presents as acute fulminant eosinophilic meningoencephalitis. Once invasion of the CNS has occurred, the prognosis is grave with or without treatment. To date, despite anthelmintic treatment of cases of *B. procyonis* neural larva migrans, there are no documented neurologically intact survivors. Epidemiologic study of human cases of neural larva migrans demonstrate that contact with raccoon feces or an environment contaminated by infective eggs and geophagia or pica are the most important risk factors for infection. In many regions of the United States, increasingly large populations of raccoons, with high rates of *B. procyonis* infection, live in close proximity to humans. Although documented cases of human baylisascariasis remain relatively uncommon, widespread contamination of the domestic environment by infected raccoons suggests that the risk of exposure and human infection is probably substantial. In the absence of early diagnosis or effective treatment, prevention of infection is the most important public health measure.

Capillaria hepatica

Klenzak, J., A. Mattia, A. Valenti, and J. Goldberg. 2005. Hepatic capillariasis in Maine presenting as a hepatic mass. *Am. J. Trop. Med. Hyg.* 72:651–653.

The authors report the first case of hepatic capillariasis in Maine. The patient was a 54-year-old male carpenter who

presented with a subacute history of severe abdominal pain, fevers, and weight loss. Initial diagnostic studies suggested a hepatic mass associated with para-aortic lymphadenopathy. The patient underwent open laparotomy for resection of the mass. He was found to have an eosinophilic granuloma in the liver; further evaluation revealed degenerating *Capillaria hepatica*. The exact route of infection in this case is unknown but most probably involves accidental ingestion of soil contaminated with mature *Capillaria* eggs. This patient had a low parasite burden and did not exhibit significant peripheral eosinophilia. After treatment with thiabendazole, he recovered uneventfully.

Gnathostoma spp.

Sangchan, A., K. Sawanyawisuth, P. M. Intapan, and A. Mahakkanukrauh. 2006. Outward migration of *Gnathostoma spinigerum* in interferon alpha treated hepatitis C patient. *Parasitol. Int.* 55:31–32.

After a hepatitis C virus (HCV)-infected Thai woman received the first injected dose of pegylated alpha-2b interferon (Peg-IFN- α -2b), she developed cyclic painful swelling nodules on the right upper quadrant of her abdomen and the right anterior lower chest wall. The nodules subsided spontaneously within 1 to 2 days but were recurrent after every Peg-IFN- α -2b injection. She also experienced acute urticaria. After 9 months of therapy, an immature *Gnathostoma spinigerum* male migrated out from the skin nodule shortly after a Peg-IFN- α -2b injection as scheduled. The worm showed a head bulb bearing eight transverse rows of spines, which indicated an immature stage. It had four well-defined pairs of caudal papillae on the posterior body, which were used to identify the male gender. The painful migratory swelling and urticaria disappeared after the parasite was removed. She was continually treated and had both virologic and biochemical responses to the HCV treatment. **This case demonstrates that outward migration of *G. spinigerum* may be stimulated by the injection of Peg-IFN- α -2b.**

Toxocara spp.

Cianferoni, A., L. Schneider, P. M. Schantz, D. Brown, and L. M. Fox. 2006. Visceral larva migrans associated with earthworm ingestion: clinical evolution in an adolescent patient. *Pediatrics* 117:e336–e339.

A 16-year-old girl developed a cough, hyper eosinophilia (absolute eosinophil count, 32,000/mm³), hypergammaglobulinemia, and multiple noncavitary pulmonary nodules 1 month after having ingested an earthworm on a dare. Spirometry revealed moderate restriction and reduced gas diffusion. Parabronchial biopsy demonstrated eosinophilic organizing pneumonitis with multiple eosinophilic microabscesses, and *Toxocara* titers were elevated (>1:4,096). Ophthalmologic examination ruled out ocular larva migrans. The patient received a 10-day course of albendazole (400 mg orally twice daily) and demonstrated significant clinical improvement with resolution of cough and pulmonary function abnormalities. Her WBC count and hypergammaglobulinemia normalized within 20 days, yet eosinophils (absolute eosinophil count, 1,780/mm³) and *Toxocara* titers

(>1:4,096) remained elevated 3 months after completion of antihelminthic therapy. In this instance, the ingested earthworm served as the paratenic carrier of *Toxocara* larvae from the soil to the patient. **This case highlights the clinical evolution of pulmonary visceral larva migrans infection caused by *Toxocara* spp. associated with a discrete ingestion in an adolescent patient. In addition, it provides a rare opportunity to define the incubation period of visceral larva migrans and emphasizes the importance of education regarding sources of *Toxocara* infection.**

Trichinella spp.

Dupouy-Camet, J. 2006. Trichinellosis: still a concern for Europe. *Eur. Surveill.* 20 Jan. [Epub ahead of print.]

Trichinellosis is a zoonotic disease caused by the ingestion of raw meat containing larvae of the nematode *Trichinella*. Four species of *Trichinella* are found in Europe: *Trichinella spiralis* (cosmopolitan), *T. britovi* (in wildlife from mountainous areas), *T. nativa* (in wildlife from colder and northern regions), and *T. pseudospiralis* (a cosmopolitan nonencapsulating species). Human trichinellosis causes high fever, facial edema, myositis, and eosinophilia. It can be a serious disease, particularly in elderly patients, in whom neurologic or cardiovascular complications can lead to death.

Turk, M., F. Kaptan, N. Turker, M. Korkmaz, S. El, D. Ozkaya, S. Ural, I. Vardar, M. Z. Alkan, N. A. Coskun, M. Turker, and E. Pozio. 2006. Clinical and laboratory aspects of a trichinellosis outbreak in Izmir, Turkey. *Parasite* 13:65–70.

Epidemiologic, clinical, and laboratory data were collected during an outbreak of trichinellosis, which occurred in Izmir, Turkey, between January and March 2004. The source of the infection was raw meatballs made with a mixture of uncooked beef and pork. Of 474 persons who were admitted to the Ataturk Training and Research Hospital during this period with a history of raw-meatball consumption, 154 (32.5%; 87 males and 67 females; mean age, 31 years; range, 6 to 67 years) were confirmed to have trichinellosis. **Among persons with a confirmed diagnosis, 79% had myalgia, 77% had weakness and malaise, 63% had arthralgia, 40% had jaw pain, 68% had fever, 63% had periorbital and/or facial edema, 49% had edema at the trunk and limb, 42% had abdominal pain, 40% had nausea and vomiting, 28% had diarrhea, 23% had subconjunctival hemorrhage, 25% had macular or petechial rash, 4% had subungual hemorrhage, 15% had cardiac complaints, and 0.2% had neurologic complaints.** Nine patients (5.8%) were hospitalized due to severe myalgia ($n = 2$), high fever ($n = 3$), neurologic manifestations ($n = 1$), thrombophlebitis ($n = 2$), or palmar erythema ($n = 1$). Eosinophilia was present in 88% of the patients with confirmed cases at admission. Elevated levels of serum creatine phosphokinase, lactate dehydrogenase, and aspartate aminotransferase were detected in 72%, 70%, and 16% of the patients with confirmed cases, respectively. Seroconversion occurred in most cases between weeks 4 and 6 after the infection. All of the patients with confirmed cases were treated with mebendazole. People with

severe symptoms were also treated with prednisolone (60 mg/day for 3 days), and those with a moderately severe clinical pattern received a nonsteroidal anti-inflammatory drug (naproxen sodium, 550 mg/day). **All the patients recovered without any clinical sequelae.**

Zhang, G. P., J. Q. Guo, X. N. Wang, J. X. Yang, Y. Y. Yang, Q. M. Li, X. W. Li, R. G. Deng, Z. J. Xiao, J. F. Yang, G. X. Xing, and D. Zhao. 2006. Development and evaluation of an immunochromatographic strip for trichinellosis detection. *Vet. Parasitol.* 137:286–293.

An immunochromatographic strip was developed for the serologic detection of trichinellosis in swine. In the strip, the excretory-secretory (ES) antigen of *Trichinella* labeled with colloidal gold was used as the detector, and the staphylococcal protein A and goat anti-ES antibody were blotted on the nitrocellulose membrane for the test and control lines, respectively. Evaluation of the strip was performed by comparing 60 clinical positive blood samples detected by the artificial-digestion method with 46 serum samples from pigs infected with parasites other than *Trichinella* and 30 serum samples from parasite-free healthy pigs. **The strip exhibited high specificity and sensitivity that were closely correlated with the ELISA results. Furthermore, the dipstick assay based on the strip is rapid (10 min) and easy to perform. This suggests that the immunochromatographic strip is an acceptable alternative for clinical laboratories lacking specialized equipment as well as for field diagnosis.**

Filarial Nematodes

Babu, S., C. P. Blauvelt, V. Kumaraswami, and T. B. Nutman. 2006. Cutting edge: diminished T cell TLR expression and function modulates the immune response in human filarial infection. *J. Immunol.* 176:3885–3889.

Patent lymphatic filariasis is characterized by profound antigen-specific T-cell hyporesponsiveness with impaired IFN- γ and IL-2 production. Because T cells express a number of Toll-like receptors (TLRs) and respond to TLR ligands, the authors hypothesized that diminished T-cell TLR function could partially account for the T-cell hyporesponsiveness in filariasis. T cells expressed TLR1, TLR2, TLR4, and TLR9, and the baseline expression of TLR1, TLR2, and TLR4, but not TLR9, was significantly lower in T cells from the filaria-infected individuals than in those from the uninfected individuals (both endemic and nonendemic). TLR function was significantly diminished in the T cells from filaria-infected individuals based on decreased T-cell activation and cytokine production in response to TLR ligands. **Thus, diminished expression and function of T-cell TLR is a novel mechanism underlying T-cell immune tolerance in lymphatic filariasis.**

Gyapong, J. O., and N. A. Twum-Danso. 2006. Editorial. Global elimination of lymphatic filariasis: fact or fantasy? *Trop. Med. Int. Health* 11:125–128.

In 1997, the World Health Assembly resolved to eliminate lymphatic filariasis as a public health problem by the year

2020. By the end of 2004, almost half of the 83 countries where infection is endemic had initiated national programs, providing mass drug administration to an at-risk population of approximately 435 million individuals. This remarkable achievement is the result of an enormous amount of technical, financial, and political support from public and private sectors at the community, national, regional, and global levels. As the global program to eliminate lymphatic filariasis enters its second quarter of operations, there are substantial opportunities to be taken and critical challenges to be addressed.

Ramirez, B. L., O. M. Howard, H. F. Dong, T. Edamatsu, P. Gao, M. Hartlein, and M. Kron. 2006. *Brugia malayi* asparaginyl-transfer RNA synthetase induces chemotaxis of human leukocytes and activates G-protein-coupled receptors CXCR1 and CXCR2. *J. Infect. Dis.* 193:1164–1171.

Lymphatic filariasis is a chronic human parasitic disease in which the parasites repeatedly provoke acute and chronic inflammatory reactions in the host bloodstream and lymphatics. Excretory-secretory products derived from filariae are thought to play an important role in the development of associated immunologic conditions; however, the specific mechanisms involved in these changes are not well understood. Recently, human cytoplasmic aminoacyl-tRNA synthetases, which are autoantigens in idiopathic inflammatory myopathies, were shown to activate chemokine receptors on T lymphocytes, monocytes, and immature dendritic cells by recruiting immune cells that could induce innate and adaptive immune responses. Filarial (*Brugia malayi*) asparaginyl-tRNA synthetase (AsnRS) is known to be an immunodominant antigen that induces strong human IgG3 responses. Recombinant *B. malayi* AsnRS was used to perform cellular function assays (chemotaxis and kinase activation assays). Unlike human AsnRS, parasite AsnRS is chemotactic for neutrophils and eosinophils. Recombinant *B. malayi* AsnRS but not recombinant human AsnRS induced chemotaxis of CXCR1 and CXCR2 single-receptor-transfected HEK-293 cell lines, blocked CXCL1-induced calcium flux, and induced mitogen-activated protein kinase. **The data suggest that a filarial parasite chemoattractant protein may contribute to the development of chronic inflammatory disease and that chemokine receptors may be therapeutic targets to ameliorate parasite-induced pathology.**

Intestinal Cestodes

Diphyllobothrium spp.

Year, H., C. Estran, P. Delaunay, M. Gari-Toussaint, J. Dupouy-Camet, and P. Marty. 2006. Putative *Diphyllobothrium nihonkaiense* acquired from a Pacific salmon (*Oncorhynchus keta*) eaten in France: genomic identification and case report. *Parasitol. Int.* 55:45–49.

The authors report a likely case of *Diphyllobothrium nihonkaiense* contracted in France through the consumption of a Pacific salmon imported from Canada. The species diagnosis was made by molecular analysis of two mitochondrial genes (COI and ND3). **This case is rather unusual in that**

D. nihonkaiense has never been detected along the Pacific coast of North America.

Taenia asiatica

Jeon, H. K., and K. S. Eom. 2006. *Taenia asiatica* and *Taenia saginata*: genetic divergence estimated from their mitochondrial genomes. *Exp. Parasitol.* 17 Mar. [Epub ahead of print.]

The authors conducted a differential identification of *Taenia asiatica* and *Taenia saginata* through the mapping of mitochondrial genomes and the sequencing of the *cox1* and *cob* genes. The entire mitochondrial genomes of *T. asiatica* and *T. saginata* were amplified by long-extension PCR and cloned; each was approximately 14 kb in size. Restriction maps of *T. asiatica* and *T. saginata* mitochondrial genomes were then constructed using 13 restriction enzymes. The resulting restriction patterns provided an estimation of their genetic divergence at 4.8%. The actual sequence divergence was computed as 4.5% from the *cox1* gene and 4.1% from the *cob* gene. These results support the designation of *T. asiatica* as a separate species from *T. saginata*.

Taenia saginata

Abuseir, S., C. Epe, T. Schnieder, G. Klein, and M. Kuhne. 2006. Visual diagnosis of *Taenia saginata* cysticercosis during meat inspection: is it unequivocal? *Parasitol. Res.* 1 Apr. [Epub ahead of print.]

A total of 267 cysts were collected from March to December 2004 from two main abattoirs in northern Germany. The cysts were classified by the usual organoleptic methods during meat inspection as *Cysticercus bovis*. The reported prevalence of cysticercosis in the two abattoirs was 0.48 and 1.08%, respectively. The cysts were examined macroscopically for their morphology and constituents and classified as viable or degenerating (dead). The DNA was extracted from these cysts and subjected to PCR amplification to evaluate the detection methods used and to make certain that the cysts did indeed belong to *C. bovis*, as indicated at the slaughterhouses. Two sets of primers were used with different sensitivity levels. The first, HDP1, was able to detect 200 fg of *Taenia saginata* DNA and 100 pg of *C. bovis* DNA. The other primer set, HDP2, was able to detect 1 pg of *T. saginata* DNA and 1 ng of *C. bovis* DNA. No more than 52.4% of the samples tested positive for *C. bovis* in the PCR using both primers, while 20% of the viable cysts and 49.2% of the degenerating cysts tested negative with both primers.

Taenia solium

Bruschi, F., M. Masetti, M. T. Locci, R. Ciranni, and G. Fornaciari. 2006. Cysticercosis in an Egyptian mummy of the late Ptolemaic period. *Am. J. Trop. Med. Hyg.* 74:598–599.

The authors describe an ancient case of cysticercosis that was discovered in an Egyptian mummy of a young woman aged about 20 years who lived in the late Ptolemaic period (second to first centuries BC). On removal and rehydration of the stomach, a cystic lesion in the stomach wall was

observed by naked eye. Microscopic examination of sections of this lesion revealed a cystic structure, with a wall, with numerous projecting eversion, a characteristic feature of the larval stage (cysticercus) of the human tapeworm *Taenia solium*. Immunohistochemical testing with serum from a *T. solium*-infected human confirmed the identity of the cyst. This finding is the oldest on record of this zoonotic parasite. This observation also confirms that in Hellenistic Egypt, the farming of swine, along with humans as an intermediate host of this parasite, occurred, and supports other archeological evidence.

Hancock, K., S. Patabhi, F. W. Whitfield, M. L. Yushak, W. S. Lane, H. H. Garcia, A. E. Gonzalez, R. H. Gilman, and V. C. Tsang. 2006. Characterization and cloning of T24, a *Taenia solium* antigen diagnostic for cysticercosis. *Mol. Biochem. Parasitol.* 147:109–117.

The third and final diagnostic antigen of the lentil lectin purified glycoproteins extracted from the larval stage of *Taenia solium* has been characterized, cloned, and expressed. T24 is an integral membrane protein that belongs to the tetraspanin superfamily. It migrates at a position corresponding to 24 kDa and as a homodimer at 42 kDa. Antibodies from cysticercosis patients recognize secondary-structure epitopes that are dependent on correctly formed disulfide bonds. A portion of T24, the large, extracellular loop domain, was expressed in an immunologically reactive form in insect cells. When tested in a Western blot assay with a large battery of serum samples, this protein, T24H, has a sensitivity of 94% (101 of 107) for detecting cases of cysticercosis with two or more viable cysts, and a specificity of 98% (284 of 290). The identification and expression of T24H sets the stage for the development of an ELISA suitable for testing single samples and for large-scale serosurveys that is not dependent on the isolation and purification of antigens from parasite materials.

Tissue Cestodes

Echinococcus spp.

Budke, C. M. 2006. Global socioeconomic impact of cystic echinococcosis. *Emerg. Infect. Dis.* 12:296–303.

Cystic echinococcosis (CE) is an emerging zoonotic parasitic disease throughout the world. Human incidence and livestock prevalence data for CE were gathered from published literature and the Office International des Epizooties databases. Disability-adjusted life years (DALYs) and monetary losses resulting from human and livestock CE were calculated from recorded human and livestock cases. Alternative values obtained by assuming substantial underreporting are also provided. When no underreporting is assumed, the estimated human burden of disease is 285,407 DALYs or an annual loss of \$193,529,740. When underreporting is accounted for, this amount rises to 1,009,662 DALYs or \$763,980,979. An annual livestock production loss of at least \$141,605,195 and possibly up to \$2,190,132,464 is also estimated. This initial valuation demonstrates the necessity for increased monitoring and global control of CE.

Carmena, D., A. Benito, and E. Eraso. 2006. Antigens for the immunodiagnosis of *Echinococcus granulosus* infection: an update. *Acta Trop.* 98:774–786.

The taeniid tapeworm *Echinococcus granulosus* is the causative agent of echinococcal disease, an important zoonosis with worldwide distribution. Accurate immunodiagnosis of the infection requires highly specific and sensitive antigens to be used in immunodiagnostic assays. The choice of an appropriate source of antigenic material is a crucial point in the improvement of the diagnostic features of tests and must be based on the developmental stage of the parasite and the host. The most common antigenic sources used for the immunodiagnosis of echinococcal disease are hydatid cyst fluid, somatic extracts, and excretory-secretory products from protoscolices or adults of *E. granulosus*. Hydatid cyst fluid is the antigenic source of reference for immunodiagnosis of human hydatidosis, which is based mainly on the detection of antigens B and 5. Somatic extracts have been widely used in the serodiagnosis of *E. granulosus* infection in dogs and ruminant intermediate hosts, although in the last few years the detection of excretory-secretory products of the worm in feces (coproantigens) has become the most reliable method of detecting of the parasite in the definitive host. **This review emphasizes recent advances in the identification and characterization of novel antigens with potential for the immunodiagnosis of echinococcal disease. Progress in recombinant technologies and synthetic peptides is also discussed.** The paper highlights the need to search for new antigenic components with high diagnostic sensitivity and specificity, a fact that remains a crucial task in the improvement of the immunodiagnosis of the disease.

Jenkins, D. J., A. McKinlay, H. E. Duolong, H. Bradshaw, and P. S. Craig. 2006. Detection of *Echinococcus granulosus* coproantigens in faeces from naturally infected rural domestic dogs in southeastern Australia. *Aust. Vet. J.* 84:12–16.

This study was designed to investigate the occurrence of *Echinococcus granulosus* in rural domestic dogs in farming areas around Yass, New South Wales, and Mansfield and Whitfield, Victoria. Feces were collected rectally from farm dogs voluntarily presented by their owners in four farming districts in New South Wales and two in Victoria. Feces were collected in the field, an extract was prepared from each sample, and *E. granulosus* coproantigens were detected using ELISA. Farmers were also questioned about their dog feeding and worming practices. *E. granulosus* coproantigens were detected in 99 (29%) of 344 dogs from 95 farms in southeastern New South Wales and 38 (17.5%) of 217 dogs from 43 farms in Victoria. Cross-reactions between *E. granulosus* coproantigen-trapping antibody and coproantigens in feces from dogs monospecifically infected with other species of intestinal helminthes (*Taenia ovis*, *T. hydatigena*, *T. pisiformis*, *Spirometra ericacei*, *Dipylidium caninum*, hookworm, *Toxocara canis*, *Trichuris vulpis*) were not evident. Dietary and worming data revealed that many owners fed raw meat and occasionally offal from domestic livestock and wildlife to their dogs and that few owners wormed their dogs frequently

enough to preclude the chance of patent *E. granulosus* being present in their dogs. *E. granulosus* occurs commonly in rural dogs in southeastern Australia, and an education program promoting the public health importance of responsible management of rural dogs is urgently needed.

Karabulut, K., I. Ozden, A. Poyanli, O. Bilge, Y. Tekant, K. Acarli, A. Alper, A. Emre, and O. Ariogul. 2006. Hepatic atrophy-hypertrophy complex due to *Echinococcus granulosus*. *J. Gastrointest. Surg.* 10:407–412.

Obstruction of a major hepatic vein, major portal vein, or biliary tree branch causes atrophy of the related hepatic region and frequently hypertrophy in the rest of the liver—the atrophy-hypertrophy complex (AHC). Whether hydatid cysts can cause AHC is controversial. The records of 370 patients who underwent surgery for hepatic hydatid disease between August 1993 and July 2002 were evaluated retrospectively. Excluding six patients with previous interventions on the liver, AHC had been recorded in the operative notes of 16 patients (4.4%); for all patients, a cyst located in the right hemiliver had caused atrophy of the right hemiliver and compensatory hypertrophy of the left hemiliver. The computed tomograms of seven patients were suitable for volumetric analysis. The median (range) right and left hemiliver volumes were 334 (0 to 686) ml and 1,084 (663 to 1,339) ml, respectively. The median (range) cyst volume was 392 (70 to 1,363) ml. **AHC due to *Echinococcus granulosus* was confirmed by objective volumetric analysis.** The presence of AHC should alert the surgeon to two implications. First, pericystectomy may be hazardous due to association with major vascular and biliary structures. Second, in patients with AHC, the hepatoduodenal ligament rotates around its axis; this should be considered to avoid vascular injury if a common bile duct exploration is to be performed.

Sapkas, G. S., T. G. Machinis, G. D. Chloros, K. N. Fountas, G. S. Themistocleous, and G. Vrettakos. 2006. Spinal hydatid disease, a rare but existent pathological entity: case report and review of the literature. *South. Med. J.* 99:178–183.

Spinal hydatid disease is a fairly common cause of spinal cord compression in countries where the infection is endemic; however, involvement of the epidural space with sparing of the vertebral column is rare. Early diagnosis and surgical decompression with total removal of the hydatid lesion, when possible, is generally considered the standard of care for this disease. The authors describe a case of massive epidural hydatid disease without involvement of the vertebral column in a 62-year-old male patient, treated with a two-stage surgical operation and administration of systemic albendazole. **The literature on the clinical features, diagnosis, treatment, and prognosis of spinal echinococcosis is reviewed.**

Yildirim, M., N. Erkan, and E. Vardar. 2006. Hydatid cysts with unusual localizations: diagnostic and treatment dilemmas for surgeons. *Ann. Trop. Med. Parasitol.* 100:137–142.

Although the liver and lungs are by far the most common localizations for the larval cysts of *Echinococcus granulosus* in humans, the cysts may develop at other sites and cause signs and symptoms that may be easily confused with those of other illnesses. In a retrospective study in Turkey, 6 male and 11 female patients with cystic echinococcosis, each with at least one cyst in an unusual site, were investigated. The patients, who had a mean age of 41.6 years, had cysts in the pancreas, intra-abdominal cavity, kidney, spleen, ovary, breast, mediastinum, chest wall, muscle, and/or subcutaneous tissue. In terms of Gharbi's classification, 15 (75%) of the 20 cysts in these patients were type I and 5 (25%) were type II. Fourteen of the patients each had single cysts, two had multiple cysts, and one had an unknown number of cysts. All but one of the patients (who had a pancreatic cyst) were treated by total cystectomy. In areas where cystic echinococcosis is endemic, any patient presenting with a cystic mass, in any tissue or organ, should be considered to have a potential case of the disease and should be carefully investigated by radioimaging and/or ultrasonography.

***Spirometra* spp.**

Nobayashi, M., H. Hirabayashi, T. Sakaki, F. Nichimura, H. Fukui, S. Ishizaka, and M. Yoshikawa. 2006. Surgical removal of a live worm by stereotactic targeting in cerebral sparganosis. *Neurol. Med. Chir.* 46:164–167.

A 64-year-old man presented with generalized tonic-clonic convulsion followed by weakness of the right lower extremity. He had a medical history of hypertension, hyperlipidemia, and right cerebellar infarction. Computed tomography showed a small, high-density nodule with an enhanced perifocal low-density area in the left occipital lobe. T₁-weighted MRI showed a ring-shaped and partial string-like nodule with enhancement by gadolinium. T₂-weighted MRI showed the white matter of the left occipital lobe as high intensity. Computed tomography and MRI seemed to indicate metastatic brain tumors, although cortical atrophy and ventricular dilation were recognized. Left parietal craniotomy was performed under stereotactic targeting to obtain a definitive diagnosis. During manipulation at the center of the targeted lesion, a white, tape-like body was found and recognized to be a live worm. Serologic testing revealed strong immunopositivity against *Spirometra mansoni*. The infection route in the present case was probably through eating raw chicken meat. Cerebral sparganosis is extremely rare but should be considered in the differential diagnosis of metastatic brain tumors, especially in areas of endemic infection.

Intestinal Trematodes

Gymnophalloides seoi

Seo, M., H. Chun, J. G. Ahn, K. T. Jang, S. M. Guk, and J. Y. Chai. 2006. A case of colonic lymphoid tissue invasion by *Gymnophalloides seoi* in a Korean man. *Korean J. Parasitol.* 44:87–89.

A 65-year-old Korean man, living in Mokpo city, Jeollanam-do, Republic of Korea, visited a local clinic complaining of

right upper quadrant pain and indigestion. At colonoscopy, he was diagnosed as having a carcinoma of the ascending colon, and a palliative right hemicolectomy was performed. Subsequently, an adult fluke of *Gymnophalloides seoi* was incidentally found in a surgical pathology specimen of the lymph node around the colon. The worm was found to have invaded gut lymphoid tissue, with characteristic morphologies of a large oral sucker, a small ventral sucker, and a ventral pit surrounded by strong muscle fibers. This is the first reported case of mucosal tissue invasion by *G. seoi* in the human intestinal tract.

Liver and Lung Trematodes

Fasciola hepatica

Molloy, J. B., and G. R. Anderson. 2006. The distribution of *Fasciola hepatica* in Queensland, Australia, and the potential impact of introduced snail intermediate hosts. *Vet. Parasitol.* 137:62–66.

A survey was conducted to establish the distribution of the liver fluke, *Fasciola hepatica*, in the state of Queensland, Australia, and to evaluate the impact of the introduced snail intermediate hosts, *Pseudosuccinia columella* and *Austropeplea viridis*. Serum samples from a total of 5,103 homebred cattle in 142 beef herds distributed throughout the state and 523 pooled milk samples from dairy herds from the state's major dairy regions were tested for antibodies to *F. hepatica* by ELISA. Snails were collected on infected properties around the limits of the *F. hepatica* distribution. *F. hepatica* infection was detected in 44 dairy herds and 2 beef herds. The distribution of infected herds indicates that *F. hepatica* is established only in southeastern Queensland. The distribution there was patchy, but the parasite was more widespread than suggested by an earlier survey. The predominant intermediate host species found along the northern limit of the distribution was *P. columella*. We conclude that the introduction of *P. columella* and *A. viridis* has not yet had a major impact on the distribution of *F. hepatica* in Queensland. However, the presence of *P. columella*, which is much more adaptable to tropical habitats than the native intermediate host, *Austropeplea tomentosa*, at the northern limit of the *F. hepatica* distribution suggests that there is potential for the parasite to expand its range.

Opisthorchis viverrini

Stensvold, C. R., W. Saijuntha, P. Sithithaworm, S. Wongratanchewin, H. Strandgaard, N. Ornbjerg, and M. V. Johansen. 2006. Evaluation of PCR based coprodiagnosis of human opisthorchiasis. *Acta Trop.* 97:26–30.

In this study, a recently developed PCR test for the detection of *Opisthorchis viverrini* in human fecal samples was evaluated using two parasitological methods as references. During a survey of food-borne trematodes (FBT) in the Vientiane Province, Lao PDR, 85 samples were collected and evaluated for FBT eggs by the Kato-Katz technique, the formalin ethyl acetate concentration technique (FECT), and a PCR analysis for the distinction between *O. viverrini* and other FBT. The

two parasitological methods did not differ in the ability of detecting FBT eggs, and a single Kato-Katz reading was characterized by a sensitivity of 85% compared to two FECT readings. The PCR analysis gave positive results only in cases where eggs had been demonstrated by parasitological examination. However, the PCR analysis gave negative results in some samples with very high egg counts. **With a PCR sensitivity of approximately 50% in samples with fecal egg counts of >1,000, the previously reported PCR sensitivity based on in vitro studies was not supported. It is believed that technical problems rather than diagnostic reference-related issues were responsible for the relatively poor PCR performance.** Further studies should aim at optimizing DNA extraction and amplification, and future PCR evaluation should include a specificity control such as scanning electron microscopy of eggs in test samples or expulsion of adult trematodes from PCR-tested individuals.

Paragonimus spp.

Le, T. H., N. V. De, D. Blair, D. P. McManus, H. Kino, and T. Agatsuma. 2006. *Paragonimus heterotremus* Chen and Hsia (1964), in Vietnam: a molecular identification and relationships of isolates from different hosts and geographical origins. *Acta Trop.* 98:25–33.

Paragonimiasis caused by *Paragonimus heterotremus* Chen and Hsia (1964) is a newly detected disease in Vietnam. Twelve samples of *Paragonimus* (Platyhelminthes: Trematoda: Digenea: Paragonimidae) from different life stages (eggs, miracidia, metacercariae, and adults from natural and experimental hosts) and host species (crab, dog, cat, and human) were collected in different geographic locations in Vietnam. DNA sequences were obtained from each sample for partial mitochondrial cytochrome *c* oxidase subunit 1 (*cox1*) (387 bp) and the entire second ribosomal internal transcribed spacer (ITS2) (361 bp). The ITS2 sequences were identical among all specimens, including those previously reported in GenBank. For *cox1*, there were sequence differences between specimens from Vietnam (four provinces, different locations) and those from Guangxi (China) and Saraburi (Thailand). Phylogenetic trees inferred from *cox1* and ITS2 sequences using sequence data for 15 *P. heterotremus* specimens and for other *Paragonimus* spp. revealed that all *P. heterotremus* strains originating from Vietnam, Thailand, and China form a distinct group. This information also confirms the identity of the Vietnamese specimens as *P. heterotremus*.

Lee, E. G., B. K. Na, Y. A. Bae, S. H. Kim, E. Y. Je, J. W. Ju, S. H. Cho, T. S. Kim, S. Y. Kang, S. Y. Cho, and Y. Kong. 2006. Identification of immunodominant excretory-secretory cysteine proteases of adult *Paragonimus westermani* by proteome analysis. *Proteomics* 6:1290–1300.

Paragonimus westermani causes inflammatory lung disease in humans. The parasite excretes a host of biologically active molecules, which are thought to be involved in pathophysiologic and immunologic events during infection. Analyses of the protein profiles of the excretory-secretory products (ESP) of adult *P. westermani* revealed approximately 147 protein

spots, at least 15 of which were identified as cysteine proteases (CPs), at pHs between 4.5 and 8.5 and molecular masses between 27 and 35 kDa. An additional three CPs (designated PwCP-3, PwCp-8, and PwCp-11) were newly recognized by TOF/TOF mass spectrometry. Their molecular biological information, which had a high-level sequence homology, was elucidated. The majority of the CPs reacted strongly with sera from paragonimiasis patients. When the authors observed the chronological changes in the antibody responses of the respective CPs to canine sera collected serially at 1, 3, 5, 7, 11, and 14 weeks after experimental infection, these molecules exhibited a multiplicity of distinct immune recognition patterns. **Results clearly showed that *P. westermani* adult ESP were composed principally of excretory-secretory CPs and that these CPs may exert effects not only on host tissue degradation and nutrient uptake but also on the immune-regulating cells via synergistic and independent interactions.**

Lee, J. C., G. S. Cho, J. H. Kwon, M. H. Shin, J. H. Lim, and W. K. Kim. 2006. Macrophageal/microglial cell activation and cerebral injury induced by excretory-secretory products secreted by *Paragonimus westermani*. *Neurosci. Res.* 54:113–139.

Cerebral paragonimiasis causes various neurologic disorders including seizures, visual impairment, and hemiplegia. The excretory-secretory product (ESP) released by *Paragonimus westermani* has a CP activity and plays important roles in its migration in the host tissue and modulation of host immune responses. To gain more insight into the pathogenesis of ESP in the brain, we investigated the inflammatory reaction and cerebral injury following microinjection of ESP into rat striatum. The size of injury was maximal 3 days after microinjection of ESP and then declined to control levels as astrocytes repopulated the injury. ED1-positive monocytes and microglia were confluent found inside the injury. The mRNA expression of inducible NOS (iNOS) occurred as early as 9 h after ESP injection and then declined to control levels within 1 day. The iNOS inhibitor aminoguanidine largely decreased the expression of iNOS but did not reduce the size of lesion caused by ESP. Interestingly, however, heat inactivation of ESP caused a decrease of injury formation with no altered expression of iNOS. **The data indicate that ESP causes brain tissue injury by recruiting activated monocytes and microglia via heat-labile protease activity.**

Wongkham, C., P. M. Intapan, W. Maleewong, and M. Miwa. 2005. Evaluation of human IgG subclass antibodies in the serodiagnosis of *Paragonimiasis heterotremus*. *Asian Pac. J. Allergy Immunol.* 23:205–211.

IgG1, IgG2, IgG3, and IgG4 responses to the excretory-secretory antigens of the lung fluke *Paragonimus heterotremus* were analyzed using the immunoblotting technique in an attempt to further improve the sensitivity and specificity for serodiagnosis of human paragonimiasis. Serum samples from patients with proven paragonimiasis, from patients with other parasitic infections, from those with pulmonary tuberculosis, and from healthy counterparts were analyzed. **The results indicate that immunoblotting for the detection**

of IgG4 antibodies to an excretory-secretory product of *P. heterotremus* with an approximate molecular mass of 31.5 kDa is the most reliable test. It has accuracy, sensitivity, specificity, and positive and negative predictive values of 97.6%, 100%, 96.9%, 90%, and 100%, respectively.

Blood Trematodes (Schistosomes)

Alonso, D., J. Munoz, J. Gascon, M. E. Valls, and M. Corachan. 2006. Failure of standard treatment with praziquantel in two returned travelers with *Schistosoma haematobium* infection. *Am. J. Trop. Med. Hyg.* 74:342–344.

A single 40-mg/kg dose of praziquantel continues to be the standard treatment for schistosomiasis caused by *Schistosoma mansoni* and *S. haematobium* in all clinical settings. Experimental development of drug resistance and the recent isolation of *S. mansoni* strains with a natural tolerance to high doses of praziquantel have raised concerns over the adequacy of such a dose. The authors describe two Spanish travelers with genitourinary schistosomiasis caused by *S. haematobium* in whom repeated standard treatment failed to clear the infection.

Doenhoff, M. J., and L. Pica-Mattocchia. 2006. Praziquantel for the treatment of schistosomiasis: its use for control in areas with endemic disease and prospects for drug resistance. *Expert Rev. Anti Infect. Ther.* 5:199–210.

Praziquantel became available for the treatment of schistosomiasis and other trematode-inflicted diseases in the 1970s. It was revolutionary because it could be administered orally and had very few unwanted side effects. As a result of marked reductions in the price of praziquantel, the rate at which it is used has accelerated greatly in recent years. For the foreseeable future, it will be the mainstay of programs designed to control schistosome-induced morbidity, particularly in sub-Saharan Africa, where schistosomiasis is heavily endemic. There is currently no evidence to suggest that any schistosomes have developed resistance to praziquantel as a result of its widespread use. Nevertheless, while resistance may not pose an obvious or immediate threat to the usefulness of praziquantel, complacency and a failure to monitor developments may have serious consequences in the longer term, since it will be the only drug that is readily available for the large-scale treatment of schistosomiasis. (See the published paper right above this one for comparison.)

El-Masry, S., M. Lotfy, M. El-Shahat, and G. Badra. 2006. Serum laminin assayed by Slot-Blot-ELISA in patients with combined viral hepatitis C and schistosomiasis. *Clin. Biochem.* 16 Feb. [Epub ahead of print.]

Hepatic schistosomiasis and chronic HCV infection are the most prevalent causes of hepatic fibrosis in humans. Laminin (LA) has been related to liver fibrosis and subsequent development of portal hypertension in chronic liver disease. There are no available data describing the pattern of LA in combined HCV- and schistosome-infected patients; the study was designed to assess the serum LA as an index of liver fibrosis in

patients with schistosomiasis and/or chronic viral hepatitis C and to evaluate a developed slot-blot ELISA as a method of estimation. This study examined four groups: group I included 34 patients with schistosomiasis, group II included 58 patients infected with HCV, group III included 68 patients with combined chronic viral hepatitis C and schistosomiasis, and group IV included 50 healthy individuals who served as a control group. The serum LA level was measured in the different groups quantitatively by ELISA and semiquantitatively by slot blot ELISA. Significantly higher serum LA concentrations measured by ELISA were found in patients with combined chronic viral hepatitis C and schistosomiasis than in patients with either chronic viral hepatitis C or schistosomiasis alone. The serum LA concentration was significantly higher in the patient groups than the control group; it was positively correlated with fibrosis grading scores. Semiquantitative results of serum LA concentrations using the developed slot blot ELISA were found to have approximately the same power of ELISA results in different groups. The overall sensitivity, specificity, positive predictive value, negative predictive value, and efficiency of ELISA for estimation of serum LA levels were 85.6%, 84.0%, 94.5%, 64.6%, and 90%, respectively, and the figures for slot blot ELISA were 87.5%, 82.0%, 94%, 67.2%, and 88%, respectively. The serum LA concentration was significantly increased in patients coinfecting with HCV and *Schistosoma mansoni*. The newly developed slot blot ELISA is a simple, rapid, and highly sensitive assay for detection of LA in patients with hepatic fibrosis. Moreover, all steps were performed at room temperature without the need to use expensive equipment; this may enhance the application of this assay in screening programs.

Hoare, M., W. T. Gelson, S. E. Davies, M. Curran, and G. J. Alexander. 2005. Hepatic and intestinal schistosomiasis after orthotopic liver transplant. *Liver Transplant.* 11:1603–1607.

Schistosomiasis affects 200 million to 250 million people worldwide. Hepatic schistosomiasis is a well-recognized cause of chronic liver disease and portal hypertension. There are no previous reports of schistosomiasis after liver transplantation. The authors report on two cases of schistosomiasis in liver transplant recipients—a case of gastric schistosomiasis and a case of hepatic schistosomiasis. A discussion of the pathology of schistosomal infection and a rationale for screening potential liver transplant recipients from areas of endemic infection is included.

Kjetland, E. F., P. D. Ndhlovu, E. Gomo, T. Mduluzza, N. Midzi, L. Gwanzura, P. R. Mason, L. Sanvik, H. Friis, and S. G. Gundersen. 2006. Association between genital schistosomiasis and HIV in rural Zimbabwean women. *AIDS* 28:593–600.

To determine the association between female genital *Schistosoma haematobium* infection and HIV, a cross-sectional study with a 1-year follow-up was undertaken. Gynecologic and laboratory investigations were performed for *S. haematobium* and HIV. Sexually transmitted infections and demographic and urogenital history were analyzed as confounders. The participants were 527 sexually active,

nonpregnant, nonmenopausal women between the ages of 20 and 49 years. The setting was a rural Zimbabwean community where *S. haematobium*-related lesions were found in 46% of the women, HIV was found in 29%, and herpes simplex virus type 2 (HSV-2) was found in 65%. **In permanent residents (>3 years' residency), HIV was found in 41% of women (29 of 70) with laboratory-proven genital schistosomiasis as opposed to 26% (96 of 375) in the schistosomal ova-negative group. In multivariate analysis, *S. haematobium* infection of the genital mucosa was significantly associated with HIV seropositivity.** All seven women who became HIV positive during the study period (seroincidence, 3.1%) had signs of *S. haematobium* at baseline. **In agreement with other studies, HIV was significantly associated with HSV-2, syphilis, and human papillomavirus.** The highest HIV prevalence (45%) was found in the 25- to 29-year age group. **Women with genital schistosomiasis had an almost threefold risk of having HIV infection in this rural Zimbabwean community. Prospective studies are needed to confirm the association.**

Lamyman, M. J., D. J. Noble, S. Narang, and N. Dehalvi. 2006. Small bowel obstruction secondary to intestinal schistosomiasis. *Trans. R. Soc. Trop. Med. Hyg.* 18 Jan. [Epub ahead of print.]

Intestinal obstruction caused by chronic schistosomiasis infection is rare, with only 12 previously recorded cases in the literature. The authors report the first recorded case in a European hospital. A 36-year-old Caucasian man who was born and lived in the United Kingdom presented with small bowel obstruction. He had visited China and Indonesia 8 years previously. **At laparotomy, there was an obstructing inflammatory mass close to the ileocecal junction and several small bowel strictures. Initially he was thought to have Crohn's disease. However, subsequent histologic testing diagnosed intestinal schistosomiasis.**

Liang, S., C. Yang, B. Zhong, and D. Qiu. 2006. Re-emerging schistosomiasis in hilly and mountainous areas of Sichuan, China. *Bull. W. H. O.* 84:139-144.

Despite great strides in schistosomiasis control over the past several decades in Sichuan Province, China, the disease has reemerged in areas where it was previously controlled. The authors reviewed historical records and found that schistosomiasis had reemerged in 8 counties by the end of 2004; 7 of 21 counties with transmission control and 1 of 25 counties with transmission interruption as reported in 2001 were confirmed to have local disease transmission. The average “return time” (from control to reemergence) was about 8 years. The onset of reemergence was commonly indicated by the occurrence of acute infections. Survey results suggest that environmental and sociopolitical factors play an important role in reemergence. **The main challenge would be to consolidate and maintain effective control in the longer term until “real” eradication is achieved.**

Makhlouf, L. M., A.-H. Servah, A. D. Abd El-Hamid, E. M. Hussein, and R. M. Saad. 2006. INF-gamma, IL-5 and IgE profiles in chronic schistosomiasis mansoni Egyptian

patients with or without hepatitis C infection. *J. Egypt. Soc. Parasitol.* 36:177-196.

The immune response to clinical forms of chronic schistosomiasis mansoni in patients with or without HCV infection was evaluated by assays of the levels of IFN- γ and IL-5 in serum to estimate cell-mediated immunity and assays of the IgE level to estimate humoral immunity. This study examined three patient groups. G.I included 25 patients with intestinal schistosomiasis, G.II included 15 patients with hepatosplenic schistosomiasis, and G.III included 40 patients with hepatosplenic schistosomiasis coinfecting with HCV. Control G.IV included 15 healthy persons matched by age and sex with the patients. G.I had high IFN- γ levels (92%) and normal IL-5 and IgE levels. The immune response was a 100% Th-1 response. G.II had high IFN- γ (26.7%), IL-5 (86.7%), and IgE (73.3%) levels. The immune response was 73.4% Th-0, 13.3% Th-1, and 13.3% Th-2. G.III had high IFN- γ (62.7%), IL-5 (100%), and IgE (92.5%) levels. The immune response was 62.5% Th-0 and 37.5% Th-2. **The shift to Th-0 and Th-2 immunity as well as the associated depression of Th-1 in the group of patients with mixed infection may be playing a role in the persistence and severity of both diseases. Such immunity defects add to the decreased response to HCV clearance.**

Silva, I. M., R. Thiengo, M. J. Conceicao, L. Rey, F. E. Pereira, and P. C. Ribeiro. 2006. Cystoscopy in the diagnosis and follow-up of urinary schistosomiasis in Brazilian soldiers returning from Mozambique, Africa. *Rev. Inst. Med. Trop. Sao Paulo* 48:39-42.

The assessment of urinary schistosomiasis in individuals returning from areas of endemic infection often requires diagnostic resources not used in areas of exposure in order to determine complications or to establish more precise criteria of cure. Cystoscopy and 24-h urine examination were performed after treatment with a single dose of praziquantel (40 mg/kg of body weight) given to 25 Brazilian military men who were part of a United Nations peace mission to Mozambique in 1994. The median age of the individuals was 29 years, and they all had a positive urine parasitological examination. The alterations detected by cystoscopy were hyperemia and granulomas in the vesical submucosa in 59.1% of the individuals and granulomas alone in 40.9%. **A vesical biopsy revealed granulomas in all patients and viable eggs in 77.3% even after a period during which the patients no longer excreted eggs in their urine. Cystoscopy after treatment, followed by biopsy and histopathologic evaluation, performed in areas where the evolution of the disease can be better monitored, was found to be a safe criterion of parasitological cure.**

Stothard, J. R., N. B. Kabatereine, E. M. Tukahebwa, F. Kazibwe, D. Rollinson, W. Mathieson, J. P. Webster, and A. Fenwick. 2006. Use of circulating cathodic antigen (CCA) dipsticks for detection of intestinal and urinary schistosomiasis. *Acta Trop.* 97:219-228.

An evaluation of a commercially available antigen capture dipstick that detects schistosome circulating cathodic

antigen (CCA) in urine was conducted in representative areas in Uganda and Zanzibar where intestinal and urinary schistosomiasis, respectively, is endemic. Under field-based conditions, the sensitivity and specificity of the dipstick was 83% and 81% for detection of *Schistosoma mansoni* infections while the positive and negative predictive values were 84%. Light egg-positive infections were sometimes CCA negative, while CCA-positive infections included egg-negative children. A positive association between fecal egg output and intensity of the CCA test band was observed in Uganda. Estimating the prevalence of intestinal schistosomiasis by school with dipsticks was highly correlated ($r = 0.95$) with Kato-Katz stool examinations, typically within $\pm 8.5\%$. In Zanzibar, however, dipsticks totally failed to detect *S. haematobium* despite examining children with egg-patent schistosomiasis. This was also later corroborated by surveys in Niger and Burkina Faso. Laboratory testing of dipsticks with aqueous adult worm lysates from several reference species showed correct functioning; however, dipsticks failed to detect CCA in urine from *S. haematobium*-infected hamsters. While CCA dipsticks are a good alternative, or complement, to stool microscopy for field diagnosis of intestinal schistosomiasis, they have no proven value for field diagnosis of urinary schistosomiasis. At approximately \$2.6 per dipstick, they are presently too expensive to be cost-effective for wide-scale use.

Summer, A. P., W. Stauffer, S. R. Maroushek, and T. E. Nevins. 2006. Hematuria in children due to schistosomiasis in a nonendemic setting. *Clin. Pediatr.* 45:177–181.

Infection with *Schistosoma haematobium* is common in immigrants from tropical Africa and commonly presents with painless hematuria. Since chronic, heavy infection can lead to significant morbidity, it is imperative for clinicians who serve the immigrant and refugee population to become familiar with this traditionally exotic disease. Increased awareness will allow earlier diagnosis and treatment of infection, avoiding complications and minimizing expensive and invasive diagnostic procedures.

Unusual Parasitic Infections

Nematodes

Eamsobhana, P. T. Mongkolporn, P. Punthuprapasa, and A. Yoolek. 2006. *Mammomonogamus* roundworm (Nematoda: Syngamidae) recovered from the duodenum of a Thai patient: a first and unusual case originating in Thailand. *Trans. R. Soc. Trop. Med. Hyg.* 100:387–391.

A pair of *Mammomonogamus laryngeus* roundworms in copula was recovered from the duodenum of a 72-year-old male Thai patient from Kanchanaburi Province. Eggs were also found in the stool of the patient. **This is the first case of *Mammomonogamus* infection originating in Thailand**, since the previous two reports from Thailand attributed the infection as originating in Malaysia. The occurrence of adult worms in the duodenum is unusual

and differs from previous findings in the larynx, posterior pharynx, tracheal wall, and bronchi.

Pampiglione, S., T. C. Orihel, A. Gustinella, W. Gatzemeier, and L. Villani. 2005. An unusual parasitological finding in a subcutaneous mammary nodule. *Pathol. Res. Pract.* 201:475–478.

While examining some histologic sections of a clinically suspected neoplastic nodule in a woman's breast, sections of *Dirofilaria repens* were noted in the same nodule along with sections of a different nematode. The latter appeared to be a specimen possibly belonging to the genus *Anatrichosoma* (family Trichosomoididae), a parasitic group of helminths rarely found in humans.

Watthanakulpanich, D., M. T. Anantaphruti, and W. Maipanich. 2005. *Diploscapter coronata* infection in Thailand: report of the first case. *Southeast Asian J. Trop. Med. Public Health* 36 (Suppl. 4):99–101.

A 73-year-old Thai woman living in Mueang District, Saraburi Province, central Thailand, presented with numerous hookworm-like nematodes, finally revealed as *Diploscapter coronata* by fecal culture. The patient exhibited no significant clinical signs of the gastrointestinal or genitourinary systems and was generally not ill as a result of this unusual infection. Less commonly, patients have presented with symptoms and signs of *D. coronata* infection. However, potentially serious consequences can occur where people are exposed to an environment that has been contaminated with infected feces or, more specifically, infective eggs; such conditions could lead to human infection with *D. coronata* worms. **This was the first reported occurrence of human *D. coronata* infection in Thailand.**

Cestodes

Padgett, K. A., S. A. Nadler, L. Munson, B. Sacks, and W. M. Boyce. 2005. Systematics of *Mesocestoides* (Cestoda: Mesocestoididae): evaluation of molecular and morphological variation among isolates. *J. Parasitol.* 91:1435–1443.

A hypothesis-based framework was used to test if three genetic strains of *Mesocestoides* (clades A, B, and C) are distinct evolutionary lineages, thereby supporting their delimitation as species. For comparative purposes, three established cestode species, *Taenia pisiformis*, *Taenia serialis*, and *Taenia crassiceps*, were assessed by the same methods. Sequence data from mitochondrial rDNA (12S) and the second internal transcribed spacer of nuclear rDNA (ITS2) revealed derived (autapomorphic) characters for lineages representing clade A ($n = 6$ autapomorphies), clade B ($n = 4$), and clade C ($n = 9$), as well as *T. pisiformis* ($n = 15$) and *T. serialis* ($n = 12$). Furthermore, multivariate analysis of morphologic data revealed significant differences among the three genetic strains of *Mesocestoides* and between *T. pisiformis* and *T. serialis*. The level of phenotypic variation within evolutionary lineages of *Mesocestoides* and *Taenia* spp. tapeworms was similar. **Results from this study support recognizing *Mesocestoides* clades A, B, and C as separate**

species and provide evidence that clade B and *Mesocestoides vogae* are conspecific.

Trematodes

Guk, S. M., J. H. Park, E. H. Shin, J. L. Kim, A. Lin, and J. Y. Chai. 2006. Prevalence of *Gymnophalloides seoi* infection in coastal villages of Haenam-gun and Yeongam-gun, Republic of Korea. *Korean J. Parasitol.* 44:1–5.

One coastal village in Haenam-gun and two in Yeongam-gun, Jeollanam-do were surveyed for intestinal parasite infections by fecal examination. The egg-positive rates of *Gymnophalloides seoi* were high, 24.1% (14 of 58 patients) in Haenam-gun and 9.3% (11 of 118 patients) in Yeongam-gun. The egg-positive rates of heterophyids, including *Heterophyes nocens*, and of *Clonorchis sinensis* were 10.3% and 6.9% in Haenam-gun and 14.4% and 8.5% in Yeongam-gun, respectively. After praziquantel treatment and purgation, a total of 37,761 fluke specimens were recovered from 17 patients, 11 in Haenam-gun and 6 in Yeongam-gun. *Gymnophalloides seoi* was the most commonly recovered species, with 37,489 specimens in total (2,205 per person). Other recovered flukes included *Heterophyes nocens*, *Stictodora fuscata*, *Heterophyopsis continua*, *Pygidiopsis summa*, and undetermined species. These results indicate that the areas surveyed are new endemic foci of *G. seoi*.

Karadag, B., A. Bilici, A. Doventas, F. Kantarci, D. Selcuk, N. Dincer, Y. A. Oner, and D. S. Erdinler. 2005. An unusual case of biliary obstruction caused by *Dicrocoelium dendriticum*. *Scand. J. Infect. Dis.* 37:385–388.

Dicrocoelium dendriticum is a liver fluke that induces biliary obstruction. Infection usually occurs in herbivores such as sheep, goats, and deer; human infection is very rarely encountered in clinical practice. The authors report on a 65-year-old female presenting with biliary obstruction caused by *D. dendriticum*. Following treatment with triclobendazole, her symptoms disappeared, and laboratory values returned to their normal range within 6 months. Parasitosis is an important cause of biliary obstruction. For patients presenting with biliary obstruction, *D. dendriticum* should be included in the differential diagnosis.

Antibody and Antigen Detection in Parasitic Infections (General Immunology) (See Also Individual Relevant Chapters)

Protozoa

Hernandez-Marin, M., I. Hernandez-Spengler, G. Ramos-Martinez, and L. Pozo-Pena. 2006. Chimeric synthetic peptides as antigens for detection of antibodies to *Trypanosoma cruzi*. *Biochem. Biophys. Res. Commun.* 339:89–92.

Six chimeric synthetic peptides (QCha-1, QCha-2, QCha-3, QCha-4, QCha-5, and QCha-6) incorporating antigenic sequences of two immunodominant repeat B-cell epitopes of *Trypanosoma cruzi* were synthesized by conventional solid-phase peptide synthesis. The antigenic activity of these

peptides was evaluated by ultramicro-ELISA by using panels of positive Chagasic sera ($n = 82$), while the specificity was evaluated by using samples from healthy blood donors ($n = 44$) and patients with other infectious diseases ($n = 86$). The antigenicity of the chimeric peptides in solid-phase immunoassays was compared with that of the monomeric peptides. Data demonstrated that the chimeric peptide QCha-5 was the most reactive. The results indicate that chimeric peptide as a coating antigen is very useful for the immunodiagnosis of Chagas' disease.

Helminths

Allan, J. C., and P. S. Craig. 2006. Coproantigens in taeniasis and echinococcosis. *Parasitol. Int.* 55(Suppl.):S75–S80.

The application of modern immunodiagnostic or molecular diagnostic techniques has improved the diagnosis of the taeniid cestode infections echinococcosis and taeniasis. One particularly promising approach is the detection of parasite-specific antigens in feces (coproantigens). This approach has been applied to both *Echinococcus* and *Taenia* species and has gained increasingly widespread use. Taeniid coproantigen tests are based on either monoclonal or polyclonal antibodies raised against adult tapeworm antigens. These tests have the following common characteristics: they are largely genus specific, their specificity is high (>95%), parasite antigen can be detected in feces weeks prior to patency, levels of coproantigen are independent of egg output, coproantigen is stable for days at a range of temperatures (–80 to 35°C) and for several months in formalin-fixed fecal samples, and coproantigen levels drop rapidly (1 to 5 days) following successful treatment. In the genus *Taenia*, most work has been done on *Taenia solium* and coproantigen tests have reliably detected many more tapeworm carriers than has microscopy. For *Echinococcus* species, there is a broad positive correlation between test sensitivity and worm burden, with a reliable threshold level for the test of >50 worms. Characterization of taeniid coproantigens in an attempt to further improve the tests is under way. Studies indicate taeniid coproantigens include high-molecular-mass (>150 kDa), heavily glycosylated molecules with carbohydrate moieties which contribute substantially to the levels of antigen detected in feces.

Arruda, G. C., E. M. Quagliato, and C. L. Rossi. 2006. Intrathecal synthesis of specific immunoglobulin G antibodies in neurocysticercosis: evaluation of antibody concentrations by enzyme-linked immunosorbent assay using a whole cysticercal extract and cyst vesicular fluid as antigens. *Diagn. Microbiol. Infect. Dis.* 54:45–49.

The demonstration of intrathecal antibody production has proven useful for showing the involvement of the CNS in several diseases. In the present study, the intrathecal synthesis of cysticercus-specific IgG antibodies was investigated in 30 patients with neurocysticercosis based on calculation of the specific IgG antibody index (AI_{IgG}). An AI_{IgG} of ≥ 1.5 was considered to be indicative of intrathecal antibody production. Antibody concentrations in serum and CSF samples

were evaluated by using an ELISA with two antigen preparations from *Taenia solium* cysticerci, namely, a whole cysticercal extract (TsoW) and the vesicular fluid of the parasite (TsoVF). Intrathecal, cysticercus-specific IgG antibody synthesis was observed in 21 and 23 patients (70% and 76.6%) when using the TsoW and TsoVF antigens, respectively. Detection of the intrathecal synthesis of specific antibodies may be a potentially useful tool in establishing involvement of the CNS in cysticercosis.

Arthropods

Nisbet, A. J., and J. F. Huntley. 2006. Progress and opportunities in the development of vaccines against mites, fleas, and myiasis-causing flies of veterinary importance. *Parasite Immunol.* 28:165–172.

Despite the potential benefits offered by vaccination against ectoparasites, there have been few commercial successes with this strategy in spite of sustained efforts involving increasingly sophisticated techniques. **This review outlines the progress and challenges offered by recent research into vaccination against some of the major ectoparasites of veterinary importance.** It also provides insight into the opportunities arising from our increased understanding of the immunology of host-parasite relationships and the potential for exploitation of this knowledge as well as knowledge arising from new genomic data provided by expressed sequence tag projects.

Nuttall, P. A., A. R. Trimmell, M. Kazimirova, and M. Labuda. 2006. Exposed and concealed antigens as vaccine targets for controlling ticks and tick-borne diseases. *Parasite Immunol.* 28:155–163.

Tick vaccines derived from Bm86, a midgut membrane-bound protein of the cattle tick, *Boophilus microplus*, are currently the only commercially available ectoparasite vaccines. Despite the introduction of these vaccines into the market in 1994 and the recognized need for alternatives to chemical pesticides, progress in developing effective antitick vaccines (and ectoparasite vaccines in general) is slow. The primary rate-limiting step is the identification of suitable antigenic targets for vaccine development. **Two sources of candidate vaccine antigens have been identified: “exposed” antigens that are secreted in tick saliva during attachment and feeding on a host and “concealed” antigens that are normally hidden from the host.** Recently, a third group of antigens has been distinguished that combines the properties of both exposed and concealed antigens. This latter group offers the prospect of a broad-spectrum vaccine effective against both adults and immature stages of a wide variety of tick species. It also shows transmission-blocking and protective activity against a tick-borne pathogen.

Blood Parasites

Diez, H., M. C. Lopez, T. M. Del Carmen, F. Guzman, F. Rosas, V. Velazco, J. M. Gonzalez, and C. Puerta. 2006. Evaluation of IFN- γ production by CD8 T lymphocytes in response to the K1 peptide from KMP-11 protein in patients infected with *Trypanosoma cruzi*. *Parasite Immunol.* 13:55–66.

The cellular response mediated by major histocompatibility protein class I-restricted CD8⁺ T cells is crucial in the control of Chagas' disease. The K1 peptide derived from *Trypanosoma cruzi* KMP-11 protein has a high binding affinity to the HLA-A*0201 molecule. Nevertheless, it is not known whether this peptide is processed and displayed as a major histocompatibility protein class I epitope during natural infection by *T. cruzi*. The aim of this study was to evaluate, by enzyme-linked immunospot assay, the ability of K1 peptide to activate CD8⁺ T lymphocytes to produce IFN- γ . Therefore, CD8⁺ T lymphocytes from 22 HLA-A*0201⁺ individuals, 12 chronic Chagas' disease patients, and 10 uninfected controls were analyzed. **The results revealed that two of the Chagas' disease patients had IFN- γ -secreting CD8⁺ T cells that were able to respond to K1 peptide with a relative frequency of 110 and 230/10⁶ CD8⁺ T cells. In contrast, none of the HLA-A*0201⁺ uninfected controls responded to K1 peptide.** Responses to HLA-A*0201-restricted peptide from the influenza virus matrix protein were found in six Chagas' disease patients and four uninfected controls with an average frequency of 175 and 111/10⁶ CD8⁺ T cells, respectively. Moreover, a flow cytometric assay for degranulation showed that Chagas' disease patients who responded had K1-specific cytotoxic CD8⁺ T cells. **It is shown here for the first time that the K1 peptide is efficiently processed, presented, and recognized by CD8⁺ T lymphocytes during the natural course of Chagas' disease.**

Hafalla, J. C., I. A. Cockburn, and F. Zavala. 2006. Protective and pathogenic roles of CD8⁺ T cells during malaria infection. *Parasite Immunol.* 28:15–24.

CD8⁺ T cells play a key role in protection against preerythrocytic stages of malaria infection. Many vaccine strategies are based on the idea of inducing a strong infection-blocking CD8⁺ T-cell response. **The authors summarize what is known about the development, specificity, and protective effect of malaria-specific CD8⁺ T cells and report on recent developments in the field.** Although work with mouse models continues to advance our understanding of the basic biology of these cells, many questions remain to be answered, particularly regarding the roles of these cells in human infections. Increasing evidence is also emerging for a harmful role for CD8⁺ T cells in the pathology of cerebral malaria in rodent systems. Once again, the relevance of these results to human disease is one of the primary questions remaining.

Riley, E. M., S. Wahl, D. J. Perkins, and L. Schofield. 2006. Regulating immunity to malaria. *Parasite Immunol.* 28:35–49.

The optimal outcome of a malaria infection is that parasitized cells are killed and degraded without inducing significant pathology. Since much of the pathology of malaria infection can be immune mediated, this implies that immune responses have to be carefully regulated. Potential regulatory mechanisms include regulatory T cells, which significantly modify cellular immune responses to various protozoan infections including leishmaniasis and malaria; neutralizing antibodies to proinflammatory malarial toxins such as glycosylphospha-

tidylinositol and hemozoin; and self-regulating networks of effector molecules. Innate and adaptive immune responses are further moderated by the broader immunological environment, which is influenced by both the genetic background of the host and coinfection with other pathogens.

Stephens, R., and J. Langhorne. 2006. Priming of CD4⁺ T cells and development of CD4⁺ T cell memory: lessons for malaria. *Parasite Immunol.* 28:25–30.

CD4 T cells play a central role in the immune response to malaria. They are required to help B cells produce the antibody that is essential for parasite clearance. They also produce cytokines that amplify the phagocytic and parasitocidal response of the innate immune system, as well as dampening this response later to limit immunopathology. Therefore, understanding the mechanisms by which T helper cells are activated and the requirements for development of specific, and effective, T-cell memory and immunity is essential in the quest for a malaria vaccine. **The authors summarize discussions of CD4 cell priming and memory in malaria and in vaccination and outline critical future lines of investigation.** Critical parameters in T-cell activation include the cell types involved, the route of infection, and the timing, location, and cell types involved in antigen presentation. **A new generation of vaccines that induce CD4 T-cell activation and memory are being developed with new adjuvants. Studies of T-cell memory focus on differentiation and factors involved in the maintenance of antigen-specific T cells and control of the size of that population.** To improve the detection of T-cell memory in the field, efforts will have to be made to distinguish antigen-specific responses from cytokine-driven responses.

Stevenson, M. M., and B. C. Urban. 2006. Antigen presentation and dendritic cell biology in malaria. *Parasite Immunol.* 28:5–14.

Dendritic cells (DCs) are important both in amplifying the innate immune response and in initiating adaptive immunity and shaping the type of T helper response. Although the role of DCs in immune responses to many intracellular pathogens has been delineated and research is under way to identify the mechanisms involved, relatively little is known about the role of DCs in immunity to malaria. The authors provide an overview and summary of previous and current studies aimed at investigating the role of DCs as antigen-presenting cells. The role of DCs in inducing innate and adaptive immunity to blood-stage malaria is discussed, and the mechanisms involved are presented. Data from studies of humans infected with *Plasmodium falciparum*, the major human parasite responsible for the high morbidity and mortality associated with malaria throughout many regions of the developing world, as well as data from experimental mouse models are presented. **Overall, the data from these studies are conflicting.** The possible reasons for these differences, including the use of different parasite species and parasite strains in the mouse studies, are discussed. Nevertheless, together the data have important implications for the development of an effective malaria vaccine since the selection of appropriate

Plasmodium antigens and/or adjuvants, targeting innate immune responses involving DCs, may provide optimal protection against malaria.

Treatment (See Also Individual Relevant Chapters)

Ellekvist P., and H. Colding. 2006. Transport proteins as drug targets in *Plasmodium falciparum*. New perspectives in the treatment of malaria. *Ugeskr. Laeger.* 168:1314–1317.

The malaria parasite *Plasmodium falciparum* infects and replicates in human RBCs. Through the use of substrate-specific transport proteins, *P. falciparum* takes up nutrients from the RBC cytoplasm. The sequencing and publication of the *P. falciparum* genome have made it possible to identify, clone, and characterize a number of these transport proteins from the parasite. Since the *P. falciparum* transport proteins differ from their human homologues, they may provide potential drug targets in the treatment of malaria. **An example of a *P. falciparum* transport protein which seems promising as a drug target is the parasite’s hexose transporter. Furthermore, the antimalarial drug artemisinin has been shown to interact specifically with the parasite’s Ca²⁺ pump. A number of other transport proteins are also discussed as possible drug targets.**

Kennedy, P. G. 2006. Diagnostic and neuropathogenesis issues in human African trypanosomiasis. *Int. J. Parasitol.* 3 Mar. [Epub ahead of print.]

Human African trypanosomiasis, also known as sleeping sickness, is caused by protozoan parasites of the genus *Trypanosoma* and is a major cause of human mortality and morbidity. The East African and West African variants, caused by *Trypanosoma brucei rhodesiense* and *Trypanosoma brucei gambiense*, respectively, differ in their presentation, but the disease is fatal if untreated. Accurate staging of the disease into the early hemolymphatic stage and the late encephalic stage is critical as the treatment for the two stages is different. **The only effective drug for late-stage disease, melarsoprol, which crosses the blood-brain barrier, is followed by a severe posttreatment reactive encephalopathy in 10% of patients, half of whom die.** There is no current consensus on the diagnostic criteria for CNS involvement, and the specific indications for melarsoprol therapy also differ. There is a pressing need for a quick, simple, cheap, and reliable diagnostic test to diagnose human African trypanosomiasis in the field and also to determine CNS invasion. Analyses of CSF and plasma from patients with human African trypanosomiasis have indicated a role for both proinflammatory and counterinflammatory cytokines in determining the severity of the meningoencephalitis of late-stage disease, and, at least in *T. brucei rhodesiense* infection, the balance of these opposing cytokines may be critical. **Rodent models of human African trypanosomiasis have proved very useful in modeling the posttreatment reactive encephalopathy of humans and have demonstrated the central role of astrocyte activation and cytokine balance in determining CNS disease.** The use of such animal models has also allowed a greater understanding of the more direct

mechanisms of the effects of trypanosome infection on CNS function including the disruption of circadian rhythms, as well as the immunologic determinants of the passage of trypanosomes across the blood-brain barrier.

Meehan, W. J., S. Badreshia, and C. L. Mackley. 2006. Successful treatment of delusions of parasitosis with olanzapine. *Arch. Dermatol.* 142:352–355.

Delusional parasitosis is a rare disorder in which patients have a fixed, false belief of being infested with parasites. It is often accompanied by a refusal to seek psychiatric care. **Delusional parasitosis is classically treated with typical antipsychotic agents, the traditional dermatologic choice being pimozide. However, pimozide's adverse-effect profile and the need for frequent electrocardiographic monitoring make such treatment less practical.** The authors describe three patients who were diagnosed as having delusional parasitosis that was successfully treated with an atypical antipsychotic agent, olanzapine (5 mg/day), which has recently been approved by the Food and Drug Administration. **Olanzapine has a more benign adverse-effect profile than typical antipsychotic agents, and its use eliminates the need for electrocardiographic monitoring.** Olanzapine therapy has been associated with such adverse effects as sedation, hyperlipidemia, weight gain, and insulin resistance, all of which were infrequent in the patients in this study. **Olanzapine is an atypical antipsychotic agent that can be used as a first-line agent in delusional parasitosis as a safer therapeutic option without a specialized monitoring regimen.**

Ramzy, R. M., M. El Setouhy, H. Helmy, E. S. Ahmed, K. M. Abd Elaziz, H. A. Farid, W. D. Shannon, and G. J. Weil. 2006. Effect of yearly mass drug administration with diethylcarbamazine and albendazole on bancroftian filariasis in Egypt: a comprehensive assessment. *Lancet* 367:992–999.

Egypt was one of the first countries to implement a national program to eliminate lymphatic filariasis based on the World Health Organization strategy of repeated rounds of mass drug administration (MDA) with diethylcarbamazine and albendazole (target population, 2.5 million in 181 localities). The authors assessed the effect of five yearly rounds of MDA on filariasis in four sentinel villages in Egypt. They studied two areas with different infection rates before MDA. The Qalubia study area had a low infection rate because of previous treatment with diethylcarbamazine; this was typical of most filariasis-endemic villages in Egypt before the advent of MDA. The Giza study area had a high baseline infection rate. The authors undertook repeated surveys in villages for treatment compliance and tests for microfilaraemia and circulating filarial antigenemia, antibodies to filarial antigen Bm14 in schoolchildren, and infections in indoor-resting mosquitoes (assessed by PCR). MDA compliance rates were excellent (>80%). In Giza after MDA, the prevalence of microfilaraemia and circulating filarial antigenemia fell from 11.5% to 1.2% and from 19.0% to 4.8%, respectively. Corresponding rates in Qalubia fell from 3.1% to 0% and 13.6% to 3.1%, respectively. Rates of antifilarial antibody and circulating filarial antigenemia in schoolchildren (aged

about 7 to 8 years), fell from 18.3% to 0.2% and from 10.0% to 0.4% in Giza, respectively, and from 1.7% to 0% and 1.7% to 0% in Qalubia, respectively. Mosquito infection rates fell from 3.07% to 0.19% in Giza and from 4.37% to 0% in Qalubia. **MDA greatly affects variables related to infection (microfilaraemia and circulating filarial antigenemia prevalence rates) and transmission (antifilarial antibodies in young children and mosquito infection rates).** Our results suggest that after five rounds of MDA, filariasis is likely to have been eliminated in most localities in Egypt where the infection is endemic.

Valecha, N., H. Joshi, A. Eapen, J. Ravinderan, A. Kumar, S. K. Prajapati, and P. Ringwald. 2006. Therapeutic efficacy of chloroquine in *Plasmodium vivax* from areas with different epidemiological patterns in India and their *Pvdhfr* gene mutation pattern. *Trans. R. Soc. Trop. Med. Hyg.* 27 Feb. [Epub ahead of print.]

Among the four human malaria parasites, drug resistance occurs mainly in *Plasmodium falciparum*. However, there are some reports of chloroquine (CQ) resistance in *P. vivax* from different geographic regions. In India, approximately 50% of a total of 2 million cases of malaria reported annually are due to *P. vivax*. CQ is the drug of choice for treatment. Since few cases of treatment failure have been reported from India, this study was undertaken to generate data systematically on the efficacy of CQ in 287 patients from different epidemiologic regions. Cure rates for 28 days were 100%, and there was rapid parasite clearance in all age groups from all study sites. Although *P. vivax* has been reported to be inherently resistant to sulfonamide and pyrimethamine, Indian isolates exhibited only double mutations in *dhfr* in vitro.

Medically Important Arthropods

Faulde, M., and W. Uedelhoven. 2006. A new clothing impregnation method for personal protection against ticks and biting insects. *Int. J. Med. Microbiol.* 6 Mar. [Epub ahead of print.]

The efficacy and residual activity of a factory-based, permethrin-impregnated military battle dress uniform (BDU) produced by using a new polymer-coating technique were evaluated by laboratory and field testing during deployment to Afghanistan and compared with those of two commercially available, widely used dipping methods. Residual permethrin concentrations and remaining contact toxicities on treated fabrics before laundering, after up to 100 launderings as well as after being worn out during deployment, were tested against *Aedes aegypti* and *Ixodes ricinus*. The residual amount of permethrin was considerably larger for the polymer-coating technique, with 280 mg/m remaining after 100 launderings. Polymer-coated BDUs collected for disposal after being worn out during military deployment showed equivalent or better residual knockdown efficacy against test arthropods than did the U.S. Army Illinois Department of Agriculture kit after 50 launderings, which represent the recommended baseline for reimpregnation or disposal of the impregnated fabric. **BDUs impregnated by the polymer-coating method were found to be effective throughout the lifetime of**

the uniform, ensuring the protection of soldiers in the field from arthropod vectors while simultaneously decreasing logistical constraints and occupational health threats.

Pasay, C., S. Walton, K. Fischer, D. Holt, and J. McCarthy. 2006. PCR-based assay to survey for knockdown resistance to pyrethroid acaricides in human scabies mites (*Sarcoptes scabiei* var. *hominis*). *Am. J. Trop. Med. Hyg.* 74:649–657.

Permethrin, in the form of a topical cream, is being increasingly used for community-based programs to control endemic scabies. The development of resistance has reduced the use of pyrethroids for the control of many arthropods of economic and health importance. The best-recognized form of pyrethroid resistance, known as knockdown resistance or *kdr*, has been linked to specific mutations in the target of these agents, the para-homologous voltage-sensitive sodium channel gene (*Vssc*). To develop tools to study resistance to pyrethroid acaricides, the authors cloned 3,711 and 6,151 bp, respectively, of cDNA and genomic fragments of the *Vssc* gene from the scabies mite, *Sarcoptes scabiei*. The sequence encompasses the major polymorphic amino acid residues associated with pyrethroid resistance. A PCR-based strategy has been developed that enables the genotyping of individual scabies mites. This will facilitate early detection and monitoring of pyrethroid resistance in scabies mite populations under drug selection pressure.

Rupp, M. R., and R. D. deShazo. 2006. Indoor fire ant sting attacks: a risk for frail elders. *Am. J. Med. Sci.* 331:134–138.

The authors have previously reported 10 indoor sting attacks by imported fire ants, most of which involved frail elderly people in the southeastern United States. Since the range of these insects is expanding and attacks often attract media attention, additional attacks may have occurred and were reported in local newspapers. The authors searched the archives from 1989 until 2004 of 182 U.S. newspapers in fire ant-endemic areas in 10 states. Ten additional cases of indoor fire ant sting attacks were reported in local newspapers between 1991 and 2004. This brings the total to 16 attacks on adults and 4 on infants. Most adult attacks occurred in long-term care facilities, but three involved hospitalized patients. Morbidity ranged from nightmares to death in seven adults. One of the infants died, and two suffered long-term morbidity. Of the 20 sting victims, 6 died within 1 week of the attack. Of the 10 attacks reported in newspapers, 7 did not result in significant medical consequences, compared with only 2 of the 10 attacks in previously published reports. **Increasing numbers of indoor fire ant sting attacks are occurring in the United States, and frail elderly people and infants are at risk. They should be removed from indoor areas where ants are present until the ants are eradicated.**

Titus, R. G., J. V. Bishop, and J. S. Mejia. 2006. The immunomodulatory factors of arthropod saliva and the potential for these factors to serve as vaccine targets to prevent pathogen transmission. *Parasite Immunol.* 28:131–141.

In general, attempts to develop vaccines for pathogens transmitted by arthropods have met with little or no success. The saliva of arthropods that transmit disease enhances the infectivity of the pathogens transmitted to the vertebrate host, and vaccinating against components of the saliva of arthropods or against antigens expressed in the gut of arthropods can protect the host from infection and decrease the viability of the arthropod. **The results of this study suggest that multi-subunit vaccines that target the pathogen itself as well as arthropod salivary gland components and arthropod gut antigens may be the most effective at controlling arthropod-borne pathogens, since these vaccines would target several facets of the life cycle of the pathogen.** This review covers known immunomodulators in arthropod salivary glands, instances when arthropod saliva has been shown to enhance infection, and a limited number of examples of antiarthropod vaccines, with emphasis on three arthropods: sand flies, mosquitoes, and hard ticks.

Testing of Stool Specimens

Nunes, C. M., L. G. Lima, C. S. Manoel, R. N. Pereira, M. M. Nakano, and J. F. Garcia. 2006. Fecal specimen preparation methods for PCR diagnosis of human taeniosis. *Rev. Inst. Med. Trop. Sao Paulo* 48:45–47.

Sample preparation and DNA extraction protocols for DNA amplification by PCR, which can be applied in human fecal samples for taeniosis diagnosis, are described. DNA extracted from fecal specimens with phenol-chloroform-isoamyl alcohol and DNAzol reagent had to be purified to generate fragments of 170 and 600 bp by HDP2-PCR. This purification step was not necessary with the QIAmp DNA stool mini kit. **The best DNA extraction results were achieved after egg disruption with glass beads, with either phenol-chloroform-isoamyl alcohol, DNAzol reagent, or the QIAmp DNA stool mini kit.**

Management Issues in Diagnostic Medical Parasitology

Conraths, F. J., and G. Schares. 2006. Validation of molecular-diagnostic techniques in the parasitological laboratory. *Vet. Parasitol.* 136:91–98.

Diagnostic laboratories today often operate according to standard quality management procedures such as ISO/IEC 17025. This requires that only validated methods be used. Validation procedures help to document that a particular protocol used by the accredited laboratory has a guaranteed performance in that particular laboratory. Several study designs exist for validation procedures. Computer programs are available to help with the statistical analysis of validation results. The results obtained in the protocol that is to be validated can be compared to those obtained in an already established test (agreement). For a method that is used under routine conditions or for epidemiologic studies, it is necessary to assess the diagnostic sensitivity and specificity of the technique. These parameters can be estimated by comparing

the method to be validated with an existing reliable method (“gold standard”). This is done by testing a standard set of well-documented samples using both techniques in parallel. Approaches using Bayes’ theorem are used to perform gold standard-free validations. Many PCR-based methods are characterized by an excellent analytical sensitivity and are thus good candidates for diagnostic tools of the required diagnostic sensitivity. However, the high level of analytical

sensitivity can also make molecular techniques susceptible to cross-contamination and carryover problems, leading to false-positive results. Moreover, the presence of inhibitors can cause false-negative results. After an initial validation, test performance must be continuously monitored, e.g., by using combined Shewhart-CUSUM control routines, and test results must be compared to those obtained by other laboratories (proficiency testing).

Glossary

Certain terms listed here do not appear in the text, but it is hoped that their inclusion will be useful. Diseases and parasites in parentheses represent some, but not all, examples that pertain to the terms listed. One of my favorite definitions is “Parasitologist: A quaint person who seeks truth in strange places” (G. D. Schmidt and L. S. Roberts, *Foundations of Parasitology*, The C. V. Mosby Co., St. Louis, Mo., 1977).

Abdominal pain Crampy abdominal pain that may be seen in amebic colitis; right upper quadrant pain in amebic abscess; severe duodenitis or jejunitis with *Strongyloides* organisms penetrating the mucosa; pain suggestive of gastric ulcer or appendicitis with anisakid larvae (penetration of gut wall).

Aberrant parasite One which is never transmitted from person to person and which develops abnormally in humans (*Echinococcus multilocularis*, *Angiostrongylus*).

Abscess A localized collection of pus caused by liquefaction necrosis of tissue (amebiasis, filariasis).

Acanthamoebiasis Infection by free-living soil and water amoebae of the genus *Acanthamoeba* that may result in a necrotizing dermal or tissue invasion, a fulmination and usually fatal primary amebic meningoencephalitis (PAM), or a subacute or chronic granulomatous amebic encephalitis (GAE).

Acaricide A mite-destroying agent.

Accidental parasite A parasite found in other than its normal host; also called an incidental parasite.

Accolé Early ring form of *Plasmodium falciparum* found at the margin of a red cell: appliqué.

Acid-fast stain, modified Developed for staining some of the coccidia (*Cryptosporidium*, *Cyclospora*); must be used with gentle decolorizer (1% sulfuric acid recommended).

Acquired immunity Immunity arising from a specific immune response, humoral or cell mediated, stimulated by antigen in the

body of the host (active) or in the body of another individual with the antibodies or lymphocytes transferred to the host (passive).

Acute abdomen An abdominal condition of abrupt onset usually associated with abdominal pain resulting from inflammation, perforation, obstruction, infarction, or rupture of intra-abdominal organs; surgical intervention is usually necessary (ascariasis, anisakiasis).

Aerosol A system of respirable particles dispersed in a gas, smoke, or fog that can be retained in the lungs.

AIDS Acquired immune deficiency syndrome.

Alae Pronounced, longitudinal cuticular ridges in nematodes, usually found in larval stages (*Ascaris lumbricoides*), although occasionally present in adult worms (*Enterobius vermicularis*).

Allergy A hypersensitive condition acquired by exposure to a particular allergen (helminth infections, house dust mites, ectoparasite bites or stings).

Amastigote Small, round, intracellular stage of *Leishmania* spp. and *Trypanosoma cruzi* in which the base of the flagellum is anterior to the nucleus but there is no external flagellum; also called Leishman-Donovan body, L-D body, or leishmanial stage.

Anamnestic response Immune response to a challenge or secondary antigen inoculation, marked by a more rapid and stronger manifestation of the immune reaction than after the primary immunizing dose.

Anaphylaxis Hypersensitivity produced by exposure to further doses of the same protein, usually when exposure is within less than 2 weeks (bee stings, echinococcosis).

Anemia A reduced number of erythrocytes per cubic millimeter, reduction in the amount of hemoglobin, or reduction in the volume of packed red blood cells per 100 ml of blood (malaria, hookworm, and *Diphyllobothrium latum* infections).

Anergic Absence of sensitivity to an antigen or the condition resulting from desensitization (cutaneous leishmaniasis).

Aneurysm Circumscribed dilation of an artery connecting directly with the lumen of an artery or a cardiac chamber connecting directly with the lumen of an artery, usually due to an acquired or congenital weakness of the wall of the artery or chamber.

Anorexia Absence of appetite.

Anthropophilic Human-seeing or human-preferring, especially with reference to blood-sucking arthropods.

Anthropozoonosis A zoonosis maintained in nature by animals and transmissible to humans.

Antigenic determinant The areas on an antigen molecule that bind with antibody or specific receptor sites on the sensitized lymphocyte; these areas determine the specificity of the antibody or lymphocyte.

Anuria Absence of urine secretion (scorpion sting).

Aphasia Partial or complete inability to speak and/or understand spoken words.

Apoptosis Single deletion of scattered cells by fragmentation into membrane-bound particles, which are phagocytosed by other cells; believed to be due to programmed cell death.

Appendicitis Inflammation of the vermiform appendix (amebiasis, *Ascaris*, *Trichuris*, and *Enterobius* infections).

Appendix Thick-walled fingerlike projection at the end of the cecum.

Appliqué Early ring form of *Plasmodium falciparum* found at the margin of a red cell; accolé.

Ascites Effusion of serous fluid into the abdominal cavity (schistosomiasis).

Aspirate Fluid removed from a cavity or lesion (leishmaniasis, hydatid disease, amebiasis).

Asthma, bronchial Disease characterized by wheezing, coughing, and difficulty in breathing caused by spasmodic contraction of the bronchi; may be the result of allergic reaction (ascariasis, strongyloidiasis, visceral larva migrans, house dust mites). Also see *Eosinophilia*.

Autochthonous Indigenous or normally found in a particular area.

Autoinfection Reinfection by an organism already present in the body with an increase in the number of parasites without their undergoing a cycle outside the body; self-infection (*Strongyloides stercoralis*, *Hymenolepis nana*, *Cryptosporidium* spp.).

Autopsy Gross and microscopic postmortem examination of the organs of the body to determine the cause of death or pathologic changes.

Axostyle Rodlike supporting structure in some flagellates that gives rigidity to the body (*Trichomonas* spp.).

Babesiosis A disease of humans that is caused by a blood protozoan of various animals; tick borne; organism morphology

similar to young rings of *Plasmodium falciparum*; more severe in compromised patients.

Band form Older trophozoites of *Plasmodium malariae* that may stretch across the red cell in the form of a band.

Barbiero Brazilian term for the blood-sucking hemipteran triatomid bug, *Panstrongylus megistus*, an important vector of Chagas' disease (caused by *Trypanosoma cruzi*).

Basket nucleus Nuclear structure that may be seen in *Iodamoeba bütschlii* cysts (occasionally trophozoites); in well-stained organisms, fibrils may be seen running between the karyosome and the chromatin granules. The "basket of flowers" has been described as follows: the karyosome forms the basket, the fibrils form the stems, and the granules form the flowers.

Baylisascaris A genus of ascarid nematodes found in the intestines of mammals, including humans.

Baylisascaris procyonis A common roundworm of raccoons (ingestion of infective eggs from the environment) that can cause larva migrans (central nervous system). Human cases present with eosinophilic meningoencephalitis (there have been several fatal cases in the United States).

Behçet's syndrome More common in men; involves dermatitis, erythema nodosum, thrombophlebitis, cerebral involvement; may include arthritis, uveitis, or iridocyclitis with hypopyon.

Benign tertian malaria Malaria caused by *Plasmodium vivax*.

Bilharziasis Another name for schistosomiasis; often used to indicate infection with either *Schistosoma mansoni* or *S. haematobium*.

Binary division Dividing of a cell into two nearly equal daughter individuals.

Biopsy Removal of tissue from a living person; examination, usually microscopic, used to make diagnosis (Chagas' disease, leishmaniasis, schistosomiasis, visceral larva migrans, amebiasis).

Blackwater fever A condition in which the diagnostic symptom is the passage of reddish to black urine (containing hemoglobin), indicating massive intravascular hemolysis (*Plasmodium falciparum*).

Blepharoplast A small, dark-staining body near the base of the flagellum that is associated with fibrillar portions of the flagellum (blood flagellates).

Botfly Robust, hairy fly of the order Diptera, often strikingly marked in black and yellow or gray, whose larvae produce a variety of myiasis conditions in humans and various domestic animals.

Bothrium One of the two shallow grooves on the scolex of *Dipyllobothrium latum*.

Bots The larvae of several species of botflies.

Bradyzoite A slowly multiplying trophozoite contained in the cyst; typical of a chronic infection with *Toxoplasma gondii*.

Buccal cavity/capsule The space between the oral opening and the beginning of the esophagus in nematodes; useful diagnostically in rhabditiform larvae (*Strongyloides stercoralis*, hookworm).

Buccal teeth/plates Toothlike structure in the mouth cavity of the adult hookworms of the genus *Ancylostoma* (in contrast to buccal plates found in the mouth cavity of the genus *Necator*).

Budding Production of daughter cell as outward growth from the original cell or germinal layer (yeastlike fungi, hydatid cyst).

Buffy coat Grayish white layer of fibrin and leukocytes that forms the upper part of the sedimented cells in whole blood after the addition of anticoagulant (examined in visceral leishmaniasis and trypanosomiasis).

Bursa Umbrella-like expansion of the cuticle at the posterior end of male nematodes; it is supported by muscular rays and aids in copulation (hookworms, trichostrongyles).

Cachexia Severe debilitated state (heavy worm infestation, visceral leishmaniasis).

Calabar swellings Transient swellings of subcutaneous tissues; associated with *Loa loa* infection.

Calcareous corpuscles Rounded masses composed of concentric layers of calcium carbonate that are found in the tissue of tapeworms, characteristic of tapeworm tissue; certain fixatives must be avoided to preserve corpuscles for identification purposes (tapeworms).

Calcifications Portions of host or parasite tissue that become hardened by the deposition of calcium salts; may be visible on radiographic studies (toxoplasmosis, cysticercosis, trichinosis, schistosomiasis).

Capitonnage Closure of a cyst cavity by using sutures (hydatid disease).

Capitulum The blood-sucking, probing, sensing, and holdfast mouthparts of a tick, including the basal supporting structure; the relative size and shape of mouthparts forming the capitulum are characteristic for the genera of hard ticks.

Carcinogen Substance capable of causing a malignant tumor in humans or animals.

Carditis Inflammation of the heart tissues (Chagas' disease).

Carrier A host that harbors a particular pathogen without showing manifestations of disease.

Casoni antigen Skin test antigen composed of sterile hydatid fluid (hydatid disease).

Cathartic A substance causing evacuation of bowels by increasing bulk, stimulating peristalsis.

Cecum A blindly ending appendage of the intestine.

Cell-mediated immunity Type of immunity that is independent of antibody and is initiated by cytotoxic T cells or by the

secretion of lymphokines by T cells. The lymphokines cause other cells, usually lymphocytes and macrophages, to aggregate in the area of T-cell-antigen interaction, leading to a local reaction such as a granuloma.

Cercaria Free-living, tailed larval stage of trematodes; may infect humans by direct penetration (schistosomes); may attach to vegetation and encyst to the metacercarial stage (*Fasciola* and *Fasciolopsis* spp.), or may penetrate tissues of vertebrates or invertebrates and encyst to the metacercarial stage (*Clonorchis* spp.).

Cestode Tapeworm.

Chagas' disease Infection caused by *Trypanosoma cruzi* (American trypanosomiasis).

Chagoma Small granuloma in the skin, caused by early multiplication of *Trypanosoma cruzi* (Chagas' disease).

Charcot-Leyden crystals Slender crystals that are formed from the breakdown products of eosinophils; shaped like double, elongated pyramids with pointed ends; can be found in feces, sputum, and tissues; indicates an immune response that may or may not be related to a parasitic infection.

Chiclero ulcer Single, self-limiting cutaneous papule, nodule, or ulcer (usually on the face or ears) (leishmaniasis).

Chigger The six-legged larva of *Trombicula* species; a blood-sucking stage of mites that includes the vectors of scrub typhus.

Chorea Irregular, spasmodic, involuntary movements of the limbs or facial muscles.

Chorioretinitis Inflammation of the posterior coat and retina of the eye (toxoplasmosis).

Chromatin Deep-staining DNA-containing portion of the nucleus (protozoa).

Chromatoidal bar/body Deep-staining, bar-shaped, round, or splinter-shaped inclusions found in the cytoplasm of certain amoebae (*Entamoeba* spp.).

Chyluria The presence of lymph and emulsified fat in the urine (filariasis).

Cilia Small, hairlike cytoplasmic projections from a cell or organism; used for motility (*Balantidium coli*).

Cirrhosis Disruption of the normal structure of the liver; destruction of liver cells and increase in connective tissue (schistosomiasis).

CLBs These organisms were thought to be a new pathogen, possibly an oocyst, a flagellate, an unsporulated coccidian, a large *Cryptosporidium* sp., a blue-green alga (cyanobacterium-like body), or a coccidian-like body. They are now known to be coccidia in the genus *Cyclospora*.

Coenurus Tapeworm larva of the genus *Multiceps*, characterized by multiple scolices invaginated into the fluid-filled bladder; no daughter cysts produced.

Colitis Inflammation of the colon.

Colon Portion of the large intestine from the cecum to the rectum.

Coma Absolute unconsciousness.

Commensalism Association in which one individual receives benefits and the other is neither helped nor harmed.

Complement A series of proteins that bind in a complex series of reactions to antibody (immunoglobulin G or M) when the antibody is itself bound to an antigen; produces cell lysis if the antibody is bound to antigens on the cell surface.

Concentration techniques Procedures, usually in fecal examinations, allowing the examination of large amounts of feces (flotation or sedimentation procedures; some available for blood specimens and urine specimens).

Concomitant immunity Type of immunity where the host harbors a population of adult worms but is immune to reinfection.

Congenital Present at, and usually before, birth (regardless of cause).

Conjunctivitis Inflammation of the membrane that lines the eyelids and covers the surface of the eyeball.

Convulsion A violent, involuntary contraction of an extensive group of muscles; disturbance of cerebral function (spider and scorpion envenomation).

Coracidium A ciliated larval tapeworm stage that occurs in the eggs of cestodes such as *Diphyllobothrium* and *Spirometra* spp. (pseudophyllidian tapeworms); this is a free-swimming stage, containing six hooks like those found in the oncospheres of other tapeworms.

Cor pulmonale Cardiopulmonary problems which may terminate in congestive heart failure; obstructive vascular disease (*Schistosoma mansoni* infection).

Corrosive Any substance that causes visible destruction of human tissue at the site of contact. The U.S. Environmental Protection Agency defines corrosivity as a substance that is highly acidic (pH < 2.1) or highly alkaline (pH > 12.4).

Creeping eruption Penetration and migration through subcutaneous tissues by skin-penetrating nematodes, resulting in intense pruritus and sometimes secondary bacterial or fungal infection (*Strongyloides* and hookworm infections, cutaneous larva migrans).

Crithidia Old term for epimastigote.

Cryptosporidiosis Intestinal infection caused by coccidia (*Cryptosporidium* spp.).

Cutaneous Pertaining to the skin.

Cuticle Outermost, three-layered portion of the body wall of nematodes (*Ascaris lumbricoides*, etc.).

Cysticercoid The solid larval stage of tapeworms containing an invaginated scolex that occurs in arthropod intermediate hosts (*Hymenolepis*, *Dipylidium*).

Cysticercosis Tissue infection with larval tapeworms in which the scolex is inverted into a fluid-filled bladder (*Taenia solium*).

Cysticercus Tapeworm larva of the family Taeniidae (includes *Taenia solium* and *T. saginata*) in which a single scolex is invaginated into a fluid-filled bladder.

Cystoenterostomy Internal drainage of pancreatic cysts into some portion of the intestinal tract (hydatid disease).

Cytoplasm The protoplasm of a cell exclusive of the nuclear material.

Daisy Colloquial term descriptive of the segmented forms (merozoites) of the mature schizont of *Plasmodium malariae*.

Decontamination A procedure that eliminates or reduces microbial or toxic agents to a safe level with respect to the transmission of infection or other adverse affects.

Definitive host Host in which the sexual reproduction of a parasite occurs.

Delayed hypersensitivity A manifestation of cell-mediated immunity, different from immediate hypersensitivity in that the maximal response is reached about 24 h or more after intradermal injection of the antigen; infection site is infiltrated by monocytes and macrophages.

Dermatitis Inflammation of the skin (filariasis, schistosomiasis, infections with *Strongyloides* and hookworm larvae, leishmaniasis, *Sarcoptes* infections).

Diarrhea Frequent passage of soft or liquid stool (no blood); may be caused by any parasite or infection normally found in any part of the intestine (*Giardia lamblia*, *Isospora belli*, *Dientamoeba fragilis*, *Balantidium coli*, *Cryptosporidium* spp., *Enterocytozoon bienersi*, *Encephalitozoon intestinalis*, possibly other microsporidia, *Cyclospora* spp., *Leishmania* spp. causing visceral leishmaniasis, *Plasmodium falciparum*, tapeworms, *Trichinella* spp., *Schistosoma* spp., hookworm).

Didelphis A genus of marsupials, commonly called opossums, that serve as reservoir hosts of *Trypanosoma cruzi*.

Diocious Having the male and female sexes of a species as separate individuals.

Direct smear (stool) Approximately 2-mg suspension of feces in water or saline for the purpose of examination for parasites; the primary aim is to see motility.

Disinfectant An agent intended to destroy or irreversibly inactivate all microorganisms, but not necessarily their spores, on inanimate surfaces, e.g., work surfaces or medical devices.

Diurnal Pertaining to the daylight portion of the 24-h day.

Duodenum The proximal portion of the small intestine (*Strongyloides stercoralis*, *Giardia lamblia*).

Dysentery Frequent watery stools, usually containing blood and/or mucus; associated with inflammation of the intestine, usually the colon (*Entamoeba histolytica*, *Trichuris trichiura*).

Dyspnea Difficulty in breathing.

Dysuria Painful or difficult urination.

Ecosystem The fundamental unit in ecology, comprising the living organisms and the nonliving elements that interact in a defined region.

Ectoparasite Organism that lives on or within the skin of its host (lice, mites, ticks).

Ectopic site Outside the normal location; i.e., the position of a parasite which lodges in an atypical part of the body.

Ectoplasm Outer layer of the cytoplasm of a cell.

Edema Presence of large amounts of fluid, usually in subcutaneous tissues (filariasis, trypanosomiasis, hookworm).

Elephantiasis Inflammation and obstruction of the lymphatic system, resulting in hypertrophy and thickening of the surrounding tissues, usually involving the extremities and external genitalia (filariasis).

Encapsulation Active process of walling off a parasite by the host through the formation of a connective tissue capsule (trichinosis).

Encephalitis Inflammation of the brain (Chagas' disease, trichinosis).

Encystment Formation of a resistant external wall by protozoa to enable them to survive drying and adverse environmental conditions; encysted forms are infective to humans.

Endemic Disease present in a localized community or area at all times.

Endoparasite Parasite that lives within the body of the host.

Endoplasm Inner portion of the cytoplasm of a cell.

Endospore The chitinous inner spore coat (microsporidia).

Engineering controls Controls (e.g., sharps disposal containers, self-sheathing needles, safer medical devices) that isolate or remove the hazard from the workplace.

Eosinophilia Formation of large numbers of eosinophilic leukocytes as a result of some type of immune response; usually found in helminth infections, particularly with tissue invasion (visceral larva migrans, trichinosis, filariasis, schistosomiasis, ascariasis, strongyloidiasis).

Eosinophilic cerebrospinal fluid pleocytosis Increased number of eosinophils in cerebrospinal fluid (*Angiostrongylus* and *Baylisascaris* infections; coenurosis, cysticercosis, echinococcosis, *Fasciola*, *Gnathostoma*, *Paragonimus*, *Schistosoma*, *Toxocara*, *Toxoplasma*, and *Trichinella* infections; possibly *Dirofilaria*, *Onchocerca*, and *Ascaris* infections).

Eosinophilic meningitis Inflammation of membranes of the brain or spinal cord accompanied by an increased number of eosinophils, usually associated with particular helminth infections (angiostrongyliasis, gnathostomiasis, cysticercosis, schistosomiasis).

Epidemic Disease that spreads rapidly and infects many people in a community or area (usually within a short time frame).

Epidermal Pertaining to the outer layer of the skin.

Epididymitis Inflammation of the epididymis (first part of the excretory duct of each testis) (Bancroftian filariasis).

Epimastigote Developmental stage of the family Trypanosomatidae; the base of the flagellum is in front of the nucleus, and as the flagellum passes through the body to emerge as the free flagellar portion, it is attached to the body by the undulating membrane. (Old term: crithidia.)

Erythema Diffuse or patchy redness of the skin; blanching on pressure as a result of congestion of cutaneous capillaries.

Erythrocytic cycle Developmental cycle of malarial parasites within the red blood cells.

Eukaryote A cell containing a membrane-bound nucleus with chromosomes of DNA, RNA, and proteins, with cell division involving a form of mitosis in which mitotic spindles (or some microtubule arrangement) are involved; mitochondria are present.

Evagination Protrusion of some part or organ from its normal position (tapeworm scolex in larval worms).

Exflagellation The extrusion of rapidly waving flagellum-like microgametes from microgametocytes; in human malaria parasites, this occurs in the blood meal taken by the proper anopheline vector within a few minutes after ingestion of the infected blood by the mosquito.

Exoerythrocytic cycle A part of the malarial life cycle in which the mosquito introduces sporozoites into the vertebrate host; sporozoites penetrate the parenchymal liver cells and undergo schizogony, resulting in the production of liver merozoites, which then initiate the erythrocytic cycle.

Exospore The proteinaceous outer spore coat (microsporidia).

Feces The unabsorbed residue of the digestive process, along with sloughed epithelium, mucus, and bacteria.

Festoon A distinguishing characteristic of certain hard tick species, consisting of small rectangular areas separated by grooves along the posterior margin of the dorsum of both males and females.

Fever A complex physiologic response to disease mediated by pyrogenic cytokines and characterized by a rise in core temperature, generation of acute-phase reactants, and activation of immunologic systems.

Filariform larvae Slender, infective larvae of *Strongyloides stercoralis* and hookworm.

Flame cell Primitive, ciliated excretory cell in trematodes; the movement of the cilia on this cell within the miracidium larva (within a schistosome egg) indicates egg viability.

Flesh flies Members of the order Diptera, whose larvae (maggots) develop in putrefying or living tissues.

Fluke Trematode (*Clonorchis*, *Paragonimus*, *Fasciola*, and *Schistosoma* spp.).

Fundus, ocular The portion of the interior of the eyeball around the posterior pole, visible through the ophthalmoscope.

Funiculitis Inflammation of the spermatic cord (filariasis).

Furcocercous Fork-tailed (cercaria of schistosomes).

Gametocyte In malaria, the sexual cell (male microgametocyte or female macrogametocyte). It is present in peripheral blood; fertilization occurs in the mosquito stomach with formation of the zygote.

Gastroenteritis Inflammation of the stomach and small and large intestines.

Genital primordium Ovoid clump of cells that becomes the reproductive system (seen in the rhabditiform larvae of *Strongyloides stercoralis* and hookworm).

Geohelminth Any helminth that is transmitted to humans from the soil (*Ascaris*, *Strongyloides*, *Trichuris*, hookworm).

Germicide A general term for an agent that kills pathogenic microorganisms on inanimate surfaces.

Granuloma Tumorlike nodule of firm tissue formed as a reaction to chronic inflammation, usually of lymphoid and epithelioid cells.

Gynecophoral groove or canal The ventral incurved fold of the body extending from the ventral sucker to the caudal extremity, for carrying the female worm (schistosomes).

Halzoun Presence of worms on pharyngeal mucosa; congestion of tissues accompanied by difficulty in breathing and possible asphyxiation (*Fasciola hepatica* and pentastome infection).

Harada-Mori culture Method of incubating fecal material on a filter paper strip in a test tube containing water (cover one-third of the length of paper strip) for the purpose of culturing and recovering nematode larvae (*Strongyloides stercoralis*, hookworm).

Helminth May refer to a nematode (roundworm), cestode (tapeworm), or trematode (fluke).

Hematuria Passage of free hemoglobin in the urine (*Plasmodium falciparum* infection, blackwater fever).

Hemoflagellate Any flagellated protozoan blood parasite (*Trypanosoma* spp.).

Hepatitis Inflammation of the liver (amebiasis, schistosomiasis, infections with liver flukes).

Hepatomegaly Enlargement of the liver.

Hermaphroditism Presence of both male and female reproductive systems in the same individual; most trematodes and cestodes are hermaphroditic.

Heterakis A genus of important nematode parasites. *H. gallinarum* is the cecal worm of chickens and turkeys and is the vector of *Histomonas meleagridis*, a protozoan that

causes histomoniasis (a model of the possible transmission of *Dientamoeba fragilis* within helminth eggs such as *Enterobius vermicularis* and *Ascaris lumbricoides*).

Heterophyids Small intestinal flukes parasitic in humans and animals (*Heterophyes* and *Metagonimus* spp.).

Hexacanth embryo Six-hooked tapeworm embryo (oncosphere).

HIV Human immunodeficiency virus.

Hives See *Urticaria*.

HMO Health Maintenance Organization.

Host An organism in or on which a parasite lives.

Hydatid, alveolar Type of hydatid cyst formed by *Echinococcus multilocularis*; budding is external, as well as internal, and there is no thick outer capsule.

Hydatid, polycystic Type of hydatid cyst formed by *Echinococcus oligarthrus* and *E. vogeli*; the structure is between those of unilocular and alveolar types of hydatid cyst.

Hydatid, unilocular Type of hydatid cyst formed by *Echinococcus granulosus*; single limiting membrane.

Hydatid cyst Tapeworm larval stage of the genus *Echinococcus*; consists of a large bladder with an inner germinal layer from which daughter cysts and scolices develop (some of which break off and drop into the fluid-filled bladder).

Hydatid sand Consists of scolices, daughter cysts, hooks, and calcareous corpuscles found in the fluid within the hydatid cyst (*Echinococcus granulosus*).

Hydatid thrill A delicate vibration felt by the hand after quick palpation or percussion over the area of the body where the hydatid cyst is located (*Echinococcus granulosus*).

Hydrocele Accumulation of serous fluid in a saclike cavity, particularly the scrotal sac (filariasis).

Hydrocephalus An abnormal accumulation of fluid in the cerebral ventricles or in the subarachnoid space of the brain (cysticercosis).

Hyperparasitemia Infection with *Plasmodium falciparum* at a density of more than 250,000 parasites/ μ l.

Hyperpigmentation Intensification of pigment; most obvious in dark-skinned races (leishmaniasis, onchocerciasis).

Hypersensitivity Enhanced state of responsiveness following sensitization to a particular antigen. There are four types, type I (anaphylaxis), type II (antibody-dependent cytotoxicity), type III (immune complex hypersensitivity), and type IV (delayed hypersensitivity).

Hypnozoite Exoerythrocytic schizont of *Plasmodium vivax* or *P. ovale* in the human liver, characterized by delayed primary development; responsible for malarial true relapse.

Hypopyon The presence of pus in the anterior chamber of the eye.

Hypostome The central unpaired holdfast organ of the tick capitulum; covered with recurved spines that serve as an anchoring device while the tick feeds.

IATA The International Air Transport Association, a body of the commercial airline industry that governs international aviation. It publishes the *Technical Instructions for the Safe Transport of Dangerous Goods by Air* and regulates dangerous goods for member airlines and anyone who tenders dangerous goods to those airlines.

Immunity The ability of an individual to resist and/or control the effects of antigens (antigen sources could be animal, plant, or mineral).

Incubation period Time span from introduction of disease-causing organisms until symptoms of the disease occur.

Induced malaria Malaria infection acquired by blood transfusions or possible sharing of needles by drug addicts (*Plasmodium* spp.).

Infectious waste Waste containing or assumed to contain pathogens of sufficient virulence and quantity that exposure to the waste by a susceptible host may result in a communicable disease.

Infestation Presence of arthropods on the surface of the body; does not refer to endoparasites (*Pediculus* spp.).

Inflammation Result of tissue reaction to injury; symptoms would be redness, pain, swelling, and fever.

Inspissate To thicken or dry a substance by removing liquids by evaporation (preparation of certain types of media used to grow some of the amebae).

Intermediate host A required host in the life cycle in which larval development takes place; this must occur before the stage is infective for the definitive host or secondary intermediate hosts.

Invagination The ensheathing, enfolding, or insertion of a structure within itself or another (tapeworm larval worms).

Jaundice A condition caused by excess bilirubin and bile pigment deposition in the skin, which may give the patient a yellow appearance, especially the eyes (*Plasmodium falciparum*).

Kala azar Another name for visceral leishmaniasis (*Leishmania donovani*).

Karyosome Concentrated clumps of chromatin material within the nucleus; position and morphology are often used to differentiate intestinal protozoa.

Kerandel's sign Delayed sensation to pain (African trypanosomiasis).

Keratitis Inflammation of the cornea (Chagas' disease, onchocerciasis, *Acanthamoeba* infection, microsporidiosis).

Keratoconjunctivitis Inflammation of the conjunctiva and of the cornea.

Kinetoplast Intensely staining rod- or disk-shaped or spherical extranuclear DNA structure found in parasitic flagellates near the base of the flagellum.

Knott technique Concentration procedure using blood and dilute formalin; designed to detect microfilaria (*Wuchereria* and *Brugia* spp.).

Kupffer cells Phagocytic epithelial cells lining the sinusoids of the liver.

Lagochilascaris minor An unusual nematode parasite of humans (ingestion of infective eggs from the environment or ingestion of infective larvae in the tissues of an intermediate host). In most cases, the worms are located in the soft tissues of the neck and throat, tonsils, mastoids, and paranasal sinuses (chronic or recurrent abscesses). Fatal encephalopathy (one case) has also been reported. All cases were in the tropical regions of the Western Hemisphere.

Larva currens Cutaneous larva migrans caused by rapidly moving larvae of *Strongyloides stercoralis*, typically extending from the anal area down the upper thighs; may also be caused by zoonotic species of *Strongyloides*.

Larva migrans, cutaneous/visceral/ocular Disease characterized by thin, red, convoluted papular or vesicular lines of eruption that extend at one end while fading at the other (dog or cat hookworm). Visceral larva migrans involves migration of larvae through the deep tissues, including the eye (dog or cat ascarids, *Toxocara* spp.).

Latex allergy Allergic reaction associated with latex glove use. The two types of allergic reactions are contact dermatitis (Type IV delayed hypersensitivity) due to chemicals used in processing latex and the more serious IgE/histamine-mediated allergy (immediate or Type I hypersensitivity) due to latex proteins.

Leishman-Donovan body Small, round, intracellular form of *Leishmania* spp. (reticuloendothelial system) and *Trypanosoma cruzi* (striated muscle); also called amastigotes or L-D bodies.

Leptomonad Old term for the promastigote stage, which is long and slender and found in the insect vector for *Leishmania* spp.; it is also recovered in artificial culture media (Novy-MacNeal-Nicolle [NNN] medium).

Leukocytosis Increase in the number of white blood cells, usually to more than 10,000/mm³.

Leukopenia Decrease in the number of white blood cells, usually to less than 4,000/mm³.

Lichen simplex A discrete flat papule or an aggregate of papules giving a patterned configuration resembling lichens growing on rocks.

Loeffler's syndrome Transient pulmonary infiltration; day-to-day clearing in 3 to 14 days; associated with marked peripheral eosinophilia (*Ascaris lumbricoides*).

Lumen Cavity of hollow, tubular organs, such as the intestine or blood vessels.

- Lymph** Plasma and white blood cells that bathe the tissue cells.
- Lymphadenitis** Inflammation of the lymph nodes (filariasis).
- Lymphangitis** Inflammation of the lymphatic vessels (filariasis).
- Lymphocytosis** Absolute or relative increase of lymphocytes in the blood.
- Lymphokine** One of several kinds of effector molecules released by T lymphocytes when an antigen to which the lymphocytes are sensitized binds to the cell surface.
- Lymph varices** Dilated lymph vessels secondary to lymphatic blockage (filariasis).
- Macrogametocyte** The mother cell producing the macrogametes, or female elements of sexual reproduction in the sporozoan and microsporidian protozoa; macrogamont.
- Macronucleus** Large, kidney bean-shaped nucleus in *Balantidium coli* (the shape is not always consistent).
- Macrophage** Motile, phagocytic, mononuclear cell that originates in the tissues and may be confused morphologically with protozoan trophozoites (particularly *Entamoeba* spp.).
- Malabsorption** Poor fat absorption in the upper small bowel (giardiasis).
- Malaise** Vague feeling of discomfort throughout the whole body; tiredness.
- Malaria** Benign tertian malaria, *Plasmodium vivax*; malignant tertian malaria, *Plasmodium falciparum*; ovale malaria, *Plasmodium ovale*; quartan malaria, *Plasmodium malariae*; relapsing malaria, renewal of clinical activity at some interval after the primary attack; remittent malaria, a malarial fever (usually due to *P. falciparum*) in which the temperature falls but not to the normal level during the interval between two pronounced paroxysms.
- Malarial pigment** Composed of heme and excess protein left over from the metabolism of hemoglobin; appears as brownish pigment after Giemsa staining (*Plasmodium* spp.).
- Malignant tertian malaria** Malaria caused by *Plasmodium falciparum*.
- Mast cell** A connective tissue cell that contains coarse, basophilic, metachromatic granules; the cell is thought to contain heparin and histamine.
- Mastocytosis** Abnormal proliferation of mast cells in a variety of tissues; may be systemic, involving a variety of organs, or cutaneous (urticaria pigmentosa).
- Maurer's dots or clefts** Irregular dots that occur infrequently in red blood cells infected with *Plasmodium falciparum* (dots tend to be more blue after Giemsa staining than do Schüffner's dots).
- Measly** Pertaining to pork or beef infected with the cysticercus of the tapeworms *Taenia solium* or *T. saginata*.
- Megacolon** Dilation of the colon (Chagas' disease).
- Megaesophagus** Dilation of the esophagus (Chagas' disease).
- Meningitis** Inflammation of the membranes of the brain or spinal cord.
- Meningoencephalitis** Inflammation of the brain and its surrounding membranes (trypanosomiasis, malaria, *Naegleria* and *Angiostrongylus cantonensis* infections).
- Merogony** Synonym for schizogony, leading to the production of daughter cells (merozoites).
- Meront** Diplokaryotic cells that grow and divide into daughter cells (merozoites).
- Merozoite** Product of schizogonic cycle in malaria; produced in the liver (preerythrocytic cycle) and in the red blood cells (erythrocytic cycle).
- Mesentery** Tissue that supports the intestinal tract.
- Metacercaria** The infective, encysted larval form of a trematode; found within the tissues of an intermediate host or on plant material (*Paragonimus*, *Clonorchis*, and *Fasciolopsis* spp.).
- Methenamine silver stain** Both hot and cold methods; involves deposition of silver onto cyst wall (*Pneumocystis jiroveci* [now classified with the fungi]).
- Microfilaria** Embryos produced by filarial worms (nematodes); usually found in the blood or tissues of patients with filariasis (*Wuchereria*, *Brugia*, and *Onchocerca* spp.).
- Microgametocyte** The mother cell producing the microgametes, or male elements of sexual reproduction in the sporozoan and microsporidian protozoa; microgamont.
- Micrometer (micron)** Unit of measure equal to 0.001 mm; abbreviated μm .
- Micron** See *Micrometer*.
- Micronucleus** Small, dotlike nucleus found in *Balantidium coli*; often very difficult to see, even in stained preparations.
- Miracidium** Free-living, ciliated larva released from a trematode egg and infective for the snail intermediate host.
- Monocytosis** Increase in the number of monocytes in the peripheral blood; may be found in both helminth and protozoan infections.
- Monoecious** Both male and female reproductive organs occur in the same individual (hermaphroditic) (trematodes, cestodes).
- Montenegro test** Delayed-hypersensitivity skin test; injection of leishmanial antigen; read after 72 h; positive reaction in cured individuals, negative in early cases (visceral and mucocutaneous leishmaniasis).
- Mordant** A substance capable of combining with a dye and the material to be dyed, thereby increasing the affinity or binding of the dye.
- MSDS** Material Safety Data Sheet. Provides detailed information about hazards and protective measures relative to hazardous chemical substance.

Multilocular cyst Cyst containing many cavities (*Echinococcus multilocularis*).

Mutualism Association in which both parties benefit and cannot survive without each other.

Myiasis Infestation with maggots (fly larvae).

Myocarditis Inflammation of the heart muscles (trichinosis, trypanosomiasis, toxoplasmosis).

Myositis Inflammation of voluntary muscles (trichinosis, *Sarcocystis* infections).

Nanophyetus salmincola Digenetic trematode that causes infections in humans (ingestion of raw, undercooked, or smoked salmon); infections have been reported from North America. Symptoms include gastrointestinal complaints, unexplained eosinophilia, and recovery of eggs from stool specimens.

Necropsy See *Autopsy*.

Negative predictive value (NPV) (Example) The probability that the individual is not infected by *Plasmodium* when the rapid test is negative.

Nit The ovum or hatched egg of a body, head, or crab louse; it is attached to human hair or clothing by a layer of chitin.

Nocturnal Pertaining to the dark portion of a 24-h day; active at night (filariasis).

Nodule A small, hard node that can be detected by touch (onchocerciasis, coenurosis, cysticercosis, myiasis).

Nucleophaga A microsporidian parasite of amoebae that destroys the nucleus of its host.

Nucleus A cellular inclusion composed of chromatin; the morphology is often used to help identify intestinal protozoa (*Entamoeba* and *Dientamoeba* spp.).

Obligate parasite Parasite that must always live in contact with the host.

Occult blood Blood present in very small amounts; usually detectable only by chemical means. The specimen is usually a stool sample. The finding may or may not be related to parasitic infection.

Occupational exposure Reasonably anticipated skin, eye, mucous membrane, or parenteral contact with a hazard that may result from the performance of an employee's duties.

Omentoplasty Use of the greater omentum to cover or fill a defect (hydatid disease).

Onchocercoma Nodule containing adult worms (onchocerciasis).

Oncosphere Spherical, six-hooked tapeworm larva within the eggshell (*Taenia* and *Hymenolepis* spp.).

Ookinete The motile zygotes of the malarial parasite that penetrate the mosquito stomach to form an oocyst under the outer gut lining. In an opened tube of human blood, this stage can develop over time as the blood cools and is oxygenated

(the malarial parasites “think” they are in the mosquito, and exflagellation and development of the ookinete can occur within the tube of blood; this is not common but is well documented, and the morphology can mimic the *Plasmodium falciparum* gametocyte).

Operculate egg Egg with a lid (trapdoor) at one end through which the larva escapes (*Diphyllobotrium*, *Clonorchis*, and *Paragonimus* spp.).

Operculum A lidlike structure at one end of the egg shell through which the larval form escapes (*Diphyllobotrium*, *Clonorchis*, and *Paragonimus* spp.).

OPIM See *Other potentially infectious material*

Opportunistic Denoting an organism capable of causing disease only in a host whose resistance is lowered (by other diseases or drugs, etc.); also denotes the disease.

Oponization Modification of the surface characteristics of an invading particle or organism by binding with antibody or a nonspecific molecule to facilitate phagocytosis by host cells.

Orchitis Inflammation of a testis; may be accompanied by swelling, pain, and fever (filariasis).

OSHA Occupational Safety and Health Administration.

Other potentially infectious material (OPIM) Human body fluids including semen, vaginal secretions, urine, cerebrospinal fluid, synovial fluid, pleural fluid, pericardial fluid, peritoneal fluid, amniotic fluid, saliva, body fluids which may be contaminated with blood, unfixed tissue, HIV- or hepatitis virus-containing cell or organ cultures, blood and tissue from an infected animal, reagents, infectious waste, and cultures.

Oviparous Egg-laying.

Pancytopenia Pronounced reduction in the number of erythrocytes, all types of white blood cells, and blood platelets in the circulating blood.

Pan-malarial antigen An antigen expressed by all four of the *Plasmodium* species which are pathogenic in humans, i.e., *P. falciparum*, *P. vivax*, *P. malariae*, *P. ovale*.

Papule Small, solid elevation of the skin.

Parasite An organism living on or in, and at the expense of, another organism.

Parasitemia The presence of parasites in the circulating blood (malaria, blood parasites, microfilariae).

Parasitophorous vacuole Extracellular but intracytoplasmic vacuole, surrounded by host cell membrane (*Cryptosporidium*).

Paratenic host A host in which a parasite survives without undergoing any additional development (a transport host only) (e.g., *Lagochilascaris minor*).

Parenteral Piercing mucous membranes or the skin through such events as needlesticks, human bites, and abrasions.

Paresis Slight paralysis (cysticercosis).

Paroxysm Rapid onset or return of symptoms or increased intensity of symptoms; usually applies to the periodicity of malaria symptoms (chills, fever, sweats).

Parthenogenesis Form of sexual reproduction in which the organism develops without fertilization by the male gamete (*Strongyloides stercoralis*, parasitic generation).

Patency The development stage at which helminths begin egg production; time to maturity (intestinal helminths).

Pathogen Any organism or substance that produces a disease state.

Pemphigus Autoimmune bullous diseases; nonspecific term for blistering skin diseases.

Pentatrichomonas A genus of parasitic protozoan flagellates, formerly part of the genus *Trichomonas*. New generic name for *Trichomonas hominis*, a nonpathogenic flagellate living in the human colon.

Pericardial tamponade Condition resulting from accumulation of excess fluid in the pericardium.

Periodic acid-Schiff stain (PAS) Involves an oxidation process by periodic acid followed by Schiff reagent (detection of newly formed aldehyde groups) and sulfurous rinses; glycogen, chitin, and mucoproteins are strongly PAS positive; lipids are PAS positive (amebae, worm cuticle, part of microsporidial spore, fungi).

Periodicity Recurrence of an event at regular intervals (nocturnal periodicity of microfilariae of *Wuchereria bancrofti*; malarial symptoms).

Peristalsis Movement of food through the intestine by contractions of the intestinal musculature.

Peritonitis Inflammation of the membrane that lines the abdominal cavity and covers the viscera.

Permissible exposure limit (PEL) Maximum allowed exposure during a time-weighted average (8-h workday or 40-h workweek).

Personal protective equipment (PPE) Specialized clothing or equipment worn by an employee for protection against a hazard.

Petechiae Minute, hemorrhagic spots in the skin or mucosa.

Pica A craving for substances not fit for food, such as starch, clay, ashes, or plaster; ingestion of clay or soil can be associated with exposure to *Ascaris*, *Trichuris*, hookworm, *Strongyloides*, *Toxocara*, and *Toxoplasma* organisms.

Pinworm Human roundworm parasite of the colon and rectum, extremely common in children; diagnostic approach is with a Scotch tape preparation (*Enterobius vermicularis*).

Pipe-stem fibrosis Granulomatous reaction around schistosome eggs in periportal tissues; fibrous tissue is white and hard (*Schistosoma japonicum*, *S. mansoni*).

Plasma Liquid portion of the blood or lymph.

Plerocercoid Tapeworm larva of the genera *Diphyllobothrium* and *Spirometra*; also known as a sparganum larva.

Pneumonitis Inflammation of the pulmonary tissue (*Ascaris*, *Strongyloides*, *Pneumocystis* spp.).

Polar filament (microsporidia) A thin tubule within the spore, attached anteriorly, extending back and lying coiled within the spore; part of the extrusion apparatus that everts and inoculates the sporoplasm into a host cell (microsporidia); same as polar tubule.

Polar filaments (*H. nana*) Filaments arising from opposite poles of the oncosphere membrane of *Hymenolepis nana*; they lie between the egg shell and the oncosphere.

Polar plugs Mucoid plugs present at both ends of the egg (*Trichuris trichiura*).

Positive predictive value (PPV) (Example) The probability that an individual actually is infected by *Plasmodium* when the rapid test is positive.

Prepatent period Time between infection of the host and the beginning of egg production (intestinal helminths).

Primary amebic meningoencephalitis (PAM) An invasive, rapidly fatal cerebral infection by soil and water amebae, chiefly *Naegleria fowleri*, found in humans and other primates. The disease is characterized by high fever, neck rigidity, and symptoms associated with upper respiratory infection (cough and nausea). The brain is the primary focus, especially the olfactory lobes and cerebral cortex; organisms enter through the nasal mucosa and through the cribriform plate. Death usually occurs 2 to 3 days after onset of symptoms.

Primary container A vessel, including its closure, which contains the specimen.

Prions Infectious, abnormal host proteins that cause transmissible spongiform encephalopathies and are resistant to a number of standard disinfection and sterilization procedures.

Proglottid Tapeworm segments containing male and female reproductive systems; may be immature, mature, or gravid (*Taenia* and *Hymenolepis* spp.).

Promastigote Development stage of the family Trypanosomatidae; the base of the flagellum is anterior to the nucleus, the free flagellar portion is short, and there is no undulating membrane.

Proteinuria Protein in the urine (*Plasmodium falciparum*).

Prurigo nodularis An eruption of hard nodules in the skin, caused by rubbing and accompanied by intense itching.

Pruritus Severe itching (cutaneous larva migrans, infection with scabies, itch mite, or pinworm).

Pseudocyst Usually refers to a large number of *Toxoplasma gondii* trophozoites enclosed in a macrophage or some other host cell; parasites bound by host cell tissue not of parasite origin.

Pyrogenic Producing fever.

Pyuria Presence of pus (bacteria, white blood cells) in the urine.

Quartan malaria Malaria caused by *Plasmodium malariae*.

Quotidian malaria Type of malaria in which fevers occur every 24 h; may indicate early infection or mixed infection.

Rash A superficial skin eruption; may be macular, maculopapular, blotchy, etc.

Rectal prolapse Extrusion of the rectal mucosa through the anus; may occur in children with heavy *Trichuris trichiura* infections. Usually no sequelae after therapy.

Rediae An elongated sac with a mouth, muscular pharynx, primitive gut, birth pore, and germinal cells, which may develop into cercariae or daughter rediae (stage within snail host: trematodes).

Regulated waste Liquid or semiliquid blood or OPIMs; contaminated items that would release blood or OPIMs in a liquid or semiliquid state if compressed; items that are caked with dried blood or OPIMs and are capable of releasing these materials during handling; contaminated sharps; and pathological and microbiological wastes containing blood or OPIMs.

Reservoir host The host of an infection in which the infectious agent multiplies and/or develops and on which the agent is dependent for survival in nature; essential host for maintenance of the infection when active transmission is not occurring.

Retinochoroiditis Inflammation of both the retina and the choroid/vascular coat of the eye (toxoplasmosis, onchocerciasis, visceral larva migrans).

Rhabditoid (rhabditiform) larvae Noninfective, thick, rod-shaped larvae of hookworm and *Strongyloides stercoralis*; rhabditoid refers to the shape of the larval esophagus.

Romaña's sign Marked edema of one or both eyes; usually dry and unilateral (Chagas' disease).

Rosette Arrangement of merozoites in mature schizont of *Plasmodium malariae* in a circle around a clump of excess pigment; also the uterine arrangement in the *Diphyllobothrium latum* proglottid.

Rostellum The anterior fixed, or invertible portion of the scolex of a tapeworm, frequently provided with a row (or several rows) of hooklets ("armed rostellum") (*Taenia solium*).

Sappinia diploidea A newly recognized human pathogen, causing amebic encephalitis.

Scabies An eruption due to the mite *Sarcoptes scabiei*; the female burrows into the skin, producing a vesicular eruption with intense pruritus between the fingers, on the male genitalia, buttocks, and elsewhere on the trunk and extremities. Norwegian scabies (Norway itch) is a severe form of scabies with innumerable mites in thickened stratum corneum. This infection has been linked with cellular immune deficiencies, including AIDS.

Schizogony A stage in the asexual cycle of the malarial parasite that occurs within the red blood cells; results in the formation of merozoites (*Plasmodium* spp.).

Schüffner's dots Tiny, red-staining granules in the cytoplasm of red blood cells infected with either *Plasmodium vivax* or *P. ovale*; true stippling (with Giemsa stain).

Scolex The head or attachment portion of a tapeworm; attachment may be by suckers or hooklets (*Taenia*, *Diphyllobothrium*, and *Hymenolepis* spp.).

Scutum In hard ticks, a plate that largely or entirely covers the dorsum of the male and forms an anterior shield behind the capitulum of the female or immature ticks.

Seatworm Another name for pinworm (*Enterobius vermicularis*).

Secondary container A vessel into which the primary container is placed for transport within an institution; it will contain a specimen if the primary container breaks or leaks in transit.

Segmentectomy Excision of a segment of an organ or gland (hydatid disease).

Sensitivity The proportion of true positives that are correctly identified by a test.

Sharps container A container approved for the transport of contaminated sharps.

Sheath Cuticle of a larval nematode that is retained around the body; may serve as protection. Used to help identify microfilariae (*Wuchereria* and *Brugia* spp., *Loa loa*).

Shock Marked decrease in blood pressure; rapid pulse, decreased kidney function (*Plasmodium falciparum* malaria, rupture of hydatid cyst, bee stings).

Short-term exposure limit (STEL) Maximum permitted continuous exposure to a hazardous substance (normally measured in a single 15-min period).

Sigmoidoscopy Visual examination of the rectum and sigmoid flexure of the colon with a lighted tube; often performed for suspected amebiasis cases (*Entamoeba histolytica*).

Sparganum A migrating tapeworm larva that invades the subcutaneous tissues, causing inflammation and fibrosis (*Diphyllobothrium* and *Spirometra* spp.).

Specificity The proportion of true negatives that are correctly identified by a test.

Spicule Accessory reproductive structure in male nematodes; useful in identification of species.

Spiracle A breathing aperture in arthropods.

Splenomegaly Enlargement of the spleen (leishmaniasis, schistosomiasis, malaria).

Splinter hemorrhages Effects of vasculitis in trichinosis; tiny linear hemorrhages in nail beds (larval migration).

Spore One of the stages in the life cycle of the microsporidia; contains a polar tubule apparatus used for infecting cells; the number of polar tubule coils in the spore is used in organism classification.

Sporocyst An elongated sac without a mouth or other distinct internal or external structure, formed after a miracidium infects a snail. May give rise to cercariae (schistosomes) or rediae (*Paragonimus* spp.).

Sporogony (microsporidia) Production of spores.

Sporogony (Plasmodium) A stage in the sexual cycle in the malarial parasite that takes place in the mosquito, with eventual production of the infective sporozoites.

Sporont The zygote stage within the oocyst wall in coccidia; gives rise to sporoblasts, which form sporocysts, within which the infective sporozoites are produced.

Sporozoite Slender, spindle-shaped organism that is the infective stage of malaria parasites; inoculated into humans by the bite of an infected female mosquito; the result of the sexual cycle in the mosquito.

Spurious parasite Organisms that parasitize other hosts passing through the human intestine and are detected in the stool after ingestion; not a true infection (ingestion of animal liver containing *Capillaria* eggs).

Standard precautions Set of precautions applied to all patients designed to reduce the risk of transmission of microorganisms in the health care setting.

Steatorrhea Malabsorption characterized by the presence of fat in the stool (giardiasis, strongyloidiasis, cryptosporidiosis, isosporiasis).

Sterilant An agent intended to destroy all microorganisms (viruses, vegetative bacteria, fungi, and large numbers of highly resistant bacterial endospores) on inanimate surfaces.

Sterilization A procedure that effectively kills a microorganism, including bacterial spores on inanimate surfaces.

Stigmal plates Characteristic breathing apparatus in fly larvae in cases of myiasis; used to identify the specific species involved; seen at the skin opening (through which the larva receives oxygen).

Strobila The entire chain of tapeworm proglottids, excluding the scolex and neck.

Superinfection Reinfection by a parasite that is already present in the body (*Strongyloides* and *Hymenolepis* spp.).

Swimmer's itch Dermatitis caused by skin penetration of humans by cercariae of schistosomes (normally infect birds and semiaquatic animals).

Symbiosis Close association between two different organisms; living together.

Syncope Fainting or loss of consciousness due to a temporary deficiency of blood supply to the brain (*Dracunculus* infection).

Systemic Involving the entire body.

Tachycardia Rapid heartbeat, usually more than 100 beats/min (trypanosomiasis).

Tachyzoite A rapidly multiplying stage in the development of the tissue phase of certain organisms such as *Toxoplasma gondii*.

Tenesmus Straining to defecate; may be painful and unproductive.

Tetrathyridium Second larval stage in which the scolex with its four suckers is invaginated into the anterior end of a plerocercoid type of body (tapeworm *Mesocostoides*).

Thrill See *Hydatid thrill*.

Tinnitus Ringing or buzzing in the ear not resulting from an external source.

Toluidine blue stain Detects the cyst walls of *Pneumocystis jiroveci* as a purple color.

Transmission Transovarial transmission: passage of parasites or infective agents from the maternal body to eggs within ovaries (transmission of viral or rickettsial pathogens to larval mites or ticks).

Traveler's diarrhea Often related to giardiasis or cryptosporidiosis.

Trichinoscope A magnifying glass used in the examination of meat suspected of containing larvae of *Trichinella* spp.

Trichrome stains Gomori's trichrome—developed for histology; Wheatley's modification—developed for staining stool specimens; modified trichrome stains (10× chromotrope dye)—used for staining microsporidian spores.

Trophozoite The feeding, motile stage of protozoa.

Trypanosome Slender, flagellate protozoan found in the blood of humans (*Trypanosoma* spp.); also referred to as trypomastigote (new term).

Trypomastigote Newer terminology for the trypanosome stage in human blood (*Trypanosoma* spp.).

Ulcer An open sore on the skin or mucous membrane, characterized by disintegration of the tissue and often by discharge of pus (leishmaniasis, amebiasis, *Dracunculus* infection).

Unilocular Cyst containing only one cavity.

Universal precautions Set of precautions designed to reduce risk of transmission of HIV, hepatitis B virus, and other blood-borne pathogens in the health care setting. Now referred to as standard precautions.

Urethritis Inflammation of the urethra (trichomoniasis).

Urticaria An allergic skin reaction characterized by the development of wheals and intense itching and burning sensations; onset and disappearance are often sudden (filarial infections).

Uta A mild form of New World or American cutaneous leishmaniasis caused by *Leishmania peruviana*, occurring in the high

Andean valleys of Peru and Bolivia; small dermal lesions on exposed skin surfaces; the dog is an important reservoir.

Uveitis Inflammation of the uvea (the pigmented, vascular layer of the eye) (*Acanthamoeba* spp.).

Vacuole Cavity in the cytoplasm of a cell that may contain ingested bacteria, yeast cells, or debris; vacuole contents and/or morphology may be helpful in identification of some of the intestinal protozoa (*Entamoeba* spp., *Iodamoeba bütschlii*).

Vaginitis Inflammation of the vagina; prolific, irritating, green or yellowish thin discharge; there may be punctate, hemorrhagic spots (trichomoniasis).

Vector A biological vector is a vector such as the *Anopheles* mosquito for malarial agents or the tsetse fly for agents of African sleeping sickness, in which the agent multiplies before being transmitted to another host; a mechanical vector is a vector that conveys pathogens to a susceptible host without essential biological development of the pathogens in the vector (transfer of organisms on the feet or mouth parts of the housefly).

Vermin Parasitic insects, such as lice and bedbugs.

Vinegar eel Free-living nematode, *Turbatrix aceti*, occasionally occurring as a contaminant in laboratory solutions.

Visceral Pertaining to the internal organs of the body, especially those within the abdominal cavity.

Visceral larva migrans Tissue migration of dog and cat ascarid larvae in humans; the life cycle cannot be completed in the human host; often characterized by high peripheral eosinophilia (*Toxocara cati* and *T. canis*).

Viviparous Discharging living young (*Trichinella*, filariae).

Whipworm Common name for roundworm (*Trichuris trichiura*).

WHO World Health Organization.

Winterbottom's sign Enlargement of the posterior cervical lymph nodes (African trypanosomiasis).

Xenodiagnosis Procedure allowing the feeding of laboratory-raised triatomid bugs (known to be infection free) on the blood of patients suspected of having Chagas' disease; after several weeks, the bug feces are checked for the intermediate stages of *Trypanosoma cruzi*; a type of concentration procedure.

Zoonanthroponosis A zoonosis that is normally maintained by humans but can be transmitted to other vertebrates.

Zoonosis A disease of animals that is transmissible to humans (*Cryptosporidium* spp.).

Zygote The cell resulting from the fusion of male and female gametes; formed in the mosquito stomach (*Plasmodium* spp.).

The Power of Plagues

Irwin W. Sherman

The Power of Plagues offers a fascinating examination of epidemic diseases within a historical context. Chapters present individual, independent plague stories complemented by relevant and historical illustrations. Major historic outbreaks are covered, including those of the Greek and Roman empires as well as the infamous Black Death. Contemporary and emerging diseases are comprehensively detailed, including HIV-AIDS, tuberculosis, malaria, smallpox, SARS, West Nile virus infection, influenza, mad cow disease, and several others.

Cases in Human Parasitology

Judith S. Heelan

Cases in Human Parasitology focuses solely on parasites that adversely affect humans. Intended as a supplement to textbooks in human parasitology for undergraduate and medical school courses, this book of 62 case studies is also an important educational reference source for health care scientists active in the field of parasitology. Each case study opens with a patient history and description of symptoms, and most are accompanied by a color image of the parasite described.

Molecular Approaches to Malaria

Irwin W. Sherman, EDITOR

Molecular Approaches to Malaria provides an overview of the rapid and significant developments that have occurred in malaria research, including the 2002 genome sequencing of *Plasmodium falciparum* and its mosquito vector, *Anopheles gambiae*. An important resource for molecular biologists, biochemists, cell biologists, chemists, pathologists, parasitologists, entomologists, and immunologists, this book is a single reference source that will serve likewise to update teachers, investigators, and public health officials on the status of malaria research.

Tick-Borne Diseases of Humans

Jesse L. Goodman, David T. Dennis, Daniel E. Sonenshine, EDITORS

Tick-Borne Diseases of Humans provides physicians and scientists with up-to-date and comprehensive information on the biology, ecology, and clinical aspects of these diseases. It will familiarize clinicians with the various disease syndromes and diagnoses, even for those diseases that commonly occur outside of their sphere of experience. The book is divided into three sections: Section I integrates divergent information relevant to the full spectrum of tick-borne diseases; Section II is devoted to in-depth profiles of specific diseases; Section III examines the geographical distribution of tick-borne diseases and their vectors.
