This book is a collective effort involving hundreds of technical specialists. It brings together a wealth of information from worldwide sources to help scientists, engineers, and technicians solve current and long-range problems.

Great care is taken in the compilation and production of this Volume, but it should be made clear that NO WARRANTIES, EXPRESS OR IMPLIED, INCLUDING, WITHOUT LIMITATION, WARRANTIES OF MERCHANTABILITY OR FITNESS FOR A PARTICULAR PURPOSE, ARE GIVEN IN CONNECTION WITH THIS PUBLICATION. Although this information is believed to be accurate by ASM, ASM cannot guarantee that favorable results will be obtained from the use of this publication alone. This publication is intended for use by persons having technical skill, at their sole discretion and risk. Since the conditions of product or material use are outside of ASM's control, ASM assumes no liability or obligation in connection with any use of this information. No claim of any kind, whether as to products or information in this publication, and whether or not based on negligence, shall be greater in amount than the purchase price of this product or publication in respect of which damages are claimed. THE REMEDY HEREBY PROVIDED SHALL BE THE EXCLUSIVE AND SOLE REMEDY OF BUYER, AND IN NO EVENT SHALL EITHER PARTY BE LIABLE FOR SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES WHETHER OR NOT CAUSED BY OR RESULTING FROM THE NEGLIGENCE OF SUCH PARTY. As with any material, evaluation of the material under end-use conditions prior to specification is essential. Therefore, specific testing under actual conditions is recommended.

Nothing contained in this book shall be construed as a grant of any right of manufacture, sale, use, or reproduction, in connection with any method, process, apparatus, product, composition, or system, whether or not covered by letters patent, copyright, or trademark, and nothing contained in this book shall be construed as a defense against any alleged infringement of letters patent, copyright, or trademark, or as a defense against liability for such infringement.

Comments, criticisms, and suggestions are invited, and should be forwarded to ASM International.

Foreword

From the efforts of volunteer editors, authors, and reviewers, this Volume 6A of the *ASM Handbook* series, provides updated and expanded coverage on the fundamentals and processes of welding technology, research, modeling and simulation. Welding and allied joining technologies are instrumental in the modern use of materials, and the many volunteers should be proud in this work to serve engineers, students, technicians, researchers, and others with authoritative, reliable reference information on welding fundamentals and processes.

Coverage of joining technologies continues to grow in the *ASM Handbook* series, and this Volume is the first of several Volumes devoted to the many new developments of materials joining. In this Volume, new coverage reflects the continued growth of solid-state welding processes and the expanded use of computer modeling in the simulation of welding processes. Procedure development, quality control, and process improvements are also emphasized for arc, resistance, and directed-energy beam welding.

ASM Handbooks are a cornerstone of ASM International, and this effort could not have been accomplished without the dedicated efforts of many volunteers. Our thanks are extended to the editors, listed on the title page, and the authors and reviewers given in the List of Contributors. We are grateful for the contribution of their time and expertise.

Preface

The ASM Handbook Volume 6A, *Welding Fundamentals & Processes*, represents the first of at least two volumes to be published on aspects of welding and joining. As indicated in the title, Volume 6A focuses on fundamental aspects of welding, and on the many welding processes. Volume 6B, planned for future publication, will concentrate on weldability and behavior of a range of alloys and materials.

As with the last edition of this Volume, the Volume Editors recognized that the researchers, engineers, technicians and students that will use this handbook have different needs with regard to their level of understanding. Accordingly, the sections of this handbook fall into two major categories. The sections on fundamentals provide in-depth background on the scientific principles associated with welding, while the sections on the various welding processes take a more practical approach. The Volume Editors have also tried to present a

comprehensive reference that can be of use to the diverse welding community.

All sections of the handbook have been reviewed to be sure that they reflect the current status of the technology. Many sections have been expanded, such as the sections on fundamentals, high-energy density, solid-state welding and especially weld modeling. New processes and process variations developed since the last printing of this Volume have been incorporated, including friction stir welding, magnetic pulse welding, hybrid processes, direct metal deposition, penetration enhancing fluxes and ultrasonic additive manufacturing. A section on safe practices has also been added.

We wish to thank our many colleagues who served as section editors and authors of the individual articles. This handbook would not have been possible without their efforts.

An Overview of Joining Processes

Robert W. Messler, Jr., Rensselaer Polytechnic Institute

FEW ENGINEERING STRUCTURES start out as a single part, so joining is often the key process in the manufacture of devices or assemblies or the erection of structures. Its purpose is to keep the component parts of such devices, assemblies, or structures together with the required proximity, arrangement, orientation, and alignment to allow the overall device, assembly, or structure to perform its intended function(s) while resisting imposed loads. Since all components or parts are made from materials, such as metals, ceramics, or polymers/plastics (materials engineers prefer the term *polymers* rather than *plastics*, because the former properly distinguishes this fundamental type of material from metals and ceramics, while the latter refers to the property of easy permanent changes to the material shape), successful joining always requires an understanding of how such materials interact when brought into contact with one another. Once such interactions are understood, an engineer can choose among a variety of options for accomplishing joining, some of which rely solely on mechanical forces, some principally on chemical forces, and some principally on physical forces that have their origin in the natural attraction that arises between atoms or molecules. These different forces, in turn, give rise to mechanical joining using either supplemental fasteners or only the shape of the mating parts in a joint, to adhesive bonding using principally chemical forces arising from surface absorption between a chemical agent and the mating parts between which it is sandwiched, or to welding using the natural force of attraction between atoms and/or molecules. Beyond these basic categories of joining, there are some subtypes, some variants, and some combinations known as hybrids. Together, the various options for joining materials are as much an enabling technology as they are a pragmatic process for manufacture, construction, or repair.

Need for Joining

Assemblies are generally manufactured in-plant from fabricated detail parts using one or more joining processes, while structures are generally erected on-site from prefabricated

parts using one or more joining processes. There are instances where very small assemblies or structures are produced from either very small parts or components or directly when the materials comprising components are created at the same time the assembly or structure—typically known as a device—is created. In both cases, joining remains a key process to enable the creation of the device. Examples of very small assemblies employing joining are microelectromechanical systems (Fig. 1). An example of a device in which the components and the device are created simultaneously, but still involving joining, is solid-state microelectronic devices, such as transistors on silicon chips (Fig. 2).

The most obvious need for joining is to make things that are too large to make in one piece because of some inevitable limitation of the process by which those things could otherwise be made. Such limitations exist for all primary processes by which materials can be shaped into parts, including casting (of metals or ceramics, including cement and concrete); molding (of polymers); forging (of metals); rolling, drawing, or extruding (of metals, glasses, and some polymers); or powder compacting (of metals or ceramics). Related to this need is the need to make things that are too complex in shape, even though they may not be too large

Fig. 1 Microelectromechanical systems, such as the one shown here, also must be assembled, typically by mechanical interlocking. Such devices are typically made using techniques first developed for use in microelectronics; i.e., photoetching and deposition.

for the aforementioned primary processes to create. For example, the secondary process of machining can be used to create parts with complex shapes, although it is limited to parts no larger than the limits of the primary processes to produce the starting stock. Otherwise, machined detail parts must be joined to produce an assembly.

Another obvious need for joining is to create assemblies or structures in which the required functions are best achieved by mixing materials of different types, whether at a fundamental level (e.g., metal, ceramic, or polymer) or within a category (e.g., two different metals or alloys). An example of the former is the need to join glass to cement or concrete, to wood, or to metal to create a window in a structural wall. An example of the latter is the need to join pure copper to stainless steel to produce the clad bimetal starting stock for cookware with heat-dispersing bottoms.

Further optimization is often desired when using as much of a material starting stock as

Fig. 2 Solid-state microelectronic devices, beginning at the silicon chip level, involve assembly, including by chemical (e.g., deposition and reaction), welding (e.g., die bonding and soldering), and mechanical (e.g., pressure contact) means. Here an assembled electrically erasable programmable read-only memory complementary metal oxide semiconductor device is shown.

4 / Fundamentals of Welding

Table 1 Reasons for and benefits of joining (by design goals)

Goal 1: Achieve functionality
<ul style="list-style-type: none">• To carry or transfer loads in an array of parts needing to act together without moving (i.e., a static structure)• To carry and transfer loads in an array of parts needing to act together by moving (i.e., a dynamic structure)• To achieve size and/or shape complexity beyond the limits of primary fabrication processes (e.g., casting, molding, forging, forming, powder processing, etc.)• To enable specific functionality demanding mixed materials• To allow structures to be portable (i.e., able to be moved to or from sites)• To allow disassembly for ultimate disposal• To impact damage tolerance in the structure beyond that inherent in the materials of construction (i.e., structural damage tolerance)
Goal 2: Facilitate manufacturability
<ul style="list-style-type: none">• To obtain structural efficiency through the use of built-up details and materials• To optimize choice and use of just the right materials in just the right place• To optimize material utilization (i.e., minimize scrap losses)• To overcome limitations on size and shape complexity from primary fabrication processes• To allow on-site erection or assembly of prefabricated details
Goal 3: Minimize costs
<ul style="list-style-type: none">• To allow optimal material selection and use (versus forcing compromise)• To maximize material utilization and minimize scrap losses• To keep the total weight of materials to a minimum (through structural efficiency)• To provide more cost-effective manufacturing alternatives (versus forcing a primary fabrication process to its limit)• To facilitate automation of assembly, for some methods• To allow maintenance, service, repair, or upgrade; all of which reduce life-cycle costs• To facilitate responsible disposal
Goal 4: Provide aesthetics
<ul style="list-style-type: none">• To enable application of veneers, facades, etc., different from the underlying structure• To allow complex shapes to be formed

Source: Ref 1

possible to minimize waste or scrap. Such improved utilization can be enabled by joining small pieces cut from large starting stock in such a way as to minimize waste (e.g., by nesting flat detail parts punched or otherwise cut from a sheet of metal) to create larger ones. This approach is used in the automobile industry with laser blanking (using pieces from different-gage sheet metal stock to create a patchwork part for forming into a body panel).

There are other reasons for joining that sometimes may be considered needs and other times may be considered benefits. These, as well as the aforementioned needs, are summarized in Table 1 and are discussed in the small number of references available on general approaches to joining listed in the Selected References at the end of this article.

Forces and Interactions in Materials Joining

The engineering options to join materials involve the application of mechanical, chemical, and/or physical forces that bind materials together. It also should be obvious from the preceding section that joining is not only valuable but sometimes an essential process for in-plant manufacturing and on-site construction. In addition, joining is (far more than may be realized or planned) an important process for

in-service repair. In fact, some of the greatest challenges to welding involve making repairs in parts or assemblies or structures that either were not created by welding in the first place or were created by welding but the identity of the metals or alloys of construction is no longer known.

Compatibility of Dissimilar Materials. Before looking at the various major options by which joining can be accomplished, first consider what forces allow two or more parts to be held together in a joint. To the materials engineer, the joining of two or more parts depends on what generic (if not specific) type of material is used for each of the different parts. Obviously, the shapes of the parts to be joined and the purpose of the joint are also important considerations; however, these factors are addressed after considering the fundamental issue of what types of materials are being joined together. After all, when different materials are joined together, the materials must be compatible with one another to form a properly functioning joint.

Compatibility of dissimilar materials involves chemical, physical, and mechanical interactions. First and foremost, the materials in a joint should be chemically compatible so that adverse reactions (e.g., galvanic corrosion) do not occur. Second, physical compatibility of joined materials is also required. For example, when service requires the joint to function

within some temperature range, it is critical to know if one material reacts to heat radically different than another material in the joint. If coefficients of thermal expansion differ by more than approximately 15 to 20% or if melting points are radically different, then this may adversely affect joint function within some temperature range. Third, mechanical compatibility is important, so that key properties of hardness, strength, or stiffness are not radically dissimilar. For example, large differences in mechanical properties may lead to performance problems, such as inordinate wear of one part by the other, intolerable stressing of one part compared to the other, or unacceptable deflection or lack of flexibility of one part versus the other.

Joining with Mechanical, Chemical, and Physical Forces. There are only three types of forces, from a fundamental standpoint, that can be used to hold two or more parts in contact against unwanted motion, regardless of the materials involved. These three are mechanical, chemical, and physical forces that arise from atomic-level attraction.

Mechanical forces arise from one part physically interfering with another part or parts because of their macroscopic shapes and microscopic surface roughness. At the macroscopic level, if the shapes of two or more abutting parts are such that one fits into—or nests within—the other(s), they are prevented from moving at least in some directions. In general, two solid bodies can move in any of three directions by translation, that is, in the x -, y -, or z -direction on a Cartesian coordinate system, or by rotation about the x -, y -, or z -axis of the Cartesian coordinate system. These six distinct types of relative motion are known as degrees of freedom, and thus, there are six degrees of freedom of motion in three-dimensional space: three in translation and three in rotation.

For example, if a protrusion on one part fits into a matching recess on the other, those two parts are prevented from sliding over one another under a shear force but are not prevented from separating from one another under tension. As seen in the next section, such interference can arise from either having a special part cause the mutual interference or by having the abutting parts themselves have shapes that mate to cause interference (Fig. 3). In both cases, strictly mechanical forces, and no atomic-level forces of any kind, operate to keep the parts together against unwanted movement in at least some directions.

Besides macroscopic-level interference caused by the shapes of mating parts, there is also always some degree of interference at the microscopic level due to surface asperities, that is, peaks and valleys. When two real surfaces, which are never perfectly smooth on an atomic scale, are in contact, the high and low points on one surface interact with the high and low points on the other surface. This microscopic mismatch between surfaces results in friction. Friction is what helps fasteners operate in mechanical joining.

Fig. 3 Schematic illustration showing how interference at both macroscopic levels between parts and/or designed- and processed-in geometric features and at microscopic levels due to ever-present surface asperities leads to mechanical interlocking. Here the example of a nail driven into two pieces of stacked wood is shown. The nail interferes with the two pieces of wood to prevent shear between them, while the forged-in cleats as well as microscopic asperities on the nail surface prevent the nail from coming out of the wood.

The advantages of using mechanical forces to accomplish joining are:

- Materials being joined mechanically need not be similar, so long as they are either chemically compatible or are separated by an intermediate, insulating material.
- Parts joined mechanically can uniquely allow relative motion between mating parts in selected directions of translation and/or rotation, while not moving in other directions.
- Parts assembled mechanically can, uniquely, be intentionally disassembled. (By proper design, unintentional disassembly can be prevented.)
- Joints created by purely mechanical forces arrest propagating cracks in parts at the part-to-part interface, where there is no material continuity. (This imparts damage tolerance to the structural assembly.)
- The level of skill needed to perform mechanical joining is relatively low compared to other methods of joining (e.g., adhesive bonding and welding).
- Mechanical joining is easy to perform in-plant or on-site.
- Resulting joints can easily approach the strength of the joint elements.

The disadvantages of using mechanical forces to accomplish joining are:

- Mechanically, joints can loosen or disassemble unintentionally.
- Stress tends to concentrate at discrete points of mechanical fastening or attachment.

- Mechanical joints can leak fluids unless special precautions are taken (e.g., gaskets, sealants, etc.).
- The labor intensity associated with mechanical fastening is high.

Chemical forces arise principally from surface adsorption between a chemical agent and the materials (i.e., parts) being joined, although they can also arise from an actual chemical reaction between the agent and the part materials. In the former case, there is no adverse effect of the chemical agent on the part materials, and the forces of attraction giving rise to adhesion are relatively weak secondary bonding forces arising from the dipole nature of molecules comprising the chemical agent. In the latter case, there can be an adverse effect if either a weak or brittle boundary layer forms between the chemical agent and one or more of the parts in the joint. When chemical reactions occur, the forces giving rise to adhesion are usually strong primary bonding forces arising from the tendency of the atoms of most chemical elements to attract one another. In both cases, the chemical agent is known as an adhesive, while the base parts involved in the joint are known as adherends. The overall joining process is known as adhesive bonding. Figure 4 shows how adhesives develop strength at a joint.

Physical forces arise between atoms and, to a lesser extent, between molecules as a natural result of their structures. These physical forces, which are electromagnetic (actually, electrostatic) in their origin and character, are the basis for joining by welding as well as the subprocesses of brazing and soldering. In each case, actual atomic-level bonding (metallic, ionic, covalent bonding) results in very high joint strengths. The atoms of all of the elements except the inert gases exert a force of attraction on one another that increases as the distance between them decreases, resulting in the formation of bonded atom pairs. When very large numbers of (ideally, all) pairs of atoms across an interface between two materials form such bonds, the two materials are held together as if they were one, that is, forming a weld. The strength of the weld can easily approach the strength of the base materials involved in the joint.

As seen in the section “Welding” that follows the sections on mechanical joining and adhesive bonding, what needs to be accomplished to actually produce welds is to facilitate this natural process of bonding between atoms.

Mechanical Joining—Fastening and Integral Attachment

There are two ways in which interference can be caused to occur between parts comprising a joint produced by mechanical forces only:

- By using a supplemental part whose sole purpose is to cause such interference

- By using the shapes of the parts themselves to cause the interference

The former approach is known as mechanical fastening, with the special supplemental part being called a fastener. The latter approach is known as integral mechanical attachment, with the mating features being called attachment features. Interested readers are referred to some excellent references at the end of this article.

Mechanical joining, in one or the other of the two forms described, accounts for more than half of all the joining performed in the world every year. The fact that mechanical joining is simple, is available in diverse forms, works with all materials (metals, ceramics, cement and concrete, glass, polymers, wood, and composites) in virtually any combination, does nothing to alter the material properties in which it is accomplished, repeatedly produces joints with high structural integrity, allows intentional disassembly without damaging the parts, uniquely allows relative motion in controlled directions between joined parts, and is highly portable accounts for its tremendous popularity. However, despite all of this, there are other viable and important approaches to joining.

Mechanical fastening is possible using a number of well-known as well as several less obvious but still familiar methods. Examples of some well-known and/or familiar mechanical

Fig. 4 Schematic illustration showing how either surface adsorption arising from the formation of secondary bonds between an adhesive and adherend(s) (top) or the formation of actual reaction zone(s) between the adhesive and adherend(s), in which primary chemical bonds are formed, contribute to adhesive bonding.

6 / Fundamentals of Welding

Fig. 5 Schematic illustration of some general mechanical fastening methods and fasteners, including (a) nail in wood, (b) metal pin (with locking Cotter pin) in metal, (c) upset rivet in metal, (d) self-tapping screw in wood, (e) nut and bolt in metal, (f) mating eyelets and grommets (commonly known as snaps) in fabric or leather, and (g) metal staple in paper, cardboard, or leather. Source: Ref 1

fastening methods and fasteners are shown in Fig. 5.

Well-known methods involve the use of metal nails, metal pins, metal or plastic rivets, metal self-tapping screws, threaded metal bolts and machine screws (either with internally threaded parts or with internally threaded metal nuts), metal or fabric washers, metal retaining clips and rings, metal eyelets and grommets (familarly known as metal snaps, as found on some leather garments and on jeans), and metal keys and keyways.

Less obvious but familiar methods include plastic, metal, or ceramic buttons and button-holes; metal or plastic zippers; metal staples; metal or polymeric stitches, lashings, splices, and knots in rope; and others. In each and every case, the sole purpose of the fastener as a part is to cause interference between the parts of the intended joint into which, or with which, they are employed. Once fastened, the joined parts are prevented from separating, at least in some directions of motion.

Mechanical fasteners vary in the specific way in which they are installed and in the way in which they resist applied forces. However, it is possible to fasten joints to achieve load-

carrying capability that equals or even exceeds that of the joint elements themselves. Joint efficiency, which is defined as the stress sustained in that feature or agent that actually allows joining divided by the stress carried in the adjoining structural members, can be high, typically close to or exceeding 100%. Fasteners allow assembled joints to be intentionally disassembled without damaging the joint elements. This said, care must be taken during both design and manufacturing/assembly to prevent unwanted, unintentional disassembly.

Integral Mechanical Attachment. Much older, and gaining popularity again, is the use of geometric features integral to the parts being assembled to cause mechanical joining. This method is known as integral mechanical attachment. Well-known examples include dovetail-and-groove joints in wood, crimps and hems in sheet metal, and so-called snap-fits in plastic or polymer parts.

Integral mechanical attachment, also referred to as integral interlocks, operates in one of three ways:

- By having the features and the parts of which they are a portion remain rigid

- By having the features deflect and then recover elastically against some relatively more rigid mating feature or part
- By being plastically deformed into parts once those parts are mated

The result is rigid interlocks (e.g., dovetail and grooves, machined ways and rails, molded threads on glass), elastic interlocks (e.g., snap-fit features such as cantilever hooks like those found on the lids of battery compartments on cell phones and torsion locks like those found on so-called child-proof plastic medicine bottles), and plastic interlocks (e.g., crimps, hems, stakes). As opposed to fasteners (which can be numerous in large assemblies such as nailed wood-frame houses or riveted aluminum alloy airliners), integral attachment features reduce part count and facilitate assembly, whether done manually or using automation. As such, they are receiving renewed interest in modern design and manufacturing.

Adhesive Bonding

Undoubtedly as old as mechanical joining using interlocking objects, another joining method is the use of naturally sticky substances to hold things together by adhesion. This is the basis of adhesive bonding. Even the earliest humans surely recognized the value of sticky plant and animal excretions (e.g., sap or pitch from trees and spittle from some beetles) and extracts (e.g., plant rubber and blood or fish glues) for joining animal skins, wood, and plant fibers. In its modern form, synthetic chemical agents, rather than naturally occurring ones, tend to dominate the joining process of adhesive bonding. However, regardless of their source, certain chemical agents have the ability to create adhesion between themselves and other materials and hence between virtually any two materials between which such agents are sandwiched. The underlying mechanism responsible for such adhesion is surface adsorption.

Surface adsorption involves the formation of relatively weak secondary bonds between at least some of the molecular species found in the chemical agent, known as an adhesive, and at least some of the molecular (or atomic) species found in the materials being joined, known as the adherends. Without going into great detail here, two possible types of such secondary bonding are van der Waals bonding and hydrogen bonding. In van der Waals bonding, certain of the molecules in the adhesive and certain of the molecules in the adherends induce dipoles in one another; creating positive and negative portions in one another. The result is that the positive portions of molecules in either the adhesive or one or both of the adherends are attracted to—and attract—the negative portions of the molecules in one or both of the adherends or the adhesive, creating bonded pairs across the joint interface. The result is

what is known as adhesion. In hydrogen bonding, hydrogen atoms in the adhesive serve as links or bridges to atoms or molecules in the adherends, creating bonding across the joint interface that tends to be stronger than that created by van der Waals bonding.

While weak compared to primary bonds, van der Waals bonding and hydrogen bonding still result in significant adhesion because such large numbers of submicroscopic bonds are created across macroscopic interfaces. In other words, while the shear (and particularly, peel) strength of adhesives (typically 20+ MPa, or less than 3000 psi) tends not to be impressive compared to the shear or tensile strengths of mechanical fasteners or welds (typically 135 to 700 MPa, or 20,000 to 100,000+ psi), the fact that adhesives are—or should be—applied over large areas allows adhesive-bonded joints to carry tremendous loads or forces. As an example, think about a square card table (36 by 36 in.) covered with soft, freshly chewed gum with a shear strength of 10 psi that is smeared over its entire surface. If such a table was turned upside down and pressed face-to-face with another such table, the force required to pull the two tables apart in shear would be almost 13,000 lb!

Because of the just-described principal mechanism for adhesion, that is, surface adsorption, successful adhesive bonding requires the joining of large surface areas. The larger the better! Once bonded, adhered joints perform best under shear stresses operating in the plane of the adhesive, as opposed to tensile forces or, worse, peel forces operating out of the plane of the adhesive. The result is that properly adhesive-bonded joints tend not to develop stress concentrations like fastened joints do, since applied loads or forces are spread over the large surface area of the bond layer, and areas of concentrated stresses can slip a little or redistribute the loads.

The relative advantages of adhesive bonding are:

- Spreading of applied forces over large areas to produce relatively low stresses
- Little or no stress concentration (except at the ends of overlapped or lapped joint elements, where peel can occur)
- Utility with a wide variety of materials (metals, ceramics, glasses, polymers, composites, wood, cement and concrete) in virtually any combination (so long as the adhesive is chemically compatible with each of the adherends involved in the joint)
- Little if any change to the chemical composition or microstructure, and thus the properties, of the adherends
- Sealing of joints against fluid intrusion or extrusion, that is, leakage
- Damping of shock loads and vibrations
- Blunting of cracks propagating within adherend(s)

Adhesive bonding is not without its shortcomings. Relative shortcomings or outright disadvantages include:

- Sensitivity to out-of-plane loads or stresses (e.g., peel or cleavage)
- Requirement of careful joint preparation
- Requirement of rigid process control for demanding applications
- Difficult inspection and virtually impossible repair of process-induced defects
- Extremely complicated stress analysis for critical applications
- Joint life that is sensitive to a wide variety of environmental factors, including temperature (not too high and not too low), moisture (not too high and not too low), cyclic changes in temperature or moisture (i.e., weathering), radiation (including ultraviolet), solvents, and various biological agents (e.g., mold, mildew, fungi, microbes, insects, and vermin)
- Limits to upper service temperature, especially for organic (polymeric) adhesives
- Protection of worker health from possible fumes, contact dermatitis, and so on

In fact, adhesives develop adhesion between adherends using more than just the chemical forces arising from surface adsorption, although true adhesives must always rely on this mechanism predominantly. Depending on the particular adhesive and on the particular adherend(s), three other mechanisms can—and often do—contribute to joint adhesion:

- Mechanical interlocking
- Diffusion
- Electrostatic attraction

Mechanical interlocking can arise when a soft, pliable adhesive fills in the nooks and crannies caused by the surface roughness (i.e., asperities) of all real surfaces. Adhesion is increased both by the dramatically increased surface area over which surface adsorption is occurring as well as from some locking of adhesive into nooks and crannies with re-entrant angles. Obviously, a contribution from mechanical interlocking arises when adherends are naturally porous or are artificially but intentionally roughened.

Diffusion can contribute to adhesion when some atomic migration occurs across the interface between the adhesive and one or both of the adherends. Such diffusion occurs when the adhesive is particularly fluid and the adherend(s) is (are) permeable, although solid-state diffusion can occur under other circumstances as well. A well-known example is how water-moistened glues or mucilage on postage stamps migrate into the spaces among the fibers of a paper envelope. Related to this type of diffusion is the entangling of the long-chain molecules making up polymers when one polymer is adhesively bonded to another using a polymeric adhesive or simply a solvent. A well-known example is how a polyvinyl chloride plastic patch is bonded to a polyvinyl chloride swimming pool liner once it has been softened with acetone in what is known as solvent cementing.

Finally, electrostatic forces of attraction (Coulomb forces) can arise in certain materials (i.e., adhesives and adherends) when charged particles (e.g., electrons and positive ions) separate within these materials by what is known as polarization. This mechanism tends to occur, if it occurs, in polymers and, to a far lesser extent, in glasses. A supposed manifestation of such an electrostatic contribution to adhesion is when transparent adhesive tape is stripped from a plastic part, and a static charge or even a static discharge occurs.

Figure 6 schematically illustrates the various mechanisms that can contribute to adhesion in adhesive bonding, one or more of which tends to operate with specific adhesives and adherends. Successful adhesive bonding requires proper joint design (to avoid out-of-plane peel or cleavage stresses in favor of pure shear stresses), proper joint preparation (which includes at least careful cleaning but also, often, preconditioning with what is known as a primer), proper adhesive selection for the adherend(s) being joined, and proper adhesive application and curing (which may involve drying or may involve setting with heat or ultraviolet radiation or a chemical catalyst). The interested reader is referred to any of several excellent references on adhesive bonding at the end of this article.

Welding

As mentioned earlier, welding is the natural consequence of bonds between atoms of all of the elements in the periodic table (except the inert gases). Atoms form bonds with one another, in certain combinations and in different specific ways. The upper portion of Fig. 7 shows schematic plots of the competing forces of attraction and repulsion that add algebraically (positive attraction forces to negative repulsion forces) to result in a zero net force at a particular spacing between atoms of similar or dissimilar types (i.e., elements) as they approach one another from what, to those atoms, seems like an infinite initial separation. Under normal circumstances (e.g., a relatively stress-free state), the atoms making up a solid material are separated from one another by this equilibrium interatomic spacing.

When atoms are involved, they are electrically neutral. As they approach one another, they induce a dipole in one another by having the center of positive charge associated with the nucleus displace from the center of negative charge associated with the surrounding orbiting electrons. Once this occurs, they attract one another with a greater and greater force as the distance between them continues to decrease. At some point, however, the negatively charged electrons orbiting in very large orbits (compared to the size of the positively charged nucleus) sense one another's presence and give rise to a repulsive force that builds more and more as the atoms move closer and closer together. In fact, the repulsive force increases

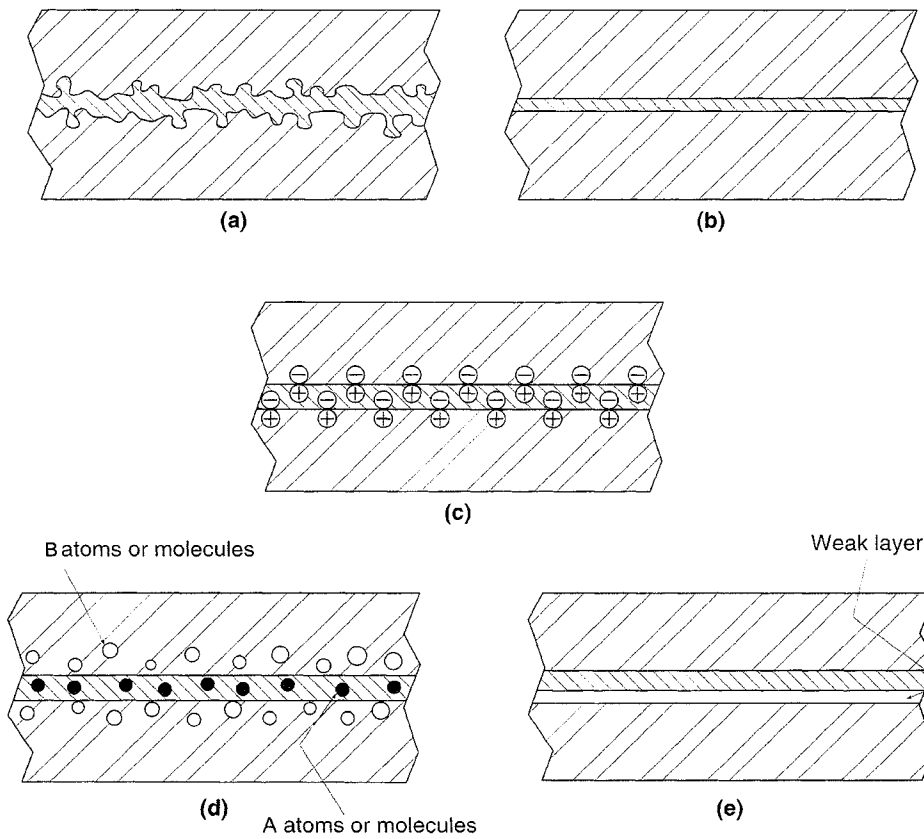

Fig. 6 Schematic illustration of the various mechanisms that can lead to adhesion during adhesive bonding, that is, (a) mechanical interlocking of adhesive into microscopic surface asperities, (b) secondary bonding from adsorption with proper wetting from surface energy effects, (c) electrostatic attraction from charge separation or polarization, and (d) diffusion of some atoms or molecules back and forth between adhesive and adherends. Also, (e) the formation of a weak boundary layer that can lead to the adhesive failure of joints. Source: Ref 1

faster than the attractive force. When the two competing forces are added, a curve of net force results, as shown in the upper portion of Fig. 7. At the point of separation where the attractive force and the repulsive force are equal but opposite, the net force is zero, and this separation is the natural bond length. The net attractive force over the distance the atoms move together adds up to form the bond energy.

So, even neutral atoms, by inducing dipoles in one another, approach one another under the resulting force of attraction until they come to a point where a rising force of repulsion caused by their outermost orbits (or shells) of electrons sensing one another comes into balance to result in a zero net force and, not incidentally, a minimum potential energy state. Once at this equilibrium interatomic spacing, the atoms bond with an energy given by the depth of the well in the net potential energy curve, that is, the binding energy or bond energy. The greater the depth of this well, the greater the strength of bonding, and hence, the greater the strength of the material mechanically (against fracture), thermally (against melting), and chemically (against reaction and,

particularly, corrosion). As a natural consequence of this behavior of all atoms (except those of the inert gases), given the opportunity, atoms of the same element or most different elements will come together and bond. In other words, they form a weld. Welding then is simply the process of enabling atoms to come together in very large numbers to do what they want to do naturally. However, there are some obstacles to be overcome to make welds in real, solid materials.

Two things about the surfaces of real, solid materials pose obstacles to the formation of a weld between two abutting pieces as a result of the natural tendency of the atoms of such materials to come together to their equilibrium interatomic spacing and form strong primary chemical bonds in very large numbers. The first, which is true of all solid materials regardless of their type (e.g., metal, ceramic, or polymer), is that real surfaces are far from smooth on an atomic scale. No matter how much effort is put into creating a smooth surface on a part, there are high and low points—hills and valleys, referred to earlier as asperities—that prevent all but a very small fraction of all the

atoms on the surface from coming into intimate enough contact to allow bond formation. Even for the most highly polished surface, the typical fraction of atoms that come into intimate contact is approximately 1 in every 10^6 to 10^8 . This means that even though strong primary atomic bonds form between these atoms, the overwhelming majority of atoms at the abutting surfaces do not come into close enough proximity to form bonds. Hence, the overall effect of such limited bonding is that the strength of the created weld is only approximately 1 one-millionth to about 1 one-billionth of the theoretical strength of the materials involved, not nearly enough to hold the pieces together under their own weight.

Figure 8 schematically illustrates how welds form naturally in ideal materials with perfectly smooth surfaces (in a and b) versus how such weld formation is hindered by the existence of surface asperities on the surfaces of real materials (in c). To increase the number of atoms on the abutting part surfaces that come into intimate contact, there are two options:

- Apply pressure to cause the contacting high points to deform plastically, bring more points into intimate contact, and form more bonds
- Add atoms to the gaps between the contacting high points to fill in those gaps and form more bonds

The easiest way to add atoms is in the form of a liquid, which can flow into the nooks and crannies, created by melting either the materials being joined or by adding a molten compatible filler material. The first bulleted option is the basis for nonfusion pressure welding, while the second bulleted option is the basis for fusion welding (both of which are described in the section “Classification of Welding Processes” in the article “Overview of Welding Processes” in this Volume).

The second thing about the surface of most real materials is that they are rarely clean at the atomic level. That is, the surface rarely consists of only atoms making up the base materials involved in what is to become the joint. Rather, the surfaces of most materials are contaminated by oxides or other tarnish layers, by adsorbed water and/or gases from the air, or, if the parts were not cleaned, by oils, greases, paint, and so on. These contaminants prevent atoms of the base materials from coming into intimate contact to form bonds and a weld.

Figure 8(d) schematically illustrates how the surfaces of real materials are covered with contaminants that prevent atoms of the base materials from coming together to form bonds. Figure 8(e to g) show how pressure can be used to overcome the obstacles of asperities and contamination of the surfaces of real materials to form a weld in the solid state. Not shown is how atoms could readily fill in the gaps between contacting high points by being added in the liquid state (i.e., as molten material) to

Fig. 7 Schematic plot of the forces (top) and potential energies (bottom) involved in atomic bond formation as the underlying mechanism of welding. Source: Ref 1

allow more bond formation. Obviously, the successful creating of welds with good properties is critically dependent on proper cleaning of the part surfaces prior to welding.

The advantages of welding include:

- Creation of joints that are permanent (as opposed to life-limited, as is the case with most adhesive-bonded joints, or possible to disassemble, as is the case for mechanical joints), precluding accidental disassembly or loosening
- Wide variety of process embodiments, to optimize selection for purpose
- Applicability to many materials within a fundamental material class, that is, within metals, ceramics, glasses, or thermoplastic polymers

- Amenability to either manual or automated operation
- General portability and suitability for use outdoors or indoors
- Creation of leaktight joints, if desired
- Achievement of excellent joint strength and efficiency

Advantages notwithstanding, there are some disadvantages, which include:

- Impossibility of disassembly without severely damaging parts, for any purpose (including recycling)
- Alteration of base material structure and disruption of base material properties by the heat associated with some process embodiments (especially involving fusion)

- Impossibility of joining fundamentally dissimilar materials (e.g., metals to glasses), although such joining can often be done using brazing or soldering
- Requirement of considerable operator skill and stringent process control for production of high-quality joints
- Relative high cost (compared to mechanical joining and adhesive bonding) due to required skills and labor intensity
- Possible high cost for capital equipment, especially for some automated processes

The real forte of welding is for joining metals, although the process can also be employed for joining similar or dissimilar glasses, for joining similar or dissimilar thermoplastic polymers, and for joining some ceramics (particularly oxide types). As such, because of the tremendous importance of metals, in general, and steels, in particular, to the technological advancement and economy of societies, welding is a particularly important joining process, accounting for more than 60% of the gross domestic product of industrialized countries.

Brazing and Soldering

Like welding, both brazing and soldering also form primary bonds (in metals, metallic bonds). Like welding processes, soldering and brazing also rely on interdiffusion between joined materials to form the soundest joints. Unlike fusion welding, however, neither brazing nor soldering requires—nor causes—any melting (or fusion) of the base materials. Rather, bond formation occurs between molten filler and the ever-solid substrates.

Both brazing and soldering involve the use of a filler material that melts at a temperature below that of the base material(s). The only difference between processes classified as brazing and those classified as soldering is that brazing fillers melt above 450 °C (840 °F), while solders melt below 450 °C (840 °F). These temperatures are actually quite arbitrary, because nothing special happens there, but melting of fillers at 450 °C has become the generally accepted break-point between the temperatures for soldering and brazing.

During brazing and soldering, the melting of filler materials is essential so that these molten fillers can:

- Wet the surface of the base materials (by lowering the surface energy of those base materials)
- Flow or spread over the surfaces of the base materials by capillary action, usually aided by separating base material parts between 0.05 and 0.2 mm (0.002 and 0.008 in.)
- Speed up needed interdiffusion

These criteria are different than those for the parent process of welding (which involves

Fig. 8 Schematic illustration of the formation of welds as the result of two perfectly smooth and clean ideal materials versus two real materials. The ideal surfaces (a) before and (b) after being brought into intimate contact. The real surfaces always contain microscopic asperities (c) and usually are contaminated with tarnish layers and/or adsorbed gases or water (d), all of which inhibit bond formation between metal atoms. Application of pressure, with or without heat, leads to progressive formation of welds (e through g). Source: Ref 1

melting of base materials and/or interdiffusion between the base materials). For both, the fillers tend to be alloys with eutectic or near-eutectic compositions from alloy systems having eutectics.

Both brazing and soldering share the following advantages:

- There is minimal disruption of the base materials by operating at relatively low temperatures.
- Joining of fundamentally different materials (e.g., metals to ceramics and metals to glasses) can be done.
- The joint forms itself by the nature of the flow, wetting, and subsequent crystallization process, even when the heat and the braze or solder are not directed precisely to the places to be joined.
- The resulting joint tends to spread loading over large surfaces and performs better in shear, especially peel, rather than in tension.
- Considerable freedom is allowed in the dimensioning of joints, so that it is possible to obtain good results even if a variety of components are used on the same product.
- The brazed or soldered connections can be disconnected if necessary, thus facilitating repair.
- The equipment for both manual and machine brazing/soldering is relatively simple.
- The processes can be easily automated, offering the possibility of in-line

arrangements of brazing/soldering machines with other equipment.

Variant and Hybrid Processes

Besides the major joining options of mechanical joining (fastening or integral attachment), adhesive bonding, and welding (including brazing and soldering), there are some so-called variant processes that are difficult to place within any one of the aforementioned categories. There also are some interesting hybrid processes, which are combinations of the major and/or variant methods. In addition, some references, most notably, the *Welding Handbook* of the American Welding Society, tend to refer to the variant and hybrid processes mentioned here, as well as some other processes, such as thermal cutting and flame straightening or shaping, as allied processes (as described in the section “Classification of Welding Processes” in the article “Overview of Welding Processes” in this Volume). Both variant processes and hybrid processes are described only briefly here for completeness. The interested reader is encouraged to seek other references, such as those listed at the end of this article.

Two variant processes are braze welding and thermal spraying. Braze welding tends to fall between what is properly classified as fusion welding and what is properly classified as

brazing. Like brazing, it employs filler that melts below the temperature of the base material(s), but unlike brazing, and more like all forms of fusion welding, it does not rely on capillary attraction to cause the molten filler to distribute in the joint. Instead, the filler in braze welding is deposited in a prepared groove between the parts to be joined. Thermal spraying involves the heating and acceleration of metallic, ceramic, or even thermoplastic polymer feedstock converted into particulate form to cause those particles to adhere to a properly prepared substrate. The process can be used to restore lost material with relatively low heat input to the substrate or to apply coatings to resist wear or corrosion, provide traction, or provide lubricity. Heating and propulsion embodiments use electric arcs, plasmas, combusted fuel gases, or detonation of fuel gases.

Hybrid processes combine two different processes to obtain some particular benefit(s), often with some synergism. Examples include the combining of spot welding and adhesive bonding in weld bonding, the combining of welding and brazing in weld brazing, and the combining of riveting and adhesive bonding in rivet bonding. Similar hybrids have also been developed within welding, combining two different welding processes to obtain some benefit(s). A few examples include laser/gas tungsten arc, laser/gas metal arc, and laser/plasma arc.

General Design Aspects

The term *design for joining* refers to creating a mechanism that allows the fabrication of a joint that meets this service condition using a suitable joining process, at minimal cost. In this context, design for joining emphasizes how to design a joint or conduct a joining process so that components can be produced most efficiently and without defects. This involves selection and application of good design practices based on an understanding of process-related manufacturing aspects such as accessibility, quality, productivity, and overall manufacturing cost.

A good design uses the inherent advantages of the selected method of joining. For example, braze joints perform very well when subjected to shear loading but not when subjected to pure tensile loading. When using a brazing process to join parts, it would be beneficial to employ innovative design features that would convert a joint subjected to tensile loading to shear loading. For example, use of butt-lap joints instead of butt joints can provide a beneficial effect in flat parts and tubular sections.

The selection of an appropriate design to join parts is based on balancing several considerations related to the product and joining process. Product-related considerations include codes and standards, fitness for service, aesthetics, manufacturability, reparability, reliability, inspectability, safety, and unit cost of

fabrication. Considerations related to the joining process include material types and thicknesses, joint (part) geometry, joint location and accessibility, handling, jiggling and fixturing, distortion control, productivity, training, and initial investment.

Joint Design. The individual parts of a component meet at joints, and the term *joint design* often emphasizes design for meeting structural requirements, because the typical function of many joints is to transmit or distribute forces from one part to the other parts of an assembly. An ideal joint is one that effectively transmits forces among the joint members and throughout the assembly, meets all structural design requirements, and can still be produced at minimal cost.

The design or selection of appropriate joint type is determined primarily from the type of service loading. For example, butt joints are preferred over tee, corner, lap, or edge joints in components subjected to fatigue loading. Joints also must be designed to reduce stress concentration. Sharp changes in part geometry near the joint tend to increase stress concentration or notch effects. Smooth contours and rounded corners tend to reduce stress-concentration effects.

The specific joint design aspects, such as the size, length, and relative orientation of the joint, are based on stress calculations that are derived from an evaluation of service loads, properties of materials, properties of sections, and appropriate structural design requirements. Joint design also can have important process implications.

Orientation and Alignment. Designs that maintain the relative orientation and alignment of component parts save valuable time during fit-up and enhance the ability to produce a high-quality joint. For example, operations involving furnace brazing or diffusion bonding with interlayers benefit from such a type of joint design, because they also require preplacement of the brazing filler or the interlayer in the joint.

Joint Location and Accessibility. Joints obviously must allow proper access. Limited accessibility can reduce the overall quality and productivity, depending on the method of joining. In arc welding, for example, weld joint designs employ bevel angles and root openings to enhance accessibility to the welding torch (or electrode) and provide adequate weld penetration. The best bevel angles provide adequate accessibility while reducing the amount of weld metal required to complete the joint.

Unequal Section Thickness. When members of an assembly have unequal section thicknesses, joint designs should provide a smooth flow of stress patterns through the unequal sections. Modifications to the design may also be needed for process reasons. When making a fillet weld using an arc welding process, if thicknesses of the members are not greatly different, directing the arc toward the thicker member may produce acceptable penetration. However,

special designs for joining will be required when large differences in section thicknesses result in large differences in heat-dissipating capacities. When a thick member is arc welded to a thin member, the welding heat input (mainly current) needed to obtain a good penetration into the thick member is sometimes too much for the thin member and results in undercutting of the thin member and a poor weld. Similarly, if the proper amount of current for the thin member is used, the heat is insufficient to provide adequate fusion in the thick member, and again a poor weld results. Too little heat input can also cause underbead cracking in certain structural materials.

A widely applicable method of minimizing heat sink differential is to place a copper backing block against the thin member during fusion welding. The block serves as a chill, or heat sink, for the thin member. Another way to obtain equalized heating and smooth transfer of stress with unequal section thicknesses is to taper one or both members to obtain an equal width or thickness at the joint. Commonly, when two pipes of dissimilar internal diameter and wall thickness are to be joined, a convenient way is to introduce a “reducer” between the two pipes. One end of the reducer will have the same size and wall thickness as the larger pipe, while the other end of the reducer will have the same size and wall thickness as the smaller pipe.

Distortion Control. Design of an appropriate weld joint can also help reduce welding-related distortion. Fusion welding processes employ localized melting and solidification to join component parts, which can result in excessive thermal strains. These thermal strains are dependent on the type of material, the welding process, and the welding procedure. Reducing the overall length of the weld or the amount of weld metal that needs to be deposited to complete a joint reduces both residual stresses and distortion. For example, intermittent welding instead of continuous welding reduces the overall length of a weld. For more details on distortion of fusion-welded joints, see the article “Residual Stresses and Distortion” in this Volume.

Summary

Joining is key to the manufacture of large or complex devices or assemblies, the construction of large, complex structures, and the repair of parts, assemblies, or structures in service. It also allows materials to be mixed to optimum advantage and utilized for maximum economy.

There are basic joining methods that use purely mechanical forces arising from physical interference between (and possibly some interlocking between) parts, chemical forces arising from surface adsorption or outright reactions, and the physical forces arising from the natural tendency for the atoms of all but the inert gas elements to form strong atomic-level bonds. These lead to the generic options of mechanical

joining, adhesive bonding, and welding, including brazing and soldering.

Mechanical joining can be accomplished using special supplemental parts whose only purpose is to facilitate joining, known as fasteners, in mechanical fastening or simply using some geometric features of the parts themselves to create interference and interlocking. The greatest advantages of mechanical joining are utility with all materials in virtually any combination, with no degradation of material properties or microstructure, and the unique abilities to allow relative motion between joined parts (if desired) and allow intentional disassembly (if desired).

Adhesive bonding relies primarily on the development of secondary bond formation between a compatible chemical agent known as an adhesive and base materials known as adherends. Other contributions to overall joint strength, that is, adhesion, can come from mechanical interlocking, limited diffusion, or electrostatic attraction from polarization between the adhesive and the adherends. The major advantage of the process is load spreading, while the major limitation is always susceptibility to environmental degradation.

Welding arises from the natural tendency of the atoms of most elements in the periodic table (except the inert gases) to form one or more ionic, covalent, or metallic atomic-level bonds. By using either enough pressure to deform surface asperities that limit the number of points of intimate, atomic-level contact or by adding atoms from a molten material source to backfill gaps, welds rivaling the strength of the base materials is possible. Welding can be accomplished with the categories of metals, ceramics, glasses, and thermoplastic polymers but not between these classes. One of two subclassifications or subtypes of welding, either brazing or soldering, can be used to join dissimilar, as well as similar, combinations of materials.

Finally, there are some special variants and hybrids of the basic joining processes. Two important variants are braze welding and thermal spraying. Three hybrids are weld bonding, weld brazing, and rivet bonding.

Overview of Welding Processes

Robert W. Messler, Jr., Rensselaer Polytechnic Institute

BECAUSE METALS AND ENGINEERING ALLOYS are used in more diverse applications than any other material, and because welding offers particular advantages for joining metals and alloys into structures wherein the joints are intended to be permanent, it is appropriate and important to survey the various ways in which welding can be performed. Welding processes can be fairly meaningfully and conveniently classified into those that achieve material continuity by melting the base metal without or with some filler metal or for those that achieve material continuity by causing plastic deformation through the application of pressure without or with some heat. The former are known as fusion welding processes, while the latter are known as nonfusion welding processes.

Once a decision is made that it is acceptable and advantageous to use fusion or not, it is important and beneficial to consider the type of energy source to be used to cause such melting or such plastic deformation, respectively. For fusion welding, chemical energy sources include combustion of fuel gas with oxygen (oxyfuel welding processes) and exothermic reaction of particulate metals and oxides (combustion synthesis welding processes), while electrical energy sources include arcs (arc welding processes), joule heating (resistance welding processes), or high-energy-density beams (radiant energy or beam welding processes). For solid-phase, nonfusion welding, mechanical energy sources predominate, including the use of pressure, friction, and solid-state diffusion, although the energy of chemical reactions can also be used for at least solid-state deposition processes.

It is also possible to produce joints between metals and even between metals and ceramics using two subtypes of welding known as brazing and soldering. In both, fillers that melt are used to create material continuity with base materials that do not melt, even at the interface. Brazing and soldering processes can be performed using a variety of chemical or electrical energy sources that are, not surprisingly, similar for these two low-temperature processes.

This article provides an overview on the classification of welding processes along with a brief overview of key process embodiments for joining by:

- Fusion welding with chemical sources for heating
- Fusion welding with electrical energy sources (arc welding or resistance welding)
- Fusion welding with directed energy sources (laser welding, electron beam welding)
- Nonfusion welding processes (regardless of the particular energy source, which is usually mechanical but can be chemical)
- Related subprocesses of brazing and soldering

Classification of Welding Processes

One of the advantages of welding processes for producing joints in metals and alloys is the diversity of specific process embodiments. This diversity maximizes the possibility of finding the right process for the right situation and application. However, at the same time, such diversity can seem confusing without some high-level scheme for classifying the various process methods or embodiments. Classification helps to divide processes into logical categories within which there are certain key similarities or certain important differences, and it relates major categories to one another to allow comparison of relative merits and shortcomings or penalties for specific application.

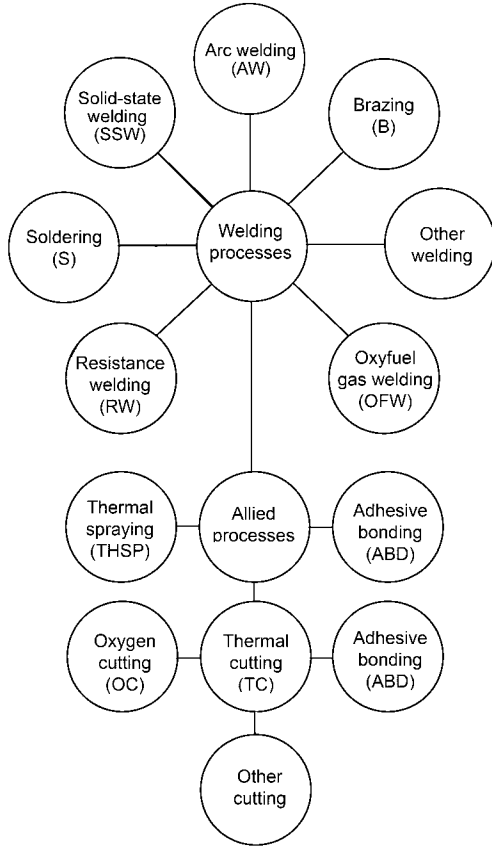

Figure 1 presents a master chart of welding and allied processes developed by the American Welding Society (AWS). It is useful for three things. First, it subdivides welding processes into major categories (e.g., arc welding, oxyfuel gas welding, resistance welding, etc.). Second, it shows the general relationship of so-called allied processes, which use similar energy sources (e.g., electric arcs and oxyfuel gas combustion) for related, thermally-based processes such as cutting and material thermal spraying. Third, it gives the AWS designation acronym for short-hand reference to a specific process (e.g., GMAW for gas metal arc welding).

While interesting, and offering some utility, this master chart fails to classify specific process embodiments within welding in such a

way as to make clear familial relationships in a hierarchical fashion; that is, it fails to provide a taxonomy. Widely used in biology and biological sciences, in that discipline, a taxonomy is an orderly classification of plants or animals according to their presumed natural relationships. First-generation parent-daughter, second-generation grandparent-granddaughter, as well as aunt-niece, cousin, and other relationships can be shown in taxonomies. When applied to classify inanimate things or, as in the case of welding, processes, a taxonomy helps with an understanding of the derivation of one process from another, with key similarities and differences, and even with the possible identification of “missing links” to stimulate invention or development.

Figure 2 presents a taxonomy of welding processes developed by the author. At the highest level of the taxonomy presented in Fig. 2, process embodiments are divided into pressure and nonpressure categories, while immediately below this level each of these is divided into nonfusion and fusion subtypes. The relationship of specific process embodiments to the fundamental ways in which welds can be created in real materials to overcome the obstacles to the establishment of material continuity is immediately obvious; that is, either pressure to cause plastic deformation or heat to cause melting can be used. Within the general subclassification of nonpressure welding processes that operate by relying on fusion, further subdivision into processes that rely on fusion of identical or virtually identical base and/or filler materials or of dissimilar base materials and fillers can be seen under headings of homogeneous (in the former case) and heterogeneous (in the latter case). Brazing and soldering appear under the heterogeneous subdivision. Further subclassifications consider use of filler or not (i.e., autogenous welding), as well as other key differences.

Not used in the taxonomy presented in Fig. 2 is the source of energy by fundamental type, that is, chemical energy, electrical energy, or mechanical energy. This notwithstanding, the classification shown tends to work quite well to understand the relationship among various process embodiments.

Chemically Driven Fusion Welding

There are two ways in which chemical energy can be harnessed to cause melting and enable fusion welding: combustion of a fuel gas in the presence of oxygen, and solid-phase reaction of certain powdered metals with certain other powdered metals, possibly with carbon, or with certain oxides of less-active metals. The former processes are called oxyfuel gas welding processes, while the latter are called combustion synthesis welding processes. Both, obviously, involve exothermic reactions. (In chemistry, an exothermic reaction or process is one that spontaneously produces or evolves heat as it occurs.)

Hydrocarbon gases, as well as plain hydrogen, can react with oxygen to combust. In

undergoing oxidation, hydrocarbon fuel gases form combustion products in two stages. In the first stage, during what is known as primary combustion, the hydrocarbon gas dissociates to form hydrogen gas and carbon monoxide as the first step in oxidation of the dissociated carbon. In the second stage, during what is known as secondary combustion, the hydrogen is oxidized to form water vapor, and the carbon monoxide is further oxidized to the final state of carbon dioxide. Each step, as shown subsequently for the example of the combustion of acetylene gas, C_2H_2 , is accompanied by the release of energy (known as enthalpy in thermodynamics and as the heat of combustion in chemistry) in the form of heat:

During primary combustion of the C_2H_2 contained in a pressurized cylinder (as a liquefied compressed gas) by oxygen contained in a pressurized cylinder (as a compressed gas), $\Delta H = 227 \text{ kJ/mol}$ of heat is released during the dissociation of the C_2H_2 at 15°C (50°F) to carbon and hydrogen, while the partial combustion (oxidation) of carbon to form carbon monoxide releases $\Delta H = 221 \text{ kJ/mol}$ of carbon. No combustion of the hydrogen takes place at this stage. During the second stage of combustion (i.e., secondary combustion), which occurs immediately after primary combustion in oxyfuel gas welding, the carbon monoxide and hydrogen react with oxygen from the surrounding air to release $\Delta H = 242 \text{ kJ/mol}$ of hydrogen and $\Delta H = 285 \text{ kJ/mol}$ of carbon monoxide, or $\Delta H = 570 \text{ kJ/mol}$ for the overall reaction (Eq 2). Considering the entire reaction, that is, primary and secondary combustion, approximately one-third of the total heat of combustion released comes from the primary combustion stage, and two-thirds comes from the secondary combustion stage.

When one looks at the combustion flame produced during oxyfuel gas welding, in general, and oxyacetylene welding, in particular, it appears as shown schematically in Fig. 3. There is a region right at the end of the gas torch where there is no flame, because combustion has not yet taken place. Beyond this colorless region is a distinct whitish-yellow to white inner cone in which primary combustion has taken place by the pressurized oxygen having been supplied to the pressurized fuel gas and the mixture having been ignited. Outside this inner cone is a blue to bluish-white outer flame in which secondary combustion has taken place when the products of partial combustion from the primary combustion region mix with oxygen from the surrounding air to further combust/oxidize. While only one-third of the total heat produced by the full combustion process is released in the primary combustion region (i.e., $\Delta H = 448 \text{ kJ/mol}$ out of $\Delta H = 1260 \text{ kJ/mol}$ for oxyacetylene welding), this region is actually hotter (that is, at a higher temperature) than the outermost secondary combustion region. The reason for this is that the density of the energy in the primary region is greater because this region is constrained by the surrounding region of secondary combustion. It is consistently true of all energy sources that the intensity of the source (which correlates to its peak temperature) is directly related to the density of the energy in that source. A familiar example is the concentration of sunlight by a magnifying glass to produce very high temperatures in the focused spot. For maximum heating,

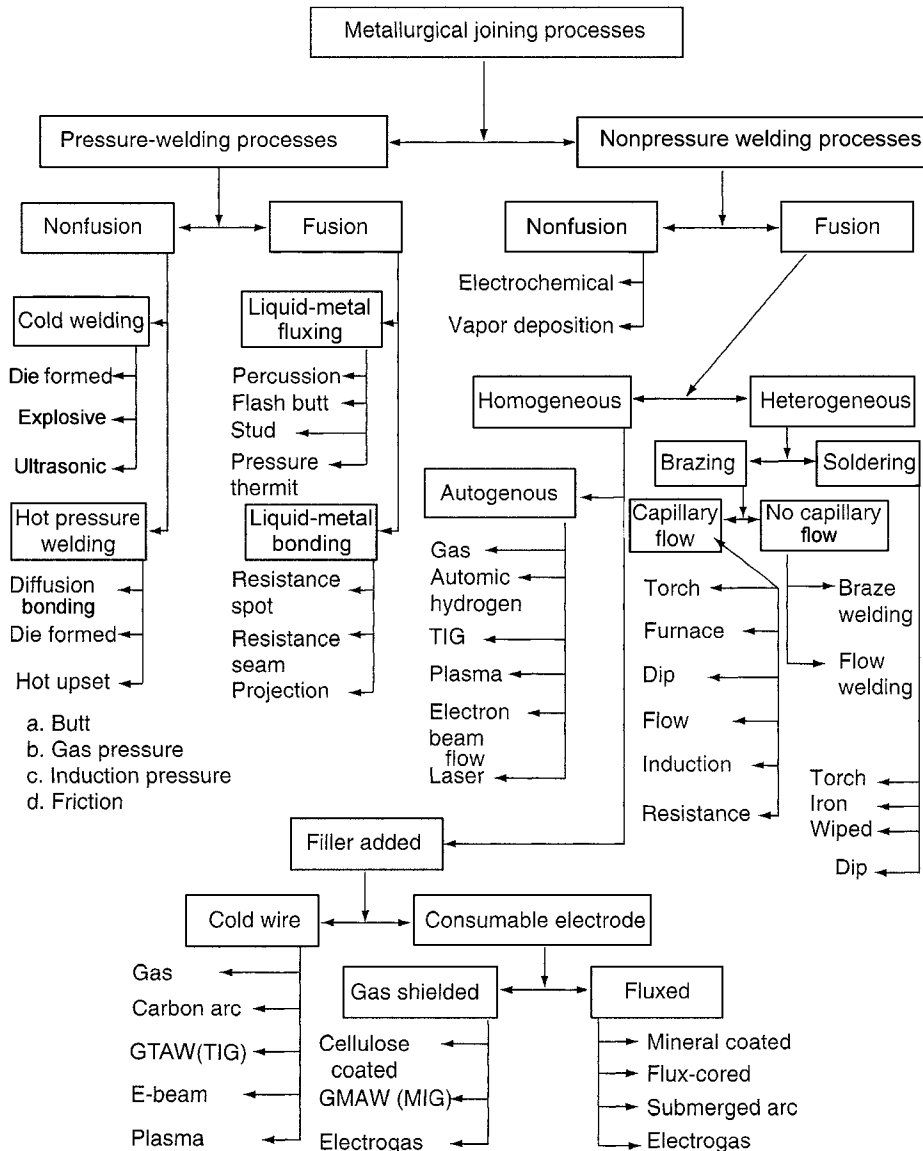

Fig. 2 Schematic representation of the overall taxonomy of welding processes. GTAW, gas tungsten arc welding; GMAW, gas metal arc welding; TIG, tungsten inert gas; MIG, metal inert gas. Source: Ref 2

whether for welding or for cutting, the tip of the inner cone should be played on the workpiece. It is possible to change the chemical nature and temperature of the flame in oxyfuel gas welding by adjusting the relative proportions (on a molar or volume basis) of oxygen and fuel gas being supplied through the torch (Fig. 4). When the ratio of fuel gas (in the case discussed previously, acetylene) to oxygen is balanced according to the chemical reaction in Eq 1, the flame is chemically neutral, that is, with neither a tendency to cause oxidation or reduction at the surface of the metal being heated/welded. This is the way an oxyfuel gas flame should be adjusted for most situations. If excess oxygen is supplied, the flame becomes oxidizing to the metal being heated/welded, and also hotter. This is the way an oxyfuel gas

flame should be adjusted either to burn off hydrocarbon contaminants (e.g., oil or grease) or to weld alloys in which one of the components has a high vapor pressure and is thus volatile and prone to loss during welding, or to cut metals. A prime example in welding is the risk for loss of zinc from brasses (i.e., copper-zinc alloys). If excess fuel gas (here, acetylene) is supplied, the flame becomes reducing to the metal being heated/welded, removing some oxides or tarnish layers to provide atomically clean metal. This is the way an oxyfuel gas flame should be adjusted for heating/welding metals or alloys that oxidize easily, such as aluminum alloys, magnesium alloys, or stainless steels (in which an ever-present corrosion-preventing oxide of chromium forms at the surface).

Fig. 3 Schematic illustration of a typical oxyfuel gas flame used in welding and cutting, here showing an oxyacetylene flame adjusted to be (a) neutral and (b) reducing. The primary and secondary regions of combustion are shown in (a), while the acetylene “feather” characteristic of a reducing flame is shown in (b). Source: Ref 2

To ignite the flame in oxyfuel gas welding, the fuel gas only should be turned on and ignited to produce a yellow, sooty flame. Oxygen should then be introduced by slowly opening the valve to the oxygen supply. The flame will become progressively less yellow and sooty and more blue to bluish-white and cleaner as more and more oxygen is mixed in. To turn off the flame, the fuel gas should be turned off first.

The neutral condition in an oxyacetylene flame, for example, can be found by turning the oxygen flow rate down until small bright-blue flecks (from unburned acetylene), known as acetylene feathers, appear around the inner cone. With excess acetylene, the flame is chemically reducing. By bringing the oxygen up to just make the acetylene feathers disappear, the flame is made chemically neutral. By increasing the oxygen flow rate above the level for a neutral flame, a chemically oxidizing flame is produced.

Oxyfuel gas welding offers easy portability but limited heating capacity in terms of peak temperatures attainable in the flame and thus limited ability to melt higher-melting-point metals and alloys. The process is used for heating, cutting, piecing, gouging, flame straightening or shaping, as well as welding or brazing metals. Table 1 lists the flame temperatures and other key features of various oxyfuel gas welding and allied processes.

The second way in which chemical reactions can be used to produce heat for welding or brazing is best known as thermit welding but which actually includes a wide variety of so-called aluminothermic reactions and, more recently, a variety of similar highly exothermic chemical reactions known as combustion synthesis reactions. What these have in common is that they all employ a highly exothermic chemical reaction between mixtures of finely divided (i.e., powdered or particulate) metals

(at least one of which is active or reactive), active metals and less-active-metal oxides, active metals and graphite, or active metals and less-active-metal nonoxide compounds (e.g., carbides, nitrides, silicon dioxide, etc.).

The aluminothermic reactions, which are the basis for thermit welding, involve the reaction between finely divided pure aluminum and a less-active-metal oxide, commonly either oxides of iron or copper. The former are used to weld iron-base alloys (principally carbon steels) and the latter to weld copper-base alloys (principally pure copper). Two (of approximately five) reactions are:

The thermit (or aluminothermic) reaction is carried out as shown in Fig. 4, in which the molten metal reaction product, being fluid and dense, runs down to the bottom of the reaction vessel or crucible to flow into a prepared joint and around joint members to form a weld upon solidification. As shown, welds can be made in either horizontally or vertically arranged joint members. Thermit welding has been used historically to weld steel reinforcing bars, steel railroad track rails (end-to-end), and large-cross-section electrical connections.

More recently, a wide variety of exothermic reactions have been studied and employed for producing refractory compounds (e.g., oxides, carbides, nitrides, silicides, borides, etc.) and, by using such compounds to cause bonding, to cause joining (predominantly by an exothermic brazing process, because there is seldom any melting of the base material) of ceramics to one another or to metals. These are collectively known as combustion synthesis reactions but are also referred to as self-propagating high-temperature synthesis reactions. The generic process has potential both for joining and for applying surfacing layers.

Electric Arc Fusion Welding

Electrical energy can be applied in various ways to heat up a material. For workpieces that are electrical conductors, the workpiece can be made part of the electric circuit with an electric power supply. Once part of the electric circuit, either electric current can be passed to the conductive workpiece through an arc from an electrode to the workpiece across a gap in a gas, or the electric current can be passed directly through the workpiece as an integral part of the circuit. Processes that use the former approach are called arc welding processes, while those that use the latter approach are called resistance welding processes. Another way of using electrons to heat a workpiece (whether an electrical conductor or not) is with a beam of intense, high-density electrons. These three basic ways are shown schematically in Fig. 5. Arc welding and resistance welding are described in this section, while electron beam welding is described in the next section,

Fig. 4 Schematic illustrations showing the typical arrangements of the thermit process for welding concrete steel reinforcing bars, horizontally or vertically. Source: Ref 3

Table 1 Flame temperatures and other key features for various oxygen-fuel gas welding processes

Fuel gas	Formula	Specific gravity(a)	Volume-to-weight ratio(a)		Oxygen-to-fuel gas combustion ratio(b)	Flame temperature for oxygen(c)		Heat of combustion					
			Air = 1	m ³ /kg		ft ³ /lb	°C	°F	Primary		Secondary		Total
								MJ/m ³	Btu/ft ³	MJ/m ³	Btu/ft ³	MJ/m ³	Btu/ft ³

“Directed-Energy Fusion Welding Processes,” along with laser beam welding.

Modes of Arc Welding

When electrons are forced to jump across a gap in a circuit made up of good (usually metal) electrical conductors, it does so in the form of an arc. The arc consists of negatively charged electrons moving through the gap between two electrodes at different electrical potentials, or voltages. One electrode (called the anode) is said to be positive with respect to the other,

while the electrode with the more negative electric potential is called the cathode. Electrons either are forced out of the cathode when it is heated (by thermal emission), or they are pulled from the cathode by the strong attractive force from the positive anode. A greater difference in the electrical potential between a cathode and an anode allows electrons to cross a larger gap between the two electrodes.

Electrons always move from negative to positive; however, in the long-established convention of a current, which is really the flow or flux of electrons from cathode to anode, the current flow is taken to occur from positive to

negative. When electrons flow across a gap in air or some other gaseous atmosphere, they can impact atoms within the air/gas gap and cause orbiting electrons to be ejected from those atoms. This ejection of electrons produces positive ions of the atoms in the air/gas gap. The resulting ions also move in the arc under the influence of the applied voltage (or potential difference), but toward the cathode. The net effect of an arc is the heating of the metal workpiece due to the impact of very fast-moving electrons and/or slower-moving ions (which have a much higher mass than electrons). Their kinetic energy is absorbed and converted to heat when the fast-moving electrons or slower-moving and heavier positive ions strike the workpiece surface.

Figure 6 schematically illustrates different modes of electric arc heating by either of two direct current polarities or by an alternating polarity. If the potential difference or voltage of the power supply is unchanging in polarity (i.e., the cathode remains the cathode and the anode remains the anode at all times that current is flowing), the electricity is said to be operating as direct current, or dc, mode. If the polarity is cycled back and forth, the electricity is said to be operating as alternating current, or ac.

With dc operation, the workpiece can be either positive relative to the electrode in the welding source, or it can be negative. The two modes of dc operation are typically referred to as follows:

- *Direct current straight polarity (DCSP)*: Arc heating when the workpiece is positive and the welding electrode is negative. This operating mode also is called dc electrode negative or dc-.
- *Direct current reverse polarity (DCRP)*: Arc heating when the workpiece is negative and the welding electrode is positive. This operating mode also is called dc electrode positive or dc+.

In ac operation, one-half of the voltage cycle operates as dc-/DCSP, while the other half operates as dc+/DCRP. In addition, it is possible to apply a small dc bias voltage on top of an ac voltage, thus shifting the half-cycles of the ac wave from being balanced between dc-/DCSP and dc+/DCRP. This accentuation of one or the other to affect the welding is described as DCSP versus DCRP. This ac arc welding mode is known as wave balance control.

The effect of these different operating modes on the shape of the resulting molten weld pool (shown in profile as a section across a weld produced by a moving heat source) is also shown in Fig. 6, as follows:

- Deep welds, with 70% of the heat of the arc found in the workpiece for the DCSP mode (left)
- In the DCRP mode (center), shallow welds and strong cleaning action at the workpiece

Fig. 5 Schematic illustrations of the three basic ways in which electrical energy, supplied by a power source, can be used to heat and fusion weld a metal, including (a) use of the kinetic energy of electrons and positive ions in an arc to bombard the workpiece and produce heat (in arc welding), (b) use of the resistance of a workpiece to the passage of current to produce Joule heating (in resistance welding), and (c) use of an intense, dense beam of either electrons or photons to bombard a workpiece and produce heat when the kinetic energy of the particles in the beam are stopped by the atoms in the workpiece material (in electron beam and laser beam welding, respectively)

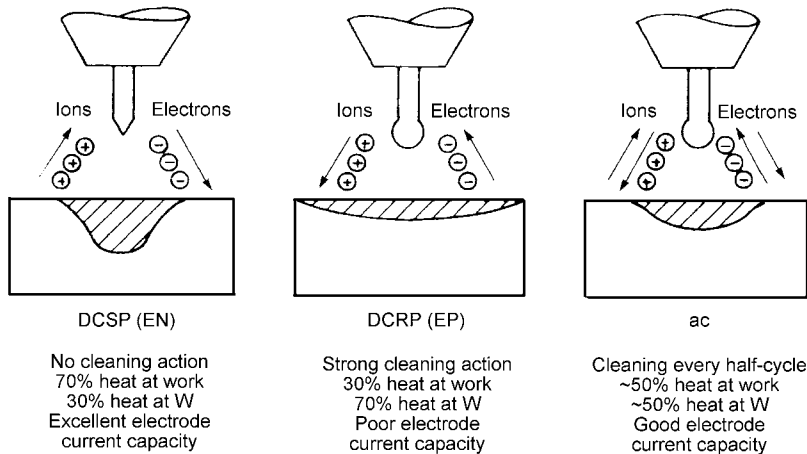

Fig. 6 Schematic illustration summarizing the characteristics of the various operating modes for gas tungsten arc welding. DCSP (EN), direct current straight polarity (electrode negative); DCRP (EP), direct current reverse polarity (electrode positive); ac, alternating current. Source: Ref 2

surface occurs from a scrubbing action by bombarding heavy ions, with 70% of the heat of the arc found in the welding electrode (center)

- In the ac mode (right), an intermediate profile is produced with some surface cleaning and fairly balanced distribution of heat from the arc in the welding electrode and in the workpiece.

Different arc welding processes, as described next, tend to run under different preferred operating modes.

Arc Welding Processes

The two broad subtypes of arc welding processes are those that employ nonconsumable electrodes and those that employ consumable electrodes. Non-consumable electrodes produce the arc and melt the base metal(s) of the workpiece(s) either without using a filler or by adding a filler wire to the molten weld pool. Consumable electrodes produce an arc and provide filler metal to the joint as they are consumed. Major modern types of nonconsumable electrode arc welding include:

- Gas tungsten arc welding (GTAW)
- Plasma arc welding (PAW)
- Stud arc or simply stud welding (SW)
- Magnetically-impelled arc butt welding (MIAB)

Major modern types of consumable electrode arc welding processes include:

- Gas metal arc welding (GMAW)
- Shielded metal arc welding (SMAW)
- Flux-cored arc welding (FCAW)
- Submerged arc welding (SAW)
- Electrode gas welding (EGW)
- Electroslag welding (ESW)

Only GTAW, PAW, GMAW, SMAW, FCAW, and SAW are described here. The

reader interested in other processes or desiring more details on the processes covered here should refer to the references listed at the end of this article or to other articles in the *ASM Handbook* series (as noted for each process described in the following).

Nonconsumable Electrode Arc Welding.

Gas tungsten arc welding and plasma arc welding are examples of processes that employ non-consumable electrodes. Both use a permanent electrode made from tungsten, the highest-melting-point metal (at 3410 °C, or 6170 °F), contained within the body of a torch designed to provide a protective shield of inert gas of argon or helium or a mixture of the two.

Electric current is delivered to the tungsten electrode through a cable by a copper contact tube. In GTAW, an arc is struck between the tungsten electrode and the workpiece, operating in either DCSP, DCRP, or ac. The heat produced melts the base metal in the workpiece and causes it to flow together with any other abutting and melted workpiece. Upon solidification, a weld is produced by this filler-free, autogenous process. Filler can be added in the form of a solid wire that is dipped into the molten weld pool as welding is taking place.

The inert shielding gas protects the tungsten electrode from oxidizing and, simultaneously, protects the molten weld pool and subsequent hot but rapidly cooling weld from undesirable oxidation. In plasma arc welding, the torch consists of an inner and an outer body. The inner body is made positive relative to the tungsten electrode so that an arc is established across the gap through which some argon is flowing. When the argon is heated and ionized, it expands greatly and, as a result of the increased pressure in this nozzle, produces an extremely hot and dense plasma or constricted arc. The plasma heats the workpiece to cause melting and produce a weld. More inert argon from the outer body of the torch provides shielding to the weld.

Figure 7 compares GTAW and PAW in schematic illustrations. Compared to GTAW, PAW produces deeper-penetrating welds, can operate at faster welding speeds, and is cleaner because of both the double-shielding and by preventing accidental touching of the tip of the tungsten electrode to the workpiece to cause contamination by tungsten. While GTAW can be operated in DCSP, DCRP, or ac modes, great care must be taken to prevent overheating and melting at the tip of the tungsten electrode by the heat being concentrated there in the DCRP mode. Plasma arc welding is operated almost exclusively in the DCSP mode. For more details, see the articles “Gas Tungsten Arc Welding” and “Plasma Arc Welding” in this Volume.

Consumable Electrode Arc Welding Processes. A gas-shielded cousin of GTAW is GMAW, in which a continuous solid-wire welding electrode is intended to be consumed to become filler metal for the weld. The process is operated in DCRP to take advantage of the concentration of heat at the tip of the welding wire electrode. As the wire melts, the molten metal transfers to the joint to contribute to the weld. Various inert or near-inert gases are used with GMAW, including argon, N₂, CO₂, and various combinations of these and, possibly small amounts of H₂ or even O₂ (1 to 2 vol%). The goal is to exclude the high percentages of N₂ and O₂ that comprise air and that lead to porosity and embrittlement. The advantage of GMAW is much higher deposition rates for welding, reaching ~5 kg (10+ lb) per hour or more.

Like all consumable electrode arc welding processes, GMAW can be operated to cause the molten metal produced at the tip of the consumable electrode to transfer to the workpiece by any of several modes, including globular, spray, and short-circuiting or dip transfer. Each has relative advantages and disadvantages (see the article “Gas Metal Arc Welding” in this Volume for more details).

The next two, very popular, forms of consumable electrode arc welding do not employ an inert shielding gas from a compressed gas source (i.e., a pressurized cylinder). Rather, they generate their own relatively protective (but not inert) shielding gas through the thermal decomposition of certain mineral ingredients contained in the fluxes found as either coatings on a fixed-length core wire (in SMAW) or within the core of a continuous tubular wire (in FCAW). In addition to the generation of a shielding gas, the flux coating on SMAW electrodes and the flux core in FCAW wires also can:

- Provide a supply of ions and electrons to facilitate arc initiation and prevent unwanted arc extinction
- Produce a molten flux that both metallurgically refines the molten metal in the weld pool and covers the weld pool and the newly formed weld to prevent unwanted oxidation
- Allow alloying additions to the core wire to adjust the composition of the deposited filler

and, occasionally, add iron powder to increase the deposition rate of iron-base fillers

Figure 8 compares the FCAW (Fig. 8a) and SMAW (Fig. 8b) processes in schematic illustrations. Both processes tend to be operated in the DCRP mode to take advantage of the arc heat being concentrated at the tip of the electrode to be consumed, but at least SMAW can be operated in DCRP or ac for some electrode types (or formulations). Because FCAW employs a continuous wire, welding productivity tends to be higher, as does the effectiveness

of shielding out-of-doors (because the shielding gas is generated at the core of the arc rather than near its surface).

The remaining major types of consumable electrode arc welding processes are intended for applications requiring very heavy metal deposition to weld thick sections or apply heavy overlays. These include SAW, EGW, and ESW. All tend to operate in DCRP using very high currents (often 1000+ A), very large-diameter filler wires (or multiple wires or even strip), and are mechanized rather than performed manually.

Figures 9 through 11 schematically illustrate SAW, EGW, and ESW, respectively. In SAW, a dry granular flux is used to cover the arc, hence the name submerged arc. Shielding comes from the protective molten flux and subsequent glasslike slag cover that forms on the weld pool and solidifying weld, respectively. Electro gas welding uses an inert gas for shielding, while ESW uses a molten slag produced by I^2R joule heating as current and molten droplets move through the molten slag layer, extinguishing the arc in the process. Submerged arc welding is restricted to welding in a horizontal plane, while EGW and ESW can be used out of position in a vertical plane as well.

Fig. 7 Schematic illustration comparing (a) gas tungsten arc welding and (b) plasma arc welding processes. Source: Ref 2

Resistance Welding Processes

When electric currents flow through conductive materials (such as metals or alloys), there is some inherent resistance to the free flow of electrons through the conductor. The amount of resistance (R) is proportional to the inherent resistivity (ρ) of the material and the length (L) of the conductor, such that $R = \rho \times L/A$, where A is the cross-sectional area of the conductor. Electrical resistance is thus lowered when conductor cross section is increased.

The resistivity (ρ) of a material is a basic physical property, of which the inverse (or reciprocal) is the material electrical conductivity, designated by σ . Resistivity of a material depends on a number of factors, such as temperature, alloy content, and/or the number of crystal defects in the alloys. This can be understood by the general nature of a conductor. The atoms in the conductor vibrate at very high

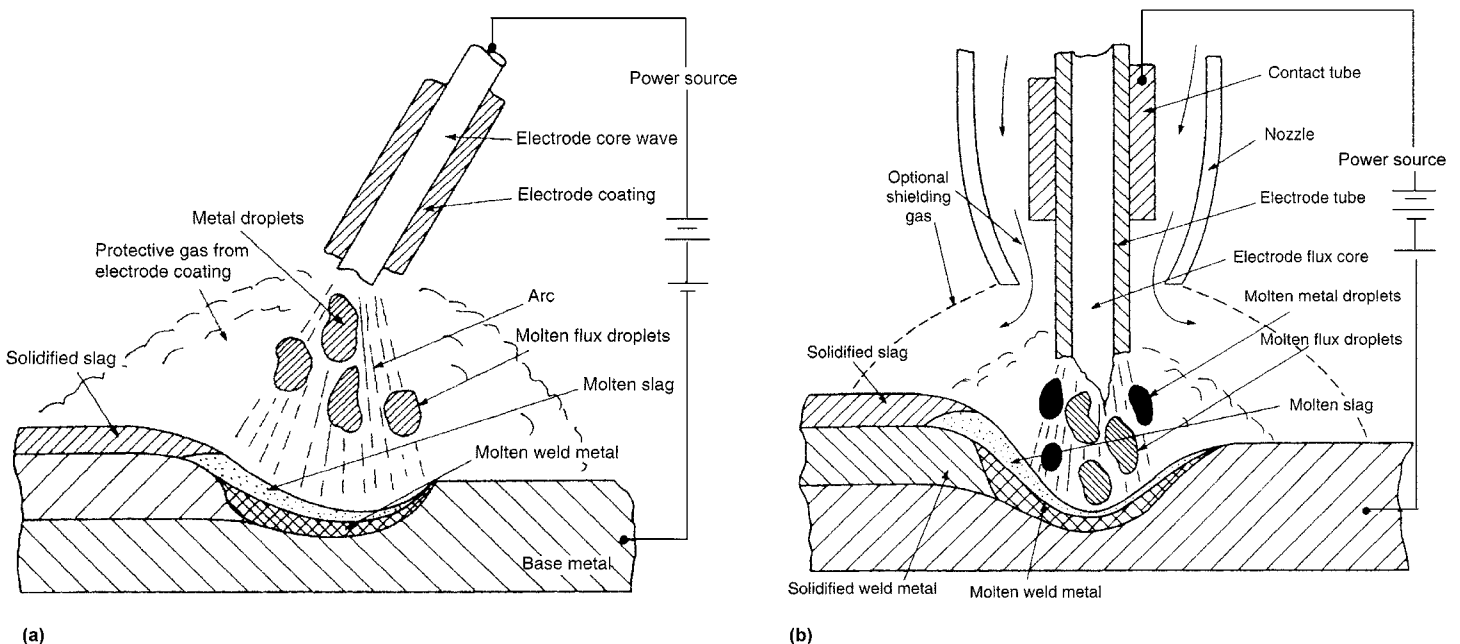

Fig. 8 Schematic illustration comparing (a) shielded metal arc welding and (b) flux-cored arc welding processes. Source: Ref 2

Fig. 9 Schematic illustration of the submerged arc welding process used for heavy deposition in plane (i.e., down-hand) only. Source: Ref 2

Fig. 11 Schematic illustration of the electroslag welding process used for heavy deposition welding in position or in a vertical plane using special tooling (as shown). Source: Ref 2

frequencies (albeit with very small amplitudes), and the crystal structures of metals also have imperfections in the arrangement of their atoms. These two factors have the effect of impeding electron flow, because the resulting perturbation of the electric field associated with the vibrating atoms and crystal imperfections of

the conductor gives rise to scattering of electrons. Thus, resistivity of a conductor becomes greater with an increase in temperature and/or with an increase in the number of crystal structure imperfections (caused by cold working, for example, or other factors). Conversely, there would be no impediment to the flow of free

electrons in a perfect crystal at absolute zero (-273°C), where the atoms do not vibrate. The resistance (R) of a physical circuit element also depends on the length of the element (L) and the cross-sectional area (A) through the relationship $R = \rho \times L/A$.

The result of current, I , flowing through a conductor with a resistance R is the production of heat Q given by I^2R in units of watts (with units of volt-amperes). This is known as joule heating and is the basis for resistance welding. It can essentially increase without limit if the current continues to flow such that the rate of I^2R heating exceeds the rate at which that heat can be dissipated by or from the conductor. For this reason, resistance welding processes are able to cause melting (or fusion) in any metal or alloy and can do so very quickly.

Figure 12 schematically illustrates one embodiment of resistance welding known as resistance spot welding (RSW). In it, sheets of metal are squeezed between copper electrodes, and a spot or nugget of molten metal is formed preferentially at the interface between the stacked sheets, where the contact resistance is the highest (so the I^2R heating is the greatest/fastest) and any cooling by heat extraction through the water-cooled electrodes is minimal.

Other methods of resistance welding include:

- *Resistance seam welding (RSEW)*: To produce overlapping spots to form a seam
- *Projection welding (PW)*: Where weld nuggets are localized at embossments or other raised portions (projections) of sheets being stacked
- *Percussion welding (PEW)*: Also known as capacitor-discharge welding, where a sudden discharge of electrical energy stored in a capacitor is used to produce a spot weld

Fig. 12 Schematic illustration of the resistance spot welding process. Source: Ref 2

Another hybrid method involves welds to be formed when two parts are slowly brought into contact to first arc (across initial points of contact) and then heat by Joule (I^2R) heating. The weld is fully formed when the two parts are rammed together using an upsetting force. Two of these, with subtle differences in the sequence of heating and upsetting, are called flash welding (FW) and upset welding (UW).

Schematic illustrations of the RSEW and the PW processes are shown in Fig. 13. Figure 14 schematically illustrates the FW process. What all resistance welding processes share in common are very limited joint configurations (being limited to lap joints for RSW and PW, and butt welds for RSEW, PEW, FW, and UW) and high heating and postweld cooling rates. The latter makes these processes attractive for welding alloys prone to degradation from exposure to high temperatures for too long, as tends to occur with the arc welding processes.

Directed-Energy Fusion Welding Processes

Beams of directed energy are another method of heating for fusion welding (so that a supply

of atoms in a liquid state fills the gaps between the surfaces of the materials being joined). A beam of very fast-moving particles impinges upon a material and can cause rapid and intense heating in the immediate vicinity of the point of impingement. Heating of the workpiece occurs when the kinetic energy of the particles in the beam is converted into the thermal energy of atoms in the workpiece. The rate of heating is, in fact, so rapid that the generated heat does not have a chance to conduct very far away. As a result, the temperature of the material at the point of impingement rises extraordinarily rapidly to the melting point and then beyond the melting point to the boiling or vaporization point. Once (or when) this occurs, and the material literally vaporizes in the path of the high-energy-density beam, a vapor cavity forms what is known as a keyhole. Surrounding this vapor cavity is an annular column of molten metal. The keyhole mode occurs when the energy density of the heating source exceeds approximately 10^{10} to 10^{13} W/m^2 . For energy densities below approximately 10^9 W/m^2 , heating occurs by what is known as the melt-in mode or conduction mode. Arc welding processes typically operate at 5×10^6 to 5×10^8 W/m^2 energy densities. The PAW process is capable of operating in either mode, depending

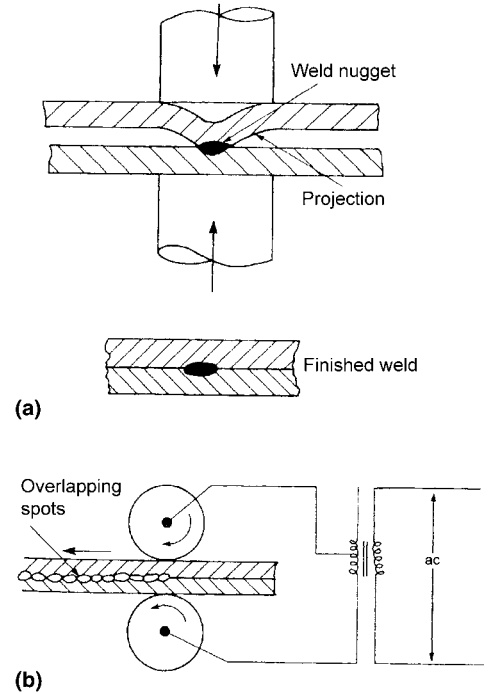

Fig. 13 Schematic illustration comparing the (a) resistance seam welding and (b) projection welding processes. Source: Ref 2

Fig. 14 Schematic illustration of (a) the flash welding process and (b) a typical as-welded flash weld. Source: Ref 2

on the current at which welding is being performed. Figure 15 schematically compares the melt-in (or conduction) and keyhole modes of welding for the PAW process, as an example.

As the beam energy source moves along (at the welding speed), the molten material surrounding the vapor cavity flows backward to the rear of the weld pool, links up by surface-tension forces, and fills the gap that was momentarily created by the moving vapor cavity or keyhole. Welding with beams of high-energy particles results in:

22 / Fundamentals of Welding

- Welds with a high aspect ratio (i.e., very deep relative to its width)
- Welds with a narrow heat-affected zone (because heating outside the weld is limited to a very narrow region)
- Very high welding velocities or speeds
- Little or no distortion from shrinkage of molten metal to solid metal or from thermal contraction of heated base metal in the heat-affected zone

The two methods of high-energy-density beam welding processes (or what are sometimes referred to as radiant energy beam welding processes) are electron-beam welding (EBW) and laser-beam welding (LBW) (Fig. 16). The former uses a dense beam of very fast-moving electrons thermally emitted from a cathode and accelerated over a potential of tens to hundreds of thousands of voltage, while the latter uses a dense beam of photons moving at the speed of light. To prevent the electrons from colliding with atoms or molecules in the atmosphere (and thus being scattered), the EBW method is almost always performed in a vacuum (typically 10^{-3} to 10^{-5} atm pressure). The LBW method can be performed in vacuum but is usually performed in an inert gas atmosphere, since photons are not scattered by atoms to any significant degree.

Electron beam welding is a high-energy-density fusion process that is accomplished by bombarding the joint to be welded with an intense (strongly focused) beam of electrons that have been accelerated up to velocities 0.3 to 0.7 times the speed of light at 25 to 200 kV, respectively. The instantaneous conversion of the kinetic energy of these electrons into thermal energy as they impact and penetrate into the workpiece on which they are impinging causes the weld-seam interface surfaces to melt and produces the weld-joint coalescence desired. Electron beam is applicable to any metal that can be arc welded; weld quality in most metals is equal to or superior to that produced by GTAW. Electron beam welding can also be used to weld some materials that cannot be welded by GTAW, such as certain ceramics.

Because the total kinetic energy of the electrons can be concentrated onto a small area on the workpiece, power densities as high as 10^8 W/cm² (10^7 W/in.²) can be obtained. That is higher than is possible with any other known continuous beam, including laser beams. The high-power density plus the extremely small intrinsic penetration of electrons in a solid workpiece results in almost instantaneous local melting and vaporization of the workpiece material. That characteristic distinguishes EBW from other welding methods in which the rate of melting is limited by thermal conduction.

As noted, one of the prime advantages of EBW is the ability to make welds that are deeper and narrower than arc welds, with a total heat input that is much lower than that required in arc welding. This ability to achieve a high

Fig. 15 Schematic illustration of the (a) melt-in or conduction versus (b) keyhole modes in high-energy-density welding processes, including plasma arc welding, electron beam welding, and laser beam welding.
Source: Ref 2

Fig. 16 Schematic illustrations of the (a) electron beam welding and (b) laser beam welding processes. The former is virtually always operated in a hard vacuum, while the latter can operate in air, in an inert gas atmosphere, or in vacuum. Source: Ref 2

weld depth-to-width ratio eliminates the need for multiple-pass welds, as is required in arc welding. The lower heat input results in a narrow workpiece heat-affected zone (HAZ) and noticeably fewer thermal effects on the workpiece.

In EBW, a high-purity vacuum environment can be used for welding, which results in freedom from impurities such as oxides and nitrides. The ability to employ higher weld speeds, due to the high melting rates associated with the concentrated heat source, reduces the time required to accomplish welding, thereby resulting in an increased productivity and higher energy efficiency for the process. Total energy conversion efficiency of EBW is approximately 65%, which is slightly higher than so-called conventional welding processes and much higher than other types of high-energy-density welding processes, such as LBW.

These EBW process can:

- Minimize distortion and shrinkage during welding
- Facilitate welding of most hardened or work-strengthened metals, frequently without significant deterioration of mechanical properties in the weld joint
- Facilitate welding in close proximity to heat-sensitive components or attachments
- Allow hermetic seal welding of evacuated enclosures while retaining a vacuum inside the component

- Permit welding of refractory metals, reactive metals, and combinations of many dissimilar metals that are not joinable by arc welding processes

The ability to project the electron beam a distance of over 510 mm (20 in.) under high-vacuum conditions, as well as the low end of medium-vacuum conditions, allows otherwise inaccessible welds to be completed.

Equipment costs for EBW generally are higher than those for conventional welding processes. The cost of joint preparation and tooling also is more than that encountered in arc welding processes, because the relatively small electron beam spot size that is used requires precise joint gap and position. The available vacuum chamber capacities are limited; workpiece size is limited, to some degree, by the size of the vacuum chamber employed. Consequently, the production rate (as well as unit cost) is affected by the need to pump down the chamber for each production load. However, when compared to other types of high-energy-density welding (such as LBW), production costs are not as high.

Laser beam welding uses a movable source of intense laser energy (with power densities on the order of 10^5 to 10^7 W/cm²). The word *laser* is the acronym for “light amplification by stimulated emission of radiation.” Lasers provide a source of very coherent radiation (such that radiating waves are highly

synchronized in terms of both frequency and phase), and the coherent nature of the laser beam allows it to be focused to a small spot, leading to high energy densities.

Laser systems had been used since the 1960s for making microwelds in electronic circuit boards, inside vacuum tubes, and in other specialized applications where conventional technology was unable to provide reliable joining. Until the 1970s, laser welding had been restricted to relatively thin materials and low speeds because of the limited continuous power available. High-power continuous-wave carbon dioxide (CO₂) and neodymium-doped yttrium-aluminum-garnet (Nd:YAG) lasers were subsequently developed with potential for deep-penetration welding.

The ability of the laser to generate a power density greater than 10^6 W/cm² (6×10^6 W/in.²) is a primary factor in establishing its potential for welding. Numerous experiments have shown that the laser permits precision (that is, high-quality) weld joints rivaled only by those made with an electron beam.

Laser welding offers the following advantages:

- Light is inertialess (hence, high processing speeds with very rapid stopping and starting become possible).
- Focused laser light provides high energy density.
- Laser welding can be used at room atmosphere.
- Difficult-to-weld materials (for example, titanium, quartz, etc.) can be joined.
- Workpieces do not need to be rigidly held.
- No electrode or filler materials are required.
- Narrow welds can be made.
- Precise welds (relative to position, diameter, and penetration) can be obtained. Welds with little or no contamination can be produced.
- The HAZ adjacent to the weld is very narrow.
- Intricate shapes can be cut or welded at high speed using automatically controlled light-deflection techniques.
- The laser beam can also be time shared.

Like EBW, precise part fit-up and alignment are much more critical in laser welding than in ordinary arc welding. The typical focal spot diameter for a laser beam ranges from 100 to 1000 μm (0.004 to 0.040 in.). Although laser welding equipment is much more expensive than power arc welding systems, laser welding can provide much higher throughput relative to conventional arc welding.

When the capital cost of LBW is compared to EBW, LBW can be a cost-effective option, because no vacuum enclosure is necessary for LBW. However, the penetration depth obtained in laser welding is less than that observed in EBW. For example, the maximum thickness of type 304 stainless steel plate that can be welded using a 77 kW CO₂ laser is on the order

of 50 mm (2 in.). In contrast, an EBW system can produce welds in type 304 stainless steel up to several inches in thickness, if EBW is done under a vacuum. The penetration depth of the EBW process extends only a relatively short distance under atmospheric pressure.

A laser beam, however, can be transmitted an appreciable distance through the atmosphere without serious attenuation or optical degradation because of its coherent nature. Laser beam welding thus offers an easily maneuverable, chemically clean, high-intensity, atmospheric welding process with narrow HAZ and subsequent low distortion. Peak penetration, p_{\max} , for LBW is defined by:

$$p_{\max} \propto P^{0.7}$$

where P is the power (in watts). In terms of weld width (w) and depth (d), both conduction-mode welding ($w/d \geq 1$) and deep-penetration welding ($w/d < 1$) can be obtained with lasers.

Nonfusion (Solid-State) Welding Processes

As described in the preceding article, "Overview of Material Joining Processes," the process of fusion (in which a supply of atoms, in the liquid state, fill the gaps between the limited number of points of intimate contact for the surfaces of real materials) is not the only way to achieve material continuity across a joint to produce a weld. The other option is to use pressure to deform these contacting high points and force more points into intimate contact. This is the basis for producing welds in the solid state in what is known and classified as nonfusion welding or solid-state welding.

The most common energy source for accomplishing nonfusion welding is mechanical and involves the application of pressure to cause either macroscopic or microscopic plastic deformation or to generate friction. Some solid-state welding methods that rely on pressure and macroscopic plastic deformation include:

- Cold welding
- Hot pressure welding
- Roll welding
- Explosion welding

Nonfusion methods using mechanical pressure also can rely on microscopic plastic deformation for solid-state welding. This includes most applications of explosion welding and some forms of diffusion welding (e.g., deformation diffusion welding).

Nonfusion welding processes also rely on energy sources other than mechanical pressure. For example, all forms of friction welding rely on frictional energy (although there is significant plastic deformation in some forms, such as friction stir welding and friction surfacing). Ultrasonic welding also involves the use of

frictional energy for solid-state welding. Nonfusion welding also can be accomplished without pressure of any significant degree by relying solely on solid-state diffusion, as in most forms of diffusion welding. Finally, there are some nonfusion methods that employ chemical reactions as a source of energy, often involving the formation of some reaction layer. These collectively fall under solid-state deposition welding.

Table 2 lists the eight major nonfusion welding processes along with variations within each. Table 3 lists the relative advantages and shortcomings of nonfusion welding processes, the two most notable being:

- Preservation of (or, at least, minimal disruption to) the original microstructure of the materials being joined
- Ability to join widely different materials, even between fundamental types (i.e., metals, ceramics, polymers) (because intermixing on a gross or macroscopic scale is not necessary)

Nonfusion pressure welding processes are based on the fact that most metals and alloys can almost always be plastically deformed; that is, they exhibit some degree of ductility. By applying pressure, the initial high points that come into intimate contact when joint elements are abutted are deformed, and more (less-high) points are brought into contact. Once high points come into contact, atoms move around (i.e., diffuse) in the solid state to attempt to increase the radius at the neck that is formed. The driving force of this mechanism is to reduce the area of free surface. Atoms at the surface of a material, whether solid or liquid, are at a higher energy than those in the interior, which are completely surrounded by other atoms making up the material.

This process can be continued for at least some time by applying greater and greater pressures, but it can absolutely be facilitated by applying some heat in addition to the deformation. By heating the base metals being pressure welded, three favorable things take place:

- The stress required to cause plastic deformation is lowered, as the strength of metals and alloys decreases with increasing temperature.
- The deforming metal is not able to strain harden, as thermal recovery processes take place.
- Atoms in each joint element migrate (i.e., diffuse) across the interface into the other joint element, tending to obliterate the interface.

When deformation is done below the recrystallization temperature of the material, the processes are known generically as cold welding. When it is done at temperatures above the recrystallization temperature, the processes are generically known as hot pressure welding. One form of pressure welding that can be performed cold or hot, or in between (i.e., warm), is roll welding. As shown schematically in

Table 2 List of the eight major nonfusion (solid-state) welding processes with variations within each

1. Cold welding	Press welding Forge welding Roll welding Toggle welding Hydrostatic impulse welding Shock-wave impulse welding
2. Hot pressure welding	Pressure gas welding Forge welding
3. Roll pressure welding	Hot, warm, or cold roll welding
4. Explosion welding	
5. Friction welding	Radial friction welding Orbital friction welding Rotational friction welding Direct-drive welding Inertia welding Angular (reciprocating) friction welding Linear (reciprocating) friction (or vibration) welding Friction stir welding Friction surfacing
6. Ultrasonic welding (USW)	Spot, ring, line, and seam USW Microminiature welding Microminiature thermosonic welding
7. Diffusion welding	Conventional diffusion welding Deformation diffusion welding Resistance diffusion welding Continuous seam diffusion welding Diffusion brazing Combined forming/welding Creep isostatic pressing Superplastic forming/diffusion bonding
8. Solid-state deposition welding	Electrochemical deposition Vapor deposition Chemical vapor deposition Chemical reaction bonding

Source: Ref 5

Fig. 17, this process squeezes two sheets of usually dissimilar metals or alloys together to form a clad bimetal. A well-known example is the roll welding of pure copper onto various stainless steels. Such bimetal feedstock is used for making high-end cookware with heat-dispersing bottoms as well as liners for electrochemical plating and processing tanks.

Diffusion Welding/Bonding. In diffusion welding, the only real need for pressure is to hold the parts to be welded in contact. The principal factor is the temperature at which the process is carried out, because atomic diffusion in the solid state increases exponentially with temperature. This means that the rate at which atoms move doubles with every 30 °C (50 °F) increase in temperature. It is easy to see that the rate of diffusion is increased many orders of magnitude (i.e., thousands to millions of

Table 3 Relative advantages and shortcomings of nonfusion welding processes

Advantages	Shortcomings
1. General absence of melting and thus solidification (so, structure is retained)	1. Stringent requirements for cleaning joint faying surfaces for some processes (e.g., CW, ROW, HPW, DFW, and solid-state deposition welding)
2. Low heat input (minimally disrupts microstructure)	2. Elaborate tooling is required for some processes (e.g., DFW)
3. Wide variety of process embodiments	3. Challenging inspection of joint quality
4. Applicable to many materials within a class as well as between classes (since there is little or no intermixing)	4. Repairing process-induced defects is difficult to impossible.
5. High joint efficiency is possible for many situations where the same cannot be said for fusion welding processes.	5. Processes require specialized equipment, are rarely portable, and almost always must be automated.

Fig. 17 Schematic illustration of the roll welding process producing clad metals or bimetal strips of sheet. Source: Ref 5

times faster). Once again, the driving force for diffusion to cause welding is the thermodynamic benefit of lowering the free surface area between materials.

Explosion Welding. An unusual nonfusion welding process is explosion welding. As shown schematically in Fig. 18, this process uses the detonation of high-velocity explosive charges to accelerate a prime component so that it slams into a base component. A weld is formed virtually instantaneously when microscopic surface asperities are deformed to bring virtually all of the atoms on both sides of the interface into intimate contact. As the prime component rushes toward the base component, the air between the two is expelled at supersonic velocities, which scrubs off any potentially weld-inhibiting tarnish layers. Examination of the metal in the vicinity of the newly formed weld (and prior interface) exhibits almost turbulent plastic flow over short dimensions in the thickness direction. The process tends to be used only for welding one thick, simply-shaped (often a plate) component to another.

Friction welding processes produce welds in essentially the same way as the just-described pressure welding processes. The main difference is that the plastic deformation occurs on a microscopic rather than a macroscopic scale. In fact, the origin of friction when one nonlubricated metal rubs over another is actually the occurrence of microwelding.

In all friction welding, it is necessary to move one part relative to the other while a squeezing force is being applied. This is what gives rise to the friction (as the force of friction is equal to the squeezing force times the coefficient of friction between the two materials/forms). The friction simultaneously generates heat at the interface and causes plastic deformation on a microscopic-length scale. Specific processes of friction welding (as shown in Table 2) include radial and orbital friction welding, direct-drive and inertia rotational friction welding, angular friction welding, and linear (reciprocating) or vibration friction welding.

Ultrasonic welding is also a friction welding process; however, the frequency of vibration between abutted parts is greater than 25 to 30 kHz (i.e., in the ultrasound region beyond human hearing), and the amplitudes of movement are very small. Ultrasonic welding has found its greatest usage in the welding of thermoplastics (i.e., those plastics that soften upon heating and stiffen upon cooling) under what is widely classified as plastics welding.

Solid-State Deposition Welding Processes. Finally, there are a few processes by which metals (as well as ceramics) can be joined in the solid state, that is, via a nonfusion process. While not often thought of as welding processes, they really are, because what is being accomplished is primary atomic bond formation by bringing atoms into intimate contact with

Fig. 18 Schematic illustration of the explosion welding process showing (a) the typical component arrangement and (b) the characteristic action between components during welding. Source: Ref 5

one another. Table 2 lists some of the more common examples of solid-state deposition welding processes.

Brazing and Soldering

Both brazing and soldering rely on primary bonding and on interdiffusion between joined materials to form the soundest joints, just as welding processes do. The difference is that neither brazing nor soldering involve any melting (or fusion) of the base materials. Rather, bond formation occurs between the ever-solid substrates and a molten filler metal with a melting point below that of the base materials. Specific embodiments within both brazing and soldering are remarkably similar in terms of the energy source used and the method of filler application, while they differ only in the melting point of fillers used. Table 4 lists a variety of the most common embodiments of brazing and soldering to allow comparisons to be made.

Brazing is a process for joining solid metals in close proximity (i.e., carefully gapped 0.025 to 0.125 mm, or 0.001 to 0.005 in.) by introducing a liquid metal that melts above 450 °C (840 °F). A sound brazed joint generally results when an appropriate filler alloy is selected, the parent metal surfaces are clean and remain clean during heating to the flow temperature of the brazing alloy, and a suitable joint design that allows capillary action is used.

Table 4 Comparison of the most common brazing and soldering process methods

	Brazing	Soldering
Chemical heat sources		
Gas torch	Torch brazing(a)	Torch soldering(a)

(a) Localized vs. generalized heating

Strong, uniform, leakproof joints can be made rapidly, inexpensively, and even simultaneously. Joints that are inaccessible and parts that may not be joinable at all by other methods often can be joined by brazing. Complicated assemblies comprising thick and thin sections, odd shapes, and differing wrought and cast alloys can be turned into integral components by a single trip through a brazing furnace or a dip pot. Metal as thin as 0.01 mm (0.0004 in.) and as thick as 150 mm (6 in.) can be brazed.

The effective strength of a brazed joint is high. The nature of the interatomic (metallic) bond is such that even a simple joint, when properly designed and made, will have strength equal to or greater than that of the as-brazed parent metal.

The mere fact that brazing does not involve any substantial melting of the base metals may offer several advantages over other welding processes. It is generally possible to maintain closer assembly tolerances and to produce a cosmetically neater joint without costly secondary operations. Even more important, however, is that brazing makes it possible to join dissimilar metals (or metals to ceramics) that, because of metallurgical incompatibilities, cannot be joined by traditional fusion welding processes. (If the base metals do not have to be melted to be joined, it does not matter that they have widely different melting points. Therefore, steel can be brazed to copper as easily as to another steel.)

Brazing also generally produces less thermally induced distortion, or warping, than fusion welding. An entire part can be brought up to the same brazing temperature, thereby preventing the kind of localized heating that causes distortion in welding.

Finally, and perhaps most important to the manufacturing engineer, brazing readily lends itself to mass-production techniques. It is relatively easy to automate, because the application of heat does not have to be localized, as in fusion welding, and the application of filler metal is less critical. In fact, given the proper clearance conditions and heat, a brazed joint tends to "make itself" and is not dependent on operator skill, as are most fusion welding processes.

Automation is also simplified by the fact that there are many means of applying heat to the joint, including torches, furnaces, induction coils, electrical resistance, and dipping. Several joints in one assembly often can be produced in one multiple-braze operation during one heating cycle, further enhancing production automation.

Soldering is a joining process by which two substrates are bonded together using a filler metal (solder) with a liquidus temperature that does not exceed 450 °C (840 °F). The substrate materials remain solid during the bonding process. The solder is usually distributed between the properly fitted surfaces of the joint by capillary action.

The bond between solder and base metal is more than adhesion or mechanical attachment, although these do contribute to bond strength. Rather, the essential feature of the soldered joint is that a metallurgical bond is produced at the filler-metal/base-metal interface. The solder reacts with the base-metal surface and wets the metal by intermetallic compound formation. Upon solidification, the joint is held together by the same attraction, between adjacent atoms, that holds a piece of solid metal together. Even after the joint has completely solidified, diffusion between the base metal and the soldered joint continues for a while as the completed part cools. Mechanical properties of soldered joints therefore are generally related to, but not equivalent to, the mechanical properties of the soldering alloy.

Mass soldering by wave, drag, or dip machines has been a preferred method for making high-quality, reliable connections for many decades. Correctly controlled, soldering is one of the least expensive methods for fabricating electrical connections.

Welding Process Fundamentals*

Thomas W. Eagar and Aaron D. Mazzeo, Massachusetts Institute of Technology

WELDING AND JOINING processes are essential for the development of virtually every manufactured product. However, these processes often appear to consume greater fractions of the product cost and to create more of the production difficulties than may be expected. There are a number of reasons that explain this situation.

First, welding and joining are multifaceted, both in terms of process variations (such as fastening, adhesive bonding, soldering, brazing, arc welding, diffusion bonding, and resistance welding) and in the disciplines needed for problem solving (such as mechanics, materials science, physics, chemistry, and electronics). An engineer with unusually broad and deep training is required to bring these disciplines together and to apply them effectively to a variety of processes.

Second, welding or joining difficulties usually occur far into the manufacturing process, where the relative value of scrapped parts is high.

Third, a very large percentage of product failures occur at joints because they are usually located at the highest stress points of an assembly and are therefore the weakest parts of that assembly. Careful attention to weldment design and joining processes can produce great rewards in manufacturing economy and product reliability.

The purpose of this Section of the Volume is to discuss the fundamentals of fusion welding processes, with an emphasis on the underlying scientific principles.

Because there are many fusion welding processes, one of the greatest difficulties for the manufacturing engineer is to determine which process will produce acceptable properties at the lowest cost. There are no simple answers. Any change in the part geometry, material, value of the end product, or size of the production run, as well as the availability of joining equipment, can influence the choice of joining method. For small lots of complex parts, fastening may be preferable to welding,

whereas for long production runs, welds can be stronger and less expensive.

The perfect joint is indistinguishable from the material surrounding it. Although some processes, such as diffusion bonding, can achieve results that are very close to this ideal, they are either expensive or restricted to use with just a few materials. There is no universal process that performs adequately on all materials in all geometries. Nevertheless, virtually any material can be joined in some way, although joint properties equal to those of the bulk material cannot always be achieved.

The economics of joining a material may limit its usefulness. For example, aluminum is used extensively in aircraft manufacturing and can be joined by using adhesives or fasteners, or by welding. However, none of these processes has proven economical enough to allow the extensive replacement of steel by aluminum in the frames of nonluxury automobiles. An increased use of composites in aircrafts is limited by an inability to achieve adequate joint strength in the original product or to repair a product that has been in service.

It is essential that the manufacturing engineer work with the designer from the point of product conception to ensure that compatible materials, processes, and properties are selected for the final assembly. Often, the designer leaves the problem of joining the parts to the manufacturing engineer. This can cause an escalation in cost and a decrease in reliability. If the design has been planned carefully and the parts have been produced accurately, the joining process becomes much easier and cheaper, and both the quality and reliability of the product are enhanced.

Generally, any two solids will bond if their surfaces are brought into intimate contact. One factor that generally inhibits this contact is surface contamination. Any freshly produced surface exposed to the atmosphere will absorb oxygen, water vapor, carbon dioxide, and hydrocarbons very rapidly. If it is assumed that each molecule that hits the surface will be

absorbed, then the time-pressure value to produce a monolayer of contamination is approximately $0.001 \text{ Pa} \cdot \text{s}$ ($10^{-8} \text{ atm} \cdot \text{s}$). For example, at a pressure of 1 Pa (10^{-5} atm), the contamination time is 10^{-3} s , whereas at 0.1 MPa (1 atm), it is only $10 \times 10^{-9} \text{ s}$ (Ref 1).

In fusion welding, intimate interfacial contact is achieved by interposing a liquid of substantially similar composition as the base metal. If the surface contamination is soluble, then it is dissolved in the liquid. If it is insoluble, then it will float away from the liquid-solid interface.

Energy-Source Intensity

One distinguishing feature of all fusion welding processes is the intensity of the heat source used to create the molten condition. Virtually every concentrated heat source has been applied to the welding process. However, many of the characteristics of each type of heat source are determined by its intensity. For example, when considering a planar heat source diffusing into a very thick slab, the surface temperature will be a function of both the surface power density and the time.

Figure 1 shows how this temperature will vary on steel with power densities that range from 400 to 8000 W/cm^2 .

At the lower value, it takes less than a minute to melt the surface. If that heat source were a point on the flat surface, as shown in Fig. 2, then the heat flow would be divergent and not melt the steel. This shows the dramatic effect of divergent heat flow and the need for higher heat intensities when the heat source is a laser, an arc, or a point source compared to a planar heat source as developed in friction welding. Rather, the solid metal would be able to conduct away the heat as fast as it was being introduced. It is generally found that point heat-source power densities of approximately 1000 W/cm^2 are necessary to melt most metals.

* Updated and revised from T.W. Eagar, Energy Sources Used for Fusion Welding, *Welding, Brazing, and Soldering*, Vol 6, *ASM Handbook*, ASM International, 1993.

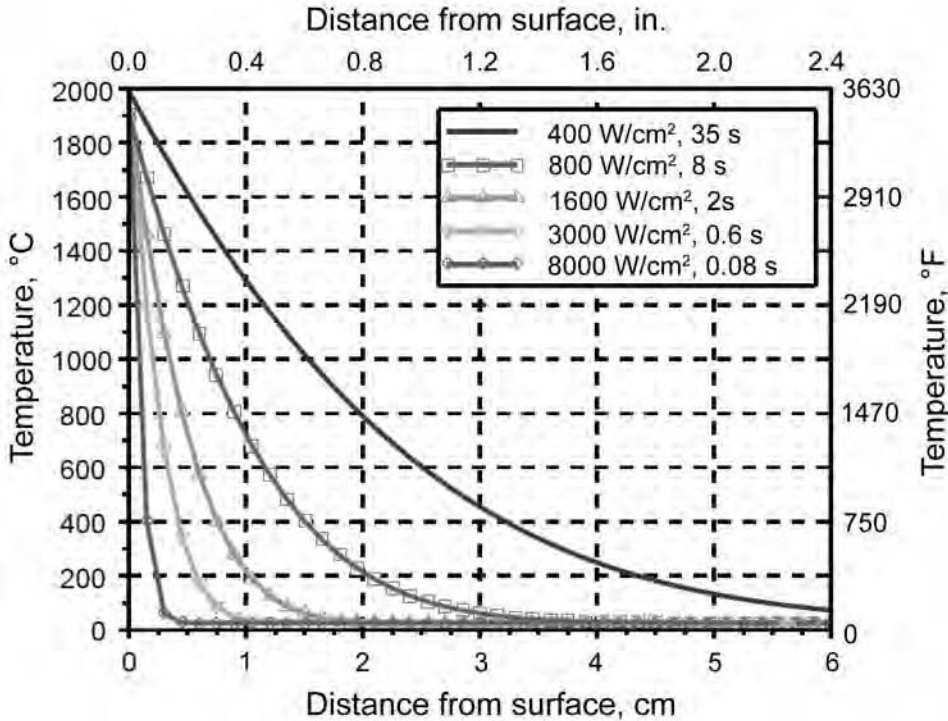

Fig. 1 Temperature distribution after a specific heating time in a thick steel plate heated uniformly on one surface as a function of applied heat intensity. Initial temperature of plate is 25 °C (77 °F), thermal conductivity is 50 W/m · K, specific heat capacity is 475 J/kg · K, density is 7800 kg/m³ (0.28 lb/in.³), and thermal diffusivity is 0.13 cm²/s.

At the other end of the power-density spectrum, heat intensities of 10⁶ or 10⁷ W/cm² will vaporize most metals within a few microseconds. At levels above these values, all of the solid that interacts with the heat source will be vaporized (resulting in hole drilling), and no fusion welding can occur. Thus, the heat sources for all fusion welding processes should have power densities between approximately 0.001 and 1 MW/cm². This power-density spectrum is shown in Fig. 3, along with the points at which common joining processes are employed (Ref 2, 3).

The fact that power density is inversely related to the interaction time of the heat source on the material is evident in Fig. 1. Because this represents a transient heat conduction problem, one can expect the heat to diffuse into the steel to a depth that increases as the square root of time, that is, from the Einstein equation:

$$x \sim \sqrt{\alpha t} \tag{Eq 1}$$

where x is the distance that the heat diffuses into the solid, in centimeters; α is the thermal diffusivity of the solid, in cm²/s; and t is the time in seconds. Tables 1 and 2 give the thermal diffusivities of common elements and common alloys, respectively. In addition, Table 3 shows how thermal diffusivity of materials can vary with temperature.

For the planar heat source on a steel surface, as represented by Fig. 1 and 4, the time in

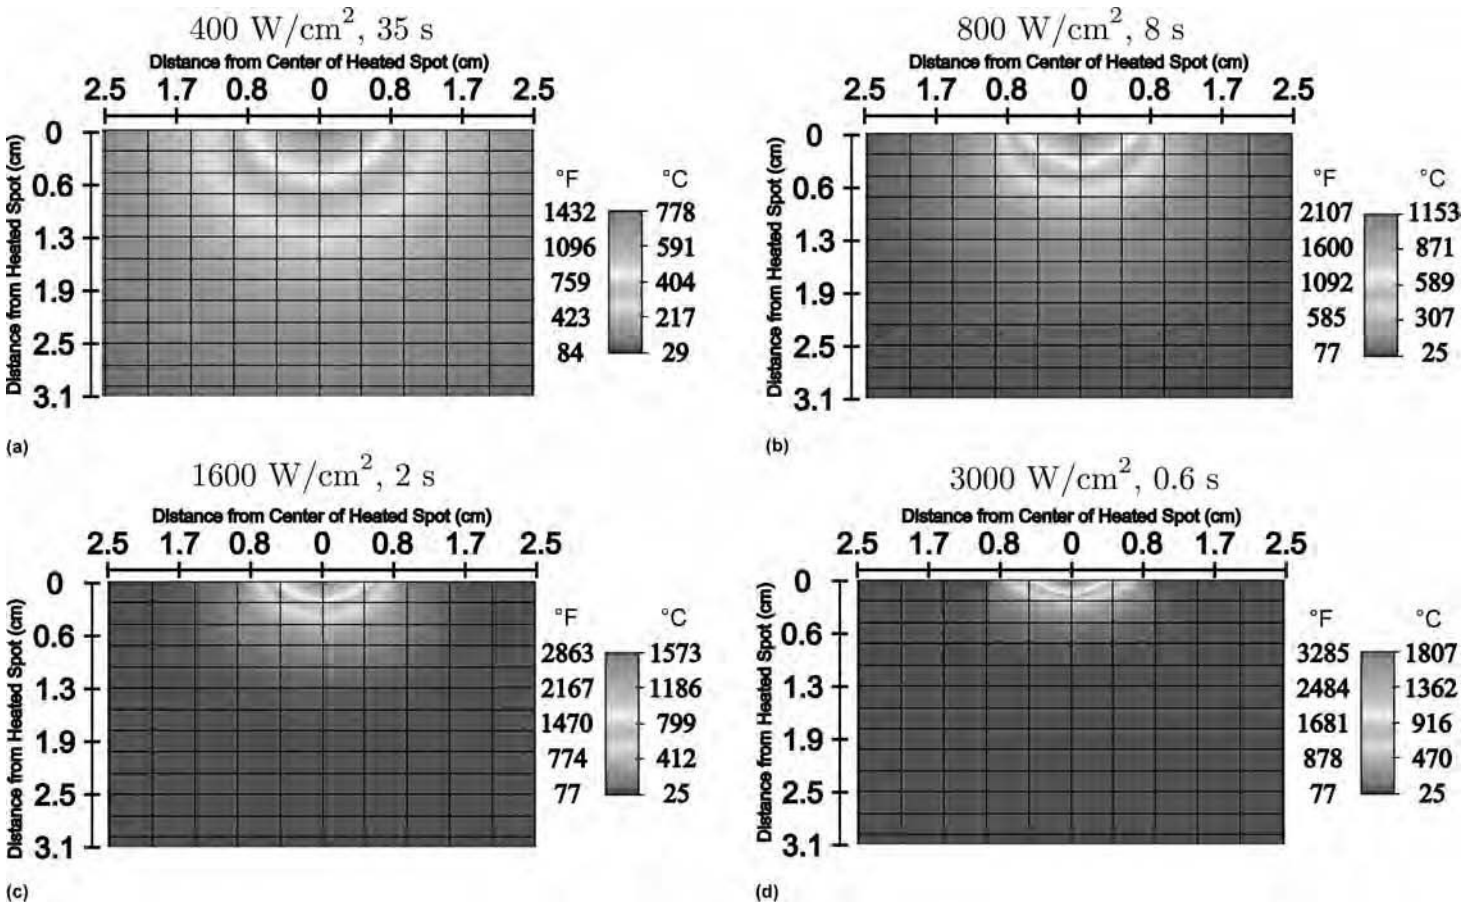

Fig. 2 Finite-element analysis temperature distribution results after a specific heating time in a thick steel plate heated over a 1 cm (0.4 in.) wide region on the top surface. Initial temperature of plate is 25 °C (77 °F), thermal conductivity is 50 W/m · K, specific heat capacity is 475 J/kg · K, density is 7800 kg/m³ (0.28 lb/in.³), and thermal diffusivity is 0.13 cm²/s. Images are magnified views of a 6.25 cm tall by 10 cm wide (2.5 in. tall by 4.0 in. wide) cross section.

Fig. 3 Spectrum of practical heat intensities used for fusion welding

seconds for the heated surface temperature to increase by an amount ΔT is given by:

$$t = \pi k^2 (\Delta T)^2 / [4\alpha(H.I.)^2 \times 10^4] \quad \text{(Eq 2)}$$

where H.I. is the net heat intensity (in W/cm^2) transferred to the workpiece, k is the thermal conductivity (in $W/m \cdot K$) of the material, and α is the thermal diffusivity of the material (in cm^2/s) (Ref 8). The time in seconds to produce melting on the surface, t_m , is given by:

$$t_m = (1800/H.I.)^2 \quad \text{(Eq 3)}$$

where H.I. is the net heat intensity (in W/cm^2).

Equation 3 provides a rough estimate of the time required to produce melting and is based on the thermal diffusivity of steel. Materials with higher thermal diffusivities—or the use of a local point heat source (with divergence of heat flux) rather than a planar heat source—will increase the time to produce melting by a factor of up to 2 to 5 times. On the other hand, thin materials tend to heat more quickly.

If the time to melting is considered to be a characteristic interaction time, t_i , then the graph shown in Fig. 5 can be generated. Heat sources with power densities that are of the order of $1000 W/cm^2$, such as oxyacetylene flames or electroslag welding, require interaction times on the order of 1 s with steel, whereas laser and electron beams, at $1 MW/cm^2$, need interaction times on the order of only 1 μs . If this interaction time is divided into the heat-source diameter, d_H , then a maximum travel speed, V_{max} , is obtained for the welding process (Fig. 6).

The reason why welders begin their training with the oxyacetylene process should be clear: this process is inherently slow and does not require rapid response time to control the size of the weld puddle. Greater skill is needed to control the more-rapid fluctuations in arc processes, where the reaction time required is less than a second. The weld pool created by the high-heat-intensity processes, such as laser beam and electron beam welding, cannot be humanly controlled and must therefore be automated. This need to automate leads to increased capital costs. On an approximate basis, the heat intensity in W/cm^2 of a process can be substituted

Note: Some specific heat and conductivity values for AISI 1025 are estimated by two-point weighted averaging values from Ref 5.

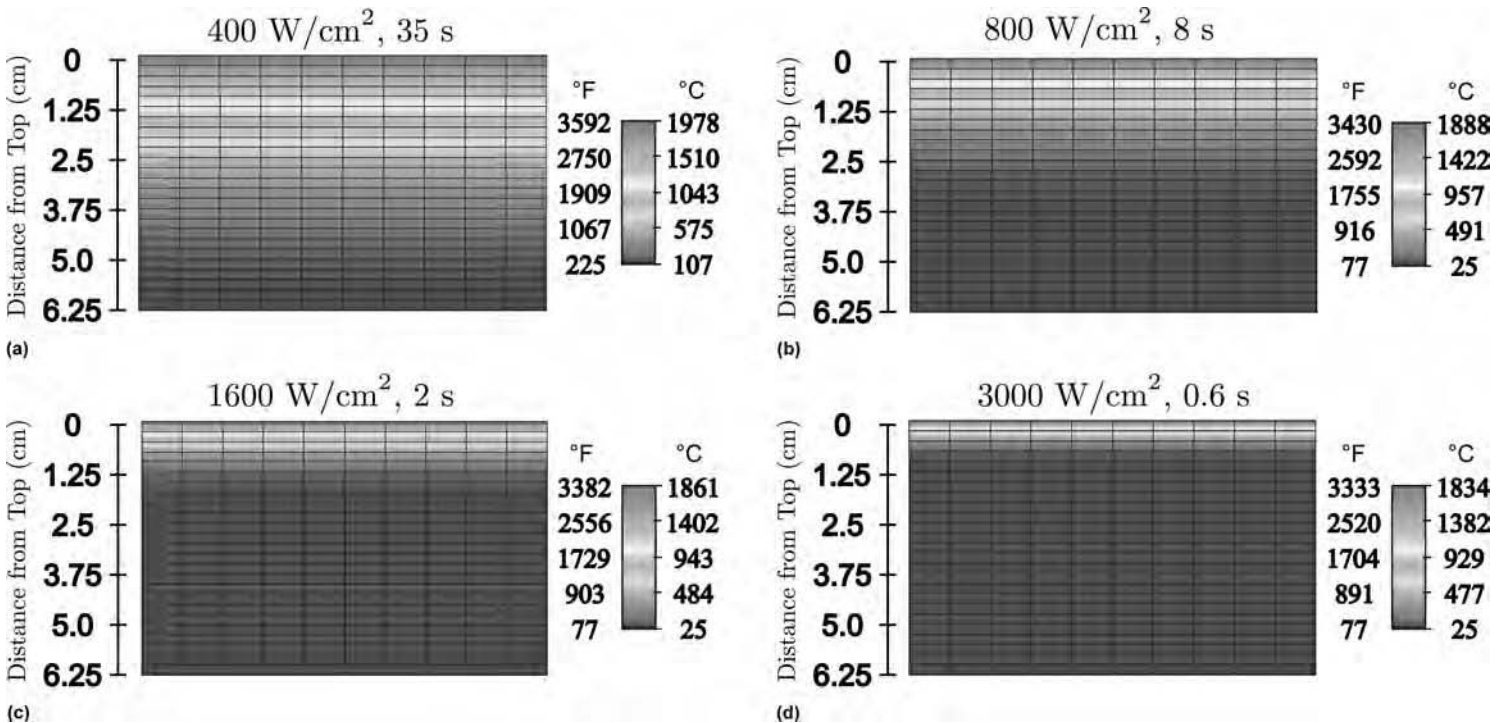

Fig. 4 Finite-element analysis temperature distribution results after a specific heating time in a thick steel plate heated uniformly on one surface as a function of applied heat intensity. Initial temperature of plate is 25 °C (77 °F), thermal conductivity is 50 W/m · K, specific heat capacity is 475 J/kg · K, density is 7800 kg/m³ (0.28 lb/in.³), and thermal diffusivity is 0.13 cm²/s.

with the dollar cost of the capital equipment. With reference to Fig. 3, the cost of oxyacetylene welding equipment is nearly \$1000, whereas a fully automated laser beam or electron beam

system can cost \$1 million. Note that the capital cost includes only the energy source, control system, fixturing, and materials handling equipment. It does not include operating,

maintenance, or inspection costs, which can vary widely depending on the specific application.

For constant total power, a decrease in the spot size will produce a squared increase in

the heat intensity. This is one of the reasons why the spot size decreases with increasing heat intensity (Fig. 6). It is easier to make the spot smaller than it is to increase the power rating of the equipment. In addition, only a small volume of material usually needs to be melted. If the spot size were kept constant and the input power were squared to obtain higher densities, then the volume of fused metal would increase dramatically, with no beneficial effect.

However, a decreasing spot size, coupled with a decreased interaction time at higher power densities, compounds the problem of controlling the higher-heat-intensity process. A shorter interaction time means that the sensors and controllers necessary for automation must operate at higher frequencies. The smaller spot size means that the positioning of the heat source must be even more precise, that is, on the order of the heat-source diameter, d_H . The control frequency must be greater than the travel velocity divided by the diameter of the heat source. For processes that operate near the maximum travel velocity, this is the inverse of the process interaction time, t_1 (Fig. 5).

Thus, not only must the high-heat-intensity processes be automated because of an inherently high travel speed, but the fixturing requirements become greater, and the control systems and sensors must have ever-higher frequency responses. These factors lead to increased costs, which is one reason that the very productive laser beam and electron beam

welding processes have not found wider use. The approximate productivity of selected welding processes, expressed as length of weld produced per second, to the relative capital cost of equipment is shown in Fig. 7.

Another important welding process parameter that is related to the power density of the heat source is the width of the heat-affected zone (HAZ). This zone is adjacent to the weld metal and is not melted itself but is structurally changed because of the heat of welding. Using the Einstein equation, the HAZ width can be estimated from the process interaction time and the thermal diffusivity of the material. This is shown in Fig. 8, with one slight modification. At levels above approximately 10^4 W/cm², the HAZ width becomes roughly constant. This is due to the fact that the HAZ grows during the heating stage at power densities that are below 10^4 W/cm², but at higher power densities it grows during the cooling cycle. Thus, at low power densities, the HAZ width is controlled by the interaction time, whereas at high power densities, the width is independent of the heat-source interaction time. In the latter case, the HAZ width grows during the cooling cycle as the heat of fusion is removed from the weld metal and is proportional to the fusion zone width.

The change of slope in Fig. 8 also represents the heat intensity at which the heat utilization efficiency of the process changes. At high heat intensities, nearly all of the heat is used to melt

the material, and little is wasted in preheating the surroundings. As heat intensity decreases, this efficiency is reduced. For arc welding, as little as half of the heat generated may enter the plate, and only 40% of this heat is used to fuse the metal. For oxyacetylene

Fig. 5 Typical weld pool/heat source interaction times as a function of heat-source intensity. Materials with a high thermal diffusivity, such as copper or aluminum, would lie near the top of the band, whereas magnesium alloys and steels would lie in the middle. Titanium alloys, with very low thermal diffusivities, would lie near the bottom of the band.

Fig. 6 Maximum weld travel velocity as a function of heat-source intensity based on typical heat-source spot diameters

Fig. 7 Approximate relationship between capital cost of welding equipment and speed at which sheet metal joints can be produced

Fig. 8 Range of weld heat-affected zone widths as a function of heat-source intensity

welding, the heat entering the metal may be 10% or less of the total heat, and the heat necessary to fuse the metal may be less than 2% of the total heat.

A final point is that the heat intensity also controls the depth-to-width ratio of the molten pool. This value can vary from 0.1 for low-heat-intensity processes to more than 10 for high-heat-intensity processes.

It should now be evident that all fusion welding processes can be characterized generally by heat-source intensity. The properties of any new heat source can be estimated readily from the figures in this article. Nonetheless, it is useful to more fully understand each of the common welding heat sources, such as flames, arcs, laser beams, electron beams, and electrical resistance.

These are described in separate articles on fusion welding processes in this Volume.

THE HEAT THAT IS SUPPLIED TO THE WORKPIECE, which then is transferred within the workpiece to produce melting, forms the basis of every welding process. The heat-transfer process, or thermal cycle, in the weldment has many consequences, including the complex metallurgical changes that take place in the fusion zone, where the metal is melted and subsequently solidified, and in the adjacent heat-affected zone, where material is heated to temperatures that are below the melting point but are sufficiently high to produce changes in the microstructure and in mechanical properties.

Three types of energy are used primarily as direct heat sources for fusion welding: electric arcs, laser beams, and electron beams. Oxyfuel gas welding is also used occasionally, and internal joule heating arising from electrical resistance is also common for welding of thin material. However, fusion welding using internal joule heating, that is, resistance welding, does not involve the use of a direct heat source. The intensity or energy distribution associated with the direct heat sources may vary dramatically and, to a large degree, dictates the use of these heat sources for welding. The total amount of heat (Q) that is provided to the workpiece is measured in watts (W) and may be defined by the welding parameters, such as welding current times welding voltage for arc processes, or directly for laser beam welding, because laser output power is usually provided in watts. The amount of energy that the welding heat source provides per unit of cross-sectional area is referred to as the heat flux (q) and is defined in watts per square meter (W/m^2). A general portrayal of the heat flux associated with a direct welding source may be described by its energy distribution. Figure 1 illustrates the differences in energy distribution of various heat sources, as well as the melting patterns of

the base metal generally associated with these sources. As illustrated in the figure, the oxyfuel gas welding process is a diffuse or distributed heat source, whereas the laser beam and electron beam welding processes are defined as high-energy-density processes. The heat source of arc welding processes may be described as being between the diffuse and high-energy-density sources. Also as shown in Fig. 1, the distribution of energy within the heat source plays an important role in determining the potential fusion zone geometry. Although the distribution of energy during welding is of significance, another critical factor is the energy-transfer efficiency, the ratio of the amount of energy provided by the heat source to the quantity that is transferred to the base material. As with energy density, the four heat sources primarily used for fusion welding vary greatly as to their energy-transfer efficiencies.

Because of the important role the heat source plays during welding, the ability to accurately define the energy provided to the workpiece, as well as the amount transferred for welding, is of interest for theoretical as well as practical considerations. The description of the input-energy source is basic to any numerical modeling formulation designed to predict the outcome of the welding process. Both the magnitude and distribution of the source are fundamental and unique to each joining process, and the resultant output of any numerical model is therefore affected by the initial description of the heat source. An understanding of both the physics and the mathematical simulation of these sources is essential for characterizing the heat source. This article briefly reviews the physical phenomena that influence the input-energy distribution and discusses several simplified and detailed heat-source models

Fig. 1 Schematic of energy densities and melt patterns associated with various heat sources used for fusion joining. (a) Oxyfuel flame. (b) Gas tungsten arc. (c) Laser beam. (d) Electron beam. Q , total amount of heat

that have been used in the modeling of arc welding, high-energy-density welding, and resistance welding processes.

Simplified Modeling of the Heat Source

Analytical modeling of the welding heat source is generally complex, because of the nature of energy transfer to the workpiece, whether the source of that energy is an arc, a high-energy-density beam of electrons or laser light, or joule heating. For numerical modeling purposes, heat input to the weldment is usually applied as a distribution of surface flux, a distribution of heat generated internally, or a combination of both. Many analytical treatments, however, have sought to simplify the characterization of the heat source by assuming that the effective thermal energy supplied by the heat source is deposited in such a narrow band of material that it may be idealized mathematically as a point or a line source, depending on the geometry of the weldment (Ref 1). Heat input idealizations of this sort lend themselves to the derivation of closed-form welding temperature solutions and the avoidance of developing numerical finite-element or finite-difference models to calculate temperatures. These solutions are valid only for simple geometries and in regions removed from the fusion and heat-affected zones, where details of the distribution of heat input from the source and accurate representations of the thermal energy transferred from the weld bead to the rest of the weld joint are not important.

The fundamental simplified heat-source model is developed for a flat plate of infinite extent bounded by the planes $z = 0$ and $z = h$. Heat is input at a point that is either stationary or is moving at uniform speed, v , in the x -direction on the surface $z = 0$, so that at any time, t , the point source is located at $x = vt$ (Fig. 2). If the end effects that result from the initiation

Fig. 2 Moving point source in infinite plate

or termination of the heat source or the finite dimensions of the weldment are neglected, then the resulting temperature distribution associated with the moving source is stationary with respect to a moving coordinate system, the origin of which coincides with the point of application of the heat source. This class of temperature response is termed quasi-stationary.

In general, for either a stationary or a moving point source, heat is conducted through the plate without hindrance until the insulating effect of the ideally adiabatic surface at $z = h$ is felt. For a sufficiently thick plate, the temperature rise at $z = h$ is so small that the solution for an infinitely thick plate, which is associated with a single source of heat, is applicable. For a moderately thick plate, the temperature rise at $z = h$ from the infinitely thick plate point-source solution is large enough to result in nonzero heat flow at $z = h$. An image source of the same strength applied at $z = 2h$ ensures that the surface $z = h$ is adiabatic. However, the image source produces nonzero heat flow at $z = 0$, and another image source applied at $z = -2h$ is now required to satisfy conditions at $z = 0$.

Carrying this imposition of image point sources of heat along ad infinitum (Fig. 3), an infinite distribution of image sources superposed with the original source at $z = 0$ yields the desired adiabatic conditions at both the $z = 0$ and $z = h$ surfaces. The temperature solution for this series of image sources is in the form of an infinite series (Ref 2), which converges more rapidly for thicker plates. The solution for the moderately thick plate applies to thin plates as well, but convergence of the infinite series would be extremely slow. As an

Fig. 3 Superposition of image sources in finite-thickness plate

alternative, the heat source can be applied as a line source distributed uniformly through the thickness (Ref 3). This simplified approach eliminates any variation of the temperature distribution through the thickness and is often used to model high-energy-density welding processes that result in the formation of a keyhole, as is discussed later.

Offshoots of these cases also have been developed. These include considerations of plates of finite width, in which case sets of image sources are needed to ensure adiabatic conditions at the edges (Ref 4); line sources of heat traveling on a circular path (Ref 5); and conditions that simulate either initiation or termination of the heat source (Ref 6). Variations of the moving point source approach have been employed (Ref 7) to calculate the temperatures needed for weld-induced residual stress calculations in piping.

Arc Welding

Gas Tungsten Arc Welding

Gas tungsten arc welding (GTAW) is the most frequently modeled arc welding process in which the heat source is a nonconsumable electrode. In the direct current electrode negative (DCEN) process, the pieces of material are joined together by energy that is transferred to the workpiece by four primary mechanisms (Ref 8):

- Kinetic energy of the electrons that constitute the arc current
- Heat of condensation of the electrons (work function) penetrating the solid work surface
- Radiation from the arc
- Thermal conduction from the arc plasma to the workpiece

The first two mechanisms constitute the major source of energy to the weldment (Ref 9). Also, because electrons are negatively charged, they inherently travel from the negative to the positive pole of the arc, and hence, welding polarity may have a large effect on the transfer of energy. Welding using direct current electrode negative (DCEN), such as with the gas tungsten arc process, utilizes the electrons traveling from the tungsten electrode to the positive workpiece to provide a fairly efficient transfer of energy to the base metal. Employing direct current electrode positive (DCEP), such as with gas metal arc welding, results in electrons being directed from the base metal to the positive consumable electrode with lower energy transfer to the workpiece. The use of variable polarity may be viewed as a compromise between DCEN and DCEP.

Because of the complicated nature in which energy is transferred from the arc, heat input to the weldment can be modeled by one of the point- or line-source approaches discussed in the preceding section of this article. If none of

these treatments is appropriate for the particular application, then a more realistic approach is to input the energy by a distribution of surface flux, a distribution of heat generated internally, or a combination of the two. If an internal heat distribution is confined to a thin layer of material adjacent to the heated surface, then the choice of heat-input model is immaterial (Ref 10). The magnitude of heat input to the workpiece is expressed simply as the product of what has traditionally been defined as the arc power (that is, the product of the voltage drop across the arc and the arc current) and the arc transfer efficiency, which account for energy losses from the arc.

Estimates of arc efficiency can be made by conducting calorimetry measurements, correlating computed temperatures with thermocouple readings from test welds, or using some other observable response to the welding thermal cycle. Because the voltage used is usually determined from measurements at some point within the power supply, estimates must be made to account for losses within the electrode and other parts of the system (Ref 11). Changes in welding process variables, such as shielding gas, electrode configuration, arc gap, and minor element additions to the arc, affect arc efficiency, as does the material that is being welded (Ref 12).

The magnitude of heat applied to the weldment surface may not be known with great accuracy, and the distribution of the heat input is even more uncertain. Input-energy distribution depends on factors related to the electrode and the physics of the arc, as well as on the interaction of the arc with the molten weld pool. For example, the arc characteristics and the depth-to-width ratio of the weld puddle will change as the vertex angle of the conical tip of the electrode is altered (Fig. 4). As the arc becomes more constricted, the heat source becomes more concentrated, thus increasing

weld penetration. Changes in heat-source distribution (that is, input current) will affect the electromagnetic forces in both the arc and the weld puddle, resulting in changes in weld-puddle motion, which can promote alterations in convection heat transfer within the weld puddle. Shielding gas composition and minor alloying elements also can influence the distribution of input energy.

When welding at low currents and high voltages, the perturbation of the weld-puddle surface may be considered to have a small effect on the heat-input distribution, and a model that considers heat to be applied as a surface flux is usually satisfactory. However, as the current increases (particularly when the arc voltage is small, indicating a short electrode-to-work surface distance), the arc jet can depress the weld-puddle surface and affect the configuration of the distribution on the surface of the weldment (Fig. 5). The effects of depressing the weld puddle can be accommodated empirically by postulating some or all of the heat from the arc to be deposited internally. However, the specification of an internal heat-generation distribution is more complex than that of a surface flux.

For models in which heat from the welding arc is postulated to be deposited on the surface of the weldment, the input energy is often assumed to be a radially symmetric, normally distributed surface flux at any instant in time (Ref 13). The heat flux provided by the source, q , can be expressed conveniently as an exponential, or Gaussian, function, such that:

$$q(r) = \left(\frac{3fQ}{\pi r'^2}\right) \exp\left[-3\left(\frac{r}{r'}\right)^2\right] \quad (\text{Eq 1})$$

where f is the bulk energy-transfer coefficient, Q is the magnitude of the heat input per unit time (Q being the product of the welding current and voltage for arc processes and laser

power for laser beam welding), r is the distance from the center of the heat source to the surface, and r' is a characteristic radial dimensional distribution parameter that defines the region in which 95% of the heat flux is deposited. In the limit as $r' \rightarrow 0$, the heat input becomes a point source of strength fQ on the surface. When using measured energy distributions for defining the spatial distribution of energy as a Gaussian function, it is appropriate to use the radius that provides an area under the distribution equal to $1-(1/e^3)$. However, for laser beam welding, the beam radius representing the usable energy is often reported as $1-(1/e^2)$, which represents 86.5% of the total energy.

The bulk energy-transfer coefficient, f , describes the total amount of energy that is transferred to the workpiece and is a measure of the transfer efficiency of the process. The energy-transfer coefficient may be estimated by determining the ratio of the total energy provided to the workpiece through calorimetry and the theoretical amount of energy that may be generated by the process, which, in the case of GTAW, is the product of the welding voltage and current. Although the efficiency depends on the material being welded and the specific process conditions, calorimetry measurements have yielded transfer coefficients for GTAW with DCEN of 0.7 to 0.9, whereas the transfer efficiency for GTAW of aluminum using alternating current has been measured to be between 0.3 and 0.4 (Ref 14–16).

Equation 1 describes the heat-input distribution from a stationary arc. The amount of heat transferred to the workpiece (fQ), the distribution parameter (r'), and the duration of heating are necessary to fully characterize the input energy. Figure 6 shows typical variations of the weld bead depth and width for stationary spot welds on 6.5 mm (0.25 in.) thick plates with both the distribution parameter and the duration of heating, t^* .

Other forms of the heat-input distribution also can be used. These include ramp, or triangular, distributions; uniform heat-input distributions over finite areas (for example, the area of the weld-puddle surface); or combinations of the two (that is, trapezoidal distributions).

Fig. 4 Arc shape and weld bead geometry as a function of electrode tip angle in a pure argon shield for 2.38 mm (0.10 in.) diameter electrodes truncated to 0.125 and 0.500 mm (0.005 and 0.2 in.); arc gap, 1 mm (0.04 in.). Source: Ref 12

Fig. 5 Effect of arc jet on depression of weld pool

Fig. 6 Weld bead dimensions for different durations of heating, t^* , and input-energy distribution parameter, r' , with $Q_0 = 1060$ W. Source: Ref 10

The axisymmetric characterization of heat input for stationary arcs enables temperatures in the weldment to be calculated using axisymmetric thermal analysis methods, if the weldment geometry justifies such an analysis. On the other hand, if the heat source is moving, then the resultant flow of heat is three-dimensional; that is, temperature gradients develop through the thickness of the weldment, as well as in directions parallel to and transverse to the welding direction. If the weldment geometry is regular (for example, flat plate), then the heat source from the arc is moving at a constant, sufficiently high speed, v , and if end effects such as the starting and stopping of the arc are neglected, then transient two-dimensional thermal analyses at cross sections normal to the welding direction may be satisfactory (Ref 17). The heat input at a section transverse to the direction of arc travel is given by:

$$q(x, t) = \left(\frac{3fQ}{\pi r'^2} \right) \exp \left[-3 \left(\frac{x}{r'} \right)^2 \right] \exp \left[-3 \left(\frac{vt}{r'} \right)^2 \right] \quad (\text{Eq 2})$$

where x is the distance from the centerline of the weld, and t is the time measured from the moment the center of the heat source passes over the weld section being analyzed. The four heat-input parameters characterizing a moving arc (f , Q , r' , v) are embodied in this formulation. The inverse of the speed of a moving arc is akin to the duration, t^* , of a stationary arc, because a moving arc supplies a heat input, fQ/v , per unit length of weld, whereas a stationary arc provides a total amount of heat, fQt^* , to the weldment.

For models in which heat is deposited internally, rather than as a surface flux, the input energy can be assumed to be deposited within a spheroidal or ellipsoidal region that is similar in shape to the weld puddle. As described by

Ref 18, the heat input can be taken to vary exponentially as a Gaussian distribution in all directions within the ellipsoid. Thus, the energy-input distribution is completely specified by the dimensions of the ellipsoid. More elaborate models can be formulated by prescribing either double-ellipsoid heat-input regions that better match weld-puddle shape or conical regions of internal energy deposition. Regardless of the methodology chosen to characterize the distribution of the heat input, the geometric parameters of the distribution should be established, at this stage of computer-modeling development, by correlating calculated thermal-response characteristics, such as the weld bead and heat-affected zone dimensions, with measured values.

Gas Metal Arc Welding

Gas metal arc welding (GMAW) modeling is more complex than that of the GTAW process, because of the need to consider thermal energy that is transferred to the workpiece not only by mechanisms similar to those associated with the GTAW process but, more importantly, by heat contained in the molten metal drops that are transferred as filler metal from the consumable electrode wire to the workpiece. Refer to Ref 19 for additional details. Because the GMAW process uses DCEP, the heat associated with the kinetic energy of the electrons and the heat of condensation is now input to the electrode. The energy previously input to the weldment is replaced by the energy of positively charged ions, which contribute a much smaller amount of heat to the weldment.

In addition, the radiation and conduction via the arc plasma make minor contributions to the heat input to the weldment. The more-important source of heat is derived from the

mass of molten material and is related directly to both the temperature and the melting rate of the electrode wire. The melting rate of the electrode is governed primarily by joule heating and by arc heating similar to that of the GTAW process. The transfer of material to the workpiece can be globular, such that the metal is deposited in droplets, the diameters of which are greater than that of the electrode, or in a spray, in which mass is transferred to the weld puddle as droplets with diameters that are smaller than that of the electrode.

The thermal energy applied to the workpiece therefore consists of two sources: the arc energy distribution generated at the cathode area (workpiece) and the thermal energy of the metal drops transferred from the filler wire. The arc input energy has a significant effect on the width of the weld puddle and thus of the solidified weld bead, whereas the energy in the molten metal contributes significantly to the melting of the workpiece (Ref 20). Furthermore, the impingement of the metal drops on the puddle significantly affects the depth of penetration (Ref 21), because the impact of each drop causes a distinct indentation in the weld puddle, especially at high currents.

Modeling of the heat input from the GMAW process should generally include the effects of heat input from the filler-metal droplets, the addition of new weld material from the filler wire, and, in many cases, the significant indentation of the weld-puddle surface, as well as a spatially distributed heat flux on the surface to represent radiation energy from the arc and positive ion impingement. Accurate representations of these phenomena are so complex that alternate treatments are essential. In Ref 22, the heat input from the GMAW process was modeled as a Gaussian distribution and accounted for the energy necessary to melt the electrode wire.

In Ref 23, a model in which heat is input partly in the weld puddle and partly as a surface flux was developed. A more common approach is to model the addition of filler metal by “creating” new metal in an analytical model.

In finite-element treatments, for example, new metal is simulated by adding sets of elements to the model. For three-dimensional models, these elements can be introduced in distinct increments of time, whereas for a two-dimensional analysis of a cross section normal to the welding direction, a set of elements corresponding to a weld bead cross section can be created. More recently, the contour outlining the weld bead has been determined experimentally and then used as the starting boundary condition for the thermal modeling of welds. As an example, the boundary condition can be a time-dependent temperature that may reach or exceed the melting temperature of the material.

Other Arc Welding Processes

Shielded metal arc welding, submerged arc welding, and flux cored arc welding are other processes in which energy is transferred to the workpiece both from the arc and from an overheated consumable electrode. The previously outlined semiempirical methodology for simulating the heat input for the GMAW process also appears to be well suited for the flux welding processes, although the introduction of a slag layer, whether it develops from the melting and solidification of electrode-covering material or from a flux feeding tube, presents another factor to be considered when calculating weld-induced temperatures.

High-Energy-Density Welding

High-energy-density welding, such as laser beam or electron beam welding, may be described as the use of a high-intensity heat source capable of very small spatial distribution. These processes employ intense energy of the focused, or nearly focused, energy beam and result in energy intensities of between 10^5 and 10^7 W/cm². Under these conditions, temperatures developed at the beam and material interaction region are sufficient to cause vaporization. Based on a constant material and thickness, the process depends on the intensity distribution and travel velocity of the incident beam. At low intensities, such as with a relatively diffuse heat source, vaporization occurs over a wide region and at a significantly lower energy. At sufficiently high intensities, as with a relatively concentrated heat source, the central region of interaction between the beam and substrate exhibits a vapor cavity or keyhole containing evaporated atoms of the substrate and ionized gas. These conditions are illustrated for diffuse and concentrated intensity distributions in Fig. 7 and 8, respectively, and coarsely reflect the two primary conditions for beam

welding, that is, conduction- and keyhole-mode welding (Ref 24).

The obvious practical difference for the conditions represented in Fig. 7 and 8 is depth of penetration; however, many subtle distinctions are also present. It has been promulgated that laser beam welding in the conduction or keyhole mode is a discreet process dictated by the intensity distribution of the beam and certain properties of the material; consequently, inadequate coupling or energy transfer between the beam and the workpiece has been described as conduction-mode welding. In actuality, there exists a more gradual transition between the conditions shown in Fig. 7 and 8 based on the material thermal and physical properties as well as the intensity distribution of the source energy. Beam welding with inadequate energy required for sufficient evaporation results in a small amount of energy being transferred to the substrate and hence only a small amount of surface melting directly under the highest intensity. In the case of laser beam welding under this condition, the transfer of usable energy under this

situation is governed purely by Fresnel absorption, with the vast majority of optical energy being reflected from the surface.

The circumstances represented by the condition shown in Fig. 8 are vastly more complex than what has been described previously. In this case, the energy density required to establish and maintain the keyhole is significantly higher than that of the conduction mode and results in significant evaporation of the substrate and the formation of a plasma. Laser beam welding under these conditions results in enhanced absorption of the beam within the plasma by photon-induced acceleration of free electrons to a higher energy and temperature and the propagation of this energy by electron collision with atoms and ions. This mechanism is termed inverse bremsstrahlung, referring to the converse of photonic energy being produced from an accelerated electric charge (Ref 25, 26).

Figure 9 illustrates the shape of the source distributions for laser beams representing three basic fundamental transverse electromagnetic

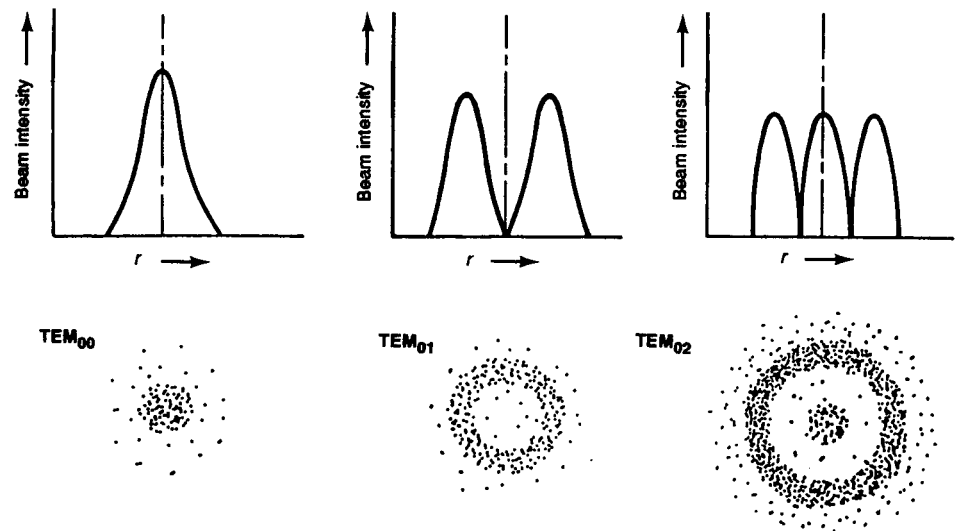

Fig. 9 Distribution of energy for laser beams representing three different transverse electromagnetic modes (TEM), with the horizontal axis showing increasing distance from the center of the heat source to the surface

modes. The fundamental transverse electromagnetic mode, TEM₀₀ (a Gaussian distribution), is often selected as the heat-input description for laser welding analysis. It is also assumed to be the source distribution for electron beam welding. The exact determination of the Gaussian width parameter, r' , depends on the optics of the laser or electron beam welding system. In many cases, a point source on the surface is an excellent approximation. In laser beam welding, if the energy is delivered via a fiber-optic system, such as with a neodymium: yttrium-aluminum-garnet or ytterbium-fiber laser, then the output source distribution is often described as a truncated Gaussian source distribution or "top hat" of specified width. Shown in Fig. 10 are measured distributions for ytterbium-fiber laser beams delivered through a fiber optic and representing Gaussian and top-hat energy distributions (Ref 27).

If a keyhole mode of welding is being formulated, then modeling of the input-energy distribution is complicated. Several different

formulations have been discussed in the literature. In the keyhole mode, the energy density is sufficiently high to cause material ablation near the center of the beam, resulting in beam penetration further into the weldment. A hole created in the material is maintained by equilibrium between vapor pressure in the keyhole, surface tension, and hydrodynamic pressure in the surrounding melt. The exact distribution of energy deposited in the hole is complicated and depends on the scattering and absorption of the beam through the weldment, as well as on the focal parameters of the system. Several different models have been used to simulate these conditions.

The simplest model for the keyhole mode of welding is that of a moving line source through the weldment (Ref 28). The appropriate solution of the heat equation was obtained by Rosenthal (Ref 29). The model does not describe the typically observed semicircular part of the weld cross section at the top, because it corresponds to a liquid region, the size of which does not vary through the

thickness of the workpiece. This simple model has been found to be very useful, however, in providing relations between such quantities as the power absorbed and the width of the weld.

A thermal analysis of the laser process has been derived for a Gaussian source moving at a constant velocity over a large range of conditions, from simple heat treating to deep-penetration welding (Ref 30). To obtain a more realistic weld shape, the simple line-source approach was modified (Ref 31) by adding a point source close to the surface of the workpiece to the line source distributed uniformly through the thickness. The line source models uniform absorption of heat by the workpiece with depth, whereas the point source corresponds to a much more concentrated region of absorption in the vicinity of the laser focus, which contrasts with the absorption from multiple reflections that occur in the main part of the keyhole. The temperature distribution from this combined-source model yields a vertical weld seam shape that reflects the general shape of that found from experimental investigations (Fig. 11).

A simple description of the input energy avoids the problem of defining the exact nature of the energy-transfer process in the keyhole itself. A more sophisticated model is necessary to characterize this effect. The attenuation of the laser beam in the vertical direction has been accounted for (Ref 32) by calculating the temperature at a depth, d , below the surface. If the temperature at depth d exceeds the boiling point of the material, then point d is deemed to be transparent. The incident power is then applied at a point below it, after suffering some absorption. This sequence continues through the substrate. The transparent grid points keep their high temperatures as if the keyhole were filled with a hot plasma.

This brief overview of several of the approaches used to model the high-energy-density welding process points out the difficulty in defining a unique methodology. Experimental data must be used for specific welding conditions to establish the overall approach, as well as the magnitude and distribution of the input source energy.

Resistance Spot Welding

The electrical resistance spot welding process for joining two materials at their common interface involves a complicated interaction of electrical, thermal, mechanical, metallurgical, and surface phenomena. Figure 12 is a simplified representation of the resistance spot welding process showing some essential features for producing a weld.

In this welding process, the faying surfaces of two or more workpieces are fused and joined at a spot by electric current flowing through the weldment (joule heating). The weldment is

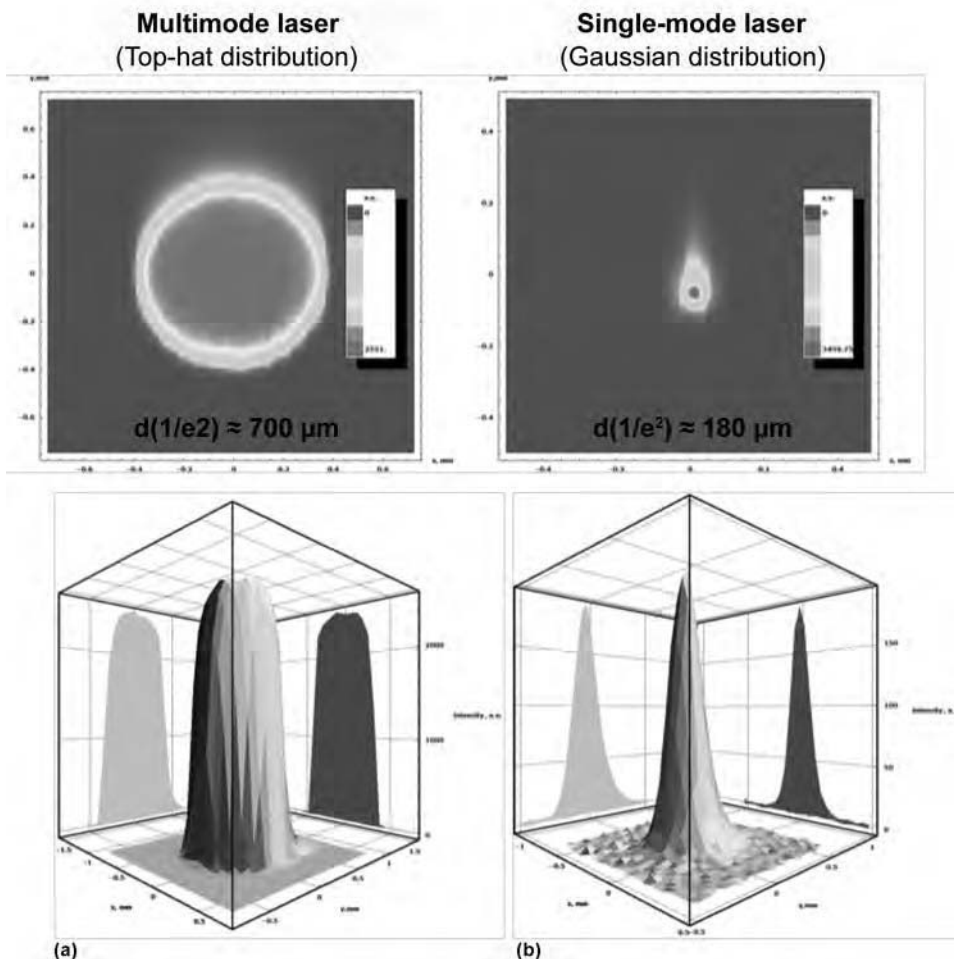

Fig. 10 Measured energy distributions for ytterbium-fiber lasers having (a) top-hat and (b) Gaussian energy distributions. Source: Ref 27

Fig. 11 Outlines of cross sections of (a) experimental and (b) calculated keyhole welds. Calculated results shown for several different point sources added to the line source. Source: Ref 31

actually held together by the compressive force exerted by the electrodes. Because the input energy in this weld process is due to joule heating, the spatial distribution of the current and the electrical resistance within the workpiece must be determined when modeling the heat source. Most importantly, the contact resistance at the surfaces of both the electrode and the workpiece, as well as the interfaces of the workpieces, must be established. The electrical contact resistance depends on the surface condition of the material, its hardness, the degree of oxidation, the amount and kind of impurities, as well as the apparent pressure at the surfaces and the temperature. The fact that these quantities are time dependent is another complication, because the joule heat source must be considered as a time-dependent parameter.

A detailed description of the process is presented in the article “Resistance Spot Welding” in this Volume. Literature reviews of the resistance spot welding process simulation are provided in Ref 33 and 34. The brief overview provided subsequently of some important findings in the literature on resistance welding highlights several points that must be considered when developing a model of the heat source.

In 1958, experimental and analytical investigations of the resistance spot welding process were performed (Ref 35). The researchers reported current density singularities at the outer rim of the contact area from theory and correlated this phenomenon with experimental results that showed heat concentration at the periphery. They concluded that the bulk of the material near the contact region was not heated appreciably by the flow of current through it but was heated indirectly by conduction from the

peripheral region of the contact area. However, further study indicated that the contact area plays a major role only in the early stages of weld-nugget formation. This fact reinforces the earlier remarks that the modeling of the heat source must consider not only the spatial distribution of the heat source but its time dependence.

Further reinforcing this idea, it was found (Ref 36) that in the beginning of the welding process, most of the voltage drop occurred at the interface between the electrode and the weldment and in the interface of the two workpieces (21 and 66%, respectively). The researchers determined that after six cycles from the instant that weldment fusion begins, most of the voltage drop takes place in the base metal (87%). This occurs because the interfacial resistance decreases as the temperature rises, which is due to melting at the interface, and because the resistivity of the base metal increases with increased temperature.

Complicating the modeling process is the unknown, but very important, contact diameter at the faying surface. This parameter depends on the geometry of the electrodes, the surface conditions, and, most importantly, the mechanical load applied by the electrode. Research (Ref 34) in modeling this process has used the diameter of the electrode face as the contact diameter between the electrode and the workpiece, but a slightly larger diameter is used to represent the contact diameter at the interface of the workpieces. Figures 13 and 14 show the current density and joule heating as functions of the nondimensional radius R/R_c , where R_c is the assumed contact radius.

Fig. 12 Resistance spot welding process

Fig. 13 Current density ratio versus nondimensional radius. Time, 2 cycles; R_c , radius of contact. Source: Ref 33

The authors of both Ref 33 and 34 stress the importance of developing a thermomechanical coupling model that will account for changes in resistance and current distributions during the welding process. This article has tried to point out that the input description of the heat source for resistance welding is extremely complicated. It depends on the electrode geometry, the weldment material, and the weldment surface condition, as well as the weld parameters (including the mechanical forces on the electrode) that must be considered as being time dependent.

Nature and Behavior of Fluxes Used for Welding

Wesley Wang, ESAB Welding & Cutting Products
S. Liu, Colorado School of Mines

FLUXES are added to the welding environment to improve arc stability, to provide a slag, to add alloying elements, and to refine the weld pool (Ref 1, 2). Different ingredients in the flux system will provide the process with different pyrometallurgical characteristics and thus different weld-metal properties (Ref 3, 4). More specifically, a welding flux must:

- Stabilize the arc and control arc resistivity
- Provide slag with the proper melting temperature
- Provide low-density slag
- Permit the use of different types of current and polarity
- Add alloying elements
- Refine the weld pool (deoxidation and desulfurization)
- Provide proper viscosity for out-of-position welding
- Promote slag detachability
- Produce smooth weld contour
- Reduce spatter and fume

The slag that forms during welding covers the hot weld metal and protects it from the atmosphere. Welding slag consists of the glass-forming components of the flux, as well as inclusions that form in the weld pool, coalesce, rise, and become incorporated into the slag.

The need to improve flux formulation to achieve optimal weld metal composition, and ultimately improve the properties of weldments, has led to fundamental studies of weld pyrochemistry. Understanding the thermodynamic and kinetic factors that are prevalent at the electrode, in the arc column, and in the weld pool has led to more precise prediction of the final weld metal composition (Ref 5–15).

In addition, quality bead appearance, the ease of welding at different positions, as well as easy slag detachability are considerations for flux formulation.

Equilibrium Parameters

Equilibrium is not achieved during welding, because of the very large temperature and density

gradients, the short reaction times, and the large electric currents. Despite these expected departures from equilibrium, thermodynamic considerations can be used as a guide for constraining chemical reactions and mechanisms involved in welding (Ref 5, 7, 9). A common approach is to assume that extremely high temperatures and high surface-to-volume ratios allow thermodynamic equilibrium to be locally attained, in spite of the short reaction times available.

Further complicating the issue is the dependence on welding parameters of the chemical partitioning between the slag and the weld metal (Ref 3, 7). This dependence suggests that the pyrometallurgical reactions involved are influenced by the processes that occur at the electrode tip. As a specific example, the welding parameters affect metal-transfer mode and metal droplet size, which in turn alter the chemical kinetics. Nonetheless, thermodynamics will reveal the direction taken by the chemical reactions (but will not accurately predict weld-metal composition).

The effective slag-metal reaction temperature has been estimated (by pyrochemical analysis of slag-metal compositions) to be approximately 1900 °C (3450 °F), a temperature intermediate between that of the hot spot at the arc root (2300 °C, or 4170 °F) and the melting point of iron (1500 °C, or 2730 °F). Thus, during the droplet lifetime, the average temperature is effectively 1900 °C (2730 °F). During this period, oxygen from the hot spot reactions is distributed throughout the droplet, and that oxygen reacts with the metallic elements to form oxides; these products of oxidation pass into the slag, and the slag-metal reactions tend toward equilibrium. Despite shielding, some nitrogen may still be present in the arc. Thus, similar considerations presented previously for oxygen should be given to nitrogen as well. Estimates of the time for which the molten slag and molten metal are in contact range from 3 to 8 s. During the process, the gaseous phase in the arc cavity contacts the metal for an estimated 0.5 to 1.0 s.

Effect of Oxygen

The most important chemical reagent in controlling weld metal composition, and thus microstructure and properties, is oxygen (Ref 3, 4, 14, 16–19). Oxygen directly reacts with alloying elements to alter their effective roles by:

- Reducing hardenability
- Promoting porosity
- Producing inclusions

All three effects are significant to weld quality.

Oxygen is introduced into the weld pool at high temperatures by:

- The presence of oxide fluxes that dissociate in the arc
- The slag-metal reactions in the weld pool
- The oxides on the surface of baked metallic powders mixed with flux or on electrode
- The aspiration of atmosphere (air) into the arc.
- Lubricants on solid and composite (metal cored and flux cored) wires

Shielding gas may contain oxidizing reagents; examples of common industrial gases used in welding are 75Ar-25CO₂ or 100% CO₂. As a result, the weld metal oxygen can range from 100 to over 1000 ppm, depending on the type of welding consumable used.

The weld metal oxygen measured directly at the molten electrode tip has been reported to be as high as 1400 ppm. Individual droplets have been found to contain as much as 2000 ppm oxygen. There are two views concerning the genesis of the high oxygen content. One suggests that pyrochemical or electrochemical reactions (or both) provide oxygen to the electrode tip, and then further oxidation occurs within the droplet as it passes through the arc. The other view is that the high oxygen levels of the droplet represent the maximum buildup of oxygen in the electrode prior to detachment, with limited reaction during flight across the arc

to the weld pool. In either case, high oxygen concentrations are introduced into the weld pool by the welding process.

At the melting point of iron, the solubility of oxygen in pure liquid iron is approximately 1600 ppm at 100 kPa (1 atm) pressure. During solidification, oxygen solubility decreases to approximately 860 ppm at 1500 °C (2730 °F) in δ-Fe. Most of the alloying elements present in liquid steel reduce oxygen solubility through deoxidation equilibria. Steelmaking processes typically yield analytical oxygen levels ranging from 70 to 100 ppm. Welds typically pick up oxygen to levels of several hundred ppm, then deoxidize to oxygen levels of approximately 200 to 300 ppm. Deoxidation of the weld metal occurs in two separate steps, the first being the primary deoxidation of the weld pool (Ref 6). Secondary deoxidation occurs during solidification as solute concentrations increase within the intercellular or interdendritic regions. The secondary deoxidation will either form very small inclusions or will coat the interdendritically trapped primary inclusions.

The high oxygen concentrations added to the weld pool by the metal droplets significantly affect deoxidation. Figure 1 shows experimentally measured soluble oxygen concentrations for various deoxidants (solid lines), along with deoxidation curves predicted by the solubility products (broken lines). The experimental deviation is caused by interactions of the deoxidant with other alloy elements. If the oxygen and metallic element concentrations resulting from the welding process exceed the equilibrium concentration for a specific reaction, inclusions will result. The ability to form a specific inclusion will correspond directly to the position of the weld pool composition relative to the activity plot for this inclusion. Thus, the thermodynamic order for the formation of primary oxides would be $Al_2O_3 > Ti_2O_3 > SiO_2 > Cr_2O_4 > MnO$.

Inclusion Formation. Inclusions form as a result of reactions between metallic alloy elements and nonmetallic tramp elements, or by mechanical entrapment of nonmetallic slag or refractory particles. Inclusions may include:

- Oxides
- Sulfides
- Nitrides
- Carbides
- Other compounds
- Multiple phases

Among these, oxides and complex oxides occur most frequently in the size range known to influence steel weld-metal microstructure.

Using only thermodynamic considerations in the analysis of slag-metal reactions, the following reactions may be considered as the ones that describe inclusion formation:

where the underlining of a component \bar{M} (\bar{O}) and the component \bar{O} (\bar{M}) indicate that \bar{M} and \bar{O} , respectively, are dissolved in the metal, and:

The equilibrium constants (K_1 and K_2) for the aforementioned two reactions are:

$$K_1 = \frac{(a_{M_xO_y})}{[a_M]^x [a_O]^y} \quad (\text{Eq 3})$$

where a_i is the activity, a function of the concentration, for component i , and:

$$K_2 = \frac{(a_{M_xO_y})}{[a_M]^x [a_{\text{FeO}}]^y} \quad (\text{Eq 4})$$

Equilibrium compositions for the weld deposit can be estimated with Eq 1 through 4 and can be used to predict trends for the weld pool pyrochemical reactions. The actual compositions may, however, differ from the calculated values due to the partitioning of alloying element

during cellular or dendritic solidification, commonly observed in steel weldments.

During solidification of a weld metal, solute elements segregate to the liquid at the solid/liquid interface, and the solute concentrations can reach high levels in the interdendritic regions, as suggested in Fig. 2. Neglecting solid diffusion, the solute composition in the liquid at the solid/liquid interface can be modeled (Ref 6) by the nonequilibrium lever rule, or Scheil equation:

$$C_L = C_0 f_L^{k-1} \quad (\text{Eq 5})$$

where C_0 is the bulk concentration in the weld pool, C_L is the solute concentration in the liquid at the interface, and k is the equilibrium partition ratio.

The equilibrium partition ratio, k , controls the direction and the extent of segregation. For most alloy elements in steel, the partition ratio is less than 1, and the element segregates to the interdendritic liquid.

Consider the deoxidation equilibrium as represented by the dissolution reaction for a complex oxide:

Fig. 1 Deoxidation equilibria in liquid iron alloys at 1600 °C (2910 °F). The broken lines show deoxidation equilibria predicted by solubility product calculations. The solid lines show experimentally determined soluble oxygen concentrations for various deoxidants. The experimental deviation is caused by variations in the activity coefficients with increasing deoxidant concentration. Source: Ref 20

Fig. 2 Schematic showing the solid and liquid composition profiles modeled by Eq 5 based on the assumption that there is complete liquid diffusion and no solid diffusion. C_0 , the initial alloy composition; k , the partition ratio of the solid to liquid compositions on the equilibrium phase diagram; kC_0 , the initial composition of the solid; and C_S and C_L , the solid and liquid compositions, respectively, at the solidification interface. Source: Ref 4

The free energy change associated with the dissolution of the $M_xN_yO_z$ can be written as:

$$\Delta G = \Delta G^0 + RT \ln \frac{[M]^x[N]^y[O]^z}{[M_xN_yO_z]} \quad (\text{Eq 7})$$

where $[M]$, $[N]$, and $[O]$ are the solute activities in the liquid; and x , y , and z are the stoichiometric constants from Eq 6. The value $[M_xN_yO_z]$ is the activity for the specific inclusion and can be assumed to have a value of 1.

The ratio of the activities of the reactants to that of the oxide can be termed the activity quotient (Q):

$$Q = \frac{[M]^x[N]^y[O]^z}{[M_xN_yO_z]} \quad (\text{Eq 8})$$

With Eq 5 representing the extent of segregation, the solute activities in the interdendritic liquid can be written as:

$$[M] = [\gamma_M][M_0]f_L^{k_M-1} \quad (\text{Eq 9a})$$

$$[N] = [\gamma_N][N_0]f_L^{k_N-1} \quad (\text{Eq 9b})$$

$$[O] = [\gamma_O][O_0]f_L^{k_O-1} \quad (\text{Eq 9c})$$

In Eq 9(a to c), $[M_0]$, $[N_0]$, and $[O_0]$ are the bulk concentrations of M, N, and O in the melt; and $[\gamma_M]$, $[\gamma_N]$, and $[\gamma_O]$ are the activity coefficients for the solutes.

Substituting Eq 9(a to c) into Eq 8 gives the free energy as a function of the remaining liquid fraction:

$$\Delta G = \Delta G^0 + RT \ln \frac{[\gamma_M M_0 f_L^{k_M-1}]^x [\gamma_N N_0 f_L^{k_N-1}]^y [\gamma_O O_0 f_L^{k_O-1}]^z}{[M_x N_y O_z]} \quad (\text{Eq 10})$$

Equation 10 expresses the free energy driving force for oxide dissolution. The first term on the right side, ΔG^0 , represents standard equilibrium conditions. The second term represents the departure from equilibrium caused by changes in reactant concentrations or by segregation during solidification.

At equilibrium, the free energy driving force, ΔG , is zero, and the equilibrium concentrations can be found by equating the two terms on the right side of Eq 10. At equilibrium, the activity quotient becomes the equilibrium constant, K_{eq} :

$$\Delta G^0 = -RT \ln \frac{[M]^x[N]^y[O]^z}{[M_xN_yO_z]} = -RT \ln K_{eq} \quad (\text{Eq 11})$$

Inclusion precipitation is possible when the concentrations of oxygen and deoxidants exceed the equilibrium values for a particular oxide. This condition, known as precipitation index, can be expressed as the ratio of the activity quotient to the equilibrium coefficient:

$$\text{Precipitation index} = \frac{Q}{K_{eq}} \quad (\text{Eq 12})$$

A precipitation index less than unity indicates that the concentrations of oxygen and deoxidants are below the equilibrium value, and the precipitation of the inclusions will not occur. A value greater than 1.0 indicates that concentrations are sufficiently high for precipitation according to the methodology described previously. The compounds Al_2O_3 , Ti_2O_3 , and SiO_2 are some of the oxides that will form in a low-carbon low-alloy steel weld. Multiple reactions can occur, and different oxides may appear in the same weld when more than one of these deoxidizers is present.

Metal Transferability during Pyrochemical Reactions. The final weld-metal concentration for a particular element is made up of contributions from the filler wire, flux, and base metal; however, losses caused by the welding process vary for each element.

Delta Quantity. The nominal composition of each weld can be calculated considering just the dilution effect of the filler wire and base metal. The extent of loss or transfer of a specific element can be evaluated by a quantity, which expresses the difference between the analytical and the nominal composition of a weld. These quantities, designated delta quantity in this article, indicate the effect of the flux on element transfer during welding. A positive delta quantity indicates an elemental transfer from the flux to the weld metal. A negative delta quantity suggests an elemental loss from the weld pool to the slag. A null delta quantity for a specific element suggests an apparent equilibrium condition, in which the flux and slag content for that element are the same. Flux compositions with null delta-quantity behavior have been used to make equilibrium calculations and thus achieve a better understanding of the chemical reactions involved in welding (Ref 8). Investigators have also quantified elemental transfer by measuring similar neutral points (null delta quantity) for various flux systems and have developed a thermodynamic

model capable of predicting neutral points for some slag systems (Ref 10).

Arc Stabilizers. Arc welding fluxes are compositionally more complex than fluxes used in other metallurgical processes, such as steelmaking. Many of the additions to the flux are not designed to assist weld-metal refinement. Some additions are present to promote arc stability, generate plasma and protective gases, control viscosity, support out-of-position welding, ensure sufficient wetting at weld toes, and promote slag detachability.

The welding arc requires an inert or chemically reducing plasma and shielding gas that can be easily ionized. Additions must be made to the flux to achieve the necessary current-carrying capacity and to maintain arc stability. Specific additions will be necessary for the various modes of current (direct current, dc, or alternating current, ac) and polarity.

Alkali metal, zirconium, and titanium additions to the arc affect the ionization process and the ease with which the welding arc is reinitiated (reinitiation is required 50 to 60 times per second with ac welding). These additions come to the welding flux as feldspar (alkali aluminum silicates), rutile, lithium carbonate, titanium aluminate, and potassium oxalate, and they play an especially important role when welding either in the dc electrode negative (DCEN) mode or in ac mode. Arc stabilizers are also important in high-speed welding when the cathode and anode spots are less stable. These additions are part of the American Welding Society (AWS) classification of electrodes, as seen by the fourth digit (E XXXX) in the classification standard for steel electrodes for shielded metal arc welding (SMAW) given in Table 1. The electrodes designed to perform with ac mode or in the DCEN mode have been specified as containing high titania or alkali metal (potassium or sodium) additions. Special additions such as Li_2O have been used to achieve multipurpose results, for example, reducing the viscosity while increasing the arc stability.

Changes in Flux Composition with Delta Quantity. Figure 3 shows a transfer of manganese for welds made with SiO_2 - TiO_2 - CaO -1wt% Na_2O fluxes at constant 40 wt% SiO_2 content. These values vary widely, depending on other alloy concentrations. The data indicate that manganese loss to the slag is very high, and that the activity of manganese varies considerably with changes in the amount of titania in the flux. Note, however, that because of high vapor pressure, manganese loss due to vaporization is expected to be high as well. Manganese is very important to weld-metal hardenability and must be closely controlled to obtain the optimum weld microstructure. Controlling the weld-metal manganese concentration in the titania-containing flux systems would require strict compositional control of the welding flux to ensure the correct manganese concentration in the weld metal.

In the same system, the delta titanium showed a constant increase with increasing titania content of the flux (Fig. 4). Because of the large amounts of titania in the flux, it is not surprising that the welds show positive compositional deviations for titanium. These results also suggest that close control of the weld-metal

titanium content will require control limits of the TiO₂ content of the flux. The optimal titanium concentration in a steel weld metal regarding Charpy V-notch impact toughness is 350 to 400 ppm.

If the delta quantity changes rapidly with flux composition, it may be difficult to maintain specific weld-metal composition, microstructure, and properties with variation in flux composition. The magnitude of the delta

quantity for specific elements is most often not as serious a concern as a rapid change in the delta quantity with variations in flux chemistry and welding parameters. The magnitude of the delta quantity can be adjusted by altering the alloy content of the welding wire or the amount of ferro-additions to the flux. Thus, a suitable combination of wire, flux, and welding parameters should achieve negligibly small delta quantities of major alloying elements.

Shielding Gas. When the shielding gas that protects the weld pool comes from the flux, it is necessary to understand the decomposition of specific flux components. Two common shielding gas atmospheres from flux dissociation are hydrogen and CO/CO₂. The hydrogen gas can be produced by the decomposition of cellulose (wood flour or similar hydrocarbons). A CO/CO₂ atmosphere results from the decomposition of carbonates such as limestone (CaCO₃) or dolomite [CaMg(CO₃)₂]. Combustion of the carbonaceous contents in the cellulose in the arc will also result in CO/CO₂. The CO/CO₂ atmosphere can be balanced to provide a reducing (and thus protective) atmosphere.

At high temperatures, CO₂ or CO will react with carbon to achieve equilibrium, which requires the presence of CO and CO₂. It is the relative amounts of CO and CO₂ that determine the reducing/oxidizing nature of the arc environment. The CO/CO₂ ratio also determines the recovery of specific alloying elements. Typical plasma atmospheres for both hydrogen-type and low-hydrogen-type electrodes are given in Table 2.

In submerged arc welding, the covering flux also produces the protective shielding gas and plasma. Other gaseous phases, including fluorine-bearing components, are also part of the plasma.

The effect of arc environment (for example, amounts of CO and CO₂) on weld-metal chemistry control for hyperbaric welding with a basic electrode is shown in Fig. 5.

Table 1 American Welding Society classification of selected shielded metal arc welding electrodes for welding mild and low-alloy steels

Electrode designation	Current and polarity(a)	Penetration	Arc stabilizers	% Fe
EXX10	DCEP	Deep	High cellulose-Na	0-10
EXXX1	ac, DCEP	Deep	High cellulose-K	0
EXXX2	ac, DCEP	Medium	High rutile-Na	0-10

AWS designation	Type	Composition, wt%			
		H ₂ O	H ₂	CO ₂	CO
6010	Cellulosic	16	41	3	40
6015	Basic	2	2	19	77

Source: Ref 15

Fig. 5 Effect of pressure on the product $m = [\%C][\%O]$ for hyperbaric welding with a basic electrode. Source: Ref 12

The high-pressure welding allows evaluation of the CO reaction. Considering the CO reaction:

the law of mass action gives:

$$k = \frac{P_{CO}}{[C][O]} \quad (\text{Eq 14})$$

where [C] and [O] are the weld-metal carbon and oxygen contents, respectively. At equilibrium, the partial pressure of CO is directly related to the total pressure by Dalton's law.

In Fig. 5, two lines are indicated. The solid line plots the product of the weld-metal oxygen and carbon as a function of total pressure when the analytical weld-metal oxygen concentration, [%O]_{anal}, was used. The broken line indicates a similar relationship; however, in this case, the weld-metal oxygen concentration has been corrected for the displacement of oxygen because of the formation of manganese silicate inclusions during welding and its transport to the slag. The equilibrium oxygen content, [%O]_{eq}, in the liquid steel at high temperatures is then given by the following expression:

$$[%O]_{eq} = [%O]_{anal} + \frac{32}{28} \Delta[%Si] + \frac{16}{55} \Delta[%Mn] \quad (\text{Eq 15})$$

where Δ[%Si] and Δ[%Mn] represent the difference between the expected compositions of these elements (from knowledge of initial consumables and base plate compositions as well as dilution) and the actual compositions measured. The linearity of these lines in Fig. 5 is evidence of the strong influence of the CO reaction in arc welding.

The evidence of water reaction control for some electrodes (for example, cellulosic electrodes) can be seen in Fig. 6. With an increase in the degree of oxidation of the deposited metal, the weld-metal hydrogen content decreases (Ref 22). The relationship between weld-metal oxygen and hydrogen contents, as seen in Fig. 6, is consistent with the functional form expected from the law of mass action for an H₂O reaction. It is apparent that with increasing weld-metal oxygen content there is a significant reduction in weld-metal hydrogen. The hydrogen content of the deposited metal can be reduced by increasing the CaCO₃ content of the coating. With the ever-increasing requirements of weld-deposit properties and the increasing need for higher productivity, pyrochemistry will play an important role for flux formulation and weld property prediction.

Basicity Index

As indicated in the section "Metal Transferability during Pyrochemical Reactions" in this article, the transfer of alloying elements during welding depends strongly on the physical and chemical properties of the flux. The ability to correlate flux properties with weld-metal

chemical compositions and properties is essential to understand the interactions between weld metal and flux.

Because of the incomplete understanding of the thermodynamic properties of slags, the empirical concept of basicity has been applied to predict flux and weld properties. A basicity index, *BI*, for welding has been proposed:

$$BI = \frac{CaO + CaF_2 + MgO + K_2O + Na_2O + Li_2O + 1/2(MnO + FeO)}{SiO_2 + 1/2(Al_2O_3 + TiO_2 + ZrO_2)} \quad (\text{Eq 16})$$

where the chemical components are given in weight percent. When the basicity index for a given flux is less than 1, the flux is considered acidic. A flux with a *BI* between 1.0 and 1.2 can be classified as neutral. A flux with a *BI* greater than 1.2 is considered basic.

In general, the higher the basicity, the cleaner the weld with respect to nonmetallic inclusions (that is, lower weld-metal oxygen content) (Ref 23). Figure 7 illustrates the correlation between weld-metal oxygen and the basicity index for some flux systems. The weld-metal oxygen content drops significantly as the *BI* is increased to 1.2 and then remains relatively constant at approximately 250 ppm O. The correlation between weld-metal oxygen, which is an indirect indication of weld-metal toughness, and basicity is acceptable for some welding flux systems, especially those that are primarily based on CaO, MgO, and SiO₂. However, Eq 16 cannot be used to correlate the strength and toughness of welds made with high flux concentrations of Al₂O₃, TiO₂, ZrO₂, MnO, FeO, and CaF₂. Although numerous basicity formulas have been considered, none has been flexible enough to deal with high amphoteric oxide contents. There is still some concern over using this index (which was primarily conceived by

steelmakers for evaluating sulfur refinement) for predicting weld-metal oxygen, or for use as a general criterion for weld metal quality (Ref 7). Additionally, the *BI* does not consider the physical properties of the fluxes, nor does it explain the kinetics of the flux-metal reactions.

Basicity index has been used by the welding industry as a measure of expected weld-metal cleanliness and mechanical properties. Consequently, manufacturers of welding consumables have classified and advertised their fluxes with this index. It is believed that high basicity means high toughness, a quality of great interest to the engineer, while an acidic flux means excellent slag behavior, a characteristic of interest to the welder attempting to improve weld bead morphology and deposition rate. Table 3 classifies the various coating formulations for SMAW electrodes using the descriptors of cellulosic, basic, acid, and rutile (alternating current stabilizer and slag former).

Considerations of SMAW Formulation

Pyrochemical Kinetics during Welding.

The ability of a flux to refine as well as protect the weld pool is related to the mass transport processes in the flux. Under normal welding conditions, the flux should melt approximately 200 °C (360 °F) below that of the alloy for proper flux coverage, molten metal refinement, and for protection of the weld deposit. One of the most important physical properties of a flux is its slag viscosity, which not only governs the way the slag flows and covers the molten weld pool but also strongly affects the transport processes involved in pore removal, deoxidation, and retention of alloying additions. The chemical processing and refining by the flux to achieve a weld deposit with low concentrations of oxygen and sulfur and optimal concentration of hardenability agents (carbon, manganese, chromium, molybdenum, nickel, and so on)

Fig. 6 Plot of weld-metal oxygen content versus weld-metal hydrogen content when welding with electrodes that contain chromium and niobium in their coating. Source: Ref 22

Fig. 7 Effect of weld-metal oxygen content on flux basicity index when using the submerged arc welding process. Source: Ref 23

may not be achieved unless slag viscosity is also adequate. The viscosity is strongly temperature-dependent, so the use of various heat inputs during welding may require different flux compositions to produce the matching slag viscosity. For simple ionic melts, the viscosity has been shown to follow an Arrhenius-type temperature dependence:

$$\eta = \eta_0 \exp\left(\frac{E_\eta}{RT}\right) \tag{Eq 17}$$

where η is the viscosity, η_0 is a system constant, E_η is the viscous activation energy, R is the gas constant, and T is the temperature.

For polymeric melts, Eq 17 often does not hold true. It has been shown that in certain cases a modified equation can be used:

$$\eta = \eta_0 \exp\left[\frac{E_\eta}{R(T - T_0)}\right] \tag{Eq 18}$$

where T_0 is a constant for a given flux composition. The presence of entrapped particulates tends to increase the slag viscosity. Slag viscosity is also affected by composition. The compositional dependence is commonly reported by considering E_η to be a function of composition at constant temperature.

The slag must be fluid enough so that it flows and covers the molten weld pool but must be viscous enough so that it does not run away from the molten metal and flow in front of the arc, leading to possible overlapping by the weld metal. (For overhead welding, surface tension becomes a primary factor because fluidity reduces coverage [opposite gravitational vector].) It has been reported that if the manganese silicate flux viscosity at 1450 °C (2640 °F) is above 0.7 Pa · s (7 P), a definite increase in weld surface pocking will occur. Pock marks have been associated with easily reducible oxides in the flux, which contribute oxygen to the weld pool. The weld pool reacts with carbon

to form carbon monoxide, which cannot be transported through a high-viscosity flux and is trapped at the liquid-metal/flux interface. The result is a weld metal surface blemished by surface defects or pocks. Because viscosity is sensitive to temperature and thus heat input, pocking can be the evidence that a flux formulated for high-current welding is being used at too low a current or too great a travel speed. The viscosity of most welding fluxes at 1400 °C (2550 °F) is in the range of 0.2 to 0.7 Pa · s (2 to 7 P).

Slag viscosity also affects the shape of the weld deposit and must be carefully controlled when covered electrodes are used out of position. The higher the slag viscosity, the greater the weld penetration will be in submerged arc welding. However, this benefit must be balanced, because if the viscosity is too high, the gaseous products cannot escape the weld pool, resulting in unacceptable porosity. This condition can be monitored by observing the density of pores trapped in the underside of the detached slag. Detached slags manifesting a honeycomb structure suggest a severe weld-metal porosity problem. This condition usually means that a given flux has experienced an insufficient heat input for the effective transport of gas through the slag.

Alloy Modification. Another required function of the welding consumables is to make alloy additions to the weld pool, usually in the form of powder metal or ferro-additions (Ref 1). Often, the composition of the wire that makes up the rod for the shielded metal arc electrode from a specific manufacturer is the same, regardless of the alloy to be welded. Alloying is achieved by powder metal additions to the flux coating. Manganese, silicon, chromium, niobium, and other alloying additions are adjusted in the weld pool by ferroalloy powder additions. Specially prepared alloy additions of Fe-50Si, Fe-80Mn, Fe-60Mn-30Si, and others are used. One concern in formulating

electrodes using ferro-additions is the alloying element recovery (that is, the amount of the element that is transferred across the arc and into the weld deposit). Values for the recovery of typical elements in steel welding are given in Table 4. The metal losses are either to the slag or to the fume.

Slipping and Binding Agents. In the case of SMAW electrodes, slipping agents are also added to the green flux formulation to improve the extrudability of the flux onto the rod (Ref 1). Glycerin, china clay, kaolin, talc, bentonite, and mica have all been used as slipping agents. Binding agents can be classified into two types. The first type comprises binders that bond the flux components to the rod without introducing a hydrogen source. These low-hydrogen binders include sodium silicate and potassium silicate. The second type of binding agent does function as a hydrogen source. The binders used for high-hydrogen electrodes can be organic in nature and include gum arabic, sugar, dextrine, and other specialized synthetic organic binders. Attempts are ongoing to identify and select nonconventional chemicals as binding agents

Table 4 Recovery of elements from selected electrode coverings

Alloy element	Form of material in electrode covering	Approximate recovery of element, wt%
Aluminum	Ferroaluminum	20
Boron	Ferroboron	2
Carbon	Graphite	75
Chromium	Ferrochromium	95
Niobium	Ferrocolumbium	70
Copper	Copper metal	100
Manganese	Ferromanganese	75

Table 3 Electrode coating formulations of selected shielded metal arc welding electrodes

Electrode		Coating formulation(a)											Comments
Type	AWS designation	Rutile	Cellulose	Quartz	Carbonates	Ferromanganese	Organics	Iron ore-manganese ore	Calcium carbonate	Complex silicates	Fluorspar	Ferroalloys	
Cellulosic	6010	20–60	10–50	15–30	0–15	5–10	Cellulose promotes gas shielding in the arc region. Hydrogen increases heat at weld. High hydrogen content (30–200 ppm). Deep penetration, fast-cooling weld
Rutile	6012	40–60	...	15–25	0–15	10–12	2–6	Slags mainly for slag shielding Relatively high hydrogen content (15–30 ppm). High inclusion content in weld deposit
	6013	20–40	...	15–25	5–25	1.4–14	0–5	
Acid-ore	6020	X	X	X	...	X	...	X	Relatively high hydrogen content. High slag content in weld metal
Basic	7015	0–10	...	0–5	20–50	...	20–40	5–10	Relatively low hydrogen levels (≤ 10 ppm), hence commonly used in welding low-alloy construction steels. Electrodes should be kept dry. Low inclusion content in weld deposit

X, data unavailable. Source: Ref 24

to substantially reduce hydrogen contents in weld metal.

Slag Formation. Slag, a mixture of glass and crystalline structure, must solidify on the already solidified weld deposit to protect the surface from oxidation during cooling. Specific physical properties are required of the slag. At 1G welding position, it could melt below the melting temperature of steel (~1450 °C, or 2640 °F), must have a density significantly less than steel to reduce slag entrapment in the weld deposit, must possess the proper viscosity in the temperature range of 1450 to 1550 °C (2640 to 2820 °F), and must easily detach from the weld deposit after welding.

Silicates, aluminates, and titanates are all primary slag formers. The high-valence cations of these compounds produce a bonding network that can promote glass formation. Most electrodes produce silicate or titanate slag. Silicates of such elements as manganese produce smooth and uniform glass deposits but also produce weld deposits that are relatively high in weld-metal oxygen content. These fluxes are said to range from acidic to neutral. The titanate and aluminate fluxes produce more rigid slag bead covering the weld. The result is generally a lower concentration of weld metal oxygen but a higher-viscosity slag. Aluminates and calcium-bearing compounds are common additions to basic fluxes for the submerged arc welding of high-toughness linepipe steels. Minerals used for slag formation include:

- Rutile
- Potassium titanate
- Ilmenite
- Alumina
- Silica flour
- Iron powder
- Fluorspar
- Feldspar
- Manganese dioxide

Asbestos (up to 50%) was used before the 1970s as a slag former but has since been removed from formulations by welding consumable manufacturers.

Slag Detachability. Slag removal is a serious productivity concern for steel fabricators. The relative ease of slag detachability influences the economic advantages of flux-related welding processes. Residual slag on the weld deposit promotes slag stringers in multipass weldments, limits the effective use of narrow-gap flux-related welding processes, and may reduce the corrosion resistance of the weldment. Welding flux formulators have modified flux compositions to alleviate or reduce this hindrance (Ref 25).

Poor slag removal has been reported to occur when the flux contains fluorite. Slags containing spinels (with $AO \cdot B_2O_3$ formula) generally have been found to attach tenaciously to the weld deposit. Slags with cordierite and $(Cr, Mn, Mg)O \cdot (Cr, Mn, Al)_2O_3$ -type spinel phases

have been reported to be difficult to remove from stainless steel weldments. It has also been reported that if $(CaO)_2SiO_2$, Cr_2TiO_5 , and $FeTiO_5$ are present, the slag readily detaches from the weld deposit (Ref 25). The compositional range for acceptable slag detachability has been reported for the $CaO \cdot CaF_2 \cdot SiO_2$ system and the $CaO \cdot TiO_2 \cdot SiO_2$ system. Easier slag removal has also been related to deoxidation with aluminum instead of titanium. Increasing the Al_2O_3 content in the flux has demonstrated improved detachability (Ref 25).

Types of Fluxes

After considering the large number of necessary requirements as described earlier, a welding flux must be carefully and deliberately formulated to achieve optimized performance. A number of different arc welding processes depend on welding fluxes. Each of these processes requires a different formulation.

SMAW Fluxes. The typical constituents and their functions in electrode coatings for the SMAW process are given in Table 5. It should be noted that the flux ingredients are based on additions of refined minerals of the earth. Natural minerals offer an economical method of keeping welding consumables at a reasonable cost. Table 6 presents the elemental content of these minerals. Table 7 gives the typical chemical compositions for flux coatings for three different SMAW electrodes.

Submerged Arc Welding (SAW). In the SAW process, the flux drops from a hopper onto the work such that the welding arc is submerged beneath the granular flux, producing an arc cavity that contains metal vapors, silicon monoxide, manganese oxide, gaseous fluorides, and other higher-vapor-pressure components of the flux. This arc welding process has been recognized as one that produces very little, if

any, fume. Submerged arc welding is limited mainly to the flat or horizontal position and requires significant setup time. It is very successful in manufacturing numerous similar parts and long-seam welding of heavy-section steel parts, such as producing welded steel pipe.

Submerged arc fluxes are made in three different forms:

- *Bonded fluxes* mix nonmetallic and ferro-additions with a low-temperature binder into mixtures of small particles.
- *Agglomerated fluxes* are similar to the bonded fluxes except that a ceramic glass binder, cured at high temperature, is used.
- *Fused fluxes* are made by pouring a homogeneous glass mixture of the proper flux composition into water, resulting in a frit.

Generally speaking, changing from bonded to agglomerated to fused fluxes improves control of the weld-metal composition, especially with respect to such impurities as hydrogen and oxygen.

There are seven types of submerged arc fluxes (Table 8). Flux classification according to basicity is the result of observed correlations between weld-metal oxygen concentration and flux composition. Table 9 gives some typical compositions for SAW fluxes.

Flux cored arc welding (FCAW) uses a hollow wire filled with flux reagents and ferro-additions. The two types of flux cored electrodes are gas-shielded flux cored electrodes and self-shielded flux cored electrodes (Ref 26). Table 10 gives typical chemical compositions for the three types of carbon-dioxide-shielded cored electrodes. Table 11 gives the typical chemical compositions for the four types of self-shielded flux cored electrodes.

There are two types of gas-shielded FCAW wires: ferrous and nonferrous. Ferrous wires, including carbon steel and stainless steels wires,

Table 5 Typical functions and compositions of constituents for selected mild steel shielded metal arc welding electrode coatings

Coating constituent	Function of constituent		Composition range of coating on electrode				
	Primary	Secondary	E6010, E6011	E6013	E7018	E7024	E7028

(a) Replaces titanium dioxide (rutile) to permit use with alternating current. (b) Replaces sodium silicate to permit use with alternating current

are the dominant part of the gas-shielded FCAW wire family. The nonferrous wires include copper-nickel alloy, Inconel, and titanium wires. In addition to the gas-shielded FCAW wires,

gas-shielded metal cored wires that use iron powder as a predominant component in their cores also have carbon steel and stainless steel types.

Most self-shielded FCAW wires are carbon steel wires. There are only a few stainless steel FCAW wires designed for hardfacing, overlay, or repairing applications.

Considerations of FCAW Formulation.

The purpose of flux formulation is to achieve a successful welding process to produce acceptable weld beads that meet predetermined qualifications through the assistance of fluxes and the resultant slag. Flux cored arc welding requires a stable arc, friendly puddle handling, easy slag removal to yield a continuous bead with a smooth and compact profile, and a proper amount of transferred alloying elements. Therefore, a flux/slag system must be designed accordingly.

A successful flux formula consists of five essential groups of ingredients. Each group not only plays its own role but also interacts with the others. They can be categorized accordingly as follows.

Group I: Viscosity Controllers. During welding, the liquid slag is pushed away from the arc column. Most of the slag builds up behind the moving puddle. To minimize the exposure of liquid metal to the welding environment, the viscosity of the liquid slag must be controlled such that the liquid slag follows the moving puddle consistently and

in a timely manner. The viscosity can be reduced by breaking down the slag network (using Ca²⁺ and other metal ions in the titanate or silicate network) to facilitate the slag flow. Usually, a liquid slag with correct viscosity can achieve a desirable balance of surface tensions at the weld toe, that is, good wetting to produce a weld with smooth transition at the weld toe and flat reinforcement crown.

Group II: Network Builders. The slag network formers are the essential ingredients with respect to the integrity of the slag covering on a weld bead. They can form a two- or three-dimensional network. They can be oxides, such as rutile (TiO₂), iron oxide, silicates, and so on, and fluorides, including CaF₂, BaF₂, and so on. These network formers determine the nature of a slag system, forming either an oxide-type slag or a fluoride-type slag or a combined one. Rutile- or CaF₂-base flux systems are commonly used for gas-shielded flux cored wires, and the iron-oxide- or BaF₂-base flux systems are used for self-shielded flux cored wires.

Group III: Deposit Volume Controllers. Metal sheath, iron powder, and metal alloys are the major contributors to a weld-metal pool. The weight or volume of a liquid puddle can affect the welding process significantly. For instance, a carbon steel flux cored wire designed to have a significant amount of iron powder (for example, 50% iron powder in an

Table 6 Typical composition of common minerals used in SMAW electrode coatings

Mineral	Chemical composition

Table 8 Fluxes used for submerged arc welding applications

Flux type	Constituents	Basicity	Flux form	Advantages	Limitations	Comments
Manganese silicate	MnO + SiO ₂ > 50%	Acid	Fused	Moderate strength; tolerant to rust; fast welding speeds; high heat input; good storage	Limited use for multipass welding; use where no toughness requirement; high weld metal oxygen; increase in silicon on welding; low in carbon	Associated manganese gain; maximum current, 1100 A; higher welding speeds
Calcium-high silica	CaO + MgO + SiO ₂ > 60%	Acid	Agglomerated, fused	High welding current; tolerant to rust	Poor weld toughness; use where no toughness requirement; high weld metal oxygen	Differ in silicon gain; some capable of 2500 A; wires with high manganese
Calcium silicate-neutral	CaO + MgO + SiO ₂ > 60%	Neutral	Agglomerated, fused	Moderate strength and toughness; all current types; tolerant to rust; single- or multiple-pass weld
Calcium silicate-low silica	CaO + MgO + SiO ₂ > 60%	Basic	Agglomerated, fused	Good toughness with medium strength; fast welding speeds; less change in composition and lower oxygen	Not tolerant to rust; not used for multiwire welding	...
Aluminate basic	Al ₂ O ₃ + CaO + MgO > 45%; Al ₂ O ₃ > 20%	Basic	Agglomerated	Good strength and toughness in multipass welds; no change in carbon; loss of sulfur and silicon	Not tolerant to rust, limited to de electrode positive	Usually manganese gain; maximum current 1200 A; good mechanical properties
Alumina	Bauxite base	Neutral	Agglomerated, fused	Less change in weld composition and lower oxygen than for acid type; moderate to fast welding speeds
Basic fluoride	CaO + MgO + MnO + CaF ₂ > 50%; SiO ₂ ≤ 22%; CaF ₂ ≤ 15%	Basic	Agglomerated, fused	Very low oxygen; moderate to good low-temperature toughness	May present problems of slag detachability; may present problem of moisture pickup	Can be used with all wires, preferable dc welding; very good weld properties

FCAW wire formulation) can produce an overweighed weld pool. When this wire is used in an out-of-position application, the slag will not be able to support the puddle, resulting in an overflow or dripping of the liquid metal. Therefore, this type of wire is limited to the flat and down-hand welding position.

Fluorides are the most effective agents to increase the fluidity of liquid slag, along with their hydrogen-removal effect. However, if the liquid slag is too fluid, it tends to flow away from the liquid steel pool, losing its protection effect.

On the contrary, if a wire is overdesigned regarding flux volume, the resultant weld pool can be overcrowded with slag, causing slag inclusion and removal problems. Hence, it reduces the welding efficiency.

It should be noted that the volume of a liquid pool and the amount of alloying elements can also be adjusted by the weight percent fill of the flux core in a wire, provided there is a constant welding condition.

Group IV: Arc Energy and Stability Controllers. In addition to the welding current and voltage, arc energy can also be provided by the flux core ingredients to achieve smooth arc performance. During welding, a stable arc is critical to achieve high arc energy efficiency; otherwise, arc stoppage, erratic metal transfer, and so on can occur and dissipate the arc energy, resulting in poor welding. Arc stabilizers with low

dissociation energy and ionization potential, such as Na₂O and Li₂O, can produce a large amount of electric charge carriers to the arc column to establish a stable plasma. Deoxidizers such as aluminum and magnesium can react with oxide ingredients in the welding flux, resulting in thermite reactions and generating exothermic heat. Aluminum and magnesium are also strong nitride formers that can react with nitrogen in the atmosphere, releasing heat. In either case, the resultant heat will increase the arc energy, contributing to a more stable arc, which also helps the metal transfer and arc stability.

Group V: Slag Formers. Other than those chemicals in groups I through IV, the rest of the nonmetallic chemicals in a formula are slag formers. They are also important in a formula to provide a supplemental support to successful welding. For example, Fe₃O₄ can effectively reduce the surface tension of the liquid pool to improve the bead morphology. Being an acidic oxide, MnO is known to effectively improve the wetting. Quite a few of the slag formers have been patented as effective additives in various formulas.

Flux ingredients in a formula can interact with each other. Thus, their content should be carefully designed to achieve a balanced slag behavior. The interactions between the two groups of ingredients are quite complicated. In general, two opposite interactions may exist.

One is positive in that the interaction will facilitate and reinforce the discussed functions of the five groups. The second is negative in that the effects of one ingredient counteract those of the ingredients from a different group. Interactions are shown in Fig. 8. The solid arrows represent negative interactions, and the dashed arrows represent positive interactions.

Negative interactions include:

- *Group I → Group II:* Ingredients of Group I can effectively disrupt the networks built by Group II ingredients. For example, calcium and other metal ions can break down the networks of titanium oxide or silicon oxide, affecting the viscosity and coverage of the weld pool.
- *Group II → Group V:* Ingredients of group II tend to react with Group V ingredients to form compounds that subsequently solidify. Therefore, Group II ingredients reduce the amount of Group V ingredients in the uncombined form and weaken the effects of these ingredients on the liquid slag. A case in point is aluminum oxide (an ingredient of Group V), which is known to render the slag more refractory with its high melting point. However, titanium oxide (an ingredient of Group II) can react with it to produce aluminum titanate. Because Al₂TiO₅ has a melting point almost 700 °C (1260 °F) lower than that of aluminum oxide (Ref 27), the refractory effect from alumina in the presence of titanium oxide is weakened. Therefore, the amount of alumina must be increased accordingly to achieve the refractory effect on the slag.
- *Group V → Group III:* Ingredients of Group V can be refractory fluxes (such as aluminum and magnesium oxides) or those with melting points higher than or close to the melting point of steel. Together with other

slag components, these ingredients can effectively restrict the flow of liquid slag and liquid metal that is from Group III ingredients.

- *Group III* → *Group IV*: Ingredients of Group III absorb part of the arc energy to melt and incorporate into the weld pool. They can potentially consume a large amount of the arc energy contributed by Group IV ingredients, resulting in a cooler arc. A fluoride-base self-shielded flux cored wire is a good example of this interaction. The formation energy of CaF_2 and CaO are -290.3 and -151.8 Kcal/mol, respectively, in separation (Ref 28). In addition, CaF_2 has two fluorine atoms to be ionized, instead of one oxygen atom in CaO . As a result, CaF_2 (an ingredient of Group III) consumes more arc energy that is partially contributed by Group IV ingredients. It indeed confirms the observation that a fluoride-base flux cored wire has a “colder” arc than an oxide-base flux cored wire.
- *Group IV* → *Group I*: It is known that temperature is the strongest variable that affects viscosity. Group IV ingredients help increase arc energy. The increased arc energy can greatly reduce the slag viscosity. Note that chemical composition control alone, that is, reducing or controlling the amount of Group I ingredients, will not be effective to adjust the slag viscosity. It is observed that when an excessive amount of aluminum is added into a rutile-base formula, the heat from the thermite reactions will cause the molten slag to drip regardless of the amount of Group I ingredients present in the formula.

Positive interactions include:

- *Group I* → *Group III*: Ingredients of Group I can reduce the viscosity of liquid slag. As a result, the liquid slag can move around more easily, which relaxes the confinement of the liquid metal deposit covered by slag and facilitates the spreading out of the liquid metal. Note that the Group IV → Group I interaction is about the viscosity of slag, and the Group I to Group III interaction here concerns the fluidity of liquid metal and weld bead formation through the slag.
- *Group III* → *Group II*: Oxides from Group III ingredients can participate in the formation of Group II networks. For example, the iron oxide produced from the liquid steel can be used to build the slag network of a Fe_3O_4 -base slag system of a self-shielded flux cored wire.
- *Group II* → *Group IV*: Many slag network builders of Group II, such as rutile and silica, can stabilize the welding arc. They definitely support the work of Group IV ingredients.
- *Group IV* → *Group V*: Strong deoxidizers and denitriders, such as titanium and aluminum, can produce oxides and nitrides with high melting points. Those products from the oxidation and nitriding reactions join Group V ingredients to become a part of the group. As a result, the supplemental function of Group V ingredients, such as holding the liquid metal at out-of-position welding, can be reinforced.
- *Group V* → *Group I*: Ingredients of Group V are not pure chemicals. They usually have a certain amount of residual elements (calcium and other metal ions, for example) that

happen to be Group I ingredients. Those residues can work together with Group I ingredients to control the viscosity of liquid slag.

Due to the complex relationship among flux ingredients in a formula, the effects of every flux ingredient must be carefully weighed and balanced in order to have a well-behaved slag system. After the slag system is successfully established, alloying and microstructure management can help to achieve qualified mechanical properties, including yield and tensile strength, elongation, Charpy V-notch impact toughness, hardness, crack tip opening displacement, and so on.

An FCAW Electrode Formulation Example.

A basic E71T-5-type flux cored wire is commonly used on critical steel structures. Having inferior welding operability to a rutile-base E71T-1-type flux cored wire, it is not as popular as the rutile-base wire. Therefore, it is of importance to improve its welding performance to populate its application. Traditional basic wires use the CaF_2 - SiO_2 - CaO flux system to design formulas. Based on that, a matrix of chemical formulas is shown in Table 12.

It was found that wire 1 was hard to weld due to the high fluidity and mixing of the molten flux with the steel pool. However, the problem of fluidity and slag/metal mixing was gradually resolved from wires 2 to 5. Wire 5 just separated the molten slag from the steel pool. Also observed, the arc stability gradually improved from wires 1 to 5. It was obvious that CaO in wire 1 broke down the slag network too much to cause the fluidity problem to allow molten slag to flow into the steel pool. In other words, the action of Group I → Group II happened strongly here. Due to the poor slag behavior, the weld was extremely convex, and the slag was firmly attached on the bead surface. In addition, it seemed that the volume of liquid steel was too excessive to be fully covered by the slag. On the other hand, increasing the amount of Group IV ingredients, Li_2O in this case, apparently improved the arc stability.

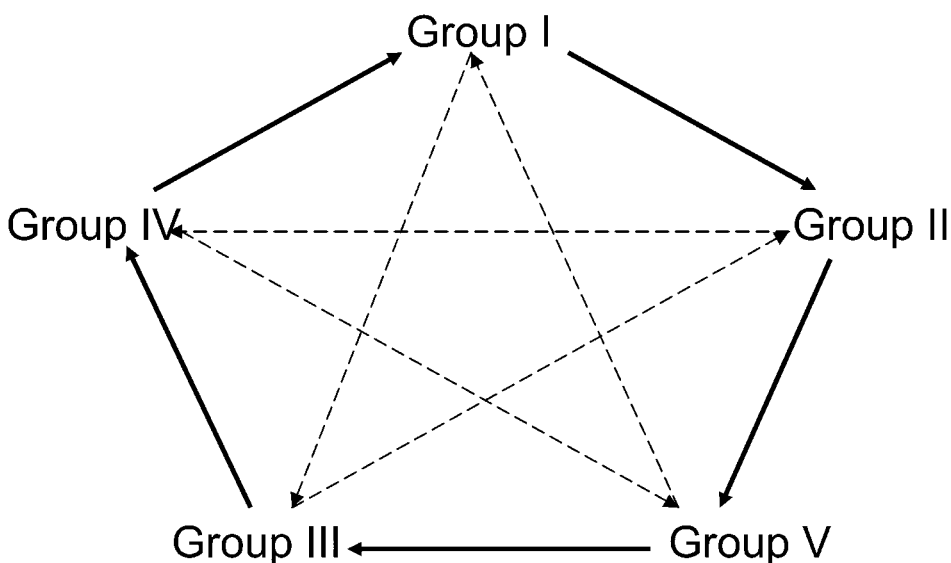

Fig. 8 Interactions between flux ingredients. The solid arrows represent negative interactions, and the dashed arrows represent positive interactions.

Table 12 Matrix of chemical formulas—phase I

Group	Ingredient	Wire 1	Wire 2	Wire 3	Wire 4	Wire 5
I	CaO	12.0	10.8	9.5	8.2	7.0
	SiO ₂	8.0	9.2	10.5	11.8	13.0
II	TiO ₂	9.8	9.8	9.8	9.8	9.8
	CaF ₂	20.8	20.8	20.8	20.8	20.8

	MgO	1.5	1.1	0.75	0.4	0.0
Total		100.0	100.0	100.0	100.0	100.0

To further improve the slag behavior, the weight percent of CaO should be reduced, and more Group II ingredients, SiO₂ and/or TiO₂, should be added to formulas. Hence, two new formulas were designed and presented in Table 13.

The formula of wire 6 increased the amount of Group II ingredient, that is SiO₂, to promote the formation of slag network and balance the negative interaction from the Group I ingredient, CaO. In addition, the amount of iron powder, that is, Group III ingredient, was reduced so that the liquid deposit could be fully covered by the slag. It was found that wire 6 produced good-looking beads. The weld bead was completely covered by the slag, and slag removal became much easier. However, the weld had porosities and wormholes, which indicated the need to reduce the oxygen content of the weld.

Instead of SiO₂, the formula of wire 7 increased the amount of TiO₂, a Group II ingredient, to develop the slag network. It also decreased the amount of CaO. As a result, the negative interaction of Group I → Group II was further depressed. To achieve a low oxygen content in the weld, metallic silicon, a Group IV ingredient, was used for deoxidation. In addition, the interaction of Group IV → Group I also suppressed the negative effect of CaO. The weight percent of iron powder was again reduced to facilitate a more complete reaction of deoxidation in the weld pool. A moderate increase of CaF₂ reduced the source of oxygen, which also benefitted the control of oxygen content in the weld. Considering the mechanical properties, carbon was deleted from the formula to avoid martensite in the weld.

An AWS plate was successfully welded by wire 7 at the 1G position. The slag was well behaved in terms of its flow, spreading, and removal. After passing x-ray examination, the plate was machined out to acquire standard samples for tension and Charpy V-notch impact tests. Detailed mechanical properties and chemical composition are shown in Table 14. Apparently, both the strength and Charpy V-notch

impact toughness failed the AWS A5.20 specification.

To increase both strength and impact toughness, more manganese was needed to promote the acicular ferrite, in addition to solid-solution strengthening by more silicon in the weld metal. On the other hand, from the viewpoint of slag adjustment, increasing the amount of CaF₂ by reducing the amount of oxides (TiO₂ and SiO₂) could reduce more oxygen in the wire. Therefore, wire 8 was formulated, as shown in Table 15.

Again, an AWS plate was successfully welded at the 1G position. The resultant mechanical properties and chemical composition passed the AWS A5.20 specification (Table 16).

Heat Flow in Fusion Welding*

Chon L. Tsai, United Ship Design and Development Center

DURING FUSION WELDING, the thermal cycles produced by the moving heat source cause physical state changes, metallurgical phase transformation, and transient thermal stress and metal movement. After welding is completed, the finished product may contain physical discontinuities that are due to excessively rapid solidification, adverse microstructures that are due to inappropriate cooling, or residual stress and distortion that are due to the existence of incompatible plastic strains.

To analyze these problems, this article presents an analysis of welding heat flow, focusing on the heat flow in the fusion welding process. The primary objective of welding heat-flow modeling is to provide a mathematical tool for thermal data analysis, design iterations, or the systematic investigation of the thermal characteristics of any welding parameters. Exact comparisons with experimental measurements may not be feasible, unless some calibration through the experimental verification procedure is conducted.

Introduction

Welding Thermal Process. A physical model of a generic moving-source (i.e., electric arc, electron or laser beam) welding system is shown in Fig. 1. The welding heat source

moves at a constant speed along a straight path. The end result, after either initiating or terminating the heat source, is the formation of a transient thermal state in the weldment. At some point after heat-source initiation but before termination, the temperature distribution is stationary, or in thermal equilibrium, with respect to the moving coordinates. This is called a “quasi-steady” state. The origin of the moving coordinates coincides with the center of the heat source. The intense welding heat melts the metal and forms a molten pool. Some of the heat is conducted into the base metal and some is lost from either the heat column or the metal surface to the environment surrounding the weld. Three metallurgical zones are formed in the plate upon completion of the thermal cycle: the weld-metal (WM) zone, the heat-affected zone (HAZ), and the base-metal (BM) zone. The peak temperature and the subsequent cooling rates determine the HAZ structures, whereas the thermal gradients, the solidification rates, and the cooling rates at the liquid-solid pool boundary determine the solidification structure of the WM zone. The size and flow direction of the pool determines the amount of dilution and weld penetration. The material response in the temperature range near melting temperatures is primarily responsible for the metallurgical changes.

Two thermal states, quasi-stationary and transient, are associated with the welding process. The transient thermal response occurs during the source initiation and termination stages of welding, the latter of which is of greater metallurgical interest. Hot cracking usually begins in the transient zone, because of the nonequilibrium solidification of the base material. A crack that forms in the source-initiation stage may propagate along the weld if the solidification strains sufficiently multiply in the wake of the welding heat source. During source termination, the weld pool solidifies several times faster than the weld metal in the quasi-stationary state. Cracks usually appear in the weld crater and may propagate along the weld. Another dominant transient phenomenon occurs when a

short repair weld is made to a weldment. Rapid cooling results in a brittle HAZ structure and either causes cracking problems or creates a site for fatigue-crack initiation.

The quasi-stationary thermal state represents a steady thermal response of the weldment with respect to the moving heat source. The majority of the thermal expansion and shrinkage in the base material occurs during the quasi-stationary thermal cycles. Residual stress and weld distortion are caused by the incompatible inelastic strains that remain in the weldment after completion of the thermal cycle.

Relation to Welding Engineering Problems. To model and analyze the thermal process, an understanding of thermally-induced welding problems is important. A simplified modeling scheme, with adequate assumptions for specific problems, is possible for practical applications without using complex mathematical manipulations. The relationship between the thermal behavior of weldments and the metallurgy, control, and distortion associated with welding is summarized as follows.

Welding Metallurgy. As already noted, defective metallurgical structures in the HAZ and cracking in the WM usually occur under the transient thermal condition. Therefore, a transient thermal model is needed to analyze cracking and embrittlement problems. Proper welding techniques, such as using end tabs or current slope control, may be used to avoid the transient thermal effects.

To evaluate the various welding conditions for process qualification, the quasi-stationary thermal responses of the weld material must be analyzed. The minimum required amount of welding heat input within the allowable welding speed range must be determined in order to avoid rapid solidification and cooling of the weldment. Preheating may be necessary if the proper thermal conditions cannot be obtained under the specified welding procedure. A quasi-stationary thermal model is adequate for this type of analysis.

Hot cracking results from the combined effects of strain and metallurgy. The strain

Fig. 1 Schematic of the welding thermal model

effect results from weld-metal displacement at near-melting temperatures, because of solidification shrinkage and weldment restraint. The metallurgical effect relates to the segregation of alloying elements and the formation of the eutectic during the high nonequilibrium solidification process. Using metallurgical theories, it is possible to determine the chemical segregation, the amounts and distributions of the eutectic, the magnitudes and directions of grain growth, and the weld-metal displacement at high temperatures. Using the heating and cooling rates, as well as the retention period predicted by modeling and analysis, hot-cracking tendencies can be determined. To analyze these tendencies, it is important to employ a more accurate numerical model that considers finite welding heat distribution, latent heat, and surface heat loss.

Welding Control. In-process welding control has been studied by researchers. Many of the investigations are aimed at developing sensing and control hardware. The link between weld-pool geometry and weld quality has also been extensively studied and developed in the past decade. For a new welding process or procedure development, transient heat-flow analyses may be used to correlate the melted surface, which is considered to be the primary control variable, to the weld thermal response in a time domain.

Welding Distortion. The temperature history and distortion caused by the welding thermal process creates nonlinear thermal strains in the weldment. Thermal stresses are induced if any incompatible strains exist in the weld. Plastic strains are formed when the thermal stresses are greater than the material yield stress. Incompatible plastic strains accumulate over the thermal process and result in residual stress and distortion of the final weldment. The material response in the lower temperature range during the cooling cycle is responsible for the residual stresses and weldment distortion. For this type of analysis, the temperature field away from the welding heat source is needed for the modeling of the heating and cooling cycle during and after welding. A quasi-stationary thermal model with a concentrated moving heat source can predict, with reasonable accuracy, the temperature information for the subsequent stress and distortion analysis.

Literature Review. Many investigators have analytically, numerically, and experimentally studied welding heat-flow modeling and analysis (Ref 1–18). The majority of the studies were concerned with the quasi-stationary thermal state. Boulton and Lance-Martin (Ref 1), Rosenthal and Schmerber (Ref 2), and Rykalin (Ref 3) independently obtained an analytical temperature solution for the quasi-stationary state using a point or line heat source moving along a straight line on a semiinfinite body. A solution for plates of finite thickness was later obtained by many investigators using the imaged heat-source method (Ref 3, 4). Tsai (Ref 5) developed an analytical solution for a

model that incorporated a welding heat source with a skewed Gaussian distribution and finite plate thickness. It was later called the finite source theory (Ref 6).

With the advancement of computer technology and the development of numerical techniques such as the finite-difference and finite-element methods, more exact welding thermal models were studied and additional phenomena were considered, including nonlinear thermal properties, finite heat-source distributions, latent heat, and various joint geometries. Tsai (Ref 5), Pavelic et al. (Ref 7), Kou (Ref 8), Kogan (Ref 9), and Ecer et al. (Ref 10) studied the simulation of the welding process using the finite-difference scheme. Hibbitt and Marcal (Ref 11), Friedman (Ref 12), and Paley and Hibbert (Ref 13) made some progress in welding simulation using the finite-element method.

Analytical solutions for transient welding heat flow in a plate were first studied by Naka (Ref 14), Rykalin (Ref 3), and Masubuchi and Kusuda (Ref 15) in the 1940s and 1950s. A point or line heat source, constant thermal properties, and adiabatic boundary conditions were assumed. Later, Tsai and Hou (Ref 16) extended the analytical solution to incorporate Gaussian heat distribution using the principle of superposition. The solution was used to investigate the effect of pulsed conditions on weld-pool formation and solidification without the consideration of latent heat and nonlinear thermal properties.

The analysis of the transient thermal behavior of weldments using numerical methods has been the focus of several investigations since 1980. Friedman (Ref 17) discussed the finite-element approach to the general transient thermal analysis of the welding process. Ecer et al. (Ref 10) developed a two-dimensional transient heat-flow model using a finite-difference scheme and a simulated pulsed-current gas tungsten arc welding process. Fan and Tsai (Ref 18) modeled the two-dimensional transient welding heat flow using a finite-element scheme to study the transient welding thermal behavior of the weldment. Frewin and Scott (Ref 19) studied a three-dimensional finite-element model of the heat flow during pulsed laser beam welding. Bonifaz (Ref 20) studied the transient thermal histories and sizes of fusion and heat-affected zones using the finite-element method, incorporating thermal efficiency in the heat-transfer analysis. DebRoy and David (Ref 21) conducted a more comprehensive review on the physical processes in fusion welding. Because of the complexity of fusion welding processes, solution of many important contemporary problems in fusion welding requires an interdisciplinary approach. Solution to the problems and issues requires science-based tailoring of composition, structure, and properties of the weld materials.

In the past two decades, the coupled heat transfer and viscous flow in a weld pool has been studied using the finite-element method by many investigators. Dilawari et al. (Ref 22)

studied two physical models for qualitative insights in the electrosag welding process using the finite-element method. It was revealed that the total weld heat may be reduced by 30% when the strip electrode was used in place of the wire electrode. McLay and Carey (Ref 23) studied the detailed structure of the flow circulation regions and layers, which incorporated the surface-tension-driven flow (Marangoni effect) and the moving phase boundary. More recently, many investigators developed three-dimensional numerical models to study the viscoplastic flow and temperature field in friction stir welding by solving the equations of conservation of mass, momentum, and energy. Nandan et al. (Ref 24, 25) determined the spatially variable non-Newtonian viscosity from the computed values of strain rate, temperature, and temperature-dependent material properties. The computed results showed that significant plastic flow occurs near the tool, where convective heat transfer is the main mechanism of heat transfer.

General Approach. The various modeling and analysis schemes summarized previously can be used to investigate the thermal process of different welding applications. With adequate assumptions, analytical solutions for the simplified model can be used to analyze welding problems that show a linear response to the heat source if the solutions are properly calibrated by experimental tests. Numerical solutions that incorporate nonlinear thermal characteristics of weldments are usually required for investigating the weld-pool growth or solidification behavior. Numerical solutions may also be necessary for metallurgical studies in the weld HAZ if the rapid cooling phenomenon is significant under an adverse welding environment, such as welding under water.

Thermally related welding problems can be categorized as:

- Solidification rates in the weld pool
- Cooling rates in the HAZ and its vicinity
- Thermally-induced strains in the general domain of the weldment

The domain of concern in the weld pool solidification is within the molten pool area, in which the arc (or other heat source) phenomena and the liquid stirring effect are significant. A convective heat-transfer model with a moving boundary at the melting temperature is needed to study the first category, and numerical schemes are usually required as well.

The HAZ is always bounded on one side by the liquid-solid interface during welding. This inner-boundary condition is the solidus temperature of the material. The liquid weld pool may be eliminated from thermal modeling if the interface could be identified. A conduction heat-transfer model would be sufficient for the analysis of the HAZ. Numerical methods are often employed, and very accurate results can be obtained.

The thermal strains caused by welding thermal cycles are due to the nonlinear temperature distribution in the general domain of the weldment. Because the temperature in the material near the welding heat source is high, very little stress can be accumulated from the thermal strains. This is due to low rigidity, that is, small modulus of elasticity and low yield strength. The domain for thermal strain study is less sensitive to the arc and fluid-flow phenomena and needs only a relatively simple thermal model. Analytical solutions with minor manipulations often provide satisfactory results.

In this article, only the analytical heat-flow solutions and their practical applications are addressed. The numerical conduction solutions and the convective models for fluid flow in a molten weld pool are not presented.

Mathematical Formulations

Conduction Equation. A diagram of the welding thermal model is shown in Fig. 1. The origin of the moving coordinates (w, y, z) is fixed at the center of the welding heat source. The coordinates move with the source at the same speed. The conduction equation for heat flow in the weldments is:

$$\nabla \cdot (\lambda \nabla \theta) + \rho C_p V \frac{\partial \theta}{\partial w} + \dot{Q} = \rho C_p \frac{\partial \theta}{\partial t} \quad (\text{Eq 1})$$

The initial condition is:

$$\theta = \theta_0, \text{ at } t = 0 \quad (\text{Eq 2})$$

and the generalized boundary condition is:

$$\lambda_w \frac{\partial \theta}{\partial w} \ell_w + \lambda_y \frac{\partial \theta}{\partial y} \ell_y + \lambda_z \frac{\partial \theta}{\partial z} \ell_z - \dot{q} + h(\theta - \theta_\infty) = 0 \quad (\text{Eq 3})$$

where ∇ is a differential operator; θ is the temperature ($^{\circ}\text{C}$); θ_∞ is the environmental temperature ($^{\circ}\text{C}$); θ_0 is the initial temperature ($^{\circ}\text{C}$); λ is the directional thermal conductivity in any coordinate system ($\text{J}/\text{mm} \cdot \text{s} \cdot ^{\circ}\text{C}$); $\lambda_w, \lambda_y,$ and λ_z are the respective orthotropic thermal conductivities ($\text{J}/\text{mm} \cdot \text{s} \cdot ^{\circ}\text{C}$) in the w -, y -, and z -directions (mm); ρ is density (g/mm^3); C_p is specific heat ($\text{J}/\text{g} \cdot ^{\circ}\text{C}$); h is the surface heat-loss coefficient ($\text{J}/\text{mm}^2 \cdot \text{s} \cdot ^{\circ}\text{C}$); $l_w, l_y,$ and l_z are the direction cosines of the boundary surface; \dot{Q} is the volumetric heat source ($\text{J}/\text{mm}^3 \cdot \text{s}$); \dot{q} is the surface heat source ($\text{J}/\text{mm}^2 \cdot \text{s}$); t is the elapsed time after initiation of the welding heat source (s); and V is the welding speed (mm/s). For materials with homogeneous thermal properties, the thermal conductivities become directional-independent ($\lambda_w = \lambda_y = \lambda_z = \lambda$) and can be factored out of the differential operators in Eq 1.

The volumetric heat source represents the joule heating in the weldment that is due to the electric current flow (or mechanical energy generation due to friction or plastic flow in friction or friction stir welding) within that conducting medium. The total energy of such

internal joule heating in welding is usually minimal, compared to the arc heat input. The majority of the energy is concentrated in a very small volume beneath the arc (Ref 5). In other words, a very high energy density generation exists in the weld pool, and it may have a significant effect on transient pool growth and solidification.

Heat-Source Formulation. The direction cosines on the surface that receives the heat flux from the welding source ($z = 0$) are $l_w = l_y = 0$ and $l_z = -1$. Within the significant heat-input area (to be defined later in this section), the heat-loss coefficient, h , is zero.

The distribution of the welding heat flux on the weldment surface can be characterized, in a general form, by a skewed Gaussian function (Ref 6):

$$\dot{q}(r, w) = \dot{q}_0 \exp\left(-Cr^2 - \frac{\beta V}{2\kappa} w\right) \quad (\text{Eq 4})$$

where β is a weight constant, κ is the thermal diffusivity of the base material (mm^2/s), C is a shape constant, \dot{q} is surface heat flux ($\text{J}/\text{mm}^2 \cdot \text{s}$) as a function of (r, w), \dot{q}_0 is heat flux ($\text{J}/\text{mm}^2 \cdot \text{s}$) at the source center, r is the radial coordinate from the source center (mm), and V is the welding speed (mm/s).

The weight constant, β , indicates the significance of the welding travel speed. A normal distribution of the welding heat flux is obtained if the weight constant is zero. For the conventional welding processes, a normal distribution is usually adequate for predicting thermal responses of a material.

In general, the total energy input to the weldment, which is a fraction of the total welding power generated by the welding machine, is the sum of the concentrated heat and the diffused heat (Ref 26). The concentrated heat is carried by the core of the energy transmission medium, for example, the arc plasma column. The diffused heat reaches the weld surface by radiation and convection energy transport from the core surface. The heat-flux distribution is a function of the proportional values between these two types of energy. The fraction of the total welding power reaching the weldment indicates the heating efficiency of the welding process, and the fraction percentage is defined as welding heat efficiency, η .

The shape constant, C , can be obtained in terms of the core diameter, D (mm), and the concentration factor, F . The concentration factor is defined as the ratio of the concentrated heat to the net energy reaching the weldment. The core diameter can be assumed to be the diameter of the plasma column in the arc welding process. The concentration factor and welding heat efficiency are not fully understood and have been subjected to manipulation during the mathematical analyses in order to obtain a better correlation with the experimental data.

Assuming a normal heat-flux model ($\beta = 0$), the core diameter and the concentrations factor are required to determine the shape

constant, C , and the heat flux at the source center, \dot{q}_0 . By integrating Eq 4 over the core heat area and the entire heat-input domain ($r = 0 \rightarrow \infty$), the shape factor can be determined by dividing the two integrals. The heat flux at the source center can then be determined from the second integral. The two constants are expressed as:

$$C = \frac{4\ell n[1/(1-F)]}{D^2} \quad (\text{Eq 5})$$

$$\frac{\dot{q}_0}{\dot{Q}} = \frac{C}{\pi} \quad (\text{Eq 6})$$

In the case of arc welding:

$$\frac{\dot{q}_0}{\eta EI} = \frac{C}{\pi} \quad (\text{Eq 7})$$

where E is the welding arc voltage (V), and I is the welding current (A).

For practical purposes, the welding heat source can be considered to be restricted within a circle of radius r_a (mm), where the heat flux drops to 1/100 of the center flux \dot{q}_0 . The radius of the significant heat-input area can be written as:

$$r_a = \sqrt{\frac{\ell n(100)}{C}} = \frac{2.146}{\sqrt{C}} \quad (\text{Eq 8})$$

Surface Heat Loss. The heat-loss coefficient, h ($\text{J}/\text{mm}^2 \cdot \text{s} \cdot ^{\circ}\text{C}$), represents both radiation and convection heat loss from the boundary surfaces outside the significant heat-input area. The formulation for both heat-loss mechanisms can be written as the radiation heat-loss coefficient (in air):

$$h_{\text{rad}} = \epsilon \sigma (\theta_w^4 - \theta_\infty^4) \quad (\text{Eq 9})$$

where ϵ is emissivity (e.g., 0.3 for an oxidized steel surface), σ is the Stefan-Boltzmann constant ($5.6704 \times 10^{-14} \text{ J}/\text{s} \cdot \text{mm}^2 \cdot \text{K}^4$, where K is the absolute temperature in $^{\circ}\text{C}$), θ_w is the surface temperature ($^{\circ}\text{C}$), and θ_∞ is the environmental temperature ($^{\circ}\text{C}$).

The natural convection heat-loss coefficient in air is in the range of $(5 \sim 25) \times 10^{-6}$ (Ref 27) and in water is in the range of 0.003 to 0.1 (Ref 28). The unit for both coefficients is in $\text{J}/\text{s} \cdot \text{mm}^2 \cdot ^{\circ}\text{C}$.

Natural convection is dominant at a temperature below $550 \text{ }^{\circ}\text{C}$ ($1020 \text{ }^{\circ}\text{F}$), whereas radiation becomes more important at temperatures above this level. The total heat-loss coefficient is the sum of radiation and convection. In underwater welding, heat losses are due primarily to heat transfer from the surface to the moving water environment. This motion is created by the rising gas column in the arc area (Ref 29), which is similar to a boiling heat-transfer phenomenon.

For an insulated surface, no heat transfer into or out of the surface is assumed. The

temperature gradient normal to the surface is zero and can be represented by:

$$\bar{n} \cdot \nabla \theta = 0 \quad (\text{Eq 10})$$

where \bar{n} is a unit vector normal to the surface and equals $(I_w^2 + I_y^2 + I_z^2)^{0.5}$.

Other Boundary Conditions. There are several other possible boundary conditions in welding heat-flow modeling that depend on the assumptions used for model simplification. One is the condition at infinity:

$$\theta = \theta_\infty \text{ or } \lim_{r \rightarrow \infty} \frac{\partial \theta}{\partial r} = 0 \quad (\text{Eq 11})$$

Another is the condition near the heat source. In the case of a line source for a thin plate:

$$-2\pi\lambda H \lim_{r \rightarrow 0} \frac{\partial \theta}{\partial r} = \eta EI \quad (\text{Eq 12})$$

where H is the plate thickness (mm).

In the case of a point source for a thick plate:

$$-2\pi\lambda \lim_{r \rightarrow 0} \left(r^2 \frac{\partial \theta}{\partial r} \right) = \eta EI \quad (\text{Eq 13})$$

In the case of a finite source for a thick plate (on a heating surface):

$$\bar{n} \cdot (-\lambda \nabla \theta) = \dot{q}(r); \quad r \leq r_a \quad (\text{Eq 14})$$

Another is represented by the conditions at the solid-liquid interface:

$$\theta_s = \theta_l = \theta_m \quad (\text{Eq 15})$$

$$[\bar{n} \cdot (\lambda \nabla \theta)]_s - [\bar{n} \cdot (\lambda \nabla \theta)]_l = \pm \rho_s L \frac{ds}{dt} \quad (\text{Eq 16})$$

where “+” indicates the melting process and “-” indicates the solidification process. The subscripts “s” and “l” indicate the temperature and the properties in a solid and liquid, respectively. The \bar{n} is a normal vector on the boundary surface or interface, r_a is the radius of the heat-input area (mm), L is the latent heat of the base material (J/g), and the subscript “m” represents the melting temperature of the base material.

Engineering Solutions and Empirical Correlation

General Solutions. The general (analytical) heat-flow solutions for fusion welding can be categorized by those appropriate for a thick plate, a thin plate, or a plate with finite thickness. In most cases, the boundary surfaces (except for the heat-input area) are assumed to be adiabatic, and the thermal properties are independent of temperature. The various metallurgical zones in the weldment are assumed to be homogeneous, and the thermal model is linear.

The solutions give the temperature for a specific point if the welding velocity, V , voltage, E , and current, I , as well as the physical properties of the plate material (ρ , λ , C_p) and the welding heat efficiency, η , are known. This specific point is defined by r and w in:

$$r = \sqrt{w^2 + y^2 + z^2} \quad (\text{Eq 17})$$

where $w = x - Vt$. The heat-flow solutions are not accurate at points near the welding arc because a point source or line source is assumed for thick and thin plates, respectively.

To approximate the transient temperature changes at the start and end of a weld, Fig. 2 shows a global coordinate system (x, y, z), the origin of which is fixed at the source initiation, where t_0 is the welding time and t_1 is the time after the welding heat-source termination. The temperature solutions at t_0 and t_1 are the temperature changes at the start and end of the weld, respectively.

The temperature solution for thick plate at the arc start location is:

$$\theta - \theta_0 = \frac{\eta EI}{2\pi\lambda V t_0} \quad (\text{Eq 18})$$

The quasi-stationary temperature distribution is:

$$\theta - \theta_0 = \frac{\eta EI}{2\pi\lambda r} \exp\left[\frac{-V(w+r)}{2\kappa}\right] \quad (\text{Eq 19})$$

At the arc termination location, the solution is:

$$\theta - \theta_0 = \frac{\eta EI}{2\pi\lambda V t_1} \quad (\text{Eq 20})$$

where κ is the thermal diffusivity, which is the ratio of thermal conductivity to the specific heat of the material:

$$\left(\kappa = \frac{\lambda}{\rho C_p}, \text{ mm}^2/\text{s}\right)$$

The transient time periods, t_0 and t_1 , are in the order of seconds for the common arc welding processes.

The temperature solution for thin plate at the arc start location is:

$$\theta - \theta_0 = \frac{\eta EI}{4\pi\lambda H} \exp\left(\frac{V^2 t_0}{2\kappa}\right) \cdot K_0\left(\frac{V^2 t_0}{2\kappa}\right) \quad (\text{Eq 21})$$

The quasi-stationary temperature distribution is:

$$\theta - \theta_0 = \frac{\eta EI}{2\pi\lambda H} \exp\left(\frac{-Vw}{2\kappa}\right) \cdot K_0\left(\frac{Vr}{2\kappa}\right) \quad (\text{Eq 22})$$

For the arc termination location, the solution is:

$$\theta - \theta_0 = \frac{\eta EI}{4\pi\lambda H} \exp\left(\frac{V^2 t_1}{2\kappa}\right) \cdot K_0\left(\frac{V^2 t_1}{2\kappa}\right) \quad (\text{Eq 23})$$

where K_0 is the modified Bessel function of the second kind of zeroth order, and ηEI is the welding heat-input rate.

Temperature for Plate with Finite Thickness. The image method enables the investigator to superimpose the solutions for an infinitely thick plate, the source of which is placed on imaginary surfaces until the proper boundary conditions on the plate surfaces are obtained. This method is based on the premise that if a solution satisfies the governing equation and the boundary conditions, then it must be not only a correct solution but the only solution (that is, the uniqueness of solution premise).

Using the image method, the solution for plates of finite thickness with adiabatic surfaces can be modified from the respective temperature solutions described previously.

Let $\phi_0(w, y, z, t)$ be the initial solution for an infinitely thick plate. The temperature solution for a finite thick plate can be obtained by superimposing the imaginary solutions $\phi_{mn}(w, y_m, z_n, t)$ and $\phi'_{mn}(w, y'_m, z'_n, t)$ to the initial solution, and this can be written in a general form as:

$$\theta - \theta_0 = -\phi_0(w, y, z, t) + \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} [\phi_{mn}(w, y_m, z_n, t) + \phi'_{mn}(w, y'_m, z'_n, t)] \quad (\text{Eq 24})$$

where $y_m = 2mB - y$; $y'_m = 2mB + y$; $z_n = 2nH - z$; and $z'_n = 2nH + z$, in which B is the half width and H is the thickness of the plate. The subscripts m and n are integers that vary from zero to infinity.

For a plate with sufficient width (i.e., this is usually the case in a practical situation), the subscript m is zero. The solution will converge and reach the correct adiabatic surface condition in six to ten superposition steps (i.e., n value is up to 6 to 10), depending on the thickness of the plate. The two-dimensional solution (that is, thin plate) is generally used for any solution that requires more than ten superposition steps.

Equation 24 can be expressed as:

$$\theta - \theta_0 = -\frac{\eta EI \exp\left(\frac{-Vw}{2\kappa}\right)}{2\pi\lambda} \cdot \left\{ \frac{\exp\left(\frac{-Vr}{2\kappa}\right)}{r} + \sum_{n=1}^{\infty} \left[\frac{\exp\left(\frac{-Vr_{2n}}{2\kappa}\right)}{r_{2n}} + \frac{\exp\left(\frac{-Vr_{2n+1}}{2\kappa}\right)}{r_{2n+1}} \right] \right\} \quad (\text{Eq 25})$$

Fig. 2 Global and moving coordinate systems for welding heat conduction

where:

$$r_{2n} = \sqrt{w^2 + y^2 + (2nH - z)^2} \text{ and } r_{2n+1} = \sqrt{w^2 + y^2 + (2nH + z)^2} \quad (\text{Eq 26})$$

Cooling Rate. Frequently, it is desirable to know the cooling rate experienced at some location in a weldment to enable a prediction of the metallurgical structure in that area. A general methodology by which cooling-rate equations are obtained from the temperature-distribution equations is discussed as follows.

Recall that the moving coordinate w is defined by $w = x - Vt$. Using this definition, it is easily shown that:

$$\frac{\partial w}{\partial t} = -V \quad (\text{Eq 27})$$

Using the chain rule, the cooling-rate equation is:

$$\frac{\partial \theta}{\partial t} = -V \frac{\partial \theta}{\partial w} \quad (\text{Eq 28})$$

Because the temperature-distribution equations are a function of w and r , the cooling-rate equations can be obtained by differentiating the temperature-distribution equations with respect to w and multiplying by $-V$.

The cooling rate is defined as the slope of a tangent line drawn on the temperature-time curve. Because the cooling rate changes with temperature, when one speaks of a cooling rate, the specific temperature, θ_c , at which it occurs must also be given. In a weldment, the variable of interest is the cooling rate at the critical temperature that ultimately defines what type of metallurgical structure will result (if the material is heat treatable). For steels, this critical temperature is the "nose" of the continuous cooling transformation curve. At this temperature, the cooling rate determines if upper transformation products (pearlite, upper bainite) or lower transformation products (martensite, lower bainite) will form. For many steels, this critical temperature ranges from approximately 200 to 540 °C (400 to 1000 °F).

The cooling rate in a weldment is also a function of location, because the temperature varies with location during welding. To find a cooling-rate equation for the quasi-stationary state, the particular location in the weldment that is of interest and corresponds to the cooling temperature at a given distance from the heat source must be defined. The resulting cooling-rate equation will be applicable only to that location.

The differentiation, $\partial\theta/\partial w$, of either Eq 19 or 25, which is required to obtain the cooling-rate expression, will result in a function of w and r . The variable r can be written in terms of w if the location of interest is defined by a given set of values of y and z . This relationship for r , once formulated, can then be substituted into $\partial\theta/\partial w$, the result being a function of w alone.

To determine w corresponding to the critical temperature, θ_c , a temperature-distribution

equation is required (Eq 19 or 25). The aforementioned r - w relationship and temperature-distribution equation (Eq 19 or 25) where θ is equal to θ_c , critical temperature, are used to determine w . Then, w is substituted into the $d\theta/dw$ expression obtained previously. The end result will be an equation that defines the cooling rate for a particular location in the weldment, and, being a function of the critical temperature, the welding conditions and thermal conductivity of the base material.

To determine the cooling rate in a thick plate along the weld centerline (that is $y = 0$) for a particular critical temperature, the cooling-rate equation can be reduced to:

$$\left[\frac{\partial \theta}{\partial t} \right]_{\theta_c} = \frac{-2\pi\lambda V(\theta_c - \theta_0)^2}{\eta EI} \quad (\text{Eq 29})$$

This equation has been used to predict weld cooling rates in shop practices. Cooling rate is inversely proportional to heat input per unit weld length (that is, \dot{Q}/V) and is proportional to thermal conductivity and the critical temperature at which the cooling rate needs to be evaluated.

On the basis of experimental results, a cooling-rate equation was developed for the HAZ of low-carbon steel weldments (Ref 30). This equation considers the combined effects of plate thickness, H (in.), preheating temperature, θ_0 (°C), and welding conditions, and is given as:

$$\left[\frac{\partial \theta}{\partial t} \right]_{\text{HAZ}} = 0.35 \left\{ \left(\frac{\theta_c - \theta_0}{I/V} \right)^{1.7} \left[1 + \frac{2}{\pi} \tan^{-1} \left(\frac{H - H_0}{\alpha} \right) \right] \right\}^{0.8} \quad (\text{Eq 30})$$

The variables α and H_0 depend on the critical temperature of interest. Several values are given in Table 1.

The units used in Eq 30 are important, because the same units that were used in developing the equation must be employed in its application. The plate thickness, H , must be given in inches, and the travel speed, V , must be given in in./min (ipm). The temperatures θ_c and θ_0 must be given in °C, and the welding current, I , must be given in amperes. Using the correct units, the application of Eq 30 will result in a predicted cooling rate (°C/s) for the HAZ of a low-carbon steel weldment made by common arc welding processes.

For low-carbon steels welded by the shielded metal arc welding (SMAW), gas metal arc welding (GMAW), and submerged arc welding (SAW) processes, an empirical equation has been developed that correlates the weld-metal cooling rate at 538 °C (1000 °F) with a 95 to 150 °C (200 to 300 °F) preheat to the weld nugget area (Ref 31):

$$^{\circ}\text{C/s} = \left(\frac{2012}{\text{Nugget area}} \right)^{1.119} \quad (\text{Eq 31})$$

where the nugget area is in mm². For low-carbon steels, an empirical chart for determining nugget area for a given welding condition (Fig. 3) also has been developed (Ref 32).

Table 1 Selected critical temperature and corresponding values for α and H_0

Critical temperature, θ_c		H_0		α	
°C	°F	mm	in.	mm	in.
700	1290	9.9	0.39	2.0	0.08
540	1000	14.2	0.56	4.1	0.16
300	570	19.8	0.78	9.9	0.39

Fig. 3 Relation between nugget area, heat input, and current

The straight line drawn to connect the current and weld bead heat input (i.e., $\eta EI/V$) intersects the nugget area at the calculated value. The product of welding heat efficiency and arc voltage remains a rather constant value in arc welding. Therefore, weld nugget area and weld-metal cooling rate are influenced primarily by the welding current and speed. Welding voltage controls weld bead shape.

Peak Temperature. An equation to determine the peak temperature in a weldment at a given distance y from the weld centerline would enable the prediction of HAZ sizes as well as weld bead widths. The general concept of obtaining a peak-temperature equation, as well as some results that have been obtained, are discussed as follows.

Consider Fig. 4 and note that the maximum, or peak, temperature is given when $\partial\theta/\partial t = 0$. For the thick-plate model, the cooling rate can be obtained by differentiating Eq 19 and multiplying by $-V$:

$$\frac{\partial\theta}{\partial t} = -V \frac{\partial\theta}{\partial w} = \frac{-V\eta EI}{2\pi\lambda r} \exp\left[\frac{-V(w+r)}{2\kappa}\right] \left[\frac{-w}{r^2} - \frac{V}{2\kappa} \left(1 + \frac{w}{r}\right)\right] \quad (\text{Eq 32})$$

Clearly, the only way that $\partial\theta/\partial t$ can be equal to zero is if

$$\frac{-w}{r^2} - \frac{V}{2\kappa} \left(1 + \frac{w}{r}\right) = 0 \quad (\text{Eq 33})$$

Equation 33 describes the relationship that must exist between the two location variables, r and w , for the temperature at that point to be equal to the peak temperature. For a given y and z in thick plate, this equation can be solved together with the geometric fact that (Eq 17):

$$r = \sqrt{w^2 + y^2 + z^2}$$

for $w = w_p$ and $r = r_p$. The subscript "p" represents the corresponding peak-temperature location. If w_p and r_p are substituted into the temperature-distribution equation for thick plates (Eq 19), the peak temperature for a given y and z can be determined.

Such a solution for r and w is not explicitly possible, however, because the equations for r and w that result are not explicit. Consequently, iterative techniques are required, resulting in a solution that is both cumbersome and time-consuming.

One method of obtaining a simpler thick-plate peak-temperature equation is to assume that the heat input is from an instantaneous line on the surface of the plate, rather than from a moving point source (that is, $V \rightarrow \infty$). This allows the elimination of the time dependency in the peak-temperature evaluation. Using this assumption, the temperature distribution is given by:

$$\theta - \theta_0 = \frac{\eta EI}{2\pi\lambda t} \exp\left(\frac{-r^2}{4\kappa t}\right) \quad (\text{Eq 34})$$

Again, to find the peak-temperature location, $\partial\theta/\partial t$ is set equal to zero and the equation is solved for r . The result is:

$$\frac{r^2}{4\kappa t} = 1 \quad (\text{Eq 35})$$

Substituting Eq 35 into Eq 34 yields the peak-temperature expression, $\theta = \theta_p$, which is:

$$\frac{1}{(\theta_p - \theta_0)} = \frac{1}{\left(\frac{\eta EI}{V}\right)} \left(\frac{e\rho C_p \pi r^2}{2}\right) \quad (\text{Eq 36})$$

It has been found that Eq 36 gives results that are too high, but that the slope of $1/(\theta_p - \theta_0)$ versus r^2 is accurate. To rectify this situation, Eq 36 is forced to fit experimental results by specifying a known temperature/location condition (θ_r at r_r). When this is done, Eq 36 becomes:

$$\frac{1}{(\theta_p - \theta_0)} = \frac{[e\rho C_p \pi (r^2 - r_r^2)]}{2 \cdot \left(\frac{\eta EI}{V}\right)} + \frac{1}{(\theta_r - \theta_0)} \quad (\text{Eq 37})$$

where θ_r and r_r are the reference temperature and distance. If the peak temperature (θ_p) evaluation is restricted to locations on the plate surface ($z = 0$), then $r = y$; and if the reference temperature and distance are assumed to be the melting temperature and the distance from the weld centerline to the fusion boundary (one-half of the weld bead width), then Eq 37 can be written as:

$$\frac{1}{(\theta_p - \theta_0)} = \frac{e\rho C_p \pi \left[y^2 - \left(\frac{d}{2}\right)^2\right]}{2 \cdot \left(\frac{\eta EI}{V}\right)} + \frac{1}{(\theta_m - \theta_0)} \quad (\text{Eq 38})$$

where θ_m is the melting temperature, and d is the weld bead width. This equation gives the peak temperature θ_p in a thick plate at a distance y from the weld centerline.

Solidification Rate. The weld solidification structure can be determined by using the constitutional supercooling criterion. Three thermal parameters that influence the solidification structure are temperature gradient normal to the solid-liquid interface, G ($^{\circ}\text{C}/\text{mm}$), solidification rate of the interface, R (mm/s), and cooling rate at the interface, $\partial\theta/\partial t$, at melting temperature ($^{\circ}\text{C}/\text{s}$ and equal to the product of GR). The microstructure may change from being planar to being cellular, a columnar dendrite, or an equiaxial structure if the G/R ratio becomes smaller. The dendrite arm spacing will decrease as the cooling rate increases. The solidification structure becomes refined at higher cooling rates.

At a quasi-steady state, the weld pool solidifies at a rate that is equal to the component of the electrode travel speed normal to the solid-liquid interface. Therefore, the solidification rate varies along the solid-liquid interface from the electrode travel speed, at the weld trailing edge, to zero, at the maximum pool width. The temperature gradient and the cooling rate at the solid-liquid interface can be determined from Eq 19, 22, and 24.

Modified Temperature Solution. The temperature solutions have a singularity at the center of the heat source. This singularity causes the predicted temperatures to be inaccurate in the area surrounding the heat source. However, a condition exists in which the peak temperature along the weld bead edge, that is, the solid-liquid interface location at the maximum pool width, is the melting temperature of the material. Using this temperature condition as a boundary condition for the temperature solutions, Eq 19 and 22 can be modified as shown subsequently: For thin plate:

$$\theta - \theta_0 = B_z \exp\left(\frac{-Vw}{2\kappa}\right) K_0\left(\frac{Vr}{2\kappa}\right) \quad (\text{Eq 39})$$

where B_z is a heat-input constant to be determined from the weld bead width, d :

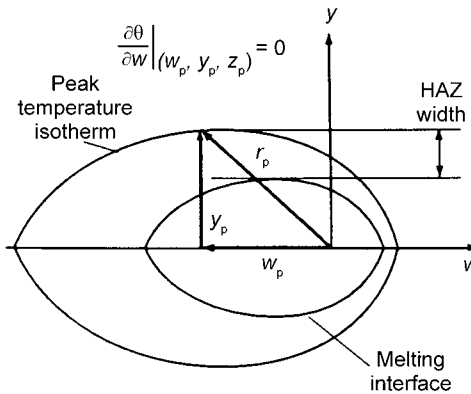

Fig. 4 Schematic showing peak temperature at (w_p, y_p, z_p) , with w_p to be determined for a given peak temperature value for a given (y_p, z_p) location. (a) Isotherms. HAZ, heat-affected zone. (b) Temperature history

$$B_z = \frac{(\theta_m - \theta_0) \exp\left(\frac{-Vr_B}{2\kappa}\right) \left[\frac{K_0(Vr_B/2\kappa)}{K_1(Vr_B/2\kappa)}\right]}{K_0\left(\frac{Vr_B}{2\kappa}\right)} \quad (\text{Eq 40})$$

with a bead width of:

$$d = 2r_B \sqrt{1 - \left[\frac{K_0(Vr_B/2\kappa)}{K_1(Vr_B/2\kappa)}\right]^2} \quad (\text{Eq 41})$$

For thick plate:

$$\theta - \theta_0 = B_z \frac{\exp[-V(w+r)/2\kappa]}{r} \quad (\text{Eq 42})$$

$$B_z = (\theta_m - \theta_0)r_B \exp\left(\frac{-Vr_B}{2\kappa}\right) \left[\frac{1}{1 + \left(\frac{2\kappa}{Vr_B}\right)} - 1 \right] \quad (\text{Eq 43})$$

with a bead width of:

$$d = 2r_B \sqrt{1 - \frac{1}{1 + \left(\frac{2\kappa}{Vr_B}\right)}} \quad (\text{Eq 44})$$

The welding heat input, \dot{Q} , is replaced by the heat-input parameter, B_z , which can be determined from measurement of the weld bead width, d . These equations can also be used to estimate the arc efficiency from the weld bead width.

A Practical Application of Heat-Flow Equations (Ref 33). The thermal condition in and near the weld metal must be established to control the metallurgical events in welding. The particular items of interests are the:

- Distribution of peak temperature in the HAZ
- Cooling rates in the weld metal and in the HAZ
- Solidification rate of the weld metal

Using aforementioned equations with some numerical values placed in them, several simple formulas are found in the published references. Although the following discussion focuses primarily on manual arc welding, certain general statements are applicable to all welding processes.

Peak Temperatures. The distribution of peak temperatures in the base metal adjacent to the weld is given by (Ref 34):

$$\frac{1}{\theta_p - \theta_0} = \frac{4.13\rho C_p H Y}{H_{net}} + \frac{1}{\theta_m - \theta_0} \quad (\text{Eq 45})$$

where θ_p is the peak temperature ($^{\circ}\text{C}$) at distance Y (mm) from the weld fusion boundary, θ_0 is the initial temperature ($^{\circ}\text{C}$), θ_m is the melting temperature ($^{\circ}\text{C}$), H_{net} is the net energy input equal to $\eta EI/V$ (J/mm), ρ is the density of the material (g/mm^3), C_p is the specific heat of solid metal ($\text{J}/\text{g} \cdot ^{\circ}\text{C}$), and H is the thickness of the base metal (mm).

Equation 45 can be used to determine the:

- Peak temperatures at specific locations in the HAZ
- Width of the HAZ
- Effect of preheat on the width of the HAZ

In addition, determination of the peak temperature at specific locations in the HAZ and the width of the HAZ can be obtained by the procedure described in the section "Engineering Solutions and Empirical Correlation" in this article.

Cooling Rate. Because the cooling rate varies with position and time, its calculation requires the careful specification of conditions. The most useful method is to determine the cooling rate on the weld centerline at the instant when the metal passes through a particular temperature of interest, θ_c . At a temperature well below melting, the cooling rate in the weld and in its immediate HAZ is substantially independent of position. For carbon and low-alloy steels, θ_c is the temperature near the pearlite "nose" temperature on the time-temperature transformation diagram. The value of $\theta_c = 550^{\circ}\text{C}$ (1020°F) is satisfactory for most steels, although not critical.

The cooling rate for thick plate (Ref 34) is:

$$R = \frac{2\pi\lambda(\theta_c - \theta_0)^2}{H_{net}} \quad (\text{Eq 46})$$

Equation 46 is comparable to Eq 29, which was obtained by the procedure described in the section "Cooling Rate" in this article. Adams (Ref 34) has developed a cooling-rate equation for thin plate along the centerline from Eq 24, which is:

$$R = 2\pi\lambda\rho C_p \left(\frac{H}{H_{net}}\right)^2 (\theta_c - \theta_0)^3 \quad (\text{Eq 47})$$

where R is the cooling rate ($^{\circ}\text{C}/\text{s}$) at a point on the weld centerline at just that moment when the point is cooling past the θ_c , ρC_p is the volumetric specific heat ($\text{J}/\text{mm}^3 \cdot ^{\circ}\text{C}$), and λ is the thermal conductivity of the base metal ($\text{J}/\text{mm} \cdot \text{s} \cdot ^{\circ}\text{C}$), respectively.

The dimensionless quantity τ , called the relative plate thickness, can be used to determine whether the plate is thick or thin:

$$\tau = H \cdot \sqrt{\frac{\rho C_p (\theta_c - \theta_0)}{H_{net}}} \quad (\text{Eq 48})$$

The relative plate thickness, τ , indicates a thermal balance between weld heat input and the material specific heat. The more energy input to the joint would lead to a more uniform temperature distribution through the plate thickness, which is analogous to a thinner plate condition. On the other hand, a smaller amount of weld heat input would cause deeper temperature slope through the thickness. The specific heat reduces the effect of heat input. In

practical situations, the thick-plate equation applies when τ is greater than 0.75, and the thin-plate equation applies when τ is less than that value.

Equations 46 and 47 are used to determine the cooling rate along the centerline for thick plate and thin plate, respectively. If one is interested in the cooling rate at the location at distance y from the centerline, iterative techniques should be used to solve the cooling rate. First, w and r can be obtained by iteration of the simultaneous equations, which consists of Eq 19 or 25, where θ equals θ_c and $r^2 = w^2 + y^2$, where y is given. Then, substitute w and r into the differentiation, $\partial\theta/\partial t = -V\partial\theta/\partial w$, from the temperature from Eq 19 or 25. The result will be the cooling rate for thick or thin plate located at y distance from the centerline:

$$\left[\frac{\partial\theta}{\partial t}\right]_{\theta_c}$$

In addition, the cooling rate for HAZ of low-carbon steel weldments can be obtained from Eq 30 directly.

Solidification Rate. The solidification rate can have a significant effect on metallurgical structure, properties, response to heat treatment, and soundness. The solidification time, S_t , of weld metal, measured in seconds, is:

$$S_t = \frac{LH_{net}}{2\pi\lambda\rho C_p(\theta_m - \theta_0)^2} \quad (\text{Eq 49})$$

where L is the heat of fusion (J/mm^3).

Example 1: Welding of 5 mm (0.2 in.) Thick Low-Carbon Steels. The thermal properties needed for heat-flow analysis are assumed to be:

Melting temperature (θ_m), $^{\circ}\text{C}$ ($^{\circ}\text{F}$)	1510 (2750)
Austenitization temperature, $^{\circ}\text{C}$ ($^{\circ}\text{F}$)	730 (1345)
Thermal conductivity (λ), $\text{W}/\text{m} \cdot \text{K}$ ($\text{J}/\text{mm} \cdot \text{s} \cdot ^{\circ}\text{C}$)	28 (0.028)
Volumetric specific heat (ρC_p), $\text{J}/\text{mm}^3 \cdot ^{\circ}\text{C}$	0.0044
Heat of fusion (L), J/mm^3	2

The welding condition is assumed to be:

Current (I), A	200
Arc voltage (E), V	20
Travel speed (V), mm/s (ipm)	5 (12)
Preheat (θ_0), $^{\circ}\text{C}$ ($^{\circ}\text{F}$)	25 (77)
Heat-transfer efficiency (η)	0.9
Net energy input, H_{net} , J/mm (kJ/in.)	720 (18.3)

Calculation of the HAZ Width. The value of Y at $\theta_p = 730^{\circ}\text{C}$ (1345°F) may be determined from Eq 45:

$$\frac{1}{730 - 25} = \frac{4.13(0.0044)5Y}{720} + \frac{1}{1510 - 25} \quad (\text{Eq 50})$$

resulting in a value for Y (the width of the HAZ) of 5.90 mm (0.23 in.).

In addition, the HAZ width can be obtained by the procedure described in the earlier section, "Peak Temperature" (relating to Eq 32 to 38). By substituting $w = w_p$, $r = r_p$, $y = y_p$, and $z = 0$ (on surface) into Eq 17 and 33, one respectively obtains:

$$r_p^2 = w_p^2 + y_p^2 \quad (\text{Eq 51})$$

$$\frac{-w_p}{r_p^2} - \frac{V}{2\kappa} \left(1 + \frac{w_p}{r_p} \right) = 0 \quad (\text{Eq 52})$$

Inserting $V = 5 \text{ mm/s}$, $\kappa = \lambda/\rho C_p = 0.028/0.0044 = 6.364 \text{ mm}^2/\text{s}$ into Eq 52:

$$\frac{-w_p}{r_p^2} = 0.393 \left(1 + \frac{w_p}{r_p} \right) \quad (\text{Eq 53})$$

From the temperature distribution equation (Eq 19) and $E = 20 \text{ V}$, $I = 200 \text{ A}$, $\eta = 0.9$, $\lambda = 0.028 \text{ J/mm} \cdot \text{s} \cdot \text{°C}$, $\theta_p = 730 \text{ °C}$, $\theta_0 = 25 \text{ °C}$, $V = 5 \text{ mm/s}$, $\kappa = \lambda/\rho C_p = 0.028/0.044 = 6.364 \text{ mm}^2/\text{s}$:

$$730 - 25 = \frac{0.9 \cdot 20 \cdot 200}{2\pi \cdot 0.028 r_p} \cdot \exp \left[\frac{-5(w_p + r_p)}{2 \cdot 0.028/0.0044} \right] \quad (\text{Eq 54})$$

$$-3.368 + \ln(r_p) = -0.393(w_p + r_p) \quad (\text{Eq 55})$$

Solving the simultaneous equations, Eq 53 and 55, the peak temperature location (r_p , w_p) is determined. The peak temperature of 730 °C boundary from the weld centerline (y_p) can be determined from Eq 51 using the obtained values of r_p and w_p . The final solution result showing the peak temperature of 730 °C location with respect to the moving arc center on the plate surface is at ($w_p = -10.51 \text{ mm}$, $y_p = 12.63 \text{ mm}$, $z_p = 0 \text{ mm}$).

To determine the HAZ width, the weld bead width or boundary of peak temperature of 1510 °C must be determined. The difference between the two distances to the weld centerline of two peak temperatures is the HAZ width (Y). Following the same mathematical procedure as used for 730 °C peak temperature location, the 1510 °C location can be determined, which is at ($w_p = -4.84 \text{ mm}$, $y_p = 6.68 \text{ mm}$, $z_p = 0 \text{ mm}$). The HAZ size $Y = 12.63 - 6.68 = 5.95 \text{ mm}$ (0.23 in.), which is less than 1% difference.

Effect of Tempering Temperature on Quenched and Tempered (Q&T) Steels. If the plate had been quenched and then tempered to 430 °C (810 °F), then any region heated above that temperature will have been "overtempered" and may exhibit modified properties. It would then be reasonable to consider the modified zone as being "heat affected," with its outer extremity located where $\theta_p = 430 \text{ °C}$ (810 °F):

$$\frac{1}{430 - 25} = \frac{4.13(0.0044)5Y_z}{720} + \frac{1}{1510 - 25} \quad (\text{Eq 56})$$

resulting in a value for Y of 14.23 mm (0.56 in.). Tempering to 430 °C increases the HAZ by 140%.

Effect of Preheating Temperature on Q&T Steels. Assume that the Q&T steel described previously was preheated to a temperature, θ_0 , of 200 °C (390 °F):

$$\frac{1}{430 - 25} = \frac{4.13(0.0044)5Y_z}{720} + \frac{1}{1510 - 200} \quad (\text{Eq 57})$$

resulting in a value for Y of 28.40 mm (1.12 in.). Preheating Q&T steel at 200 °C will double the HAZ size. Therefore, an upper limit on the preheating temperature is specified for Q&T steels in most of the welding codes.

Effect of Energy Input on Q&T Steels. Assume that the energy input into the Q&T steel (without preheating) increases 50% (that is, 1.08 kJ/mm , or 27.45 kJ/in.):

$$\frac{1}{430 - 25} = \frac{4.13(0.0044)5Y_z}{1080} + \frac{1}{1510 - 25} \quad (\text{Eq 58})$$

resulting in a value for Y of 21.34 mm (0.84 in.). Increasing the energy input by 50% will also increase HAZ by 50%.

Example 2: Welding of 6 mm (0.24 in.) Thick Low-Carbon Steels. The thermal properties needed for heat-flow analysis are assumed to be:

Melting temperature (θ_m), °C (°F)	1510 (2750)
Austenitization temperature, °C (°F)	730 (1345)
Thermal conductivity (λ), W/m · K (J/mm · s · °C)	28 (0.028)
Volumetric specific heat (ρC_p), J/mm ³ · °C	0.0044
Heat of fusion (L), J/mm ³	2

The welding condition is assumed to be:

Current (I), A	300
Arc voltage (E), V	25
Preheat (θ_0), °C (°F)	25 (77)
Heat-transfer efficiency (η)	0.9

Critical Cooling Rate at 550 °C (1022 °F) (θ_c). A critical cooling rate exists for each steel composition. If the actual cooling rate in the weld metal exceeds this critical value, then hard martensitic structures may develop in the HAZ, and there is a great risk of cracking under the influence of thermal stresses in the presence of hydrogen.

The best way to determine the critical cooling rate is to make a series of bead-on-plate weld passes in which all parameters, except the arc travel speed, are held constant. After the hardness tests on the weld passes deposited at travel speeds of 6, 7, 8, 9, and 10 mm/s (14, 17, 19, 21, and 24 ipm), it was found that at the latter two travel speeds, the weld HAZ had hardness exceeding the critical value (e.g., 350 HV). Therefore, the critical cooling rate was encountered at a travel speed of approximately 8 mm/s

(19 ipm). At this speed, the net energy input (i.e., the minimum requirement) is:

$$H_{\text{net}} = \frac{25(300)0.9}{8} = 844 \text{ J/mm} \quad (\text{Eq 59})$$

From Eq 48, the relative plate thickness is:

$$\tau = 6\sqrt{\frac{0.0044(550 - 25)}{844}} = 0.31 \text{ mm} \quad (\text{Eq 60})$$

Because τ is less than 0.75, the thin-plate equation (Eq 47) applies:

$$\frac{R}{2\pi\lambda} = 0.0044 \left(\frac{6}{844} \right)^2 (550 - 25)^3 = 32.20 \quad (\text{Eq 61})$$

resulting in R being equal to $2\pi(0.028)32.20$, which is equal to 5.7 °C/s (10.3 °F/s). This value is the maximum safe (critical) cooling rate for this steel, and the actual cooling rate cannot exceed this value.

Preheating Temperature Requirement. Although the critical cooling rate cannot be exceeded, in the actual welding operation a pre-heat can be used to reduce the cooling rate to 5.7 °C/s (10.3 °F/s).

Assume that the welding condition is:

Current (I), A	250
Arc voltage (E), V	25
Heat-transfer efficiency (η)	0.9
Travel velocity (V), mm/s (ipm)	7 (17)
Plate thickness (H), mm (in.)	9 (0.35)

The energy heat input, H_{net} , is:

$$H_{\text{net}} = \frac{25(250)0.9}{7} = 804 \text{ J/mm} \quad (\text{Eq 62})$$

Assuming that the thin-plate equation (Eq 47) applies:

$$\left(\frac{R}{2\pi\lambda} \right)_{\text{max}} = 32.20 = 0.0044 \left(\frac{9}{804} \right)^2 (550 - \theta_0)^3 \quad (\text{Eq 63})$$

resulting in a θ_0 of 162 °C (325 °F).

The relative plate thickness should be checked:

$$\tau = 9\sqrt{\frac{0.0044(550 - 162)}{804}} = 0.41 \quad (\text{Eq 64})$$

Because τ is less than 0.75, the thin-plate equation does apply. If the initial plate temperature is raised either to or above 162 °C (325 °F), then the cooling rate will not exceed 5.7 °C/s (10.3 °F/s). For this case, a minimum preheat temperature should be 162 °C (325 °F).

Equation 31 is an empirical equation for predicting the cooling rate in the weld bead. The nugget area can be determined from Fig. 3 using the weld bead heat input of 0.8 kJ/mm (20 kJ/in.), welding current of 250 A, and without preheating, which leads to an approximate value of 28 mm^2 (0.04 in.^2). The cooling rate calculated from Eq 31 is:

$$^{\circ}\text{C/s} = \left(\frac{2012}{28}\right)^{1.119} = 119 \text{ }^{\circ}\text{C/s} \quad (\text{Eq 65})$$

This cooling rate would be too high, and preheating must be used.

Effect of Joint Thickness. If the plate thickness increases from 9 to 25 mm (0.35 to 1 in.), but there is the same level of energy input, then the calculation of the required preheat temperature would be as follows. First, using the thin-plate equation (Eq 47):

$$\begin{aligned} \left(\frac{R}{2\pi\lambda}\right)_{\max} &= 32.2 \\ &= 0.0044 \left(\frac{25}{804}\right)^2 (550 - \theta_0)^3 \end{aligned} \quad (\text{Eq 66})$$

resulting in a value for θ_0 of 354 °C (669 °F).

The relative plate thickness, τ , should be checked:

$$\tau = 25 \sqrt{\frac{0.0044(550 - 354)}{804}} = 0.82 \quad (\text{Eq 67})$$

Because τ is greater than 0.75, the use of the thin-plate equation is inadequate. Using the thick-plate equation (Eq 46):

$$32.2 = \frac{(550 - \theta_0)^2}{804} \quad (\text{Eq 68})$$

resulting in a value for θ_0 of 389 °C (730 °F).

The relative plate thickness should be checked:

$$\tau = 25 \sqrt{\frac{0.0044(550 - 389)}{804}} = 0.74 \quad (\text{Eq 69})$$

Although τ is less than, but close to, 0.75, using the thick-plate equation is adequate. Therefore, the initial temperature should be raised to 389 °C (730 °F) by preheating to avoid exceeding the cooling rate of 5.7 °C/s (10.3 °F/s).

Now, if the plate thickness increases to 50 mm (2 in.), but there is the same level of energy input, then the thick-plate equation (Eq 46) applies and, again, the value for θ_0 is 389 °C (730 °F).

The relative plate thickness should be checked:

$$\tau = 50 \sqrt{\frac{0.0044(550 - 389)}{804}} = 1.48 \quad (\text{Eq 70})$$

Because τ is greater than 0.75, the use of the thick-plate equation is adequate.

Under some welding conditions, it is not necessary to reduce the cooling rate by using preheat. For example, if the plate thickness is 5 mm (0.2 in.) and there is the same level of energy input:

$$\begin{aligned} \left(\frac{R}{2\pi\lambda}\right)_{\max} &= 32.2 \\ &= 0.0044 \left(\frac{5}{804}\right)^2 (550 - \theta_0)^3 \end{aligned} \quad (\text{Eq 71})$$

resulting in a value for θ_0 of -24 °C (-11 °F). Therefore, using preheat is unnecessary.

Fillet-Welded Tee Joints. For a weld with a higher number of paths, as occurs in fillet-welded tee joints, it is sometimes necessary to modify the cooling-rate equation, because the cooling of a weld depends on the available paths for conducting heat into the surrounding cold base metal.

When joining 9 mm (0.35 in.) thick plate, where $H_{\text{net}} = 804 \text{ J/mm}$ (20.4 kJ/in.), and when there are three legs instead of two, the cooling-rate equation is modified by reducing the effective energy input by a factor of 2/3:

$$H_{\text{net}} = \frac{2}{3}(804) = 536 \text{ J/mm} \quad (\text{Eq 72})$$

Using the thin-plate equation (Eq 47):

$$\begin{aligned} \left(\frac{R}{2\pi\lambda}\right)_{\max} &= 32.2 \\ &= 0.0044 \left(\frac{9}{536}\right)^2 (550 - \theta_0)^3 \end{aligned} \quad (\text{Eq 73})$$

resulting in a value for θ_0 of 254 °C (490 °F).

The relative plate thickness should be checked:

$$\tau = 9 \sqrt{\frac{0.0044(550 - 254)}{536}} = 0.44 \quad (\text{Eq 74})$$

Because τ is less than 0.75, using the thin-plate equation is adequate. A higher preheat temperature is required for welding a tee joint because of the added cooling mass. The minimum preheat temperature should be increased from 162 to 254 °C (324 to 489 °F) when changing weld joint type from butt to tee of 9 mm (0.35 in.) plate thickness using the same amount of welding heat input.

Example 3: Cooling Rate for the Location at Distance y (mm) from the Centerline.

For a steel plate of 25 mm (1 in.) thickness (H), the welding condition is assumed to be:

Current, A	300
Arc voltage, V	25
Arc efficiency, η	1.00
Heat input (ηEI), kW (J/s)	7.5 (7500)
Travel speed (V), mm/s (ipm)	1.0 (2)
Preheat (θ_0), °C (°F)	20 (68)

The thermal properties needed for heat-flow analysis are assumed to be:

Melting temperature (θ_m), °C (°F)	1400 (2552)
Thermal conductivity (λ), W/m · K (J/mm · s · °C)	43.1 (0.0431)
Volumetric specific heat (ρC_p), J/mm ³ · °C	0.0037
Thermal diffusivity (κ), mm ² /s	11.65

Assume that one is interested in the critical cooling rate at the location on the surface ($z = 0$) at distance $y = 20$ mm from the centerline at the instant when the metal passes through the specific temperature of 615 °C (1140 °F). Initially, the relative plate thickness should be checked. From Eq 48, the relative plate thickness is:

$$\tau = 25 \sqrt{\frac{0.0037 \cdot (615 - 20)}{7500}} = 1.37 \quad (\text{Eq 75})$$

Because τ is greater than 0.75, this plate can be treated as a thick plate. Equation 32 should be used to calculate the cooling rate for thick plate at the location where the variables are w and r and at critical temperature $\theta = \theta_c$. To solve Eq 32, the value of w and r must be calculated first. From Eq 19, the temperature distribution of thick plate, and Eq 17, where $z = 0$, the following two simultaneous equations are obtained:

$$\begin{aligned} 615 - 20 &= \frac{7500}{2\pi(0.0431)r_p} \exp\left[\frac{-1 \cdot (w_p + r_p)}{2 \cdot 11.65}\right] \\ \text{and } r_p &= \sqrt{w_p^2 + 20^2} \end{aligned} \quad (\text{Eq 76})$$

The value of w_p and r_p can be solved by using iteration techniques to solve the aforementioned simultaneous equation. The result is that $w_p = -82.77$ mm and $r_p = 85.15$ mm.

Substituting w_p and r_p into Eq 34:

$$\begin{aligned} \left[\frac{\partial\theta}{\partial t}\right]_{\theta_c} &= -V \frac{\partial\theta}{\partial w} \\ &= \frac{-1 \cdot (7500)}{2\pi(0.0431)(85.15)} \\ &\quad \cdot \exp\left[\frac{-1 \cdot (-82.77 + 85.15)}{2(11.65)}\right] \\ &\quad \cdot \left[\frac{-(-82.77)}{85.15^2} - \frac{1.0}{2(11.65)}\right] \\ &\quad \cdot \left(1 + \frac{-82.77}{85.15}\right) \end{aligned} \quad (\text{Eq 77})$$

Therefore:

$$\left[\frac{\partial\theta}{\partial t}\right]_{\theta_c=615} = -3 \text{ }^{\circ}\text{C/s} \quad (\text{Eq 78})$$

From Eq 46 we can calculate the cooling rate along the centerline at the same temperature (615 °C, or 1140 °F):

$$R = \frac{2\pi(0.0431)(615 - 20)^2}{7500} = 12.8 \text{ }^{\circ}\text{C/s} \quad (\text{Eq 79})$$

Also from the empirical equation, Eq 30, one can calculate the cooling rate in the HAZ at a temperature of 615 °C (1140 °F):

$$\begin{aligned} \left[\frac{\partial\theta}{\partial t}\right]_{\theta_c=615} &= 0.35 \left\{ \left[\frac{615 - 20}{300/2} \right]^{1.7} \right. \\ &\quad \left. \left[1 + \frac{2}{\pi} \tan^{-1} \left(\frac{1.0 - 0.486}{0.125} \right) \right]^{0.8} \right\} \\ &= 3.7 \text{ }^{\circ}\text{C/s} \end{aligned} \quad (\text{Eq 80})$$

H_0 and α can be determined from Table 1, and using the linear interpolation method between the temperature differences, the values at 615 °C (1140 °F) are $H_0 = 0.486$ and $\alpha = 0.125$.

At the same temperature of 615 °C (1140 °F), the cooling rate at the centerline is approximately three times greater than the cooling rate at the location a distance $y = 20$ mm (0.8 in.) from the weld centerline. The predicted cooling rate at this location is close to the estimated cooling rate of the HAZ, using the empirical formula, under the given welding condition.

Example 4: Solidification Rate. A weld pass of 800 J/mm (20.3 kJ/in.) in net energy input is deposited on a low-carbon steel plate (using material properties shown in example 2 in this article). The initial temperature is 25 °C (77 °F). The solidification time in the weld pool (Eq 49) would be 0.94 s:

$$S_t = \frac{2(800)}{2\pi(0.028)(0.0044)(1510 - 25)^2} = 0.94 \text{ s} \quad (\text{Eq 81})$$

Parametric Effects

To show the effects of material property and welding condition on the temperature distribution of weldments, the welding of 304 stainless steel, low-carbon steel, and aluminum are

simulated for three different welding speeds: 1, 5, and 8 mm/s (2, 12, and 19 ipm). The thermal conductivity and thermal diffusivity of 304 stainless steel are 26 W/m · K (0.026 J/mm · s · °C) and 4.6 mm²/s (0.007 in.²/s), respectively. For low-carbon steel, the respective values are 50 W/m · K (0.050 J/mm · s · °C) and 7.5 mm²/s (0.012 in.²/s); whereas for aluminum, the respective values are 347 W/m · K (0.347 J/mm · s · °C) and 80 mm²/s (0.124 in.²/s). The heat input per unit weld length was kept constant, 4.2 kJ/s (1 kcal/s), for all cases. The parametric results are described as follows.

Effect of Material Type. Figures 5(a) to (c) depict the effect of thermal properties on isothermperature contours for a heat input of 4.2 kJ/s (1 kcal/s), and travel speeds of 1, 5, and 8 mm/s (2, 12, and 19 ipm). The temperature spreads over a larger area and causes a larger weld pool (larger weld bead) for low-conductivity material. The isothermperature contours also elongate more toward the back of the arc for low-conductivity material. For aluminum, a larger heat input would be required to obtain the same weld size as the stainless steel weldment.

Effect of Welding Speed. Figures 6(a) to (c) show the effect of welding speed on isothermperature contours. When the travel speed increases, the weld size decreases and the

isothermperature contours are more elongated toward the back of the arc. Larger heat inputs would be required for faster travel speeds in order to obtain the same weld size.

Figure 7 shows the effect of welding heat input on the peak temperature at two locations, 6.4 and 13 mm (¼ and ½ in.) from the weld centerline. (The material simulated in this illustration is low-carbon steel plate with a large thickness.) Within the practical range of welding conditions for the GMAW process of low-carbon steels, the peak temperature at both locations increases linearly, as the welding current increases, and decreases exponentially, with the travel speed. To increase welding current proportionally with travel speed for constant heat input per unit weld length (that is, $\dot{Q}/V = \text{constant}$), the peak temperature at two locations increases with the travel speed, which implies a larger weld size resulting from higher heat input. The welding current has a more significant effect on peak temperature than does the travel speed. However, the increase in peak temperature is more dominant at the 6.4 mm (¼ in.) location. The influence of proportional increase in welding current and travel speed on peak temperature diminishes as the distance from the weld centerline increases and when the travel speed becomes high.

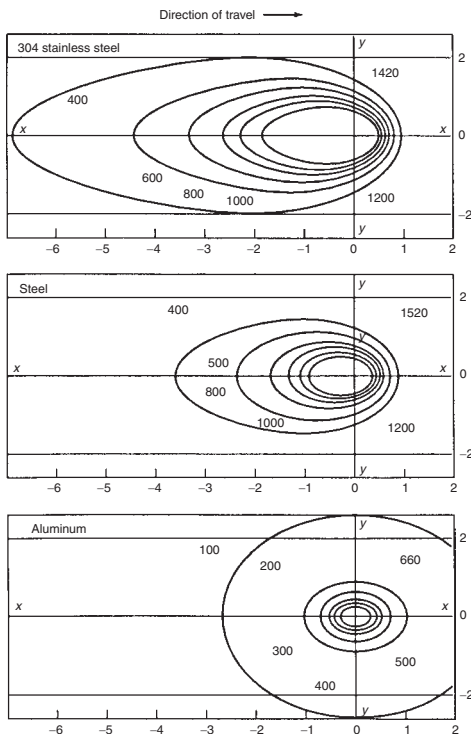

Fig. (5a) Effect of thermal property on isothermperature contours for a heat input of 4.2 kJ/s (1 kcal/s) at a welding speed, V , of 1 mm/s (2 ipm) and the respective thermal conductivities of each material (refer to text for values). Values for x and y are given in cm, and temperatures are given in °C.

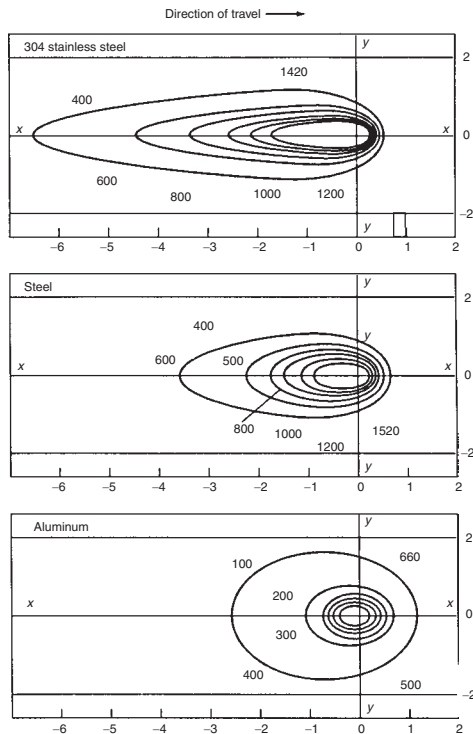

Fig. (5b) Effect of thermal property on isothermperature contours for a heat input of 4.2 kJ/s (1 kcal/s) at a welding speed, V , of 5 mm/s (12 ipm) and the respective thermal conductivities of each material (refer to text for values). Values for x and y are given in cm, and temperatures are given in °C.

Fig. (5c) Effect of thermal property on isothermperature contours for a heat input of 4.2 kJ/s (1 kcal/s) at a welding speed, V , of 8 mm/s (19 ipm) and the respective thermal conductivities of each material (refer to text for values). Values for x and y are given in cm, and temperatures are given in °C.

Factors Influencing Heat Flow in Fusion Welding

Ole Runar Myhr, Hydro Aluminium and Norwegian University of Science and Technology
Øystein Grong, Norwegian University of Science and Technology

IN GENERAL, a quantitative analysis of metallurgical reactions in fusion welding requires detailed information about the weld thermal history. To obtain a broad overview of factors affecting heat flow in a real welding situation, the analytical modeling approach is preferable, because this makes it possible to derive relatively simple equations that provide the required background for an understanding of the temperature-time pattern. An important aspect of the approach is the use of dimensionless groups for a general outline of the temperature distribution (Ref 1). Although this practice inevitably increases the complexity of the mathematical treatment, it is a convenient way to reduce the total number of variables to an acceptable level and hence condense general information about the weld thermal program into two-dimensional maps or diagrams. Consequently, readers who are unfamiliar with the concept should accept the challenge and try to overcome the barrier associated with the use of such dimensionless groups in heat flow analyses.

Introduction

Fusion Welding Processes

Fusion welding is a collective term that includes the following processes (the terminology used here is in accordance with the American Welding Society's recommendations, Ref 2):

- Shielded metal arc welding (SMAW)
- Gas tungsten arc welding (GTAW)
- Gas metal arc welding (GMAW)
- Flux cored arc welding (FCAW)
- Submerged arc welding (SAW)
- Laser welding
- Electron beam welding (EBW)

Arc Efficiency Factors

In arc welding, which includes the first five processes listed previously, heat losses by

convection and radiation to the surroundings are taken into account by the efficiency factor, η , defined as:

$$\eta = q_0 / (IU) \quad (\text{Eq 1})$$

where q_0 is the net power received by the weldment (e.g., measured by calorimetry), I is the welding current (amperage), and U is the arc voltage. For SAW, the efficiency factor has been reported in the range of 90 to 98%; for SMAW and GMAW, from 65 to 85%; and for GTAW, from 22 to 75%, depending on polarity and materials (Ref 3). A summary of ranges is given in Table 1.

Thermal Properties of Some Metals and Alloys

A precondition for obtaining simple analytical solutions of Fourier's second law of heat conduction is that the thermal properties of the base material are constant and independent of temperature. The thermal properties in question are the thermal conductivity, λ , the thermal diffusivity, a , and the volumetric heat capacity, ρc . For most metals and alloys, λ , a , and ρc may vary significantly with temperature. In addition, the same thermal properties are also dependent upon the chemical composition and the thermal history of the base material, which further complicates the situation.

Table 2 Physical properties for some metals and alloys

Material	λ , W · mm ⁻¹ · °C ⁻¹	a , mm ² · s ⁻¹	ρc , J · mm ⁻³ · °C ⁻¹	T_m		$H_m - H_0(a)$, J · mm ⁻³	ΔH_m , J · mm ⁻³
				°C	°F		
Carbon steels	0.040	8	0.005	1520	2770	7.50	2.0

(a) Does not include the latent heat of melting (ΔH_m). Source: Ref 1, based on data from Ref 5–8

By neglecting such effects in the heat flow models, several limitations are imposed on the applications of the analytical solutions. Nevertheless, experience has shown that these problems, to some extent, can be overcome by the choice of reasonable average values for λ , a , and ρc within a specific temperature range. Table 2 (Ref 5–8) contains a summary of relevant thermal properties for various metals and alloys, based on a critical review of literature data. It should be noted that the thermal data in Table 2 do not include a correction for heat consumed in melting of the parent material. Although the latent heat of melting is temporarily removed during fusion welding, experience has shown that this effect can be accounted for by calibrating the equations against a known isotherm (e.g., the

Table 1 Recommended arc efficiency factors for various welding processes

Welding process	Arc efficiency factor, η	
	Range	Mean
Submerged arc welding (steel)	0.91–0.99	0.95
Shielded metal arc welding (steel)	0.66–0.85	0.80
Gas metal arc welding (CO ₂ -steel)	0.75–0.93	0.85
Gas metal arc welding (Ar-steel)	0.66–0.70	0.70
Gas tungsten arc welding (Ar-steel)	0.25–0.75	0.40
Gas tungsten arc welding (He-Al)	0.55–0.80	0.60
Gas tungsten arc welding (Ar-Al)	0.22–0.46	0.40

Source: Ref 1, based on data from Ref 3, 4

fusion boundary). In practice, such corrections are done by adjusting the arc efficiency factor, η , until a good correlation is achieved between predictions and experiments.

Analytical Solutions of the Thermal Field around Moving Point and Line Sources

The purpose of this section is to review the classical models for the pseudo-steady-state temperature distribution around moving heat sources. The analytical solutions to the differential heat flow equation under conditions applicable to fusion welding were first presented by Rosenthal (Ref 9, 10), but the theory was later extended and refined by a number of other investigators (Ref 3, 11–13).

Thick-Plate Model

The thick-plate model consists of an isotropic semiinfinite body at initial temperature T_0 limited in one direction by a plane that is impermeable to heat. At time $t=0$, a point source of constant power, q_0 , starts on the surface at a given position, moving in the positive x -direction by a constant speed, v . The rise of temperature, $T-T_0$, in a point P at time t is then sought. The detailed mathematical derivation of the general thick-plate solution is given in Ref 1, 9, and 10. Here, only the resulting equations are presented and discussed.

General Solution. The general thick-plate solution describing the pseudo-steady-state temperature distribution for a moving-point heat source is given by (Ref 9, 10):

$$T - T_0 = \frac{q_0}{2\pi\lambda} \left(\frac{1}{R}\right) \exp\left(-\frac{v}{2a}(R+x)\right) \quad (\text{Eq 2})$$

This equation is often referred to as the Rosenthal thick-plate solution (Ref 9, 10) in honor of D. Rosenthal, who first derived the relation by solving the differential heat flow equation directly for the appropriate boundary conditions. The Rosenthal equation gives, with the limitations inherent in the assumptions, full information about the thermal conditions for point sources on heavy slabs and is thus a true three-dimensional model. A schematic representation of Eq 2 is shown in Fig. 1.

Simplified Solution for a Fast-Moving High-Power Source. It follows from Eq 2 that the isotherms behind the heat source become increasingly elongated as the power, q_0 , and the welding speed, v , increase. In the limiting case, when $q_0 \rightarrow \infty$, $v \rightarrow \infty$ and q_0/v remains finite, the isotherms will degenerate into surfaces that are parallel to the welding x -direction, as shown in Fig. 2 (Ref 1). Conduction of heat will then occur exclusively in the directions normal to the x -axis, meaning that the mode of heat flow becomes essentially two-dimensional (i.e., restricted to the y - z plane).

As shown by Rykalin (Ref 11), the solution is then given by the equation:

$$T - T_0 = \frac{q_0/v}{2\pi\lambda} \left(\frac{1}{t}\right) \exp\left(-\frac{(r^*)^2}{4at}\right) \quad (\text{Eq 3})$$

where r^* is the two-dimensional radius vector in the y - z plane.

Equation 3 represents the simplified solution for a fast-moving high-power source on a semi-infinite slab and is valid within a limited range of the more general Rosenthal equation for three-dimensional heat flow (Eq 2).

Thin-Plate Model

The thin-plate model considers a line source in a wide sheet of thickness d and initial temperature, T_0 . At time $t = 0$, the source starts to move at a constant speed, v , in the positive x -direction. The rise of temperature, $T-T_0$, in a point P at time t is then sought. Details of the mathematical derivation of the general thin-plate solution are given in Ref 1, 9, and 10.

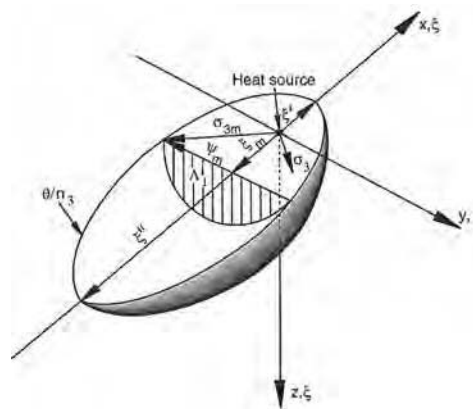

Fig. 1 Three-dimensional graphical representation of the Rosenthal thick-plate solution (schematic). Source: Ref 1

Fig. 2 Fast-moving high-power source on a semiinfinite slab. Source: Ref 1

General Solution. At pseudo-steady state, the general thin-plate solution reads:

$$T - T_0 = \frac{q_0/d}{2\pi\lambda} \exp\left(-\frac{vx}{2a}\right) K_0\left(\frac{vr}{2a}\right) \quad (\text{Eq 4})$$

where K_0 is the modified Bessel function of the second kind and zero order.

Equation 4 is often referred to as the Rosenthal thin-plate solution. It follows that this model is applicable to all types of welding processes (including electron beam, plasma arc, and laser welding), provided that a full through-thickness penetration is achieved in one pass. Under such conditions, the mode of heat flow will be essentially two-dimensional (i.e., restricted to the x - y plane). A graphical representation of Eq 4 is shown in Fig. 3 (Ref 1, 14).

Simplified Solution for a Fast-Moving High-Power Source. Similar to the conditions existing during thick-plate welding, the isotherms behind the heat source become increasingly elongated as the arc power, q_0 , and the welding speed, v , increase. In the limiting case, when $q_0 \rightarrow \infty$, $v \rightarrow \infty$, and q_0/v remains finite, the isotherms will degenerate into surfaces that are parallel to the welding x -direction, as shown in Fig. 4. Under such conditions, the mode of heat flow becomes essentially one-dimensional, which means that the temperature distribution is given by the following equation (Ref 11):

$$T - T_0 = \frac{q_0/vd}{\rho c(4\pi at)^{1/2}} \exp(-y^2/4at) \quad (\text{Eq 5})$$

Fig. 3 Graphical representation of Rosenthal thin-plate solution (schematic). Source: Ref 1, 14

Fig. 4 Graphical representation of a fast-moving high-power source in a thin plate. Source: Ref 1

Equation 5 represents the simplified solution for a fast-moving high-power source in a thin sheet and is valid within a limited range of the more general Rosenthal equation for two-dimensional heat flow (Eq 4).

In situations where the inherent assumption of adiabatic plate surfaces is not fulfilled (e.g., due to the use of external heat sinks or forced air cooling), it is still possible to employ analytical solutions similar to the ones presented previously. However, this requires the introduction of an additional term in the constitutive equations containing the efficient heat-transfer coefficient, which, in a semiempirical manner, allows for transfer of heat across the plate surfaces to the surrounding cooling medium. Further details are given in Ref 11 to 13 and 15.

Medium-Thick-Plate Model

In a real welding situation, the assumption of three- or two-dimensional heat flow inherent in the Rosenthal equations is not always met because of variable temperature gradients in the through-thickness z -direction of the plate.

General Solution. The general medium-thick-plate model considers a point heat source moving at constant speed across a wide plate of finite thickness d . With the exception of certain special cases (e.g., watercooling of the back side of the plate), it is a reasonable approximation to assume that the plate surfaces are impermeable to heat. Thus, to maintain the net flux of heat through both boundaries equal to zero, it is necessary to account for mirror reflections of the source with respect to the planes of $z = 0$ and $z = d$. This can be done on the basis of the "method of images," as illustrated in Fig. 5.

Fig. 5 Real and imaginary point sources on a medium-thick plate

By including all contributions from the imaginary sources $\dots 2q_{-2}, 2q_{-1}, 2q_1, 2q_2, \dots$ located symmetrically at distances $\pm 2id$ below and above the upper surface of the plate, the pseudo-steady temperature distribution is obtained in the form of a convergent series (Ref 10):

$$T - T_0 = \frac{q_0}{2\pi\lambda} \exp\left(-\frac{vx}{2a}\right) \sum_{i=-\infty}^{i=+\infty} \left(\frac{1}{R_i}\right) \exp\left(-\frac{vR_i}{2a}\right) \quad (\text{Eq 6})$$

where:

$$R_i = \sqrt{x^2 + y^2 + (z - 2id)^2}$$

In practice, the number of imaginary heat sources necessary to achieve the required accuracy depends on the chosen values of R_0 and $vd/2a$. It follows from Eq 6 that the thermal conditions will be similar to those in a thick plate close to the center of the weld. Moreover, Rosenthal (Ref 9, 10) has shown, on the basis of a Fourier-series expansion, that Eq 6 converges to the general thin-plate solution (Eq 4) for points located sufficiently far away from the source. However, at intermediate distances from the heat source, the pseudo-steady-state temperature distribution will deviate significantly from that observed in thick- or thin-plate welding because of variable temperature gradients in the through-thickness direction of the plate. This leads to a mixed mode of heat flow, which, in the following, is referred to as 2.5-dimensional (2.5-D). Within the 2.5-D "transition region," the thermal program is only defined by the medium-thick-plate solution (Eq 6).

Simplified Solution for a Fast-Moving High-Power Source. Also in the medium-thick-plate welding situation, a simplified solution exists in the limiting case when $q_0 \rightarrow \infty$, $v \rightarrow \infty$, and q_0/v remains finite. The isotherms will then degenerate into surfaces that are parallel to the welding x -direction, and conduction of heat will then occur exclusively in the directions normal to the x -axis. The pseudo-steady-state temperature distribution is then given by the following equation:

$$T - T_0 = \frac{q_0/v}{2\pi\lambda} \left(\frac{1}{t}\right) \sum_{i=-\infty}^{i=+\infty} \exp(-r_i^2/4at) \quad (\text{Eq 7})$$

where:

$$r_i = \sqrt{y^2 + (z - 2id)^2}$$

Note that Eq 7 is actually the simplified solution for a fast-moving high-power source in a thick plate (i.e., Eq 3) summed for each source. Within the validity range of this equation, the mode of heat flow is mixed (i.e., 1.5-dimensional), meaning that it is a special solution of the more general Eq 6.

General Outline of the Pseudo-Steady-State Temperature Distribution in Bead-on-Plate Welding

To obtain a general survey of the pseudo-steady-state temperature distribution, it is convenient to present the different solutions in a dimensionless form. The following parameters are defined for this purpose (Ref 1, 14):

- Dimensionless temperature:

$$\theta = \frac{T - T_0}{T_c - T_0} \quad (\text{Eq 8})$$

- Dimensionless operating parameter:

$$n_3 = \frac{q_0 v}{4\pi a^2 \rho c (T_c - T_0)} = \frac{q_0 v}{4\pi a^2 (H_c - H_0)} \quad (\text{Eq 9})$$

- Dimensionless plate thickness:

$$\delta = \frac{vd}{2a} \quad (\text{Eq 10})$$

- Dimensionless x -coordinate:

$$\xi = \frac{vx}{2a} \quad (\text{Eq 11})$$

- Dimensionless y -coordinate:

$$\psi = \frac{vy}{2a} \quad (\text{Eq 12})$$

- Dimensionless z -coordinate:

$$\zeta = \frac{vz}{2a} \quad (\text{Eq 13})$$

Isothermal Contours and Mode of Heat Flow

Because of the number of variables involved, it is not possible to present two-dimensional plots of the isotherms without first specifying the dimensionless plate thickness. Examples of calculated isotherms in different planes are shown in Fig. 6 and 7 for δ equal to 0.5 and 5, respectively. It is evident that an increase in the dimensionless plate thickness from 0.5 to 5 has a dramatic effect on the shape and position of the isothermal contours. However, to explain these observations in an adequate manner, it is necessary to condense the results into a two-dimensional diagram. As shown in Fig. 8, this can be done by plotting the calculated field boundaries at maximum width of the isotherms versus the parameters θ_p/n_3 and $vd/2a$, as described in Ref 1 and 14.

It is seen from Fig. 8 that a large plate thickness generally will favor three-dimensional heat flow. With decreasing values of θ_p/n_3 , the conditions for a fast-moving high-power source are approached before the transition from the thick-plate to the thin-plate solution occurs. In such cases, the isotherms at the bottom of the plate will be strongly elongated in the welding direction, ξ , and shifted to positions far behind

the heat source. The opposite is observed at small values of $vd/2a$, because a rapid equalization of the temperature gradient in the through-thickness direction of the plate will result in elliptical isotherms at both surfaces, located in an approximately equal distance from the heat source. In either case, the temperature at which the cross-sectional isotherms approach a semicircle or become parallel with the $\zeta(z)$ -axis can be obtained from Fig. 8 by reading-off the intercept between the line for the dimensionless plate thickness and the respective field boundaries.

Table 3 contains a summary of the various solutions for the pseudo-steady-state temperature distribution in bead-on-plate welding. Note that each special solution is valid within certain ranges of θ_p/n_3 and δ , as defined by the field boundaries in Fig. 8. In contrast, the general medium-thick-plate solution is always valid in the sense that it contains the five other solutions listed in Table 3.

Case Studies. Consider stringer bead GMAW on 12.5 mm (0.5 in.) thick plates of low-alloy steel and aluminum (i.e., an Al-Mg-Si alloy), respectively, under the conditions $E = 1.5$ kJ/mm and $\eta = 0.8$. Details of welding parameters for the four series involved are given in Table 4. Computed peak temperature contours in the transverse section of the welds are given in Fig. 9 and 10.

Aluminum Welding. Figures 9(a) and (b) reveal a strong influence of the welding speed on the shape and position of the cross-sectional isotherms at a constant gross heat input of 1.5 kJ/mm. It is evident that the extension of the fusion zone and the neighboring isotherms becomes considerably larger when the welding speed is increased from 2.5 to 5 mm/s (0.1 to 0.2 in./s). This effect can be attributed to an associated shift from elliptical to more elongated isotherms at the plate surfaces (Fig. 8), which reduces heat conduction in the welding direction. It follows from Fig. 8 that the upper left corner of the map represents the typical operating region for aluminum welding.

Because of the pertinent differences in the heat flow conditions, the temperature-time pattern will also vary significantly between series A1 and A2. Hence, in the case of aluminum welding, the usual procedure of reporting arc power and travel speed in terms of an equivalent heat input per unit length of bead is highly questionable, because this parameter does not define the weld thermal program. In general, the correct course would be to specify q_0 , v , and d and compare the weld thermal history on the basis of the dimensionless parameter n_3 and δ .

Steel Welding. If welding is performed on a steel plate of similar thickness, the operating region will be shifted to the lower right corner of Fig. 8. Under such conditions, the isotherms adjacent to the fusion boundary will be strongly elongated in the x-direction even at very low welding speeds (Fig. 7). This implies that the thermal program approaches a state

where the temperature distribution is uniquely defined by the net heat input ηE , corresponding to the limiting case of a fast-moving high-power source. As a result, the calculated shape

and width of the fusion boundary and neighboring isotherms are seen to be virtually independent of choice of q_0 and v , as illustrated in Fig. 10(a) and (b).

Analytical Solutions of the Thermal Field around Distributed Heat Sources

In some cases, it is also necessary to consider the important effects of heat distribution on the bead morphology and the resulting shape of the heat-affected zone (HAZ) isothermal contours.

Fig. 10 Computed peak temperature contours in steel welding at pseudo-steady state. (a) Weld S1. (b) Weld S2. Black regions indicate fusion zone. Operational conditions as in Table 4. Source: Ref 1, 14

Of particular interest in this respect is the formation of the so-called weld crater/weld finger frequently observed in GMAW and SAW stringer bead weldments (Fig. 11). Although the nature of these phenomena is very complex,

Fig. 11 Schematic diagram showing the weld crater/weld finger formation during stringer bead welding. HAZ, heat-affected zone. Source: Ref 1

they can readily be accounted for by applying an empirical correction for the effective heat distribution in the weld pool.

General Solution. The general model of Myhr and Grong is described in Ref 1. The heat distribution used to simulate the weld crater/weld finger formation is shown schematically in Fig. 12(a). Here, two discrete distributions of elementary point sources are considered, which extend in the y - and z -directions of the plate, respectively. The contribution from each source to the temperature rise in an arbitrary point P located within the plate is calculated on the basis of the "method of images," as shown in Fig. 12(b) and (c). For a heat source displaced in the y -direction (Fig. 12b), the temperature field is given by Eq 6:

$$T(q_a) = \frac{q_a}{2\pi\lambda} \exp\left(-\frac{vx}{2a}\right) \sum_{i=-\infty}^{i=+\infty} \left(\frac{1}{R_i}\right) \exp\left(-\frac{vR_i}{2a}\right) \quad (\text{Eq 14})$$

where:

$$R_i = \sqrt{x^2 + y^2 + (z - 2id)^2}$$

Fig. 12 General heat flow model for welding on medium-thick plates. (a) Physical representation of the heat distribution by elementary point sources. (b) Method for calculating the temperature field around an elementary point source displaced along the y -axis. (c) Method for calculating the temperature field around an elementary (submerged) point source displaced along the z -axis. Source: Ref 1

Similarly, for a submerged point source located along the z -axis (Fig. 12c):

$$T(q_b) = \frac{q_b}{4\pi\lambda} \exp\left(-\frac{vx}{2a}\right) \left[\sum_{j=-\infty}^{j=+\infty} \left(\frac{1}{R_j}\right) \exp\left(-\frac{vR_j}{2a}\right) + \sum_{k=-\infty}^{k=+\infty} \left(\frac{1}{R_k}\right) \exp\left(-\frac{vR_k}{2a}\right) \right] \quad (\text{Eq 15})$$

where:

$$R_j = \sqrt{x^2 + y^2 + (z - 2jd - \Delta)^2}$$

and

$$R_k = \sqrt{x^2 + y^2 + (z - 2kd + \Delta)^2}$$

Note that Eq 15 correctly reduces to Eq 14 when Δ approaches zero. The total temperature rise in point P is then obtained by superposition of the temperature fields from the different elementary heat sources, taking:

$$T(t) = T_0 + \sum_i [T(q_a^i) + T(q_b^i)] \quad (\text{Eq 16})$$

where:

$$q_0 = \sum_i (q_a^i + q_b^i) = \eta UI \quad (\text{Eq 17})$$

In practice, the heat distribution can be subdivided into a relatively small number of elementary point sources, and usually a total number of eight to ten sources is sufficient to obtain good results (i.e., smooth isothermal

contours). However, the relative strength of each heat source and their distribution along the y - and z -axes must be determined individually through trial and error by comparing the calculated shape of the fusion boundary with the real (measured) one.

Figure 13 shows the results from such calculations, carried out for a single-pass (bead-in-groove) gas metal arc steel weld. It is evident that the important effect of the weld crater/weld finger formation on the HAZ peak temperature distribution is adequately accounted for by the present model. A weakness of the model is, of course, that the shape and location of the fusion boundary must be determined experimentally before a prediction can be made.

Simplified Solution for a Fast-Moving High-Power Source. Similar to the situation described previously, a point heat source will clearly not be a good model when the heat source is supplied over a large area. Welding with a weaving technique and surfacing with strip electrodes are prime examples of this kind.

In the model of Grong and Christensen (Ref 16), the Rosenthal thick-plate solution is considered for the limiting case of a high arc power, q_0 , and a high welding speed, v , maintaining the ratio q_0/v within a range applicable to arc welding. Consider next a distributed heat source of net power density, $q_0/2L$, extending from $-L$ to $+L$ on either side of the weld centerline in the y -direction, as shown schematically in Fig. 14. It follows from Eq 3 that an infinitesimal source, dq_y , located between y' and $y' + dy'$ will cause a small rise of temperature in point P at time t as (Ref 16):

$$dT_{y'} = \left(\frac{dq_y/v}{2\pi\lambda}\right) \left(\frac{1}{t}\right) \exp\left[-\frac{(r')^2}{4at}\right] \quad (\text{Eq 18})$$

where:

$$r' = \sqrt{(y - y')^2 + z^2}, \quad dq_y = q_0 dy'/2L, \quad \text{and } \lambda = \rho c$$

Substituting:

$$u = (y - y')/\sqrt{4at}, \quad dy' = -du\sqrt{4at}$$

and integrating from $y' = -L$ to $y' = +L$ gives:

$$T - T_0 = \left(\frac{q_0/2vL}{\rho c\sqrt{\pi}}\right) \left(\frac{\exp(-z^2/4at)}{\sqrt{4at}}\right) \left[\operatorname{erf}\left(\frac{y+L}{\sqrt{4at}}\right) - \operatorname{erf}\left(\frac{y-L}{\sqrt{4at}}\right) \right] \quad (\text{Eq 19})$$

where $\operatorname{erf}(u)$ is the Gaussian error function.

General Outline of the Peak Temperature Distribution. Because of the complex nature of Eq 19, the variation of peak temperature with distance in the y - z plane can only be obtained by numerical or graphical methods. Accordingly, it is convenient to present the various solutions in a dimensionless form. The following parameters are defined for this purpose (Ref 1, 16):

- Dimensionless operating parameter:

$$n_w = \frac{q_0/2vL^2}{\sqrt{\pi}\rho c(T_c - T_0)} = \frac{q_0/2vL^2}{\sqrt{\pi}(H_c - H_0)} \quad (\text{Eq 20})$$

Fig. 13 Calculated peak temperature contours in the transverse section of a gas metal arc steel weldment. Operational conditions: $I = 450$ A, $U = 30$ V, $v = 2.6$ mm/s (0.1 in./s), $d = 50$ mm (2 in.). Source: Ref 1

Fig. 14 Distributed heat source of net power density $q_0/2L$ on a semiinfinite body assuming two-dimensional heat flow. Source: Ref 1, 16

- Dimensionless time:

$$\tau_5 = \frac{\sqrt{4at}}{L} \quad (\text{Eq 21})$$

- Dimensionless y-coordinate:

$$\beta = \frac{y}{L} \quad (\text{Eq 22})$$

- Dimensionless z-coordinate:

$$\gamma = \frac{z}{L} \quad (\text{Eq 23})$$

Substituting these parameters into Eq 19 yields

$$\frac{\theta}{n_w} = \frac{1}{\tau_5} \exp\left[-\left(\frac{\gamma}{\tau_5}\right)^2\right] \left[\text{erf}\left(\frac{\beta+1}{\tau_5}\right) - \text{erf}\left(\frac{\beta-1}{\tau_5}\right) \right] \quad (\text{Eq 24})$$

where θ is the dimensionless temperature defined previously in Eq 8.

The variation of peak temperature, θ_p , with distance in the y - z plane has been numerically evaluated from Eq 24 for chosen values of β and γ (i.e., $\beta = 0$, $\beta = 3/4$, $\beta = 1$, and $\gamma = 0$). The results are presented graphically in Fig. 15 and 16 for the through-thickness ($z = z_m$) and the transverse ($y = y_m$) directions, respectively. These figures provide a systematic basis for calculating the shape of the weld pool and neighboring isotherms under various welding conditions.

In Fig. 17, the weld width-to-depth ratio has been computed and plotted for various combinations of n_w and θ_p . It is evident that the predicted width of the isotherms generally is much greater and the depth correspondingly smaller than that inferred from the point source model. Such deviations tend to become less pronounced with decreasing peak temperatures (i.e., increasing distance from the heat source). At very large values of n_w , the theoretical shape of the isotherms approaches that of a semicircle, which is characteristic of a point heat source.

Implications of the Heat Distribution. Figure 18 shows a graphical presentation of the calculated peak temperature contours for a gas metal arc steel weld deposition using a weaving technique. It is evident from these plots that the predicted shape of the isotherms, as evaluated from Eq 24, departs quite strongly from the semicircular contours required by a point heat source. Moreover, a closer inspection of Fig. 18 shows that inclusion of the heat distribution also gives rise to systematic variations in the weld thermal program along a specific isotherm, as evidenced by the steeper temperature gradient in the y -direction compared with the z -direction of the plate. This point is more clearly illustrated in Fig. 19, which compares the HAZ temperature-time program for the two extreme cases of $z = 0$ and $y = 0$, respectively. It follows from Fig. 19 that the retention time within the austenite regime is considerably longer in the latter case, although the cooling time from 800 to 500 °C (1470 to 930 °F), $\Delta t_{8/5}$, is reasonably similar. These results clearly underline the important difference between a point heat source and a distributed heat source as far as the weld thermal program is concerned.

Analytical Solution of the Thermal Field around a Moving Keyhole

The analytical keyhole model is shown in Fig. 20. In this case, the circular keyhole moves relative to the workpiece with a constant velocity of v . According to the assumptions, the diameter of the keyhole is equal to $2r_0$, and the wall temperature is equal to T_0 . At pseudo-steady state, the temperature distribution around the keyhole is given by (Ref 18):

$$\frac{T - T_0}{T_v - T_0} = \exp\left(-\frac{vr \cos \phi}{2a}\right) \sum_{n=0}^{\infty}$$

$$\varepsilon_n I_n\left(\frac{vr_0}{2a}\right) \frac{K_n\left(\frac{vr}{2a}\right)}{K_n\left(\frac{vr_0}{2a}\right)} \cos(n\phi) \quad (\text{Eq 25})$$

General Outline of the Temperature Distribution. For a general representation of the pseudo-steady-state temperature distribution, it is convenient to rewrite Eq 25 in a dimensionless form. The following parameters are defined for this purpose (Ref 17, 19):

$$\Omega = \frac{T - T_0}{T_v - T_0} \quad (\text{Eq 26})$$

$$\xi = \frac{vr \cos \phi}{2a} = \frac{vx}{2a} \quad (\text{Eq 27})$$

$$\kappa = \frac{vr_0}{2a} \quad (\text{Eq 28})$$

$$\sigma = \frac{vr}{2a} \quad (\text{Eq 29})$$

Analogy with the Line Source Solution

Hemmer and Grong (Ref 17) have further investigated the analogy between the key-hole solution and the line source solution to predict the penetration depth in electron beam welding (EBW). At pseudo-steady state, the temperature distribution around a moving line source is given by Eq 4. By replacing the plate thickness d with the penetration depth p , it reads:

$$T - T_0 = \frac{q_0/p}{2\pi\lambda} \exp\left(-\frac{vx}{2a}\right) K_0\left(\frac{vr}{2a}\right) \quad (\text{Eq 32})$$

Equation 32 can be written in a dimensionless form in terms of the following group variables (Ref 17):

$$n_2 = \frac{q_0/p}{2\pi\lambda(T_m - T_0)} = \frac{q_0/p}{2\pi a(H_m - H_0)} \quad (\text{Eq 33})$$

$$\theta = \frac{T - T_0}{T_m - T_0} \quad (\text{Eq 34})$$

where T_m now refers to the melting point (or liquidus temperature) of the base material. Substituting these parameters into Eq 32 gives:

$$\theta/n_2 = \exp(-\xi) K_0(\sigma) \quad (\text{Eq 35})$$

The half-width of the isotherms ψ_m can be found by differentiating Eq 35 with respect to ξ . Hence, ψ_m is also a unique function of the dimensionless operating parameter n_2 . In practice, this means that the penetration depth can be linked to the group variables Ω and κ by way of Eq 30 and 31.

Coupling of Models and Prediction of the Penetration Depth. Because of the analogy between the two solutions, they can be combined to obtain the set of master curves shown in Fig. 22. From these curves, the normalized (scaled) penetration depth can be read for various combinations of process parameters (i.e., v and $2r_0$) and material properties (i.e., a , T_m , and T_v). Conversion into real (metric) units is then carried out by way of Eq 33, using appropriate input data for the applied beam power, q_0 , and the heat content of the base material at the melting point, $H_m - H_0$.

It follows from Fig. 22 that the penetration depth in EBW is uniquely defined by three group variables: Ω , which includes the keyhole wall temperature, T_v ; n_2 , which includes the beam power density, q_0 ; and κ , which includes the electron beam diameter, $2r_0$, and the welding speed, v . In addition, the thermal properties of the base material come into play through the parameters λ , a , and T_m . Provided that all necessary input parameters are known, it has been shown that the penetration depth during EBW can be estimated with an accuracy of $\pm 25\%$ for titanium alloys and $\pm 15\%$ for both aluminum alloys and duplex stainless steels

Fig. 15 Calculated peak temperature distribution in the through-thickness direction of the plate at various positions along the weld surface. Dimensionless parameters are defined in Eq 20 to 24. Source: Ref 1, 16

Fig. 16 Calculated peak temperature distribution in the transverse direction of the plate at position $\gamma(z) = 0$. Dimensionless parameters are defined in Eq 20 to 24. Source: Ref 1, 16

Substituting these parameters into Eq 25 gives:

$$\Omega = \exp(-\xi) \sum_{n=0}^{\infty} \varepsilon_n J_n(\kappa) \frac{K_n(\sigma)}{K_n(\kappa)} \cos(n\phi) \quad (\text{Eq 30})$$

In the cross section of the plate, the shape of the isotherms is characterized by their depth-to-width ratio. Referring to Fig. 21(a), the dimensionless half-width of the isotherms is given by:

$$\psi = \psi_m = \frac{vy}{2a} = \frac{vr \sin \phi}{4a} = \sigma \sin \phi \quad (\text{Eq 31})$$

The parameter ψ can be evaluated numerically from Eq 30 and 31 for various starting conditions. The results are summarized in Fig. 21(b) for a limited range of values of ψ and κ . It follows that ψ_m is uniquely defined by these two group variables.

Fig. 17 Effects of n_w and θ_p on the weld width-to-depth ratio. Dimensionless parameters are defined in Eq 20 to 24. Source: Ref 1, 16

- Time-dependent welding speed and net heat input
- Continuous addition of filler material during welding (Ref 22–25)
- Gradual release of the latent heat of fusion between the solidus and liquidus temperatures during solidification (Ref 22–25)
- Weld-metal fluid flow (Ref 20, 26–28)

In the following, the importance of some of these additional factors is further evaluated and explored. However, the intention is not to cover all aspects of numerical simulations but rather to illustrate the similarities between the analytical and numerical approaches and the inherent limitations of the former one.

In the present case, the numerical simulations are carried out using the general-purpose finite-element code WELDSIM. The program accounts for all of the effects listed previously, except weld-metal fluid flow. A detailed description of the various components of the program is given in Ref 22 to 25.

Temperature-Dependent Material Properties

As previously stated in the section “Thermal Properties of Some Metals and Alloys,” a precondition for obtaining simple analytical solutions of Fourier’s second law of heat conduction is that the material properties of the base material are constant and independent of temperature. Because this assumption represents a crude oversimplification of the problem, it will, in certain cases, impose restrictions on the use of analytical solutions. In practice, however, their limitations are best illustrated by means of specific examples, based on a comparison with outputs from numerical simulations.

Effect of Latent Heat of Fusion. In numerical simulations, the latent heat of fusion, ΔH_m , can be readily included in the expression for the specific heat function, thereby allowing alloys with a freezing range to be simulated (Ref 20). This is not possible in the analytical case, where ΔH_m must either be included or ignored when calculating the dimensionless operating parameter n_3 based on Eq 9. Figure 23 shows how this affects the resulting peak temperature contours in conventional bead-on-plate steel welding. As expected, the isothermal zone widths are significantly smaller when the latent heat of fusion is accounted for in the analytical solutions compared to the situation where $\Delta H_m = 0$. This is in contrast to that observed in the numerical simulations, where the effect of ignoring or including the latent heat of fusion is seen to be small because the contribution, in a real welding situation, is just temporary and therefore less striking. Hence, the two different numerical simulations tend to yield the same isothermal zone widths with increasing distance from the weld centerline. These results are, in turn, almost identical to those obtained using the analytical model with $\Delta H_m = 0$.

Fig. 18 Predicted shape of fusion boundary and A_{c1} isotherm during gas metal arc welding of steel with an oscillating electrode. Solid lines: distributed heat source; broken lines: point heat source. Operating conditions: $I = 315$ A, $U = 25$ V, $v = 5$ mm/s (0.2 in./s), $2L = 20$ mm (0.8 in.), $T_0 = 20$ °C (70 °F). using the model of Hemmer and Grong (Ref 17).

Numerical and Analytical Solutions of the Thermal Field in Complex Welding Operations

Over the years, numerical simulation of heat flow phenomena in fusion welding has become more and more common and largely reduced the need for further developments of the

analytical solutions. This is because a number of important side effects can easily be accounted for in the numerical analyses without contributing to a significant increase in the computational efforts. These are:

- Complex geometries
- Advanced boundary conditions
- Temperature-dependent thermal properties (Ref 20)
- Realistic representation of the heat source (Ref 21)

Effects of Thermal Conductivity and Volumetric Heat Capacity. In addition, the analytical models assume that the thermal properties—thermal conductivity, λ , and volumetric heat capacity, ρc (and thus a)—are constant and independent of temperature. The justification of this simplifying assumption is further investigated in Fig. 24, based on a comparison with numerical simulations of the same peak temperature contours in ordinary bead-on-plate welding. It is evident from the figure that the use of temperature-dependent thermal properties has very little effect on the computed isothermal contours and that the analytical solutions give results that are in close agreement with those obtained in the numerical simulations. Hence, the assumption of constant thermal properties is deemed to be reasonable in most welding situations.

Start and Stop in Welding

During start and stop in welding, the assumption of pseudo-steady state is no longer valid, implying that transient effects will dominate. Although the mathematical treatment of the problem is complicated, both the heating and cooling case can be handled analytically, along the lines indicated in Ref 1.

Duration of the Transient Heating Period. For example, in thick-plate welding the duration of the transient heating period is determined by two group variables, that is, the dimensionless radius vector, σ_3 , and the dimensionless time, τ , defined as:

$$\sigma_3 = \frac{vR}{2a} \tag{Eq 36}$$

and

$$\tau = \frac{v^2 t}{2a} \tag{Eq 37}$$

Similarly, in thin-plate welding the governing length scale parameter is σ_5 , taking (Ref 1):

$$\sigma_5 = \frac{vr}{2a} \tag{Eq 38}$$

Equations 36 and 38 imply that a dimensionless distance may be “short” for one combination of welding speed, v , and thermal diffusivity, a , while the same position may represent a “long” distance for another combination of v and a . Similarly, Eq 37 shows that the dimensionless time τ may be “short” or “long” at a given number of seconds, depending on the ratio $v^2/2a$. Hence, transient effects during start and stop will be much more dominant in aluminum welding compared to steel welding, because of the pertinent difference in

Fig. 23 Effect of the latent heat of fusion (melting) on the predicted peak temperature contours (500, 700, and 1000 °C, or 930, 1290, and 1830 °F) in conventional bead-on-plate steel welding. Solid and broken lines represent analytical and numerical calculations, respectively, whereas black regions indicate fusion zone. Operating conditions: $I = 280$ A, $U = 22$ V, $v = 2.5$ mm/s (0.1 in./s), $\eta = 0.8$, and $T_0 = 20$ °C (68 °F)

Aluminum Welding. Figure 25 shows how the isothermal contours in the weld cross section change with position from the start of the welding operation in series A1. A closer inspection of the figure reveals that the width of the isotherms continuously increases during the transient heating period. Even after 50 mm (2 in.) (referred to as the start position), pseudo-steady state has not yet been reached. This follows from a comparison between Fig. 25(b) and (c). Hence, the pseudo-steady-state solutions listed in Table 3 should not be applied to aluminum welding unless the welds are very long.

Steel Welding. Figure 26 shows corresponding results for steel welding (series S1). In this case, the width of the isotherms is almost identical at all three positions, indicating that pseudo-steady state has already been reached after a weld length of 20 mm (0.8 in.). Therefore, the pseudo-steady-state solutions are much more applicable to steel welding than aluminum welding because the time to reach saturation, in practice, is short when the thermal diffusivity is low, as in steel.

Groove Welding

Numerical simulation tools can also handle complex geometries and accurately represent most joint configurations of practical interest. The analytical models, on the other hand, are less flexible because they are, in principle, restricted to simple plate geometries. Still, their field of application can readily be extended to groove welding by proper adjustment of the net arc power without changing the underlying constitutive equations, as shown for the following geometries.

Simple Joint Geometries. By introducing a correction factor, f , in the models, which takes into account variations in the effective heat diffusion area, groove welding can readily be handled analytically. Taking f equal to 1 for ordinary bead-on-plate welding (b.o.p.), the net power of a groove weld can be defined as (Ref 1):

$$[q_0] = f[q_0]_{b.o.p.} \tag{Eq 39}$$

Recommended values of the correction factor f for some joint configurations are given in Fig. 27. For example, if q_0 in bead-on-plate welding is 4.93 kW, and groove welding is to be carried out under identical thermal conditions, Eq 39 implies that the net arc power in the analytical solutions should be adjusted as follows in each case:

- Welding in a V-groove ($\phi = 90^\circ$): $f = 2$, $[q_0] = 4.93/2 = 2.46$ kW
- Welding in an X-groove ($\phi = 90^\circ$): $f = 1$, $[q_0] = 4.93$ kW
- Welding of a T-joint: $f = 2/3$, $[q_0] = 4.93 \times (3/2) = 7.40$ kW

The resulting peak temperature contours, as calculated from numerical simulations

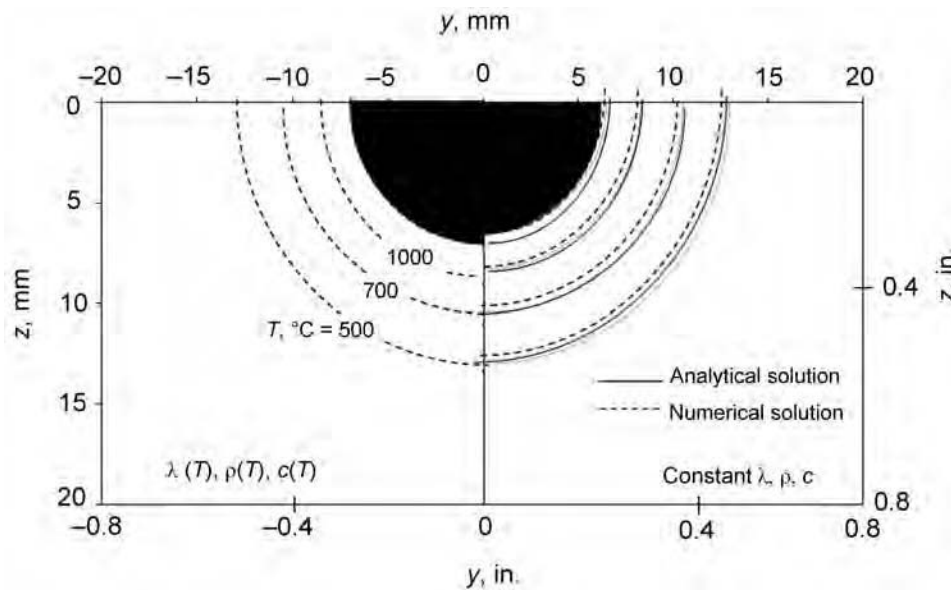

Fig. 24 Effect of thermal conductivity (λ) and volumetric heat capacity (ρc) on the predicted peak temperature contours (500, 700, and 1000 °C, or 930, 1290, and 1830 °F) in conventional bead-on-plate welding. Left side: temperature-dependent thermal properties; right side: constant thermal properties. Solid and broken lines represent analytical and numerical calculations, respectively, whereas black regions indicate fusion zone. Operational conditions: $I = 280$ A, $U = 22$ V, $v = 2.5$ mm/s (0.1 in./s), $\eta = 0.8$, and $T_0 = 20$ °C (68 °F)

the thermal properties of the two base materials (Table 2). This point is further elaborated in the case studies presented subsequently.

Case Studies. Consider the same examples presented previously in the section “Case Studies” under “Isothermal Contours and Mode of Heat Flow,” that is, stringer bead GMAW on 12.5 mm (0.5 in.) thick plates of

low-alloy steel and aluminum, respectively, under the conditions $E = 1.5$ kJ/mm and $\eta = 0.8$. Details of welding parameters are given in Table 4. Numerical methods shall be used to evaluate how the cross-sectional isotherms will evolve with time (i.e., change with position along the weld) in series A1 and S1, respectively.

Fig. 25 Computed peak temperature contours in aluminum welding at various positions along the weld. Figures (a), (b), and (c) provide snapshots at positions 20, 50, and 150 mm (0.8, 2, and 6 in.) from the start of the weld, respectively. Operational conditions as for series A1 in Table 4

Fig. 26 Computed peak temperature contours in steel welding at various positions along the weld. Figures (a), (b), and (c) provide snapshots at positions 20, 50, and 150 mm (0.8, 2, and 6 in.) from the start of the weld, respectively. Operational conditions as for series S1 in Table 4

and the Rosenthal thick-plate solution (i.e., Eq 2), respectively, are shown in Fig. 28. As expected, both the width and the shape of the isotherms are seen to be identical in all four cases (i.e., they are all segments of the same circles). Moreover, it is interesting to note that the Rosenthal thick-plate solution

yields results that are very close to those obtained using more sophisticated numerical analyses. This is true as long as the welding conditions are comparable and correspond to pseudo-steady state, as discussed previously in the section “Start and Stop in Welding.”

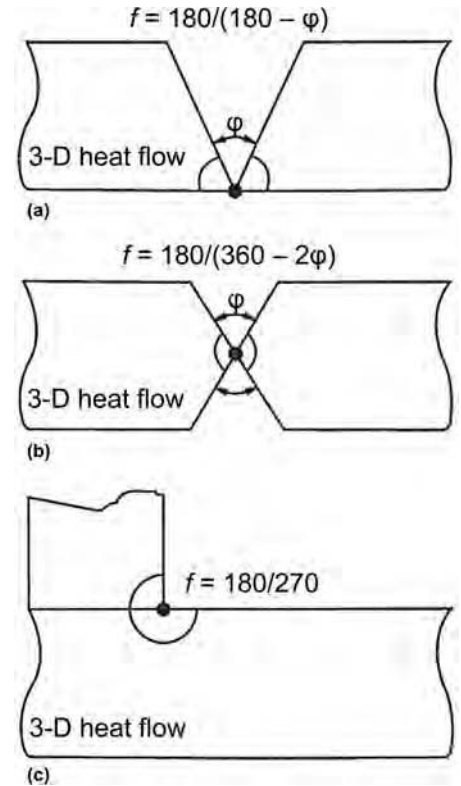

Fig. 27 Recommended correction factors, f , for some joint configurations. (a) Single V-groove. (b) Double V-groove. (c) T-joint. Source: Ref 1

Complex Joint Geometries. More complex joint geometries can only be handled by means of numerical methods. For example, the case shown in Fig. 29 is a good illustration of this, in which two aluminum plates of variable thickness, forming a T-joint, are joined using GMAW. Because of the high thermal conductivity of aluminum, the assumption of infinite plate thickness is not valid for any of the members. In the example, a filler material is also continuously deposited from a consumable electrode during welding. In the numerical simulation, this is accounted for by continuous activation of elements that are part of the weld reinforcement at material points that coincide with the instantaneous position of the moving heat source (Ref 22–25). None of these features can be handled analytically.

Advanced Boundary Conditions

Furthermore, the numerical modeling approach allows for the use of advanced boundary conditions, for example:

- Position- and temperature-dependent heat-transfer coefficients to represent forced-air cooling at defined positions
- Local heat sinks, such as a steel backing supporting the weld

The effect of using a steel backing in single-pass butt welding of aluminum is illustrated in

Fig. 28 Numerical and analytical calculations of peak temperature contours for various joint configurations in fusion welding of steel. (a) Bead-on-plate. (b) V-joint. (c) X-joint. (d) T-joint. Operational conditions: $I = 280$ A, $U = 22$ V, $v = 2.5$ mm/s (0.1 in./s), $\eta = 0.8$, and $T_0 = 20$ °C (68 °F)

Fig. 29 Numerical calculations of peak temperature contours in gas metal arc welding of an aluminum T-joint with continuous addition of a filler material. Operational conditions: $I = 250$ A, $U = 20$ V, $v = 8.0$ mm/s (0.3 in./s), $\eta = 0.8$, and $T_0 = 20$ °C (68 °F)

Fig. 30. In these simulations, the heat-transfer coefficient, h , between the steel backing and the aluminum plate is varied systematically, keeping the plate thickness, d , the net arc power, q_0 , and the welding speed, v , constant and within a sensible range typical for gas metal arc butt welding of 2 mm (0.08 in.) thin aluminum plates. Specifically, Fig. 30 shows plots of the predicted isothermal contours in the cross section of the welds for three different cooling conditions: $h = 0$ (adiabatic surfaces—no heat loss to the surroundings), $h = 800 \text{ W} \cdot \text{m}^{-2} \cdot \text{°C}^{-1}$ (moderate pressure between the aluminum plate and the steel backing), and $h = \infty$ (full metallic contact between the aluminum plate and the steel backing). Although the thermal gradients in the transverse direction of the weld increase with increasing values of the heat-transfer coefficient, the predicted cross-sectional isotherms appear to be reasonably straight in the through-thickness direction of the plates. In addition, they are sufficiently elongated at the top and bottom of the plate surfaces to limit extensive heat diffusion in the welding direction in all three cases (not shown here). Hence, the use of a steel backing does not significantly alter the mode of heat flow within the HAZ of single-pass butt welds of sheet

Fig. 30 Predicted isothermal contours in cross section of 2 mm (0.08 in.) thin aluminum plate with and without the use of a steel backing. Operational conditions: $q_0 = 2.4$ kW, $v = 15$ mm/s (0.6 in./s), and $d = 2$ mm (0.08 in.). (a) $h = 0$ (adiabatic surfaces—no heat loss to the surroundings). (b) $h = 800 \cdot \text{Wm}^{-2} \cdot ^\circ\text{C}^{-1}$ (moderate pressure between the aluminum plate and the steel backing). (c) $h = \infty$ (full metallic contact between the aluminum plate and the steel backing). Source: Ref 25

materials. This essentially means that the HAZ temperature-time pattern at pseudo-steady state is uniquely defined by the group variables q_0/vd when the actual values of the plate thickness, d , and the heat-transfer coefficient, h , between the aluminum plate and the steel backing are fixed.

Transfer of Heat and Mass to the Base Metal in Gas Metal Arc Welding*

Ian Harris, Edison Welding Institute

HEAT AND MASS TRANSFER in arc welding is normally studied from the standpoint of the weld pool and heat-affected zone (HAZ); however, it is also instructive to examine heat and mass transfer from the arc to the base metal. This article describes the latter topic in terms of the gas metal arc welding (GMAW) process and provides practical information related to the development of welding procedures and the general operation of the process.

Welding procedures emphasize control of parameters such as electrode wire-feed speed (or current), arc voltage, welding travel speed, contact tip-to-workpiece distance, as well as welding current pulse parameters (peak and background current, and peak and background time, Fig. 1). It is therefore easy to overlook the fact that the process is ostensibly a source of heat and mass inputs to the weldment. Melting of the base metal, dilution of the filler metal, solidification of the weld bead, microstructural development in the weld bead and HAZ, and thermomechanical distortion and residual stresses all follow from the heat and mass inputs. The conventional parameters identified previously are variables that control the heat and mass inputs. An example of the relationship between the conventional parameters of electrode speed and welding speed to heat and mass transferred to the weldment is shown in Fig. 2 for certain conditions, as applied to the welding of thick-section steel.

The issues described in this article include the following:

- Total heat transferred to the base metal
- Partitioning of heat transfer between the arc and the molten electrode droplets
- Transfer modes of the droplets
- Role of the arc in droplet transfer
- Simple model for welding procedure development based on an understanding of heat and mass transfer to the base metal

Fig. 1 Current, voltage, and wire-feed control for reciprocating wire-feed gas metal arc welding. Courtesy of Edison Welding Institute

* Revised from H.B. Smartt, Transfer of Heat and Mass to the Base Metal in Gas-Metal Arc Welding, *Welding, Brazing, and Soldering*, Vol 6, *ASM Handbook*, ASM International, 1993, p 25-29

Heat Transfer

The total transfer of heat, H (neglecting pre-heating), from the GMAW process to the weldment per unit time is given by:

$$H = \eta EI \tag{Eq 1}$$

where E is voltage, I is current, and η is the heat-transfer efficiency. The rate at which heat is transferred to the weldment per unit length of weld is given by:

$$H = \frac{\eta EI}{R} \tag{Eq 2}$$

where R is welding speed. Calorimeter-based heat-transfer experiments reveal that the heat-transfer efficiency for welding thick-section steel is nominally 80 to 90%, as indicated in Fig. 3. The total heat-transfer efficiency is altered somewhat by changing other parameters. For example, it increases slightly as the power supply open-circuit voltage is decreased (for a silicon-controlled rectifier-regulated power supply), and it increases slightly with increasing contact tube-to-base metal distance. However, 85% is a reasonable estimate for most conditions.

Partitioning of Heat Transfer. In the GMAW process, the molten droplets of electrode material carry a significant portion of the total heat transferred to the weld pool. This is seen in calorimetry experiments (Fig. 3), where the total heat-transfer efficiency of the GMAW process is partitioned into those portions associated with transfer by the arc and by the molten droplets. At low electrode speeds, approximately 60% of the total heat transferred is associated with the arc. As electrode speed increases, the fraction of total heat transferred associated with the droplets

increases, reaching nominally 50% at current levels in excess of approximately 220 A (that is, at approximately 230 mm/s, or 9.1 in./s, electrode speed) for the conditions used.

Mass Transfer

Droplet Transfer Modes. Although the International Institute of Welding (IIW) lists eight distinct metal-transfer modes (Ref 3), the modes commonly used in U.S. welding practice are short circuiting, globular, spray, streaming spray, and rotating spray. The mode terms *drop* and *repelled* used by the IIW are often referred to as *globular*, and the mode term *projected* is generally referred to as *spray*. The globular, spray, streaming, and short-circuiting transfer modes are shown in Fig. 4 to 7.

When all other parameters are held constant, the metal-transfer mode at the lowest wire-feed speed (and associated current level) is short circuit. As wire speed (and therefore current) increases, the mode changes rapidly from globular to spray. With an additional increase in wire speed (and current), spray transfer becomes streaming transfer. Figure 8 shows the droplet sizes during the transition from globular to spray to streaming transfer for direct and pulsed current welding. If an adequately high current, contact tube-to-base metal distance, and voltage exist, then rotating transfer, wherein the lower part of the electrode becomes molten over a considerable length and rotates in

a helical spiral under the influence of the magnetic field surrounding the arc, can occur. As it rotates, a controlled stream of droplets is transferred from the electrode tube to the weld pool over a relatively wide area. Additional increases in wire feed/current at low voltage shorten the arc length and, eventually, the wire stubs into the weld pool. In addition, with appropriate conditions (for example, carbon dioxide, argon-carbon dioxide mixtures, and helium-base shielding gases), droplets can be transferred directly, by surface tension forces, after contact of the drop with the weld pool, a condition called short-circuiting transfer.

In practical applications, the optimal transfer mode depends in part on the thickness of the base metal being welded. For example, very thin sections (in all positions) require the short-circuiting mode (with low current levels and appropriate settings of voltage and other operating parameters, including shielding gas composition). Thicker sections show best results with spray or streaming transfer. These transfer modes also produce high heat input, maximum penetration, and a high deposition rate. In welding steel, they are generally limited to welding that occurs in the flat position and the horizontal fillet position, except when pulsed current is used. Rotating transfer can be used in a deep groove in thick-section material. One- and two-pass heavy fillet welds are also a major area of application for this process variation.

Globular transfer (Fig. 4) involves a droplet that, generally, is much larger in diameter than

Fig. 2 Plot of welding speed versus electrode speed as a function of heat transfer per length of weld, H , and mass transfer expressed in terms of reinforcement, G . Power supply open-circuit voltage, E_0 , is 32 V; contact tube-to-base metal distance, C_T , is 15.9 mm (0.625 in.). Shaded area denotes region in which spray and streaming transfer modes occur; globular transfer occurs at lower electrode speeds, and electrode contacts the weld pool at higher electrode speeds. Source: Ref 1

Fig. 3 Plot of heat-transfer efficiency to base metal versus electrode speed for 0.89 mm (0.035 in.) diameter steel electrode in an Ar-2% O_2 shield gas. Total heat-transfer efficiency is shown partitioned into arc and molten drop components. Power supply open-circuit voltage, E_0 , is 32 V; contact tube-to-base metal distance, C_T , is 15.9 mm (0.625 in.). Source: Ref 2

Fig. 4 Globular transfer mode in gas metal arc welding of steel. (a) Schematic showing transfer of electrode material globules onto cathode base metal. (b) High-speed photograph of globular metal transfer

the electrode wire. Globular transfer can involve a transfer rate of approximately 1 to 10 drops/s, and the arc has a soft, rounded appearance. Droplet detachment and transfer are mainly due to the gravitational force, which limits globular transfer to in-position welding. For spray transfer (Fig. 5), droplet and electrode diameters are roughly equivalent.

Spray transfer can involve 100 drops/s, and the arc noticeably contracts, or stiffens. Drops usually travel in-line down the center of the arc, but several drops may be in flight at the same instant.

In streaming transfer (Fig. 6), a well-developed liquid column extends from the solid electrode down into the arc and breaks into small droplets before contacting the weld pool (see the following discussion on spatter). Streaming transfer can involve 1000 drops/s, and the arc has a characteristic cone shape, as shown in Fig. 6.

In short-circuiting transfer, the arc is very short (Fig. 7a). During metal transfer, the

Fig. 5 Spray transfer mode in gas metal arc welding of steel. (a) Schematic showing transfer of electrode material droplets onto cathode base metal. (b) High-speed photograph of spray metal transfer mode

undetached molten droplet contacts the weld pool, shorting out the arc (Fig. 7b), which then extinguishes. Surface tension plays an important role in transferring the drop to the weld pool, but detachment of the drop from the electrode is due to electromagnetic pinch forces. Reignition of the arc in conventional short-circuit arc welding is violent (Fig. 7c), resulting in considerable spatter. Development of higher levels of electronic control of power sources has resulted in several additional variants of electronically controlled short-circuit transfer mode. In these cases, the arc reignition is controlled to very low current level, which significantly minimizes spatter generation. There are also reciprocating wire-feed systems from at least two manufacturers that control the wire feed in both forward and reversing motions. These systems, combined with electronic current control, are capable of eliminating spatter on arc reignition and even on initial arc strike (Ref 5) (Fig. 9).

Fig. 6 High-speed photograph of streaming transfer mode in gas metal arc welding of steel

Systems involving two gas metal arcs in a single torch provide interesting additional challenges and opportunities to increase welding speed and deposition rate. These systems typically operate with current isolation and asynchronous pulsing (Fig. 10) of the welding arcs to avoid electrical interference and arc blow, which otherwise substantially destabilize the metal transfer. The arcs can be operated in pulse/constant-voltage (CV), CV/pulse, and pulse/pulse modes, depending on the desired arc characteristics, deposition rate, and welding position (Ref 5).

As seen in Fig. 8, the transition from one mode to another actually involves continuous variations in droplet size. Because the product of droplet volume and transfer rate equals the electrode melting rate (in appropriate dimensions), there is also a continuous variation in droplet transfer rate. Detailed experimental studies have shown that rapid, cyclic transition from globular to spray to globular and so on occurs in the transition region between globular and spray transfer (Ref 6). Although it is generally not possible for the welder to see droplet transfer events in the spray and streaming transfer modes (except under ideal conditions for spray transfer), the changes in arc shape and the associated changes in electrical and acoustic noise allow a trained welder to readily identify all of the transfer modes. The section "Electrical and Acoustic Signals" in this article describes this event more fully. Welding is increasingly mechanized, robotic, or deployed in methods other than manual (referred to as semiautomatic in GMAW because the wire is fed automatically). The skill sets of a good welder and/or welding engineer are still needed to set up and maintain the correct operation of the process, arguably more so because the intent is to increase productivity and throughput while maintaining an acceptably high level of weld quality.

Assuming that mass is conserved as welding occurs, the transverse cross-sectional area of the weld bead added to the weldment for a single weld pass, G , is given by:

Fig. 7 Short-circuiting transfer mode in gas metal arc welding of steel. (a) Schematic showing transfer of electrode material by surface tension of weld pool onto cathode base metal. (b) High-speed photograph of material transfer when arc length is very short. (c) High-speed photograph of cyclic shorting of arc by the electrode during metal transfer to weld pool. (d) High-speed photograph of violent arc reignition with associated spatter

$$G = \frac{S \pi d^2}{R^4} \quad (\text{Eq 3})$$

where S is electrode speed, R is welding speed, and d is electrode diameter. For the spray and streaming transfer modes, the assumption that mass is conserved is reasonably good. However, because short circuiting and other conditions generate considerable spatter, the actual reinforcement will be slightly less than the value calculated by Eq 3.

Droplet Velocity and Temperature. In spray and streaming transfer, the droplets are accelerated rapidly through the arc to the weld pool. Velocities of 1 m/s (40 in./s) are typical, increasing with voltage (Fig. 11). Calorimetry-based experimental results indicate that steel droplets can reach temperatures of approximately 2600 K (4220 °F) (Ref 2). This explains

why the droplets transport one-half of the total heat transferred to the base metal.

A result of the activity of molten electrode droplets in heat transfer to the base metal is that they also play an important role in convective heat transport in the weld pool and thus in weld penetration (Ref 7). This can be seen in Fig. 12, a transverse cross section of a gas metal arc bead-on-plate weld on carbon steel. The region of deep penetration in the center of the weld bead is associated with the heat convected to the lower portion of the weld pool by the entering droplets.

Electrical and Acoustic Signals. As the droplets of molten metal detach from the electrode, an almost instantaneous change occurs in the electrode extension, which results in a sudden, although small, change in the electrical resistance between the contact tube and the base

metal. The results are spikes in the secondary circuit voltage and welding current, accompanied by pressure changes in the arc. Thus, both electrical and acoustic noise (Fig. 13) are generated by the GMAW process and are characteristic of the droplet transfer mode. The waveforms for globular transfer show prominent spikes associated with individual droplet transfer events. This can also be seen in Fig. 14, a plot of the computer-digitized current for a weld on carbon steel, where a change from globular to spray transfer has occurred at approximately 8 s into the weld. The power spectra of the current changes dramatically for the two transfer modes (Fig. 15), leading to a means of detecting transfer mode during welding.

Several specific techniques have been identified (Ref 9) for detecting the mode of metal transfer: Fourier transform, standard deviation, peak ratios, and integrated amplitude of the current and voltage signal. In a similar manner, spatter, lack of shielding gas, and contact tube wear can also be detected. Similar power spectra changes also occur in the secondary circuit voltage and acoustic noise. The change in acoustic noise allows the aural detection of the transfer mode. An experienced welder can readily hear, for example, the difference between globular and spray transfer.

Contact of the molten droplet with the weld pool, while the droplet is still attached to the electrode, also results in a sudden change in electrical resistance. This is important, because spatter is generally produced when this electrode-to-weld pool contact breaks. (Spatter can also be produced by rapid expansion of gas bubbles in the electrode as it melts.) The resulting electrical and acoustic noise can be used to detect that spatter is being produced.

Procedure Development

The preceding discussion leads to a logical approach toward selecting welding parameters during the development of welding procedures. First, given a nominal power supply arc voltage and contact tip-to-workpiece distance, the electrode wire-feed speed can be set to determine the welding current. It can be shown that:

$$S = \frac{4\eta GI}{H\pi d^2} (E_O + HI) \quad (\text{Eq 4})$$

where E_O is the power supply arc voltage. It is assumed that the proper selection of electrode type and shielding gas have been made, and that the electrode diameter is appropriate for the application, which, based on the number of shielding gases, wire types, and diameters available, is worth checking with a welding engineer.

Second, the arc voltage is adjusted to give either an acceptable arc length or electrode extension. The objective is to prevent either burnback (transfer of the arc to the contact tube) or spatter caused by shorting of the

Fig. 8 Droplet sizes attainable under selected current pulsing conditions in gas metal arc welding of steel. Source: Ref 4

molten electrode droplets with the weld pool prior to detachment from the electrode. Fine adjustment of voltage may be necessary to obtain a clean start of the process, thus avoiding a short period of spatter or globular transfer following arc ignition. The combination of current and voltage for a given contact tip-to-workpiece distance determines the droplet transfer mode.

Third, the welding current determines the melting rate of the electrode. The electrode melting rate (\$M_{tp}\$) is a quadratic function of current (Ref 10):

$$M_{tp} = (C_1 + C_2A)I + C_3 \frac{LI^2}{A^i} \quad (\text{Eq 5})$$

where \$A\$ is the cross-sectional area of the electrode, and \$C_1, C_2, C_3\$, and \$i\$ are constants.

Another researcher (Ref 11) defines \$M_{tp}\$ by:

$$M_{tp} = C_4I + C_5 \frac{LI^2}{A} \quad (\text{Eq 6})$$

where \$C_4\$ and \$C_5\$ are constants.

Fig. 16 Plot of reinforcement versus heat input to show parameters that favor spray transfer mode for gas metal arc welding of steel. Power supply open-circuit voltage, E_0 , is 32 V; contact tube-to-base metal distance, C_T , is 15.9 mm (0.625 in.).

Fig. 14 Plot of digitized current versus time during a gas metal arc weld in carbon steel in which a transition from globular to spray transfer occurred (at $\sim t = 8$ s) as current was increased. Source: Ref 1

Given a desired melting rate, the welding travel speed is set to obtain the desired weld bead area. The welding current, arc voltage, and welding travel speed have all now been set, thus determining the heat input per length of weld ($H = \eta EI/R$).

It should be noted that it is actually possible to independently vary heat input and mass input (in terms of weld bead reinforcement) to the weld, over at least a small range. This is shown in Fig. 16, where the same data presented in Fig. 1 are replotted in terms of reinforcement as a function of heat input per length of weld.

The previous discussion on procedure development ignores second-order effects, such as the dependence of arc length on weld travel speed. It should also be realized that several iterations through the steps defined earlier may

be required for final parameter determination. Items such as the correct torch travel angle and work angle relative to the welding direction and the joint, including the weld position (flat, horizontal, vertical, overhead), are additional important factors when it comes to the performance and functionality of the weld and its acceptance. Proper power supply settings must be used, and code requirements must be met, typically in terms of both visual criteria (visual testing, liquid penetrant testing) and volumetric inspection (liquid penetrant testing, radiographic testing), depending on the welding specification and code requirements. Increasingly, data recorders and loggers are used for quality-assurance purposes and to alarm fault conditions to minimize scrap production that would otherwise increase in an automated, high-productivity environment.

Fluid Flow Phenomena during Welding*

Updated by W. Zhang, Oak Ridge National Laboratory

MOLTEN WELD POOLS are dynamic. Liquid in the weld pool is acted on by several strong forces, which can result in high-velocity fluid motion. Fluid flow velocities exceeding 1 m/s (3.3 ft/s) have been observed in gas tungsten arc (GTA) welds under ordinary welding conditions, and higher velocities have been measured in submerged arc welds. Fluid flow is important because it affects weld shape and is related to the formation of a variety of weld defects. Moving liquid transports heat and often dominates heat transport in the weld pool. Because heat transport by mass flow depends on the direction and speed of fluid motion, weld pool shape can differ dramatically from that predicted by conductive heat flow. Temperature gradients are also altered by fluid flow, which can affect weld microstructure. A number of defects in GTA welds have been attributed to fluid flow or changes in fluid flow, including lack of penetration, top bead roughness, humped beads, finger penetration, and undercutting. Instabilities in the liquid film around the keyhole in electron beam and laser welds are responsible for the uneven penetration (spiking) characteristic of these types of welds.

Mass Transport in the Arc

High-velocity gas motion occurs in and around the arc during welding. The gas motion is partially due to shielding gas flow, but, more importantly, it is driven by electromagnetic forces associated with the arc itself. In gas metal arc (GMA) welds, liquid filler metal is also being transferred through the arc from the electrode to the workpiece. Both the mode and velocity of metal transfer have major effects on weld pool shape. Mass transport in and around the arc is important in GTA welding (GTAW) and even more so in GMA welding (GMAW). A detailed description of this phenomenon can be found in the articles on arc physics and metal transfer and weld behavior in this Volume; only the effects of this transport on the weld pool are discussed in this article.

Gas Tungsten Arc Welding

Most experimental and theoretical work on weld pool fluid flow and its effects has been directed toward GTAW. The motivation for much of this work was the observation of dramatically different weld pool shapes for GTA welds made using identical welding parameters on different heats of the same material with the same nominal composition. An extreme example of weld shape variability is shown in Fig. 1. Early observations of variable weld shape (often referred to as variable penetration) were not only an intellectual puzzle but also an indication of a growing practical problem. Gas tungsten arc welding is commonly used for high-precision, high-quality automated welding applications where reproducibility of weld shape or penetration is critical.

The possibility that fluid flow in the weld pool could alter weld shape has been recognized for many years. For example, in 1965 Christensen et al. (Ref 1) proposed that convection is partially responsible for weld pool shapes that deviate from those predicted by conduction solutions. The forces driving fluid flow in GTA weld pools have also been long known. The four primary driving forces are surface tension gradients, electromagnetic or Lorentz forces, buoyancy forces, and aerodynamic drag forces caused by passage of the arc plasma over the weld pool surface.

Surface-Tension-Driven Fluid Flow Model.

Surface tension gradients were first proposed by Ishizaki et al. (Ref 2) as potential driving forces for weld pool fluid flow. Surface-tension-driven fluid flow was first described by Thomson (Ref 3) in 1855, but the phenomenon is commonly called Marangoni convection from the work of Carlo Marangoni (Ref 4).

In 1982, Heiple and Roper (Ref 5) proposed that surface tension gradients are commonly the dominant forces driving fluid flow in GTA welds, and that these gradients could be drastically altered by very small concentrations of certain trace elements. Surface tension gradients exist on a weld pool surface because the surface tension is temperature dependent, and there are large temperature gradients on a weld pool surface. For pure metals and many alloys, the surface tension decreases as temperature increases; that is, the surface tension temperature coefficient is negative. For weld pools in such materials, the surface tension will be greatest on the coolest part of the pool surface at the edge, and lowest on the hottest part under the arc near the center of the pool. Such a surface tension gradient produces outward surface fluid flow, as shown schematically in Fig. 2 (a). This fluid flow pattern transfers heat efficiently from the hottest part of the weld pool (near the center) to the edge and produces a relatively wide and shallow weld.

* Updated and revised from C.R. Heiple and P. Burgardt, "Fluid Flow Phenomena During Welding," *Welding, Brazing, and Soldering*, Vol 6, *ASM Handbook*, ASM International, 1993

Certain elements are surface active in molten metals; that is, they segregate to the surface of the solvent liquid metal and lower the magnitude of the surface tension, often drastically. Small concentrations of surface-active additions can also change the temperature dependence of the surface tension of the solvent metal or alloy so that, for a limited range of temperature above the melting point, the surface tension increases with increasing temperature. With a positive surface tension temperature coefficient, the surface tension will be highest near the center of the weld pool. Such a surface tension gradient will produce fluid flow inward along the surface of the weld pool and then down, as indicated schematically in Fig. 2(b). This fluid flow pattern transfers heat efficiently to the bottom of the weld pool and produces a relatively deep, narrow weld.

Experimental Observations. This physical model (i.e., surface-tension-driven fluid flow model) was developed and verified with a series of experiments in which stainless steel base metal was doped with low concentrations of various elements and the effect of the doping on weld pool shape measured. High-speed motion pictures of the weld pool surface suggested the fluid flow patterns indicated in Fig. 2. The addition of sulfur, oxygen, selenium, and tellurium to the stainless steel in low concentrations (less than 150 ppm) was shown to substantially increase GTA weld depth-to-width ratio (d/w). All these elements are known to be highly surface active in liquid iron. Measurements of the temperature dependence of the surface tension for steels with different GTA weld penetration characteristics produced an impressive correlation between a positive surface tension temperature coefficient arising from surface-active impurities and high d/w ratio welds (Fig. 3).

When additions were made to the weld pool of elements known to react with surface-active

elements already present in the steel to form compounds that are not surface active, the GTA weld d/w ratio decreased. Aluminum reacts with oxygen, producing wider, shallower welds in 21-6-9 stainless steel. Cerium reacts with both sulfur and oxygen, also producing lower d/w ratio welds. The effects of trace elements on weld shape have also been observed in a number of other alloys. These observations are summarized in Table 1.

The simple physical model illustrated in Fig. 2 has been remarkably successful in qualitatively explaining trace element effects. For example, changing GTAW conditions alters the magnitude and distribution of arc energy input to the weld, which in turn changes temperature gradients on the weld pool surface. From Fig. 2, a change in welding conditions that makes the center of the weld hotter, such as increasing current, should drive the existing fluid flow pattern more strongly. As shown in Fig. 4, increasing current improves the d/w ratio of steel doped with surface-active elements and reduces it for high-purity base metal. If the center of the weld becomes so hot that there is a region where the temperature coefficient of the surface tension is no longer positive, then the fluid flow pattern necessary for deep penetration is disrupted and the d/w ratio decreases. This effect is seen at high currents in Fig. 4. Similar results have been obtained for other welding parameters. The surface temperature at which the change from positive to negative surface tension temperature coefficient occurs for stainless steel is estimated by extrapolation in Fig. 3 to be approximately 2050 °C (3720 °F). Detailed thermodynamic calculations of the temperature dependence of the surface tension of iron-sulfur alloys predict that the transition from positive to negative dy/dT will occur at 2032 °C (3690 °F) for the high-sulfur alloy in Fig. 3. Recent spectrographic weld pool temperature measurements and numerical

simulations have indicated that this temperature can be exceeded in stainless steel GTA weld pools under normal welding conditions.

Sahoo et al. (Ref 8) analyzed the published data on interfacial tension of several binary systems, including iron-sulfur and iron-oxygen, and developed a formulation to satisfactorily describe the surface tension and its dependence on temperature and concentration for those systems. In particular, their formulation shows that the temperature coefficient of surface tension for iron-sulfur and iron-oxygen systems can change from negative to positive value as the temperature increases, which is consistent with that shown in Fig. 3.

The surface-tension-driven fluid flow model should be applicable to non-arc processes, provided the energy input distribution is similar to a GTA arc. This condition is satisfied for conduction-mode electron beam and laser welds. Dramatic increases in weld d/w ratio in selenium-doped zones in stainless steel have been observed for both traveling laser and electron beam conduction-mode welds. The weld shape changes were similar to those observed for GTA welds.

Conduction-mode electron beam welds can also be used to demonstrate that variations in weld shape with changes in welding parameters, as illustrated in Fig. 4, are not a result

Table 1 Effect to trace element impurities on GTA weld penetration of selected alloys

of some complex arc/weld pool interaction. One of the results of an investigation of the effect of changes in beam focus on weld shape in electron beam welds on low- and high-sulfur materials is shown in Fig. 5. The high-sulfur material exhibits a maximum in d/w ratio with increasing power density at a moderate power density away from sharp focus, which is analogous to that shown with increasing current in Fig. 4. (The low- and high-sulfur stainless steels have deep and nearly identical penetration near sharp focus. Near sharp focus, where the power density is high, penetration is by a keyhole mechanism in which average penetration is unrelated to surface-tension-driven fluid flow.) Measurements of the electron beam power-density distribution verified that there were no anomalous changes in the beam, such as a beam width maximum, with increasing peak power density. The d/w ratio maximum away from sharp focus is therefore proposed to originate from exactly the same mechanism as for increasing current with GTA welds.

Measurements of electron beam power distribution were made as a function of beam focus and were used to calculate the beam power density at the d/w maximum. The power density was also calculated at the d/w maximum for GTA welds. Calculation of weld pool surface temperatures using a traveling distributed heat-source model showed the central surface temperatures to be essentially identical at the d/w maxima for the electron beam and GTA processes. The calculated surface temperatures using the traveling distributed heat-source conduction approximation are much too high because, as indicated previously, most of the heat transport in the weld pool is by mass flow rather than by conduction. Nevertheless, the equality of the calculated weld pool peak temperatures at the d/w maxima provides strong confirmation that the mechanism responsible for the presence of the maximum in weld d/w with increasing input power density is independent of heat source and is not a result of an arc phenomenon.

Fig. 5 Plot of electron beam weld pool ratio (d/w) versus electron beam power density for low-sulfur (20 ppm) and high-sulfur (>120 ppm) type 304L stainless steel. Keyhole formation begins at approximately 2×10^3 W/mm².

A final example of the success of the fluid flow model in explaining GTAW phenomena is provided by butt welding together two steels with large differences in weld penetration characteristics. The weld pool is not centered over the joint; rather, it is displaced toward the material with low d/w behavior (Ref 9), as indicated schematically in Fig. 6. The low d/w material has a low concentration of surface-active impurities and therefore a high surface tension. Thus, there is a net surface tension gradient across the weld pool toward the low d/w material, producing the fluid flow pattern and weld cross section indicated in Fig. 6. The actual fluid flow pattern is certain to be more complicated than that illustrated.

Numerical Simulations. Direct measurement of weld pool fluid flow is very difficult. Surface flow has been studied by observing the motion on the surface of slag or intentionally added particles, as has bulk flow in transparent liquid/solid systems using simulated welding heat sources. There are a number of numerical calculations of weld pool fluid flow and shape, the most comprehensive of which appears to be that of Zacharia et al. (Ref 10). These numerical fluid flow simulations agree in broad terms with the physical model illustrated in Fig. 2; however, they differ in detail with Fig. 2 and with one another. One result of the analysis of Zacharia is that the weld pool surface temperature reached in stationary welds exceeds that in traveling welds. Trace element effects should therefore be less pronounced in stationary welds, because a larger portion of the pool surface is above the temperature range where a positive surface tension temperature coefficient exists. This prediction is in agreement with experimental observations. A detailed review of recent numerical models of heat and mass transfer in the weld pool is provided in the article "Modeling of Heat and Mass Transfer in Fusion Welding" in this Volume.

Interactions. Experiments in which low concentrations of various elements have been added to the base metal have demonstrated clear changes in weld pool shape. However, when weld d/w ratio is plotted versus chemical analysis for numerous heats of material, considerable scatter is observed. A comparison of

Fig. 6 Schematic showing typical fluid flow generated when butt welding two heats of material with different penetration characteristics. Source: Ref 9

weld d/w ratio in a standard weldability test versus sulfur content for approximately 200 lots of steel is shown in Fig. 7. There is a clear trend of increasing d/w with increasing sulfur, but the variability for a given sulfur content is substantial. Some of this variability is associated with imprecision in chemical analysis for sulfur and some with variations in oxygen content. However, it appears that much of the variability is related to interactions of the surface-active elements sulfur and oxygen with other components of the steel. Calcium is known to react with oxygen and, to a lesser extent, with sulfur to form stable compounds unlikely to be surface active. Aluminum and silicon also react with oxygen to form stable compounds. Thus, the amount of sulfur and oxygen available for segregation to the weld pool surface is a complicated function of the total weld pool chemistry.

There is an additional complication, illustrated in Fig. 8. When oxygen is added to the shielding gas, weld d/w ratio increases, passes through a maximum, and then declines with increasing oxygen content. Similar effects are seen with SO₂ additions. The surface of welds made with torch gas concentrations above the d/w maximum are heavily oxidized. A possible explanation for the decreasing d/w ratios at higher oxygen concentrations is that a liquid oxide film (slag) is formed on the weld pool surface, altering the surface tension gradients.

Oxygen can be added to the weld pool in other ways. Oxidizing the plate surface prior to welding adds oxygen to the weld pool and increases the weld d/w ratio. Wire brushing and grit blasting an originally clean surface increases both the surface oxide thickness and the surface area, thereby adding oxygen to the weld pool. The d/w ratio of JBK-75 stainless steel (a modification of ASTM A-286) GTA welds as a function of amount of wire brushing is similar in form to Fig. 8. Welds on plate brushed beyond the weld d/w maximum had extensive slag on the weld surface. The weld

Fig. 7 Plot of weld d/w ratio versus sulfur content for approximately 200 heats of type 304L stainless steel. Each point is an average of multiple sulfur analyses and weld d/w ratio measurements. If single values are used, the scatter is greater. Source: Ref 11

d/w ratio on JBK-75 stainless steel appears to be particularly sensitive to oxygen additions. Similar wire-brushing experiments on type 304 stainless steel showed smaller effects.

Although the origin of the difference in sensitivity between JBK-75 and type 304 is not known, one possibility is indicated by surface tension measurements on iron-silicon alloys in contact with carbon dioxide. The effect of CO_2 on the surface tension was a strong function of silicon content. For low-silicon alloys, the surface tension dropped sharply when contacted with CO_2 . For alloys with more than 1.2% Si, the surface tension increased when contacted with CO_2 . The different behavior was attributed to differences in slag formation on the liquid metal surface. Thus, silicon appears to interfere with the ability of oxygen to produce a positive surface tension temperature coefficient on liquid iron. The JBK-75 stainless steel used in the wire-brushing experiments contained only 0.06% Si, and the 21-6-9 used for the torch gas experiment (Fig. 8) contained only 0.16% Si. Type 304 stainless steel typically contains more than 0.5% Si. Thus, the high sensitivity of JBK-75 to oxygen additions may be related to its unusually low silicon content. Reports in the literature on the effect of oxygen on GTA weld penetration have been somewhat variable; differences in weld pool silicon content may be partially responsible for this variability.

Effects of High Current. Electromagnetic (Lorentz) stirring of the weld pool becomes more important at higher currents. The direction of the Lorentz force produces the deep penetration fluid flow pattern indicated in Fig. 2(b). At sufficiently high current, the Lorentz force dominates other forces that drive fluid flow, and the effects of trace elements become less important. In addition, the plasma jet becomes stronger with increasing current and, at high enough currents, produces a significant depression of the weld pool surface. The plasma jet forces are resisted by surface tension forces on the weld pool. Halmoy (Ref 13) has shown

Fig. 8 Plot of weld d/w ratio versus oxygen concentration in the torch gas for tungsten arc bead-on-plate welds on 21-6-9 stainless steel. Source: Ref 12

that for a traveling weld, the radial pressure gradient from the plasma jet tends to transport liquid from the front to the rear of the weld (Fig. 9). For a sufficiently strong pressure gradient, p_B , the liquid level under the arc may be pushed down to the bottom of the pool, as shown in Fig. 9(c). High-speed motion pictures of the effect of sulfur additions on weld pool fluid flow in 21-6-9 stainless steel showed behavior similar to that in Fig. 9(c) after large sulfur additions. Sulfur additions substantially reduce the weld pool surface tension and thereby increase the effect of the plasma jet.

In addition, a surface depression almost certainly changes the energy distribution input to the weld pool by the arc compared with a flat weld pool surface. Finally, under some high-current conditions, a vortex has been observed near the center of weld pools.

Strategies for Controlling Poor and Variable Penetration. A number of techniques have been developed to reduce penetration variability and improve penetration. Sometimes the weld pool shift illustrated in Fig. 6, which occurs when heats with different penetration characteristics are welded together, can be minimized by very tight heat sinking. The sensitivity of weld shape to trace element differences is a function of welding parameters, as illustrated in Fig. 4 for current; thus, combinations of welding parameters can be chosen that minimize heat-to-heat penetration variability. For wire-fed joints, some joint designs are more tolerant of penetration variability than others. For example, joints with thinner, wider lands are less sensitive than narrower grooves with thicker lands.

Material control by selection or specification is another approach. It was originally anticipated that stainless steels with less than 20 ppm S would have poor, but consistent, penetration. However, the data illustrated in Fig. 7 demonstrate that penetration variability is substantial even at these very low sulfur levels. Stainless steels with more than approximately 100 ppm S generally have consistently good penetration. A related approach is to test incoming material for welding characteristics and then select material with desired welding behavior for critical applications.

Finally, the weld pool can be doped with enough surface-active elements to ensure good

penetration. Sulfur and oxygen are the most practical dopants for ferrous alloys. The addition of oxygen or sulfur dioxide to the torch shielding gas has been shown to improve penetration and reduce penetration variability; however, this approach presents several practical problems. Oxygen can also be added to the weld pool by oxidizing the weld joint or by otherwise increasing the oxygen content of the weld groove surface—by wire brushing, for example. Probably the most useful approach is to dope the weld pool in the wire-fed joints by using a special filler wire. A group of defense contractors had a special heat of type 380L stainless steel produced with a sulfur content in the range of 100 to 150 ppm. The heat was then converted into weld wire. Welds made with this wire on a variety of stainless steel base metals have exhibited consistent and good penetration.

Deep-Penetration Electron Beam and Laser Welds

Keyhole Formation. A fundamental difference between arc heat sources and electron or laser beam heat sources is that electron and laser beams are capable of delivering heat over a small area at much higher power densities. As the power density of the welding heat source is increased, the peak surface temperature of the weld pool rises. For many metals, vapor pressure rises nearly exponentially with temperature and becomes appreciable (above 4000 Pa, or 30 torr, for an electron beam operating in a vacuum) near $0.8 T_b$, where T_b is the material boiling point in degrees Kelvin. As the surface temperature approaches this value, the liquid surface under the power source is depressed by the vapor pressure. As the liquid moves away from the power source, the surface is depressed and a cavity is formed. This is the basic theory of keyhole formation by an electron or laser beam.

Fluid Flow in the Keyhole. The keyhole is a cavity having roughly the size and shape of the beam; that is, it is usually approximately cylindrical. Fluid flow in the thin layer around the cavity plays a major role in determining the behavior of deep-penetration, keyhole-mode electron beam and laser welds. The first flow

Fig. 9 Effect of arc pressure on the weld pool for stationary and traveling welds. (a) $v = 0$. (b) $v > 0$, with weak radial pressure gradient, p_1 . (c) $v > 0$, with strong radial pressure gradient, p_B . Source: Ref 13

required for a traveling weld is transport of metal melted at the front wall of the cavity to the rear (where it eventually solidifies). Because of the weld geometry, this liquid must move around the keyhole cavity as a thin, high-velocity layer on the walls of the cavity. The dominant driving force for this motion appears to be surface tension gradients. As in GTAW, these gradients arise because the surface tension is temperature dependent and there is a substantial temperature difference between the front and rear of the cavity.

Calculations of the fluid flow have been performed by Wei and Giedt (Ref 14). Their calculations for pure iron predict that liquid metal is moved from the front to the rear of a sharp focus keyhole in a film that is approximately 0.02 mm (0.0008 in.) thick and is moving at a velocity of approximately 250 mm/s (10 in./s). The fluid is driven by a temperature difference of approximately 400 °C (720 °F). These results are only nominal values from the calculations, but they change little with the assumptions used and are representative of electron beam welds in general.

There is an interesting potential problem with this model. As discussed previously, the surface tension temperature coefficient, $d\gamma/dT$, can be positive over a limited temperature range in steels and some other alloys if surface-active impurities are present in sufficient quantity. If $d\gamma/dT$ is positive, then it would appear that molten metal would not be transported around the cavity. The likely resolution of this difficulty is that the liquid dwells slightly longer in the front of the cavity and is heated by the beam above the temperature at which a transition to negative $d\gamma/dT$ occurs. Some perturbation of the normal fluid flow may occur under these circumstances. Effects of such a perturbation on weld characteristics appear to be uncommon. The only available evidence for such an effect comes from electron beam welds performed on a heat of type 304 stainless steel with very low residual impurity content, except for approximately 340 ppm S. These welds had very high porosity compared with identical welds in other heats of material.

Instability in Keyhole Fluid Flow. In addition to the steady-state flow of liquid around the keyhole, significant instability in the fluid motion has been seen. For example, Mara et al. (Ref 15) used side-view, self-illuminated x-ray films to show that the beam location shifts between full penetration and nearly zero penetration in an irregular fashion. High-speed x-ray photographs show that the variable penetration is caused by a lump of metal that sags into the keyhole from high up on the cavity rear wall. The sequence of events that creates weld penetration irregularity was analyzed by Tong and Giedt (Ref 16) and is illustrated schematically in Fig. 10. First, the beam forms a keyhole and produces a lump of very hot displaced metal at the top rear of the traveling cavity (Fig. 10a). After some period of time, the weld reaches the full penetration allowed by heat flow (Fig. 10b).

The lump of displaced metal is unstable and eventually falls into the cavity, partially filling it. The beam must now drill through this additional material. The sequence (a) to (c) in Fig. 10 occurs repeatedly, but irregularly, and produces weld penetration variability. When particularly severe, the irregular penetration is called spiking. Spiking also leads to a tendency for voids to become trapped in the root of the weld.

A mathematical model that is the basis for understanding this keyhole instability was developed by Giedt et al. (Ref 14, 16). Stability of the keyhole is basically a balance between vapor pressure, which keeps the cavity open, and surface tension, which tries to close the cavity. Vapor pressure and surface tension are both functions of temperature. Vapor pressure increases nearly exponentially with temperature for many materials, while surface tension generally decreases slowly with temperature. Because there is a substantial temperature gradient from the top to the bottom of the keyhole, both vapor pressure and surface tension vary with depth in the keyhole. Direct measurements of cavity wall temperatures for electron beam welds indicate that the temperature at the top is nearly equal to the melting temperature, while the temperature at the bottom is high enough that the vapor pressure there is large. In type 304 stainless steel, the temperature at the bottom of the cavity is approximately 1200 °C (2200 °F). The data indicate that the temperature profile is insensitive to welding variables and is determined primarily by material properties, that is, by the temperature where the vapor pressure exceeds approximately 1330 Pa (10 torr).

Based on temperature measurements of a typical keyhole, the vapor pressure decreases approximately exponentially with height from the bottom of the keyhole and approaches zero at the top of the keyhole. The vapor pressure is balanced primarily by surface tension. For pure iron and many other materials, the surface tension decreases approximately linearly

with temperature. Thus, the inward surface tension pressure increases slowly from the bottom to the top of the keyhole. The balance of vapor pressure and surface tension is such that the cavity is stable near the bottom, where the vapor pressure tending to expand the cavity exceeds the surface tension tending to collapse it. At the top, the cavity is unstable because the surface tension tending to collapse it exceeds the vapor pressure tending to expand it. Thus, the cavity will always tend to be filled by liquid originating from above some height, H , in the keyhole, the pressure crossover height. This cavity filling produces weld penetration irregularity, which is a consequence of the nature of the keyhole in deep-penetration welding. More recently, Matsunawa (Ref 17) studied the role of keyhole instability in porosity formation using high-speed x-radiography observations. It was found that cavity formation caused by keyhole fluctuation could be reduced or suppressed by stabilizing the keyhole. For example, controlled pulse modulation in continuous-wave laser welding can effectively reduce porosity formation by imposing forced oscillation of the keyhole.

Penetration irregularity is usually less severe if H (as measured from the top) is a small fraction of the keyhole depth. In such cases, the volume of the lump is small, and liquid tends to flow into the cavity relatively smoothly. If H is a large fraction of the keyhole depth, then the liquid lump has a relatively large volume, and when it falls into the keyhole at irregular times, it nearly fills the cavity and produces large penetration variations.

Gas Metal Arc Welding

Fluid flow certainly occurs in GMA weld pools, but reports on the details of its nature and effects are quite limited. In the spray transfer mode, the impact of the stream of droplets from the electrode on the weld pool forms a

Fig. 10 Schematic showing keyhole instability. (a) Keyhole is formed by heat generated by electron beam. (b) Maximum penetration that can be produced by heat flow. (c) Liquid cools, causing impending collapse of displaced metal. The keyhole is filled by a lump of cooling material at the end of (c), which returns the keyhole to condition (a) to restart the sequence.

substantial depression or crater. This is the mechanism responsible for the typical finger-like penetration observed with argon as the torch gas. Thus, the depth of penetration is primarily dependent on the momentum of the stream of droplets. A plot of penetration versus the momentum of the droplet stream shows an excellent correlation (Fig. 11). Because the major force driving the droplets toward the weld is drag from the plasma jet, the kinematic viscosity (density times viscosity) of the shielding gas is important. For example, argon has a substantially higher kinematic viscosity than helium, so argon drives the droplet stream more effectively, resulting in a deeper, narrower penetration finger than with helium torch gas. The strength of the plasma jet can also be altered by changing the ambient pressure. For GMA welds on aluminum, Amson and Salter (Ref 19) saw a steady decrease in penetration with pressure until at 13,300 Pa (100 torr) there was essentially no penetration at all. Another way to modify the penetration depth is to spread the stream of droplets over the surface of the weld. This can be accomplished by applying a varying transverse magnetic field.

Fig. 11 Plot of gas metal arc weld penetration in mild steel for spray transfer mode versus momentum of droplet stream. Source: Ref 18

Submerged Arc Welding

Currents commonly employed in submerged arc welding are much higher than those used in GTAW or GMAW. Submerged arc welding currents often exceed 1000 A. Thus, the electromagnetic or Lorentz force combined with the tendency of the radial pressure gradient in the moving cavity to transport liquid to the rear of the cavity (Fig. 9) is likely the dominant force driving fluid flow. The generally accepted flow pattern is indicated schematically in Fig. 12. A cavity is formed at the front of the moving weld pool by arc pressure and by the momentum of drops from the rapidly melting electrode. Metal that is melted at the front of the pool flows underneath and on either side of the cavity. At the rear of the pool, the flow reverses and metal flows back toward the cavity along and near the surface. Flow velocities can be very high; Eichhorn and Engel (Ref 21) measured 4 m/s (13 ft/s) at 720 A. The flow pattern was derived from observations of the motion of marker elements, added to the weld pool, as determined from subsequent metallographic sections, and from the motion of radioactive tracer additions. The general features illustrated in Fig. 12 appear to be supported by x-ray fluoroscopy observations. Major perturbations in the indicated fluid flow have been demonstrated, including reversal of the flow direction. These perturbations have been associated with weld defects.

Transport Equations for Weld Fluid Flow

Although the aforementioned welding processes vary significantly in many aspects, such as welding equipment, the fluid flow phenomena during welding can be described mathematically by a common set of transport equations. The different fluid flow characteristics and resulting weld nugget shapes in those welding processes are largely attributed to the different boundary conditions and material states. The transport equations are available in many

standard textbooks, such as Ref 22. For incompressible laminar flow of Newtonian fluids, the transport equations are as follows:

$$\nabla \cdot \vec{v} = 0 \tag{Eq 1}$$

$$\rho \left(\frac{\partial \vec{v}}{\partial t} + \vec{v} \cdot \nabla \vec{v} \right) + = -\nabla p + \mu \nabla^2 \vec{v} + S_v \tag{Eq 2}$$

$$\rho \left(\frac{\partial h}{\partial t} + \nabla \cdot (\vec{v}h) \right) + = \nabla \cdot (kT) + S_h \tag{Eq 3}$$

where v is fluid velocity, ρ is density, t is time, p is pressure, μ is molten metal viscosity, h is sensible heat, k is thermal conductivity, T is temperature, and S_v and S_h are heat-source terms. The sensible heat is expressed as:

$$h = \int C_p dT$$

where C_p is the specific heat. Equations 1 through 3 are the continuity, moment conservation, and energy conservation equations, respectively. Detailed discussion on the solution of the transport equations and associated boundary conditions to calculate heat and mass transfer in the weld pool is provided elsewhere in this Volume (see, for example, the article “Factors Influencing Heat Flow in Fusion Welding” and the articles in the Section “Fundamentals of Weld Modeling”).

Concluding Remarks

This article is a modification of a previous article in an earlier edition of the ASM Handbook. In order to maintain the conformance with original authors, major parts of the article has been maintained to allow for contiguity. It is noted that significant progresses have been made recently towards understanding the fluid flow phenomena in arc plasma and weld pool. Examples include, the formation of unusual, wavy fusion boundaries caused by welding parameters and material properties (Ref 23); unsteady Marangoni flow in a molten pool consisting of immiscible dissimilar metals (Ref 24); welding of stainless steel plates containing different concentrations of sulfur (Ref 25); heat transfer and fluid flow during key-hole mode laser welding (Ref 26, 27); Formation of Humped Beads in High Speed Gas Metal Arc Welding due to Strong Backward Fluid Flow (Ref 28); unified model for stationary tungsten-inert-gas welding process taking into account the close interaction between the arc plasma and the weld pool (Ref 29); and direct visualization of Marangoni convection in a simulated transparent weld pool of NaNO_3 heated with a defocused CO_2 laser beam (Ref 30). Since the numerical modeling plays an essential role in gaining the understanding, details on these recent progresses are discussed in another article, which is focused on the modeling of fluid flow phenomena during welding.

Fundamentals of Weld Solidification

John N. DuPont, Lehigh University

MICROSTRUCTURAL EVOLUTION during solidification of the fusion zone represents one of the most important considerations for controlling the properties of welds. A wide range of microstructural features can form in the fusion zone, depending on the alloy composition, welding parameters, and resultant solidification conditions. The primary objective of this article is to review and apply fundamental solidification concepts for understanding microstructural evolution in fusion welds.

Microstructural Features in Fusion Welds

Figures 1 through 3 schematically demonstrate the important microstructural features that must be considered during solidification in fusion welds (Ref 1, 2). On a macroscopic scale, fusion welds can adopt a range of grain morphologies similar to castings (Fig. 1), in which columnar and equiaxed grains can potentially form during solidification. The final grain structure depends primarily on alloy composition and the heat-source travel speed. Although some of the concepts applicable to grain structure formation in castings apply to welds, there are also some unique differences. While the columnar and equiaxed zones can form in welds, the fine-grained chill zone at the mold wall represented by the fusion line is rarely observed in welds. Fundamental concepts associated with nucleation are needed to understand these differences. In addition, the solid/liquid interface in welds is typically curved and its rate of movement is controlled by the heat-source travel speed, which leads to differences in formation of the columnar zone within welds. These differences can be understood through application of competitive grain growth processes that occur during solidification.

On a microscopic scale, there can also be a wide range of substructural morphologies within the grains (Fig. 2), including planar (i.e., no substructure), cellular, columnar dendritic, and equiaxed dendritic. The type and relative extent of each substructural region is governed by the process of constitutional supercooling in which the liquid becomes

cooled below its liquidus temperature due to compositional gradients in the liquid. The extent of constitutional supercooling in the weld is determined by the alloy composition, welding parameters, and resultant solidification parameters. Lastly, the distribution of alloying elements and relative phase fractions within the substructure (Fig. 3) are also important microstructural features that strongly affect weld-metal properties. The particular example shown in Fig. 3 represents a case in which extensive residual microsegregation of alloying elements exists across a cellular substructure after nonequilibrium solidification. This microsegregation, in turn, produces a relatively high fraction of intercellular eutectic and associated secondary phase. The microsegregation behavior and concomitant amount of secondary phase that forms can each be understood with solute redistribution concepts. Lastly, dendrite tip undercooling can become important at high solidification rates associated with high-energy-density welding processes. Tip undercooling can lead to significant changes in the primary solidification mode, distribution of solute within the solid, and final phase fraction balance. Rapid solidification concepts are needed to understand these phenomena. All of these fundamental solidification concepts (nucleation, competitive grain growth, constitutional supercooling, solute redistribution, and

Fig. 1 Types of grain morphologies that can form in fusion welds

Fig. 2 Types of substructure morphologies that can form within the grains of fusion welds

rapid solidification) depend on the solidification parameters during welding. Thus, the important solidification parameters are briefly described, followed by detailed discussions and application of fundamental solidification concepts for understanding microstructural evolution.

Solidification Parameters

The temperature gradient (G), solid/liquid interface growth rate (R), and cooling rate (ϵ) are the important solidification parameters. These three parameters are related by:

$$\epsilon = GR \tag{Eq 1}$$

This simple relation is not always intuitive and can be understood more clearly with the help of Fig. 4. This figure shows a fixed temperature gradient moving from right to left at a rate R so that $t_1 > t_2$. At a fixed position x^* , the temperature is reduced from T_1 to T_2 within the time $t_1 - t_2$. In other words, the time it takes for a temperature reduction (i.e., the cooling rate) is governed by the rate of movement (R) of the temperature gradient (G) through space.

The solidification parameters are not controlled directly in fusion welding but are governed by the welding parameters. As explained in more detail subsequently, the growth rate is determined largely by the speed of the heat source and shape of the weld pool. The cooling rate and temperature gradient are controlled primarily by the heat input (HI), which is defined as:

$$HI = \frac{\eta P}{S} \tag{Eq 2}$$

Fig. 3 Potential distribution of alloying elements and phase fractions that can form in fusion welds. Example shown is for a simple eutectic system that forms primary α phase and intercellular α/β eutectic under conditions of nonequilibrium solidification. Location of composition trace is across primary and eutectic α phase, as shown by horizontal dotted line.

where η is the heat-source transfer efficiency, P is the heat-source power, and S is the heat-source travel speed. The heat input represents the amount of energy delivered per unit length of weld. It should be noted that ϵ , G , and R cannot be represented by single values during solidification. Due to the complex nature of heat flow in the weld pool, the spatial distribution of temperature is not linear. Similarly, the value of R typically varies throughout the weld pool due to the change in growth directions between the solid/liquid interface and heat source. As a result, the values of ϵ , G , and R are functions of position and time. In general, the temperature gradient and cooling rate each decrease with increasing heat input. Detailed heat-flow equations can be used to quantify the influence of welding parameters on solidification parameters. Heat flow in welding is discussed in more detail in other articles in this Volume (see, for example, the article “Factors Influencing Heat Flow in Fusion Welding”).

Nucleation Considerations in Fusion Welding

Although the microstructures of castings and welds share some similarities, there are also some significant differences. For example, as shown schematically in Fig. 5 (Ref 3), castings typically exhibit a chill zone that consists of fine equiaxed grains which form near the mold wall. This zone forms as a result of nucleation at the mold/casting interface. This region is typically followed by a columnar zone and another equiaxed zone near the center of the casting. The columnar grain region and the central equiaxed grain zones can also form in fusion welds. However, the equiaxed grains associated with the chill zone generally do not form in fusion welds. The differences in these features can be understood with the application of

Fig. 4 Schematic illustration showing relation between temperature gradient (G), growth rate (R), and cooling rate. The cooling rate is controlled by the rate of movement of the temperature gradient.

nucleation theory, which is covered in this section.

Nucleation Theory

Figure 6 compares examples of homogeneous nucleation in a liquid (Fig. 6a, b) and heterogeneous nucleation on a preexisting mold wall (Fig. 6c, d). The change in free energy associated with homogeneous nucleation (ΔG_{hom}) is given by (Ref 4):

$$\Delta G_{\text{hom}} = -V_s \Delta G_v + A_{\text{SL}} \gamma_{\text{SL}} \tag{Eq 3}$$

where V_s is the volume of the nuclei, ΔG_v is the volume free-energy change associated with nucleation, A_{SL} is the solid/liquid interfacial area, and γ_{SL} is the solid/liquid interfacial energy. The volume free energy is the driving force for solidification and is shown schematically in Fig. 7(a), which shows the variation in volume free energy for the solid and liquid as a function of temperature. Note that $\Delta G_v = 0$ at the melting point, so there is no driving force for solidification at $T = T_m$. Thus, undercooling is generally required to drive the nucleation process. The interfacial energy is a positive contribution to the overall free-energy change and therefore works to oppose formation of the nucleus. The change in volume free energy with undercooling (ΔT) is given by:

$$\Delta G_v = \frac{L \Delta T}{T_m} \tag{Eq 4}$$

where L is the latent heat of fusion. A spherical nucleus is favored over other shapes because it provides the minimum surface area/volume ratio, thus providing the largest possible reduction in ΔG_{hom} by maximizing the negative $V_s \Delta G_v$ term and minimizing the positive $A_{\text{SL}} \gamma_{\text{SL}}$ term. For a spherical

Fig. 5 Schematic illustration of grain structures that can form in castings, showing the chill zone near the mold wall, the columnar zone, and the equiaxed zone in the center of the casting. Source: Ref 3

nucleus of radius r , the free-energy change for homogeneous nucleation is given by:

$$\Delta G_{\text{hom}} = -\frac{4}{3}\pi r^3 \Delta G_v + 4\pi r^2 \gamma_{\text{SL}} \quad (\text{Eq 5})$$

Equation 5 is plotted in Fig. 7(b), which shows the individual contributions to ΔG_{hom} and the overall change in ΔG_{hom} . The overall change in ΔG_{hom} goes through a maximum, which describes the critical radius (r^*) at which point the reduction in ΔG_{hom} due to $-\frac{4}{3}\pi r^3 \Delta G_v$ begins to become larger than the increase in ΔG_{hom} associated with the $4\pi r^2 \gamma_{\text{SL}}$ term. A nucleus that forms with a radius smaller than r^* is unstable, because any further increase in the nuclei radius will produce an increase in ΔG_{hom} . Conversely, any nuclei that forms with a radius larger than r^* is stable, because further growth in the nuclei leads to an overall reduction in ΔG_{hom} . The maximum in ΔG_{hom} is denoted as ΔG^* and represents the activation energy associated with homogeneous nucleation. This condition is given by:

$$\frac{d\Delta G_{\text{hom}}}{dr} = -4\pi r^2 \Delta G_v + 8\pi r \gamma_{\text{SL}} = 0 \text{ at } r^* \quad (\text{Eq 6})$$

From which the following expressions can be derived for r^* and ΔG^* :

$$r^* = \frac{2\gamma_{\text{SL}}}{\Delta G_v} \quad (\text{Eq 7a})$$

$$\Delta G^* = \frac{16\pi\gamma_{\text{SL}}^3}{3(\Delta G_v)^2} \quad (\text{Eq 7b})$$

Fig. 6 Schematic illustrations of homogeneous (a and b) and heterogeneous (c and d) nucleation. Figures on the left are for a temperature above the melting point. Figures on the right are for a temperature below the melting point. The wetting angle, θ , is shown in (d).

Equations 7 and 4 can be combined to reveal the influence of undercooling on r^* and ΔG^* :

$$r^* = \left(\frac{2\gamma_{\text{SL}}}{L}\right) \frac{T_m}{\Delta T} \quad (\text{Eq 8a})$$

$$\Delta G^* = \left(\frac{16\pi\gamma_{\text{SL}}^3}{3L^2}\right) \left(\frac{T_m}{\Delta T}\right)^2 \quad (\text{Eq 8b})$$

Note that, according to Eq 8(a) and (b), r^* and ΔG^* are infinite when $\Delta T = 0$, indicating that nucleation cannot occur without some undercooling. The undercooling is needed so that the reduction in ΔG_{hom} due to the volume free-energy change (by way of Eq 4) is larger than that due to the increase in ΔG_{hom} associated with the interfacial energy term. Thus, r^* and ΔG^* each decrease with increased undercooling.

For heterogeneous nucleation on an existing mold wall, the overall free-energy change is given by (Ref 4):

$$\Delta G_{\text{het}} = -V_s \Delta G_v + A_{\text{SL}} \gamma_{\text{SL}} + A_{\text{SM}} (\gamma_{\text{SM}} - \gamma_{\text{LM}}) \quad (\text{Eq 9})$$

The first two terms are identical to those for homogeneous nucleation. The third term ($A_{\text{SM}} \gamma_{\text{SM}}$) represents the increase in overall free energy from formation of the solid/mold interface, while the fourth term ($A_{\text{SM}} \gamma_{\text{LM}}$) represents the reduction in overall free energy associated

with elimination of some of the liquid/mold interface due to formation of the nucleus. Note that the interfacial energy between two solids is typically less than that between a solid and a liquid. Thus, the $A_{\text{SM}}(\gamma_{\text{SM}} - \gamma_{\text{LM}})$ term is typically negative so the $\Delta G_{\text{het}} < \Delta G_{\text{hom}}$. The values of V_s , A_{SL} , and A_{SM} will depend on the shape of the nucleus as determined by the wetting angle, θ (Fig. 6d). The value of θ , in turn, is governed by the relative values of surface energies and is given by a force balance in the horizontal direction as:

$$\gamma_{\text{LM}} = \gamma_{\text{SM}} + \gamma_{\text{SL}} \cos \theta \quad (\text{Eq 10a})$$

$$\theta = \cos^{-1} \left(\frac{\gamma_{\text{LM}} - \gamma_{\text{SM}}}{\gamma_{\text{SL}}} \right) \quad (\text{Eq 10b})$$

Assuming the nucleus forms as a spherical cap, the values of A_{SL} , A_{SM} , and V_s are given by:

$$A_{\text{SL}} = 2\pi r^2 (1 - \cos \theta) \quad (\text{Eq 11a})$$

$$A_{\text{SM}} = \pi r^2 \sin^2 \theta \quad (\text{Eq 11b})$$

$$V_s = \pi r^3 (2 + \cos \theta) \frac{(1 - \cos \theta)^2}{3} \quad (\text{Eq 11c})$$

Equations 9 to 11 can be combined for an expression for ΔG_{het} :

$$\Delta G_{\text{het}} = \left(-\frac{4}{3}\pi r^3 \Delta G_v + 4\pi r^2 \gamma_{\text{SL}} \right) S(\theta) \quad (\text{Eq 12})$$

where:

$$S(\theta) = (2 + \cos \theta) \frac{(1 - \cos \theta)^2}{4} \quad (\text{Eq 13})$$

Note that $0^\circ \leq \theta \leq 180^\circ$ and $0 \leq S(\theta) \leq 1$. Thus, it is apparent that $\Delta G_{\text{het}} \leq \Delta G_{\text{hom}}$. This is shown schematically in Fig. 8. Low values of θ are an indication that the solid/mold interfacial energy is low so that the solid easily wets the mold wall. This leads to low values of $S(\theta)$ and reduced values of ΔG_{het} ; that is, nucleation is made easier for reduced values of γ_{SM} .

Application to Fusion Welding

Fusion welding represents a unique case that can be most easily understood by starting with Eq 10(b) and noting that the mold wall and the solid are identical, because the base metal acts as the mold in fusion welding. Thus, it can immediately be noted that fusion welding leads to the following conditions:

$$\gamma_{\text{SM}} = 0 \quad (\text{Eq 14a})$$

$$\gamma_{\text{LM}} = \gamma_{\text{SL}} \quad (\text{Eq 14b})$$

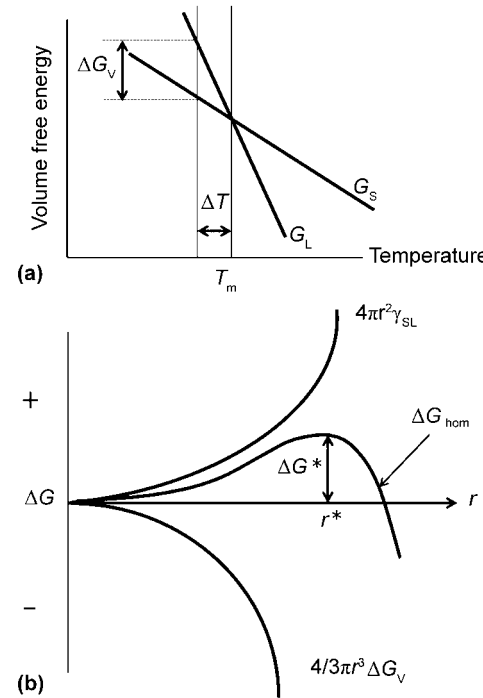

Fig. 7 (a) Variation in volume free-energy with temperature for the solid and liquid. (b) Variation in surface energy term, volume free-energy term, and ΔG_{hom} with nucleus radius for homogeneous nucleation

$$\theta = \cos^{-1} \left(\frac{\gamma_{SL}}{\gamma_{SL}} \right) = 0 \quad (\text{Eq 14c})$$

$$S(\theta = 0) = 0 \quad (\text{Eq 14d})$$

Thus, from Eq 12, the activation energy in fusion welding (ΔG_{fw}) for nucleation is given simply by $\Delta G_{fw} = 0$. This is compared to ΔG_{hom} and ΔG_{het} in Fig. 8. This can be interpreted by noting that the base-metal mold presents a perfect crystallographic match for growth of the solid fusion zone. Thus, there is no solid/mold interface in fusion welding due to this perfect crystallographic matching. An example of this in a fusion weld made with the electron beam process is shown in Fig. 9 (Ref 5). Note that there are no fine equiaxed grains at the fusion line, as often observed in the chill zone of castings. Instead, the weld-metal grains grow directly from the pre-existing base-metal grains. As a result, there is no barrier to formation of the solid. This condition is referred to as epitaxial growth, because growth occurs directly from the preexisting solid without the need for nucleation. Therefore, there is no undercooling required to initiate solidification at the fusion line, and solidification commences at the liquidus temperature of the alloy. It should be noted that undercooling can still occur near the weld centerline due to the process of constitutional supercooling, as explained in more detail later. This can lead to the formation of the central equiaxed zone often observed in fusion welds. Undercooling can also be required for nucleation of new phases during solidification.

Grain Structure of Fusion Welds

As described previously, the weld-metal grains will grow epitaxially from the preexisting base-metal grains. However, not all of these grains will be favorably oriented for continued growth. Two primary factors control the continued competitive growth of weld-metal grains:

Fig. 8 Comparison of free-energy changes associated with homogeneous nucleation, heterogeneous nucleation, and fusion welding

- The grains tend to grow in a direction anti-parallel to the maximum direction for heat extraction.
- The solid will grow in the “easy-growth” crystallographic directions.

The first criterion results from the need to transport the latent heat of solidification down the temperature gradient into the cooler base metal. Because the temperature gradient is highest in a direction perpendicular to the solid/liquid interface, the resultant heat-flow rate is also highest in this direction. Thus, the grains tend to grow in a direction perpendicular to the solid/liquid interface. The second criterion results from the preferred crystallographic growth direction, which, for cubic metals, is along the [100] directions. By combining these two criteria, it can be seen that grains that have their easy-growth direction most closely aligned to the solid/liquid interface normal will be most favorably oriented to grow, thus crowding out less-favorably-oriented grains. This phenomenon accounts for the columnar grain zone that is often observed in castings, shown schematically in Fig. 5. In this case, the grains that nucleated near the mold wall and have their easy-growth direction aligned normal to the mold/casting interface outgrow the less-favorably-oriented grains, leading to the columnar region.

The situation is slightly more complex in fusion welding, because the pool shape produces a curved solid/liquid interface that is constantly in motion as it follows the heat source. This is shown schematically in Fig. 10 (Ref 6). Grains at the fusion line may initially be oriented in a favorable direction for growth, but their direction may become unfavorable as the curved solid/liquid interface changes its position. These grains may then eventually be overgrown by other grains that exhibit more favorable orientation for growth as the solid/liquid interface sweeps through the weld. An example of this is shown on a weld in nearly pure (99.96%) aluminum in Fig. 11(a) (Ref 7).

Fig. 9 Example of epitaxial growth from the fusion line in an electron beam weld of alloy C103. Original magnification: 400x. Source: Ref 5

As may be expected, the pool shape can have a strong influence on competitive grain growth and the resultant grain structure of the weld. In turn, the pool shape can be influenced by the welding parameters. At low-to-moderate heat-source travel speeds, the pool shape is generally elliptical and typically produces the grain structure pattern shown in Fig. 11(a). However, at higher travel speeds, the pool shape becomes elongated into a teardrop shape in which the solid/liquid interface is straight. This elongated shape is attributed to the low thermal gradient and high growth rate that exist at the weld centerline. The release of latent heat is proportional to the growth rate. Because the growth rate is highest at the weld centerline, the release rate of latent heat is also highest at the weld centerline. However, the temperature gradient is at a

Fig. 10 Schematic illustrations of competitive grain growth in welds. (a) Early growth of grains near the fusion line. (b) Continued growth of favorably-oriented grains at a later time. Source: Ref 6

minimum at the weld centerline, so it is difficult to transport the latent heat away from the pool to permit solidification. This causes elongation of the pool near the weld centerline and leads to the teardrop shape. In this case, the direction of grain growth does not change (because the solid/liquid interface is no longer curved), and the grains grow straight toward the weld centerline until grains growing from each side of the weld intersect. This process typically leads to a centerline grain boundary, as shown in Fig. 11(b) (Ref 7).

Axial grains that grow along the direction of heat-source travel can also occasionally be observed in fusion welds. The various types of grain morphologies are summarized in Fig. 12 (Ref 6). Examples of grain structures produced with elliptical and teardrop-shaped weld pools were shown in Fig. 11. Figures 12(c) and (d) represent conditions in which an axial grain grows along the direction of the heat-source travel. These grains form in the region where the solid/liquid interface is generally perpendicular to the direction of heat-source travel, so that it becomes favorable for one or more grains to grow in this direction. The width of this zone can depend on the pool shape. The region of the interface that is perpendicular to the heat-source direction is relatively small in an elongated weld pool, so the width of axial grains will also be small. By comparison, this perpendicular region is relatively larger for an elliptical pool, so the axial grain region can also be larger.

The large columnar grains and the potential presence of centerline grain boundaries are generally undesirable from a weldability and mechanical property point of view. Centerline grain boundaries can often lead to solidification cracking associated with solidification shrinkage and low-melting-point films that become concentrated at the centerline. Fine, equiaxed grains are desired over coarse columnar grains for improvements in both cracking resistance and mechanical properties (at low temperature). One effective means for minimizing or eliminating the coarse columnar grains is through manipulation of the pool shape. Figure 13 shows an example of a weld in which the arc was oscillated at a frequency of 1 Hz in a direction normal to the heat-source travel (Ref 8). In this case, the continuously changing direction of the solid/liquid interface makes it difficult for the columnar grains to extend over large distances, thus providing a degree of grain refinement. Grain size reduction can also be achieved through the use of inoculants. This process takes advantage of heterogeneous nucleation (discussed previously) and liquid undercooling that occur due to constitutional supercooling. This topic is described in more detail in the next section.

Substructure Formation in Fusion Welds

As shown previously in Fig. 2, grains in welds typically exhibit various substructural

morphologies within the grains that can be cellular, columnar dendritic, or equiaxed dendritic. Cellular and columnar dendritic morphologies develop due to breakdown of the initially planar solid/liquid interface that forms at the fusion line, while equiaxed dendrites form by nucleation of solid in undercooled liquid, typically

near the weld centerline. Formation of these features can be understood with the concept of constitutional supercooling. The basics of this topic are described first, followed by application of the theory to understanding the substructure formation in fusion welds.

Constitutional Supercooling

As shown by the phase diagram in Fig. 14(a), formation of a solid leads to rejection of solute into the liquid. The extent of solute enrichment in the liquid progresses as solidification proceeds and the liquid composition follows the liquidus line. The solute rejected by the solid at the solid/liquid interface must be transported away from the interface by diffusion and/or convection in the liquid. If the solid/liquid interface growth rate is relatively high (which leads to a high rate of solute rejection) and/or the transport of solute into the liquid by diffusion or convection is low, then a solute boundary layer can develop in the liquid near the solid/liquid interface. Because solute enrichment leads to a reduction in the liquidus temperature (for an element that partitions to the liquid), it follows that the presence of a solute

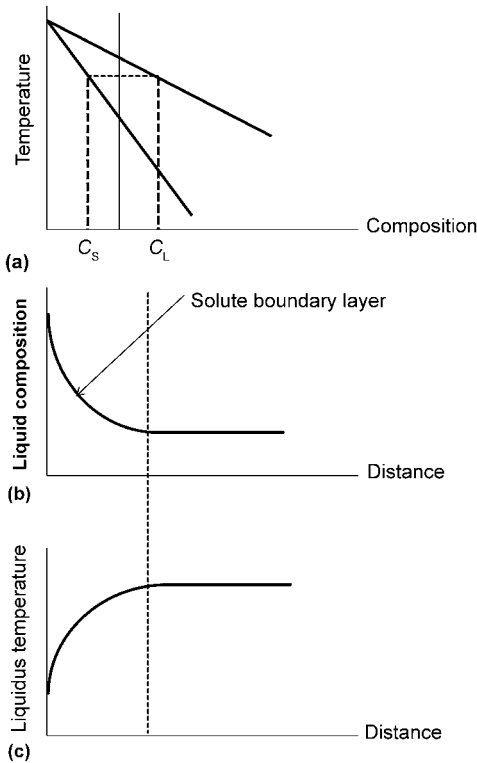

Fig. 14 Schematic illustration showing (a) solute enrichment in liquid during solidification, (b) formation of a solute boundary layer in the liquid, and (c) variation in liquidus temperature near the solid/liquid interface due to formation of the solute boundary layer

boundary layer leads to a gradient in the liquidus temperature near the solid/liquid interface. This is shown schematically in Fig. 14(b) and (c), where the liquidus temperature is relatively low at the solid/liquid interface due to the large amount of solute in the liquid at that point. The liquidus temperature gradually increases away from the interface as the solute concentration decreases. The liquidus temperature does not change outside the solute boundary layer.

Next, consider how the relative magnitudes of the liquidus temperature (T_L) gradient described previously (dT_L/dx) and the actual temperature (T_a) gradient (dT_a/dx) in the liquid affect the stability of a planar solid/liquid interface that forms as the alloy initially starts to solidify. Figure 15(a) shows the condition for a relatively steep temperature gradient such that $dT_a/dx > dT_L/dx$ in the liquid. The planar interface is moving to the right and develops protrusions during growth. Such protrusions can occur in practical situations due to interface pinning effects from inclusions in the liquid and/or differences in the rate of growth between neighboring grains that exhibit different crystallographic orientations relative to the solid/liquid interface (as described previously in the section about competitive grain growth). For this case in which $dT_a/dx > dT_L/dx$, the tip of the protrusion encounters liquid that is at a

temperature above the liquidus temperature of the alloy. Thus, the solid protrusion is not stable and melts back so that the planar interface remains stable. Under this condition, no substructure forms.

Figure 15(b) shows the case for a relatively low-temperature gradient in which $dT_a/dx < dT_L/dx$ in the liquid. In this case, the tips of the protrusions encounter liquid that is below the liquidus temperature of the alloy. This condition is referred to as constitutional supercooling because the liquid is cooled below its liquidus temperature due to constitutional variations within the liquid. Under this condition, the solid at the tips is stable because it is growing into liquid that is cooled below the liquidus temperature. In addition, because the growth rate of the solid is proportional to the undercooling, the growth rate at the tips will be higher than at the roots of the protrusions. As a result, the growth rate at the tips is faster than that at the roots, and the planar interface breaks down into a cellular interface. Note that solute redistribution in this case now occurs in three dimensions, and solute can build up at the cell boundaries as neighboring cells converge. Depending on the cooling rate and solute diffusivity in the solid, this local solute enrichment may persist after solidification (see the section “Solute Redistribution during Solidification” in this article for more details). The presence of the cell walls reflects differences in solute concentration that are revealed by etching. The condition for breakdown of the planar solid/liquid interface and concomitant formation of a cellular substructure is thus given by the condition at which $dT_a/dx < dT_L/dx$. This can be determined quantitatively by first developing an expression for the solute concentration gradient in the liquid (dC_L/dx) and then converting dC_L/dx into dT_L/dx via the phase diagram.

Assuming a linear solute gradient in the liquid, a mass balance about the solid/liquid interface is given by:

$$R(C_L - C_o) = -D_L \left(\frac{dC_L}{dx} \right) \quad (\text{Eq 15})$$

where C_L is the liquid composition at the solid/liquid interface, C_o is the nominal alloy composition, and D_L is the solute diffusivity in the liquid. The left side of Eq 15 represents the solute flux into the interface due to solute rejection by the solid, while the right side of Eq 15 represents the flux of solute down the gradient in the liquid (assuming a linear concentration gradient). At steady state, these two fluxes balance. For a phase diagram with a linear liquidus line, a given value of dC_L/dx produces a corresponding change in the liquidus temperature dT_L/dx that is given by:

$$\frac{dT_L}{dx} = m_L \left(\frac{dC_L}{dx} \right) \quad (\text{Eq 16})$$

where m_L is the liquidus slope. Combination of Eq 15 and 16 provides an expression for the constitutional criterion:

$$\frac{dT_a}{dx} < -\frac{Rm_L(C_L - C_o)}{D_L} \quad (\text{Eq 17})$$

The value of dT_a/dx is typically noted simply as G . At steady state, the value of C_L is given by $C_L = C_o/k$ (Ref 9), where k is the distribution coefficient given by $k = C_s/C_L$, where C_s is the solid composition. Thus, the expression for constitutional supercooling can be expressed as:

$$\frac{G}{R} < -\frac{m_L C_o (1 - k)}{k D_L} \quad (\text{Eq 18})$$

The parameters on the left are solidification parameters, while those on the right are parameters controlled by the alloy. The expression $m_L C_o (1 - k)/k$ represents the equilibrium solidification range of the alloy (ΔT_{eq}), so that the constitutional supercooling condition can also be written as:

$$\frac{G}{R} < -\frac{\Delta T_{eq}}{D_L} \quad (\text{Eq 19})$$

This condition represents the onset of undercooling and formation of a cellular substructure. Other substructural zones can form with increased undercooling. For example, the planar regions separating neighboring cells can undergo constitutional supercooling between the cells, thus leading to formation of columnar dendrites. With further undercooling, the liquid ahead of the dendritic interface can be supercooled to the point where nucleation can occur within the liquid, thus leading to formation of the equiaxed zone often observed in welds and castings and shown previously in Fig. 1(c) and Fig. 5. The equiaxed zone forms near the center of the weld or casting because the temperature gradient is the lowest at this location.

Examination of Eq 19 and reference to Fig. 15 indicate that supercooling is induced by low values of G and high values of R . The influence of G is readily apparent in Fig. 15, in which the extent of undercooling in the liquid increases as G decreases. The effect of R is to increase the concentration gradient in the liquid (Eq 15), which, in turn, increases the liquidus temperature gradient in the liquid. Thus, initial breakdown of the planar interface into a cellular one occurs at relatively high values of G/R . As G/R decreases, the substructural morphology can change from cellular to columnar dendritic to equiaxed dendritic. This is often summarized on a substructural diagram, as shown in Fig. 16.

Application to Fusion Welds

Fusion welds represent an interesting case of substructure formation because the values of G and R change continuously and in opposing directions around the solid/liquid interface within the weld pool. The value of G is relatively high at the fusion line because the molten pool is in contact with relatively cool base metal that has not been melted. The value of

Fig. 15 Schematic illustrations showing (a) stability of a planar interface for a condition in which the actual temperature gradient in the liquid is greater than the liquidus temperature gradient and (b) breakdown of a planar interface for a condition in which the actual temperature gradient in the liquid is lower than the liquidus temperature gradient

Fig. 16 Schematic illustration of a *G-R* diagram showing regions of various substructural morphologies

G decreases as the weld centerline is approached because the molten pool is in contact with resolidified weld metal that was already heated well above the liquidus temperature. An opposite trend exists for the growth rate. Figure 17 shows the relation between the heat-source travel speed (*S*) and growth rate (*R*) in terms of the angles α and β , where

Fig. 17 Schematic illustration showing the relation between the heat-source travel speed (*S*) and growth rate (*R*) in terms of the angles α and β , where α represents the angle between the welding direction and normal to the solid/liquid interface, and β represents the angle between the welding direction and $[100]$ growth direction (for a cubic metal)

α represents the angle between the welding direction and normal to the solid/liquid interface, and β represents the angle between the welding direction and $[100]$ growth

direction (for a cubic metal). The growth rate *R* is given by:

$$R = \frac{S \cos \alpha}{\cos(\alpha - \beta)} \tag{Eq 20}$$

In many cases, the value of $(\alpha - \beta)$ is small so that $\cos(\alpha - \beta) \sim 1$, and the relation between the growth rate and heat-source travel speed is given simply as:

$$R = S \cos \alpha \tag{Eq 21}$$

From this it can be seen that $R \sim 0$ at the fusion line and $R \sim S$ at the weld centerline. Thus, the value of *G/R* is very high at the fusion line and decreases appreciably as the weld centerline is approached. This can be portrayed on the *G-R* diagram as shown in Fig. 16. As a result, the fusion zone initially forms as a planar interface, which breaks down into cellular and columnar dendritic morphologies as the centerline is approached. If enough undercooling is obtained, an equiaxed zone can form in the centerline of the weld. The relative positions of these substructural morphologies are shown schematically in Fig. 2. An example of the equiaxed zone is shown in Fig. 18 (Ref 2).

It is interesting to note that the planar zone typically occupies a very small fraction of the fusion zone. This suggests that the planar

solid/liquid interface is inherently unstable under most solidification conditions. This can be verified by direct application of Eq 18, and results of this for the aluminum-copper system are shown in Table 1. These results show the critical value of R required for breakdown of the solid/liquid interface for various values of G and C_o that may be encountered for typical G values representative of casting, arc welding, and laser welding. For these calculations, values of m_L (~ -3.3 °C/wt%) and k (~ 0.17) were obtained directly from the aluminum-copper phase diagram, and the value for solute diffusivity was taken as $D_L \sim 10^{-3}$ mm²/s. Note that the critical growth rates for constitutional supercooling are significantly lower than actual growth rates expected during solidification, thus verifying that a planar interface is inherently unstable. This implies that the initially planar interface growing from the fusion line will break down into a cellular one very quickly as the value of G/R decreases, which is indeed observed experimentally.

Columnar-to-Equiaxed Transition

The transition from cellular or columnar dendritic growth at the fusion line to heterogeneous nucleation near the weld centerline is often referred to as the columnar-to-equiaxed transition (CET). As discussed subsequently, the CET occurs due to the relatively large

constitutional undercooling near the weld centerline. In welds of polycrystalline alloys, the CET can be exploited for grain refinement. This is typically accomplished by adding inoculants to the weld to promote heterogeneous nucleation sites. The most effective inoculants are those that minimize the activation energy (ΔG_{het}^*) required for heterogeneous nucleation, so that nucleation can occur with minimal undercooling. Equation 9 can be used to provide some insight into effective inoculants, which, for heterogeneous nucleation on an inoculant, can be written as:

$$\Delta G_{het} = -V_s \Delta G_v + A_{SL} \gamma_{SL} + A_{SI} (\gamma_{SI} - \gamma_{LI}) \quad (\text{Eq 22})$$

This is identical to Eq 9, except that it is written for heterogeneous nucleation on an inoculant (I) rather than a mold wall (M). As previously discussed, the first two terms in Eq 22 are similar to those for homogeneous nucleation. The free-energy change associated with heterogeneous nucleation on an inoculant can be minimized by minimizing the interfacial energy between the solid and inoculant (γ_{SI}), so that the $A_{SI}(\gamma_{SI} - \gamma_{LI})$ term is as large and negative as possible. The inoculant/solid interfacial energy can be minimized by optimizing the crystallographic matching between the inoculant and solid. Common examples of inoculants include the use of titanium and zirconium in aluminum welds (Ref 10) and TiN in ferritic stainless steels (Ref 11).

Fusion Welding of Single Crystals

Nickel-base superalloy single crystals are often welded to rejuvenate worn blades or to repair miscast blades. Successful repair of these alloys requires preservation of the single-crystal structure during solidification of the weld pool by avoiding the CET. Constitutional supercooling has been supported as the CET mechanism by a wide range of experimental observations in studies conducted on single-crystal alloys using a variety of techniques, including autogenous laser surface melting (Ref 12–14), laser cladding (Ref 15), and electron beam welding (Ref 16). For example, studies on electron beam and pulsed laser beam welds of a single-crystal nickel-base superalloy PWA 1480 by David et al. showed that it was difficult to maintain the single-crystal structure during welding due to the formation of equiaxed stray grains. In contrast, similar experiments conducted on a relatively pure austenitic Fe-15Cr-15Ni stainless steel single crystal (Ref 17) demonstrated nearly perfect retention of the single-crystal nature in electron beam welds. The difference in these results can generally be attributed to the solute content of the different alloys. Although chromium and nickel segregate to the liquid during solidification, it is well known (Ref 18) that the equilibrium partition coefficients (k) for both chromium and nickel are close to unity, and they do not segregate strongly during solidification. This,

combined with the low level of other elements in the Fe-15Cr-15Ni alloy, minimizes the buildup of solute in the liquid during solidification. As a result, the liquidus temperature variation is minimized and provides a concomitant reduction in the level of constitutional supercooling in the liquid. Thus, the reduced level of solute segregation makes it easier to avoid the CET. In contrast, commercial single crystals require the addition of substitutional and interstitial alloying elements, many of which partition strongly during solidification. This leads to higher concentration gradients in the liquid and enhanced constitutional supercooling.

Hunt (Ref 19) was the first to develop an approximate analytical expression that described the CET. In that work, expressions for the nucleation rate were combined with dendrite growth undercooling equations to establish the condition for the CET. The type of growth that occurred was assumed to depend on the volume fraction of equiaxed grains that formed in the undercooled region when the advancing columnar front met the equiaxed grains. The structure was assumed to be fully columnar, and thus the CET was avoided, when the volume fraction of equiaxed grains was less than 0.0066. This led to the following condition for avoiding the CET:

$$G > 0.617(100N_o)^{1/3} \left[1 - \frac{(\Delta T_N)^3}{(\Delta T_c)^3} \right] \Delta T_c \quad (\text{Eq 23})$$

where G is the temperature gradient in the liquid, N_o is the total number of heterogeneous sites available for nucleation per unit volume, ΔT_N is the associated undercooling required for nucleation, and ΔT_c is the undercooling at the solid/liquid interface, which depends on the temperature gradient and growth rate. The value of ΔT_c can be calculated using dendrite growth undercooling models (Ref 20, 21). The practical difficulty in the application of Eq 23 lies in the ability to determine appropriate values of ΔT_N and N_o . Nevertheless, the model is useful because it was shown to correctly capture the observed effects of various factors on the CET, such as growth rate, temperature gradient, and alloy composition.

More recently, Gauman et al. (Ref 22) extended the analysis proposed by Hunt. The composition profile in the liquid was calculated directly using the appropriate solution of the diffusion equations for an isolated dendrite with a parabolic tip geometry. This was then used to determine the liquidus temperature profile (T_L). The actual local temperature profile in the liquid ($T_{q,z}$) was considered to be controlled by heat extraction through the solid and was determined through knowledge of the temperature gradient and dendrite tip temperature as determined by the Kurz, Giovanola, Trivedi (KGT) model (Ref 21). The actual undercooling (ΔT_z) at any location within the liquid is then given by:

$$\Delta T_z = T_z - T_{q,z} \tag{Eq 24}$$

Equiaxed grains will nucleate anywhere in this undercooled region where the actual undercooling is more than that required for nucleation, $\Delta T_z > \Delta T_N$. The critical volume fraction required for a fully equiaxed structure originally proposed by Hunt was used as the critical CET value.

Figure 19 shows an example of a microstructure selection map that was generated for the nickel-base single-crystal CMSX-4 using the approach described previously (Ref 12). The solid continuous line in the plot represents the transition between values of the solid/liquid interface growth rate and temperature gradient in the liquid that lead to the CET. A G - R combination below this line will result in columnar single-crystal growth, while combinations above this line lead to equiaxed growth and loss of the single-crystal structure. Material parameters required for calculation of the map were determined using a multicomponent thermodynamic database. The values of N_0 and ΔT_N were assumed to be $N_0 = 2 \times 10^{15}/m^3$ and $\Delta T_N = 2.5 \text{ }^\circ\text{C}$. An increase in the value of N_0 or a decrease in the value of ΔT_N will widen the range where equiaxed growth occurs. This map is useful in a practical sense because it identifies combinations of G and R that permit retention of the single-crystal structure during weld repair. The use of heat-flow equations can then be used to link R and G to the weld processing parameters, such as heat-source power, travel speed, and preheat temperature, in order to develop process-microstructure maps for successful weld repair.

Gauman et al. (Ref 12, 15) developed a simplified relationship between the temperature gradient, growth velocity, volume fraction of equiaxed grains (ϕ), and nuclei density (N_0) as:

$$\frac{G^n}{R} = a \cdot \left[\sqrt[3]{\frac{-4\pi N_0}{3 \ln(1-\phi)}} \cdot \frac{1}{n+1} \right]^n \tag{Eq 25}$$

where a and n are material constants that are determined by fitting calculations of the constitutional tip undercooling from the KGT model

Fig. 19 Processing map for alloy CMSX-4 showing range of G - R conditions that produce columnar dendritic and equiaxed dendritic growth. Adapted from Ref 12

to an equation of the form $\Delta T = (aR)^{1/n}$. For CMSX-4, these values are $a = 1.25 \times 10^6 \text{ K}^{3.4}/\text{ms}$ and $n = 3.4$. This relation is valid under high-temperature gradient conditions in which the value of N_0 is most important for controlling nucleation and the value of ΔT_N can be ignored. Welds can be prepared under various values of G and R , and the resultant volume fraction of equiaxed grains (ϕ) can be directly measured on the weld cross sections. In this case, N_0 is the only unknown in Eq 25 and can thus be determined experimentally by fitting Eq 25 to the measured values of ϕ . For CMSX-4, this results in $N_0 = 2 \times 10^{15}/m^3$. When the original condition for a fully columnar microstructure proposed by Hunt is invoked ($\phi = 0.0066$), all values on the right side of Eq 25 are known and lead to the following condition for avoiding the CET:

$$\frac{G^n}{R} > K \tag{Eq 26}$$

where K is a material constant that depends on N_0 , ϕ , a , and n . For CMSX-4, $K = 2.7 \times 10^{24} \text{ K}^{3.4}m^{-4.4}s$. This approximate condition is shown as the dotted line in Fig. 19, and it can be seen that this approximation is more restrictive than the results obtained by the detailed calculations. However, Eq 25 is useful because it permits straightforward coupling of R and G to the weld processing parameters.

Figure 20 shows an example of a microstructure selection map for three different welds on alloy CMSX-4 (labeled "A," "B," and "C") prepared under different processing conditions. This plot shows the variation in the G^n/R ratio as a function of depth in the weld pool. As expected, the G^n/R ratio is highest at the fusion line (bottom of the weld) and decreases as the top of the weld is approached. The critical value for the CET of CMSX-4 is superimposed on the plot. Welds prepared under conditions in which the critical value of G^n/R remains below this critical value everywhere in the weld are expected to retain the single-crystal structure (e.g., weld A), while welds prepared with regions less than this value (e.g., welds B and C) will undergo the CET and lose the single-

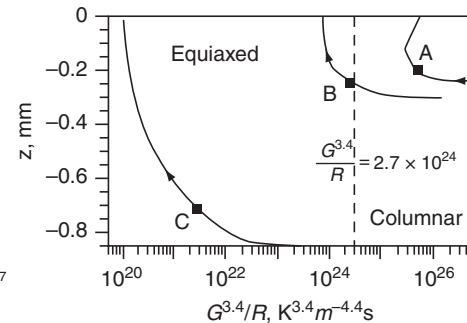

Fig. 20 Microstructure selection map for three different welds on alloy CMSX-4 (labeled "A," "B," and "C") prepared under different processing conditions. Source: Ref 12

crystal structure. Experimental identification of stray grains showed good agreement with the predictions of Fig. 20.

Figure 21 shows a process-microstructure map that was proposed to reveal semiquantitative relations between the important processing parameters of heat-source travel speed (V_b), power (P), and preheat temperature (T_0). This map was calculated using a single, integrated average of the G^n/R ratio to represent the variation in G and R that occurs with position in the melt pool. The region of high V_b and low P represents very low heat-input conditions that are insufficient to cause melting. At any travel speed, a reduction in power is beneficial, and this can be attributed to an increase in the temperature gradient. The results suggest that the effect of heat-source travel speed depends on the level of heat-source power. At low powers (i.e., $< \sim 550 \text{ W}$), the travel speed has no significant effect. Apparently, at this low power level, the gradient is high enough to avoid reaching the level of undercooling required for nucleation, regardless of the travel speed and resultant growth rate. At higher powers, the calculated results suggest that an increase in travel speed is deleterious to preserving the single-crystal columnar zone.

Experimental results generated to date generally confirm the expected influence of power described previously, but not travel speed. For example, Yoshihiro et al. (Ref 23) recently investigated the microstructure of welds on alloy CMSX-4 prepared over a wide range of powers and travel speeds using both the laser and gas tungsten arc (GTA) heat sources. A summary of their experimental results is shown in Fig. 22. They identified three types of morphologies: single crystals with directional dendrites that only grow in the [001] direction from the bottom of the weld, single crystals with disoriented dendrites, and welds with stray grains. The single-crystal welds with disoriented dendrites simply indicate the presence of dendrites that grew in directions orthogonal to the [001] direction. These results demonstrate that a reduction in power and increase in travel speed are always beneficial for preserving the single-crystal structure

Fig. 21 Process-microstructure map for alloy CMSX-4 that reveals the semiquantitative relations between heat-source travel speed (V_b), power (P), preheat temperature (T_0), and the type of dendrite growth. Source: Ref 12

within the range of parameters investigated. The processing window for the GTA welds is slightly smaller than the laser welds. This is probably associated with the higher-intensity heat source of the laser that produces a higher temperature gradient.

Vitek (Ref 24) improved upon the model developed by Gauman et al. (Ref 12) that permitted a more in-depth analysis of the effect of travel speed. In the early model, the G''/R ratio was used as an indicator of stray grain formation, and a simple G''/R value was calculated at the centerline of the weld and averaged through the thickness. This neglects orientation effects of the solidification front and does not provide an accurate representation of stray grain tendency, because the fraction of stray grains does not vary linearly with G''/R . With the newer approach, the fraction of stray grains was determined directly at discrete positions in the weld pool and used to determine an area-weighted average of stray grains as an indicator of stray grain tendency. This improves the accuracy by accounting for the pool shape and variations in G and R around the pool.

Figure 23 shows the calculated variation in the weighted area fraction of stray grains in the weld ($\bar{\phi}_c$) as a function of welding speed for different weld powers. The tendency for stray grain formation decreases ($\bar{\phi}_c$ decreases) with a decrease in power and an increase in welding speed. Increasing travel speed is particularly advantageous. The only minor exception to this trend is observed at the lowest power and travel speed, where an increase in travel speed causes a small increase in $\bar{\phi}_c$ initially before $\bar{\phi}_c$ then decreases with increasing travel speed. These results indicate that, within this regime, the potential beneficial effect of the increase in temperature gradient produced by increasing travel speed is outweighed by the detrimental effect of an increase in growth rate that occurs with increasing travel speed. This can be understood by noting that the formation of stray grains depends on the G''/R ratio (where $n = 3.4$ for CMSX-4, for

example). Thus, stray grain formation is more sensitive to G than R . The anomalous effect of travel speed at low power has been attributed to changes in weld pool shape. At low powers and travel speeds, the weld pool shape is one in which the area susceptible to stray grain formation is a relatively large fraction of the total weld pool area. However, this trend is quickly diminished with further increases in travel speed.

Factors Affecting Substructural Scale. Dendrite spacing (λ) can have an important influence on the mechanical properties and time required for postweld homogenization treatments and therefore deserves some consideration. Kurz and Fisher (Ref 25) have proposed a geometrical model for primary dendrite spacing that leads to a relationship of the form:

$$\lambda \propto G^{-0.5}R^{-0.25} \quad (\text{Eq 27})$$

which suggests that R and G have different functional relationships on λ . Recall that G and R are related to the cooling rate through Eq 1. In most cases, dendrite spacing is related semiempirically to the cooling rate through an equation of the form:

$$\lambda = Ae^{-n} \quad (\text{Eq 28})$$

where A and n are material constants and typically $0.3 \leq n \leq 0.5$. Thus, dendrite spacing decreases with increasing cooling rate. This concept can be added to the G - R diagram shown previously in Fig. 16. Note that the ratio of G/R controls the type of substructure, while the quantity $GR (= \varepsilon)$ controls the substructural scale. As discussed previously, the cooling rate is inversely proportional to the heat input. Thus, high heat inputs lead to low cooling rates and large dendrite spacings in the weld; this has been observed experimentally in a number of alloy systems (Ref 26–28). It should also be noted that the cooling rate will vary throughout the weld due to changes in G and R , so that variations in λ within the fusion zone due to these changes are also expected.

Solute Redistribution during Solidification

Binary Models. Solute redistribution is an important topic because it controls both the distribution of alloying elements across the cellular/dendritic substructure and the type/amount of phases that form in the fusion zone during solidification. For many applications, solute redistribution can be effectively assessed with the aid of several simple models developed for binary alloys. These are reviewed first, followed by models developed for ternary alloys. Example application of the models to multicomponent alloys is also described, followed by a discussion on the application of thermodynamic models developed for multicomponent alloys.

There are various solute redistribution models available for binary alloys that account for such factors as solute diffusivity in the liquid and solid, dendrite tip undercooling, and coarsening. A good review on the subject is available in Ref 29. For many fusion welding applications, a large extent of solute redistribution behavior can be understood with the fairly simple equilibrium and nonequilibrium (Scheil) (Ref 30) models that account for the extreme cases of solute redistribution:

Equilibrium lever law :

$$C_s = \frac{kC_o}{(1-k)f_L + k} \quad (\text{Eq 29a})$$

$$C_L = \frac{C_o}{(1-k)f_L + k} \quad (\text{Eq 29b})$$

Nonequilibrium :

$$C_s = kC_o[1 - f_s]^{k-1} \quad (\text{Eq 30a})$$

$$C_L = C_o[f_L]^{k-1} \quad (\text{Eq 30b})$$

Fig. 23 Calculated variation in the weighted area fraction of stray grains in the weld as a function of welding speed for three different weld powers. Source: Ref 24

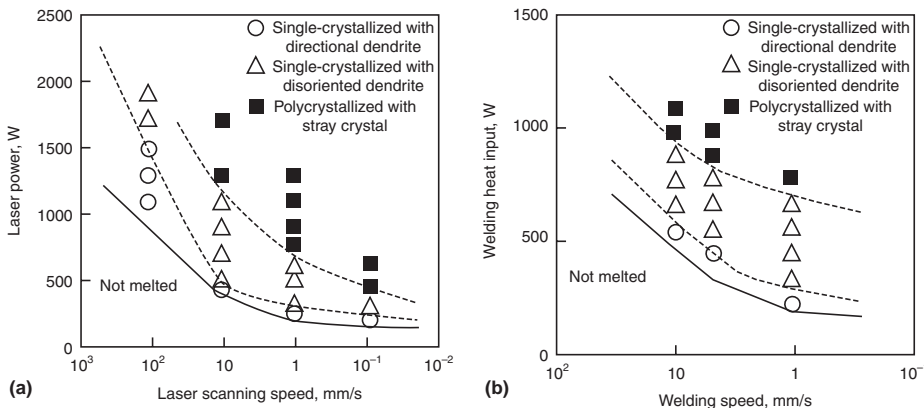

Fig. 22 Influence of heat-source power and travel speed on stray grain formation for alloy CMSX-4 for (a) laser welds and (b) gas tungsten arc welds. Source: Ref 23

where C_s and C_L are the solid and liquid compositions at the solid/liquid interface, C_o is the nominal alloy composition, f_s and f_L are the fraction solid and fraction liquid, and k is the equilibrium distribution coefficient, which is given by $k = C_s/C_L$. These expressions assume linear solidus and liquidus lines so that k is constant throughout solidification. The value of k is an important parameter because it describes the extent to which a particular element partitions between the solid and liquid. For $k < 1$, the solute partitions to the liquid, and the smaller the value of k , the more aggressive the partitioning to the liquid. For elements in which $k > 1$, the solute partitions to the solid during solidification.

The equilibrium lever law assumes complete diffusion in the liquid and solid during solidification, equilibrium at the solid/liquid interface, and no undercooling during growth. The nonequilibrium lever law (often referred to as the Scheil equation) carries similar conditions, except that diffusion in the solid is assumed to be negligible. These two cases represent the extreme conditions of residual microsegregation after solidification. The equilibrium lever law represents the case where there are no concentration gradients in the liquid or solid during solidification, and there is no residual microsegregation in the solid after solidification. In contrast, nonequilibrium conditions represent the most severe case of residual microsegregation in the solid after solidification because solid diffusivity is negligible.

As an example, consider a binary eutectic A-B system, shown in Fig. 24(a), that exhibits linear solidus and liquidus lines, a value of $k = 0.02$ (for solute element B), a eutectic composition of 20 wt% B, and a maximum solubility limit of 4 wt% B. Figures 24(b) and (c) show the variation in liquid composition during solidification under equilibrium and nonequilibrium conditions for two alloys: one below the maximum solid solubility with $C_o = 2$ wt% B and one above the maximum solid solubility with $C_o = 5$ wt% B. For the 2 wt% B alloy, the solidification conditions under each extreme are quite different. Under equilibrium conditions, the liquid composition never becomes enriched to the eutectic composition because solute in the solid is uniformly distributed and therefore capable of dissolving all the solute before the eutectic point is reached in the liquid. Note from Eq 29(b) that the maximum solute enrichment in the liquid for the equilibrium condition is given as C_o/k , which occurs when $f_L = 0$. In this case, $C_o/k < C_e$ (the eutectic composition). The resultant microstructure directly after solidification would simply consist of primary α with a uniform distribution of B. For the nonequilibrium case, the liquid composition will always become enriched to the eutectic point. Thus, directly below the eutectic temperature, the 2 wt% B alloy exhibits primary α with a concentration gradient and 0.06 weight fraction of the α/β eutectic when solidified under nonequilibrium conditions.

The two extreme solute redistribution behaviors for the 5 wt% B alloy are compared in Fig. 24(c). For the equilibrium case, the liquid composition will become enriched to the eutectic point because the nominal composition is above the maximum solid solubility. In other words, $C_o/k > C_e$. This eutectic reaction occurs when there is 0.06 weight fraction remaining liquid. Thus, the solidification microstructure directly after equilibrium solidification consists of primary α with a uniform distribution of B at the maximum solid solubility of 4 wt% and 0.06 weight fraction of the α/β eutectic. For the nonequilibrium case, the liquid composition is always higher at any stage during solidification (i.e., any particular value of f_L), because the solid does not dissolve as much solute. As a result, more liquid remains when the eutectic composition is reached (0.18 weight fraction), and more of the eutectic constituent forms in the solidification microstructure. The final alloy here exhibits primary α with a concentration gradient and 0.18 weight fraction of the α/β eutectic (three times the weight fraction of eutectic that formed for the equilibrium case). Figure 24(d) shows the corresponding solute profiles in the α solid phase after solidification for the 2 wt% B alloy. Under equilibrium conditions, there is simply primary α with a uniform distribution of 2 wt% B. For nonequilibrium conditions, the primary α phase exhibits a concentration gradient with a minimum of $kC_o = 0.4$ wt% B and a maximum at the solubility limit of 4 wt% B. The portion of solid that exhibits a uniform composition of 4 wt% B represents the eutectic α (the composition of the eutectic β is not shown).

Equations 30(a) and (b) have the interesting property that $C_L \rightarrow \infty$ as $f_L \rightarrow 0$ and $C_s \rightarrow \infty$ as $f_s \rightarrow 1$ (for $k < 1$), which indicates that the solid will always be enriched to the maximum solid solubility, while the liquid will always be enriched to the eutectic composition under nonequilibrium conditions. This can be attributed to the lack of diffusion in the primary α phase, which leads to the inability of all the solute to be incorporated into the primary phase. This can be understood by direct inspection of Fig. 24(d) and noting that the dissolved solute in the solid is given by the area under the $C_s - f_s$ curve. For the equilibrium case, the total dissolved solute is obviously 2 wt% B, which is the nominal value. However, the dissolved solute for the nonequilibrium case is always less than this due to the regions in the solid where $C_s < C_o$. In this case, the excess solute must be accommodated by formation of the eutectic constituent that contains the B-rich β phase.

Strictly speaking, it is important to note that the solute redistribution equations described in this section do not account for undercooling effects that can occur at the cell/dendrite tip during nonplanar solidification. Under high-energy-density welding processes that are operated at high travel speeds, this undercooling effect may become significant. This subject is discussed in more detail in the section "Rapid

Solidification Considerations" in this article. However, this effect is typically not significant under many moderate cooling-rate conditions typical of arc welding and high-energy-density processes operating at low heat-source travel speeds. In these cases, the models described for planar solidification can be applied on a local scale within a small volume element that encompasses a planar interface. An example

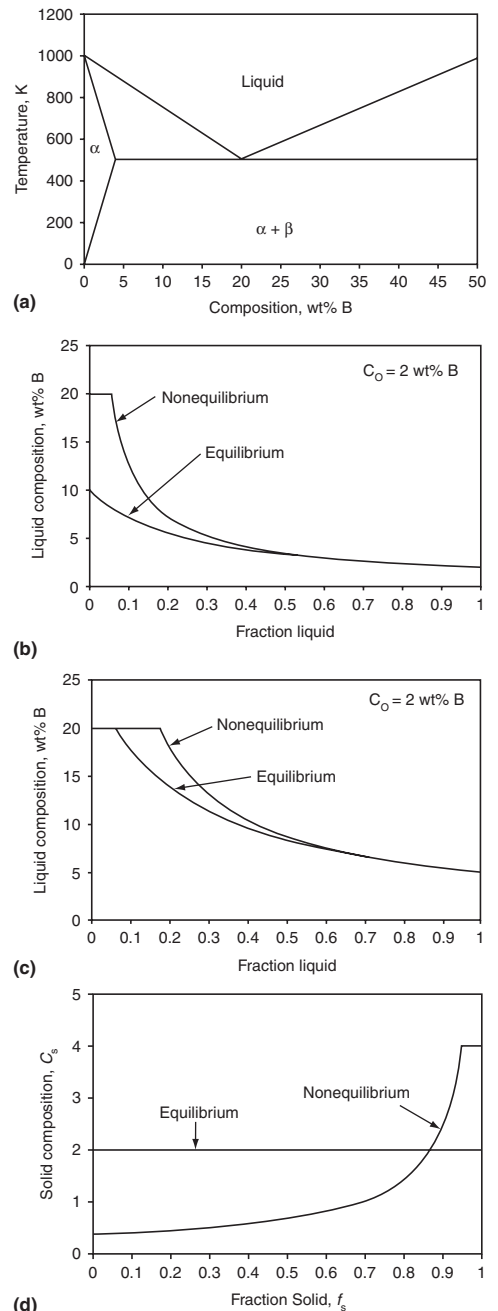

Fig. 24 Example of solute redistribution calculations for equilibrium and nonequilibrium conditions. (a) Hypothetical phase diagram. (b) Variation in liquid composition for $C_o = 2$ wt%. (c) Variation in liquid composition for $C_o = 5$ wt%. (d) Variation in solid composition for $C_o = 2$ wt%

of this is shown in Fig. 25 for cellular solidification. Here, the solidification process can be represented by the enclosed region shown and noting that solidification starts at the cell core (where $f_s = 0$) and finishes at the cell boundary when two cells meet ($f_s = 1$). The solute redistribution then occurs locally within the given volume element that exhibits an essentially planar interface between the liquid and solid.

The only difference that separates these two extreme cases of solute redistribution during solidification is the solute diffusivity in the solid. Thus, it is useful to consider the extent of solute diffusivity expected for a given set of parameters and resultant cooling rate. The Brody-Flemings model was the first attempt at taking back-diffusion into the solid into account during solidification and is given as (Ref 31):

$$C_s = kC_o \left[1 - \frac{f_s}{1 + \alpha k} \right]^{k-1} \quad (\text{Eq 31a})$$

$$C_L = C_o \left[1 - \frac{1 - f_L}{1 + \alpha k} \right]^{k-1} \quad (\text{Eq 31b})$$

$$\alpha = \frac{D_s t_f}{L^2} \quad (\text{Eq 31c})$$

The α parameter in Eq 31(c) is a dimensionless diffusion parameter, while D_s is the diffusivity of solute in the solid, t_f is the solidification time (cooling time between the liquidus and terminal solidus), and L is half the dendrite arm spacing. The $D_s t_f$ term in the numerator of Eq 31(c) essentially represents the distance that solute can diffuse in the solid during solidification, while the half dendrite arm spacing, L , represents the length of the concentration gradient. Thus, when $D_s t_f \ll L^2$, the solute is able to diffuse only a small fraction of the total gradient length, and solid-state diffusion will be insignificant. This represents the case in which $\alpha \approx 0$ and Eq 30 reduces to the Scheil equation. Clyne and Kurz (Ref 32) pointed out that Eq 31(a) and (b) do not reduce to the lever law as $\alpha \rightarrow \infty$. They proposed an alternate form of α that is given by:

$$\alpha' = \alpha \left[1 - \exp\left(-\frac{1}{\alpha}\right) \right] - 0.5 \exp\left(-\frac{1}{2\alpha}\right) \quad (\text{Eq 32})$$

Although this is not based on a physical model, use of α' correctly reduces Eq 31 to the lever law when $\alpha = \infty$ and to the Scheil equation when $\alpha = 0$. It should be noted that Kobayashi provided a more comprehensive model of solute diffusivity in the solid that can be used when more detailed calculations are required (Ref 33).

The potential for back-diffusion in the solid during fusion welding can be assessed by determination of the simple α parameter. The t_f and L terms in Eq 31(c) will each depend on the cooling rate of the weld (ϵ) via:

$$t_f = \frac{\Delta T}{\epsilon} \quad (\text{Eq 33})$$

$$L = \frac{\lambda}{2} = \frac{A\epsilon^{-n}}{2} \quad (\text{Eq 34})$$

where ΔT is the solidification temperature range, λ is the dendrite spacing, and A and n are material constants. (Equation 33 assumes a linear cooling rate through the solidification temperature range.) Thus, by knowing the solidification temperature range, cooling rate, and dendrite spacing/cooling rate relationship, the α parameter can be directly estimated as a function of cooling rate and the potential influence of solid-state diffusion can be determined.

Many studies have used these simple equations to explore the solidification behavior of welds in austenitic alloys. These studies have demonstrated that the solute redistribution behavior and resultant weld-metal microstructure are controlled primarily by the pertinent values of k and D_s for the alloying elements of interest. The value of D_s will control the potential for back-diffusion in the solid during solidification. Elements with very low k values can produce steep concentration gradients across the cellular or dendritic substructure of the weld. Table 2 shows an example that summarizes diffusivity data for many alloying elements in nickel (Ref 34). Upper bound values of α for each element can be calculated by determining D_s at the liquidus temperature, approximately 1350 °C (2460 °F) for many nickel alloys (Ref 35, 36), using a large but representative value of ΔT of 200 °C (360 °F) and reported values of $A = 32$ and $n = 0.31$ (Ref 37). Using these values, α can be calculated as a function of cooling rate and is shown in Fig. 26 for the substitutional alloying elements listed in Table 2. The values of A and n used here were for alloy 713. However, the values do not vary significantly among many nickel-base alloys (Ref 38). The α value decreases with increasing cooling rate due to the decrease in solidification time (t_f) with increasing cooling rate. More importantly, note that $\alpha \ll 1$ for all the elements considered under a wide range of cooling rates. The use of various values of ΔT , A , and n representative of other nickel-base alloys does not change this result significantly. It is also important to note that an upper bound value of D_s was calculated at a typical liquidus temperature of 1350 °C (2460 °F). The value of α can only decrease with the use of D_s values calculated at lower solidification temperatures.

These results clearly demonstrate that solid-state diffusion of substitutional alloying elements in austenitic alloys is insignificant during solidification of fusion welds. Experimental evidence has been published that supports these calculations for a variety of elements, including iron, chromium, niobium, molybdenum, and silicon (Ref 39, 40). In that work, dendrite core compositions were experimentally measured in

samples that were solidified under a wide range of cooling rates, including samples quenched during solidification and samples cooled at 0.2 °C/s and 650 °C/s. The dendrite core compositions were identical in all cases, indicating that solid-state diffusion is indeed negligible. In these cases, the simple form of Eq 30 can be used for quantitative calculations of final solute profiles and phase fractions. An example is provided later in this section.

Back-diffusion during weld solidification can be significant in body-centered cubic systems and for the diffusion of interstitial alloying

Fig. 25 Volume element for modeling solute redistribution during cellular solidification. The solidification process can be represented by the enclosed region shown and noting that solidification starts at the cell core (where $f_s = 0$) and finishes at the cell boundary when two cells meet ($f_s = 1$).

Table 2 Diffusion data for various alloying elements in nickel

Element	Diffusion coefficient (D_o), m^2/s	Activation energy (Q), kJ/mol
Fe	8.0×10^{-5}	255
Cr	1.1×10^{-4}	272
Co	1.4×10^{-4}	275
Nb	7.5×10^{-5}	264
Mo	1.0×10^{-4}	275
W	2.0×10^{-4}	299
Al	1.9×10^{-4}	268
Ti	4.1×10^{-4}	275
Cu	5.7×10^{-5}	258
C	8.0×10^{-6}	135

elements. For example, calculation of the α parameter for carbon in nickel will yield values that are significantly greater than unity. This is to be expected, because carbon diffuses by an interstitial mechanism and therefore exhibits diffusion rates that are orders of magnitude higher than the substitutional alloying elements. Evidence for this is reflected in the activation energy term (Q) for diffusion of carbon in nickel shown in Table 2. Note that Q for the substitutional alloying elements varies over a fairly narrow range of 255 to 299 kJ/mol, while the value for carbon is approximately half this at 135 kJ/mol.

Figure 27(a) shows calculated results for solute redistribution of carbon in nickel (Ref 39). In this figure, the solute redistribution behavior was calculated with Eq 31 and 32 using the temperature-dependent diffusion rate of carbon in nickel. Comparison is made between the nonequilibrium Scheil equation and the lever law. Note that the detailed results from the Clyne-Kurz model are essentially identical to that of the lever law, indicating that complete solid-state diffusion of carbon is expected in nickel-base alloys during solidification. A similar effect can be expected for nitrogen in nickel. This calculation was conducted for a cooling rate of 650 °C/s (1170 °F/s) through the solidification temperature range. Higher cooling rates typical of high-energy-density welding may alter this result and begin to limit carbon

diffusion in the solid. Aside from this possibility, these results demonstrate that carbon (and nitrogen) can be expected to exhibit complete diffusion in the solid during most welding conditions. Figure 27(b) shows a similar calculation for substitutional diffusion of titanium in a body-centered cubic Fe-10Al-5Cr alloy that was calculated using the detailed model proposed by Kobayashi (Ref 33, 41). These results are somewhat similar to those for carbon in nickel in that solid-state diffusion is essentially complete at moderate cooling rates. However, diffusion may become insignificant at very high cooling rates typical of high-energy-density processes. These results are meant to serve as example calculations that can be applied to understanding solute redistribution behavior in fusion welds of any alloy system when the pertinent alloy parameters are known.

For conditions in which solid-state diffusion is negligible, microsegregation will persist in the as-solidified weld (except for the case in which $k = 1$). An example of this is shown in Fig. 28 for fusion welds in a niobium-bearing superalloy (Ref 36, 42). The final degree of microsegregation can be assessed by direct determination of the k value for the element of interest, where the degree of microsegregation will increase with decreasing k value (for k values < 1). For example, the lowest concentration will occur at the dendrite core where solidification initiates. Direct inspection of Eq 30

indicates that, at the start of solidification when $f_s = 0$, the dendrite core composition (which is the first solid to form) is given by kC_0 .

Although the models described earlier were strictly developed for binary alloys, they can be used in a quantitative manner for multicomponent engineering alloys when the alloy properly mimics the solidification behavior of a binary system. An example is provided here by application of the simple binary Scheil equation to Ni-Cr-Mo-Gd alloys. A typical as-solidified microstructure of an alloy is shown in Fig. 29(a). These alloys exhibit γ dendrites and an interdendritic γ/Ni_5Gd eutectic-type constituent. Research (Ref 43, 44) has shown that gadolinium controls the solidification behavior of these alloys. In particular, the solidification temperature range and amount of terminal eutectic-type constituent that forms at the end of solidification are essentially dominated by the gadolinium concentration. Solidification of these alloys initiates at the liquidus temperature by the formation of primary γ -austenite. As solidification proceeds, the liquid becomes increasingly enriched in gadolinium until the liquid $\rightarrow \gamma + Ni_5Gd$ eutectic-type reaction is reached, at which point solidification is terminated.

This reaction sequence and temperature range is similar to that expected in the binary nickel-gadolinium system. Simple binary

nickel-gadolinium alloys with less than approximately 13 wt% Gd exhibit a similar two-step solidification sequence consisting of primary austenite formation followed by a terminal eutectic reaction involving the $Ni_{17}Gd_2$ intermetallic at 1275 °C (2327 °F). By comparison, the multicomponent Ni-Cr-Mo-Gd alloys complete solidification at ~1258 °C (~2295 °F) by a terminal eutectic-type reaction involving the Ni_5Gd intermetallic. Thus, although the secondary phase within the terminal eutectic constituent is different in each case, the terminal reaction temperatures are very similar. As shown in Fig. 29(b), a pseudo-binary solidification diagram can be developed for this system that is similar to the phase diagram of a binary eutectic alloy. In this case, the solvent is represented by the Ni-Cr-Mo solid-solution γ -austenite phase, and gadolinium is treated as the solute element. The similarity of this γ -gadolinium binary system to a binary eutectic system is readily evident in several ways:

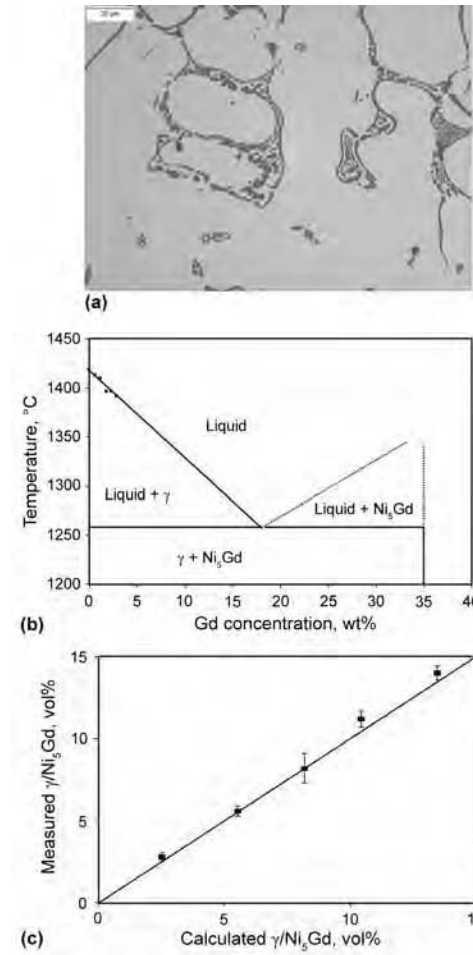

Fig. 29 (a) Microstructure of fusion weld on a Ni-Cr-Mo-Gd alloy. (b) Pseudo-binary phase diagram for the γ -gadolinium system. (c) Comparison of the measured and calculated γ/Ni_5Gd fraction eutectic from fusion welds made on alloys with various gadolinium concentrations. Source: Ref 44

- The as-solidified microstructure consists of primary γ dendrites surrounded by an inter-dendritic eutectic-type constituent in which the secondary phase in the eutectic is solute rich.
- The amount of eutectic-type constituent increases with increasing solute content.
- The proportional amount of each phase within the eutectic constituent is relatively insensitive to nominal solute content.

It was also observed that the eutectic temperature is not strongly dependent on the nominal gadolinium concentration. Key points of the diagram shown in Fig. 29(b) were determined with a combination of thermal analysis and quantitative microstructural characterization techniques. Figure 29(c) shows a comparison of the measured and calculated γ/Ni_5Gd fraction eutectic from fusion welds made on alloys with various gadolinium concentrations. In this plot, a comparison is made with the calculated

eutectic fraction using the simple Scheil equation. The Scheil equation can be used for eutectic fraction calculations by noting that, when $C_L = C_e$ (the eutectic composition), the remaining fraction liquid (f_L) transforms to fraction eutectic (f_e), so that:

$$f_e = \left(\frac{C_e}{C_0}\right)^{1/k-1} \quad (\text{Eq 35})$$

Good agreement is observed between the measured and calculated values. This supports the use of a pseudo-binary analog for modeling the solidification behavior of these alloys.

Ternary Models. The expressions derived earlier for binary alloys can be used quantitatively in multicomponent alloys when the alloy behaves like a binary system. However, many engineering alloys exhibit multiple reactions during solidification that occur over a range of temperatures and exhibit more than one eutectic constituent. Thus, they typically cannot be treated in a quantitative fashion with the simpler models described earlier. In this case, models for ternary alloys can be useful, and relatively simple solidification path equations can be derived for limiting cases of solute redistribution in ternary alloys. Two sets of solute redistribution equations are needed to fully describe the solidification paths of ternary alloys. The first set describes the variation in liquid composition and fraction liquid during the primary stage of solidification. These expressions can be used to identify if the liquid composition is enriched to a monovariant eutectic-type reaction and, if so, what type of reaction will occur and the fraction of total eutectic constituent that will form in the microstructure. The second set of expressions describes the variation in liquid composition and fraction liquid during the monovariant eutectic reaction. These expressions can be used to determine if the liquid composition is enriched to the ternary eutectic reaction and the fractions of both the monovariant and ternary eutectic constituents. Only the primary solidification path expressions are discussed here. More detailed information on the full ternary model can be found elsewhere (Ref 45).

For ternary solidification, three limiting cases can be identified based on the diffusivity of solute in the solid phases:

- Negligible diffusion of each solute in the solid phases, referred to as nonequilibrium solidification
- Negligible diffusion of one solute in the solid phases and infinitely fast diffusion of the other solute in the solid phases, referred to here as intermediate equilibrium.
- Infinite diffusion of each solute in the solid phases (equilibrium)

Expressions for the primary solidification paths for these three conditions are given by:

Equilibrium:

$$C_{LA} = \frac{C_{oA}}{\left(\frac{1-k_{zA}}{1-k_{zB}}\right)\left(\frac{C_{oB}-k_{zB}C_{LB}}{C_{LB}}\right) + k_{zA}} \quad (\text{Eq 36a})$$

Intermediate equilibrium:

$$C_{LA} = C_{oA} \left(\frac{C_{oB} - k_{zB}C_{LB}}{(1 - k_{zB})C_{LB}}\right)^{k_{zA}-1} \quad (\text{Eq 36b})$$

$$\text{Nonequilibrium: } C_{LA} = C_{oA} \left(\frac{C_{LB}}{C_{oB}}\right)^{\frac{k_{zA}-1}{k_{zB}-1}} \quad (\text{Eq 36c})$$

where f_L is the fraction liquid, C_{oj} is the nominal concentration of element j , C_{Lj} is the concentration of element j in the liquid, and k_{ij} is the equilibrium distribution coefficient for element j in phase i . When the liquid composition given by Eq 36 intersects a monovariant eutectic line, the remaining fraction liquid transforms to a binary-type eutectic and possibly the ternary eutectic. Thus, the value of f_L at the intersection point of the primary solidification path and monovariant eutectic line defines the total amount of eutectic in the microstructure. Details on the calculation procedure for determining this value are provided elsewhere (Ref 45). The difference among the three cases considered here is governed by the diffusivity of solutes in the solid phases. Thus, the condition that most closely describes the solidification behavior for an actual application can be determined by calculation of the α parameter for each of the solute elements of importance.

Figure 30 shows an example of primary solidification path calculations made for fusion welds on multicomponent superalloys that form the γ/NbC and γ/Laves eutectic-type constituents at the end of solidification (Ref 46). Although these alloys contain multiple elements, they can be treated as a pseudo-ternary $\gamma\text{-Nb-C}$ system. Niobium and carbon are treated as the important solute elements here because each element partitions aggressively to the liquid during solidification and leads to the formation of the niobium- and carbon-rich NbC phase and the niobium-rich Laves phase. For this system, niobium exhibits negligible diffusion, while carbon diffuses infinitely fast. Thus, Eq 36(b) was used for these calculations. Calculations are shown for alloys with similar niobium concentrations and various amounts of carbon. Note that the addition of carbon pushes the primary solidification path up into the carbon-rich side of the liquidus projection. The liquid composition must then “travel” a long distance down the γ/NbC eutectic line as the γ/NbC constituent forms. This accounts for the observed influence of carbon that leads to large amounts of the γ/NbC constituent in these alloys. It was also observed that carbon additions increase the start temperature of the $L \rightarrow \gamma + \text{NbC}$ reaction. This effect is not intuitive, because solute additions in which $k < 1$ (such

as carbon) typically lower reaction temperatures. The calculations demonstrate the reason for this effect. The dotted arrow near the γ/NbC eutectic line represents the direction of decreasing temperature (as determined through thermal analysis). Note that carbon additions drive the solidification path to the carbon-rich region of the diagram where the $L \rightarrow \gamma + \text{NbC}$ reaction is relatively high, thus accounting for the observed effect. Reasonable agreement was obtained between the measured and calculated volume fractions using these expressions (Ref 46).

Modeling of Multicomponent Alloys. The relatively simple models described previously are useful for assessing the solidification behavior of alloys that behave in a manner analogous to binary or ternary alloys. However, such approaches may be limited in some engineering alloys. Multicomponent thermodynamic and kinetic software is now available that can also be used for understanding solidification behavior in such systems, and a simple example is provided here. Figure 31(a) shows a light optical micrograph of a weld between a superaustenitic stainless steel (CN3MN) with ~6 wt% Mo and a nickel-base filler metal (IN686) with ~14 wt% Mo (Ref 47). This weld was prepared at the 21% dilution level. Welds in these alloys solidify with a primary $L \rightarrow \gamma$ solidification mode and then terminate solidification by a $L \rightarrow \gamma + \sigma$ reaction. Thus, the final weld microstructure consists of primary γ dendrites and interdendritic γ/σ eutectic. The σ phase is a molybdenum-rich phase. Welds made at low dilution levels (i.e., high molybdenum levels) would be expected to form relatively large fractions of the σ phase. However, as shown in Fig. 31(b), the σ -phase content does not change significantly with weld dilution level and associated nominal molybdenum concentration of the alloy. This immediately suggests that other factors besides the nominal concentration of molybdenum are also affecting the σ -phase content.

Fig. 30 Example of primary solidification path calculations made for fusion welds on multicomponent superalloys that form the γ/NbC and γ/Laves eutectic-type constituents at the end of solidification. Source: Ref 46

The σ -phase content is controlled by the amount of eutectic constituent that forms during the end of solidification. The fraction of eutectic is, in turn, controlled by the nominal alloy composition (C_o), eutectic composition (C_e), and distribution coefficient (k) for molybdenum (Eq 35). Note that the nickel and iron contents in the weld change appreciably with changes in dilution, and these changes in nickel and iron may affect the values of k and C_e . Figure 32(a) shows the variation in liquid composition during solidification using a multicomponent Scheil simulation with Thermocalc (Ref 48). The Scheil simulation is justified here because, as shown in Fig. 26, all the substitutional elements of interest are known to exhibit insignificant diffusion rates during solidification in austenite. Results are shown for welds at various dilution levels. Solidification starts at the nominal composition (C_o), which is controlled by the dilution level. The eutectic composition (C_e) is given by the inflection point where the eutectic reaction $L \rightarrow \gamma + \sigma$ begins. It is apparent that the eutectic composition decreases appreciably with increasing dilution. Figure 32 (b) shows the variation in the molybdenum partition coefficient (k) for the same dilution levels of interest. The partition coefficient for a given dilution does not vary significantly during solidification, but it increases slightly (from

Fig. 31 (a) Light optical micrograph showing primary austenite and interdendritic σ phase that forms in a dissimilar weld between a superaustenitic stainless steel base metal and nickel-base filler metal. (b) Variation in σ -phase content with dilution. Source: Ref 47

Fig. 32 Multicomponent Scheil calculations for fusion welds made between a superaustenitic stainless steel alloy and a nickel-base filler metal showing (a) variation in liquid composition with fraction liquid, (b) variation in k_{Mo} with fraction solid, and (c) variation in C_o , C_e , and k_{Mo} with dilution

~ 0.67 to 0.84) with decreasing dilution. Figure 32(c) summarizes the variations in C_o , C_e , and k as a function of dilution. An increase in C_o and a decrease in C_e and k will increase the fraction eutectic and resultant amount of secondary phase. These results demonstrate there are offsetting effects in these parameters that keep the σ -phase content relatively independent of the weld-metal composition. In other words, C_e and k each decrease with increasing dilution, which would, in itself, lead to an increase in fraction eutectic and amount of σ phase. However, these changes are offset by the decrease in nominal molybdenum concentration that occurs with increasing dilution. This accounts for the relatively constant σ -phase content observed in these welds.

The final σ -phase content will also depend on the maximum solid solubility of molybdenum in the austenite and σ phases. All of these factors can be accounted for with a complete multicomponent Scheil simulation. Table 3 shows the amount of σ phase calculated for all the dilution levels of interest. There is reasonable agreement between the measured and calculated amounts of σ phase. These results also carry important practical implications, because IN686 filler metal can be used at various dilution levels with minimal changes to the σ -phase content in the weld, which is beneficial from a solidification cracking and toughness standpoint.

Rapid Solidification Considerations

The conditions described previously ignore the effects of the nonplanar interface and solute buildup in the liquid on dendrite tip undercooling. Such factors can become important at high solidification rates associated with high-energy-density welding processes. These undercooling effects are shown schematically in Fig. 33. The liquidus and solidus lines for a planar interface (tip radius, $r = \infty$) are shown by the solid lines. Solute enrichment in the liquid at the solid/liquid interface results from solute rejection directly from the tip and diffusion down the solute gradient that exists between the cells. This local enrichment produces a reduction in the tip temperature, ΔT_C , as shown in Fig. 33. Undercooling is also produced by the surface energy effects due to the tip with a finite radius. In this case, the solidus and liquidus lines are depressed relative to those for an infinite

Table 3 Comparison of the percent σ values calculated using ThermoCalc and measured experimentally

Dilution, %	Calculated σ phase, %	Measured σ phase, %
100	1.9	1.4 ± 0.2
83	2.4	1.7 ± 0.3
52	2.3	1.6 ± 0.2
37	1.9	2.0 ± 0.4
21	1.4	2.1 ± 0.4

radius, as shown by the dotted lines. The corresponding undercooling associated with a finite tip radius is given by the ΔT_r term in Fig. 33. As a result of these two effects, the liquid temperature and composition can be changed significantly from (T_o, C_o) to (T_t, C_t) , as shown in the figure. Also note that this produces an increase in the dendrite core composition from kC_o to kC_t . This change in the operating point of the dendrite tip can have a significant effect on the stability of the primary solidification phase, the final distribution of solute in the solid, and the final phase distribution.

Different approaches have been used to solve the dendrite undercooling problem in order to determine the local tip temperature and composition. For example, Burden and Hunt (Ref 49) assumed that the dendrite tips grow with a radius that minimizes undercooling. This assumption was used to solve directly for the tip radius, which then provided a direct solution for the undercooling and resultant tip composition. However, this assumption does not capture the observed behavior in which a dendritic interface eventually reverts to a cellular and then planar interface at high solidification velocities. Note also that this reversion to a planar interface is not captured within the classical constitutional supercooling criteria (described previously), because the model neglects surface tension effects. At high solidification velocities, the cell spacing is decreased, which leads to an increase in the solid/liquid interfacial area. The increase in surface area helps accommodate the rapid rate of solute rejection required at high solidification velocities but also leads to increased surface energy. At very high velocities, the cellular interface is no longer energetically favorable, and a planar interface reappears.

The dendrite tip radius and solute redistribution around the tip are actually coupled, so that the assumption of a cell tip growing to minimize undercooling is not completely accurate. This condition has been considered in greater detail by Kurz et al. (Ref 21). In the KGT model, the tip radius is related to the temperature gradient and growth rate through the Peclet number (Pe) by:

$$R^2 \left[\frac{\pi^2 \Gamma}{Pe^2 D_1^2} \right] + R \left[\frac{m_1 C_o (1-k)}{D_1 [1 - (1-k)I(Pe)]} \right] + G = 0 \quad (\text{Eq 37})$$

where Γ is the Gibbs-Thomson parameter (ratio of specific solid/liquid interfacial energy to melting entropy), Pe is the Peclet number given by $Pe = Rr/2D_1$, and $I(Pe)$ is given by $I(Pe) = Pe \exp(Pe) E_1(Pe)$, where E_1 is the exponential integral function.

Direct solution of Eq 37 for the dendrite tip radius is not possible because Pe is defined in terms of both R and r . Thus, the expression must be solved numerically in which a wide range of Pe values are selected to determine $I(Pe)$, and then the quadratic Eq 37 is solved for R numerically. Once R is known, the dendrite radius is given by $r = 2PeD_1/R$. The

resultant tip temperature and composition are then given by:

$$C_t^* = \frac{C_o}{1 - (1-k)I(Pe)} \quad (\text{Eq 38})$$

$$T_t = T_o + m_1 C_t^* - \frac{2\Gamma}{r} \quad (\text{Eq 39})$$

As shown schematically in Fig. 33, this new “operating point” of the dendrite tip (i.e., the change in tip composition and temperature from (T_o, C_o) to (T_t, C_t)) also affects the subsequent solute redistribution because the new core composition is changed from kC_o to kC_t . Sarreal et al. (Ref 50) addressed this problem by assuming that undercooling at the dendrite tip is dissipated by forming a certain fraction of primary solid phase, f_s^o , that is given by the lever law at the undercooled temperature:

$$f_s^o = \frac{C_o - C_t^*}{C_t^* (k - 1)} \quad (\text{Eq 40})$$

Under conditions in which solute diffusion in the solid is negligible (which is often the case for substitutional alloying elements at high solidification velocities), the final fraction of eutectic that forms is then given by the modified form of the Scheil equation:

$$f_e = (1 - f_s^o) \left(\frac{C_e}{C_t^*} \right)^{\frac{1}{k-1}} \quad (\text{Eq 41})$$

Various levels of complexity can be accounted for with the KGT model. For example, D_1 and m_1 can each vary with temperature, while k can vary with both temperature and solidification velocity. At high solidification velocities, the value of $k \rightarrow 1$ due to solute trapping in the solid. This velocity dependence can be accounted for with the model proposed by Aziz (Ref 51) in which the effective distribution coefficient, k' , is given by:

$$k' = \frac{k + \frac{a_i R}{D}}{1 + \frac{a_i R}{D}} \quad (\text{Eq 42})$$

where a_i is related to the interatomic distance and is typically between 0.5 and 5 nm. Equation 42 has the form in which $k' = k$ at low values of R and $k' = 1$ at high R values.

Figure 34 shows example calculations of the KGT model for an Ag-5wt%Cu alloy. The results demonstrate how the tip radius (denoted as R in Fig. 34a), temperature, and core composition (C_s^* in Fig. 34c) change with increasing solidification velocity. The curves in Fig. 34(a) and (c) demonstrate how various assumptions about D_1 , m_1 , and k affect the results. Note that the dendrite radius initially decreases with increasing velocity but then rapidly increases and becomes infinite at high growth velocities. This is the condition in which a planar interface is restabilized. The

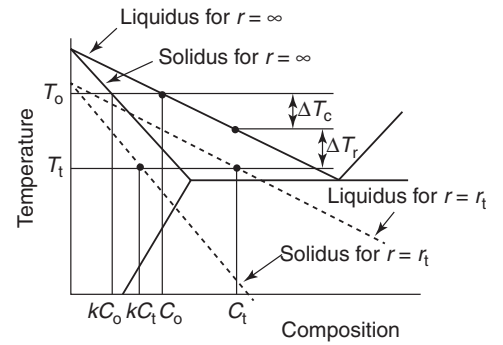

Fig. 33 Schematic illustration showing dendrite tip undercooling

Fig. 34 Results from Kurz, Giovanola, Trivedi (KGT) model calculations showing variation in (a) dendrite radius, (b) dendrite tip temperature, and (c) cell core composition as a function of growth rate. Source: Ref 21

extent of undercooling at high velocities can be quite significant and can lead to subsequent enrichment in the cell core composition relative to that under ideal Scheil conditions (Fig. 34c). This effect provides one mechanism for reducing the extent of residual microsegregation that occurs in many alloys that exhibit low solute diffusivity in the solid.

Stainless steels represent an important group of engineering alloys in which dendrite tip undercooling can have a significant influence on the primary phase that forms. The composition of many commercial stainless steels is adjusted to induce primary delta-ferrite (δ) solidification. The delta-ferrite phase is desirable as the first solidification phase because it exhibits a higher solubility for tramp elements, such as phosphorus and sulfur. Thus, with primary ferrite solidification, more of the phosphorus and sulfur are kept in solution and avoid the low-melting-point phosphorus- and sulfur-rich phases that are known to aggravate solidification cracking. In contrast, the solubility for these tramp elements is relatively low in austenite (γ), and stainless steels that solidify as primary austenite are well known to be relatively sensitive to this form of cracking. Although some stainless steels have a nominal alloy composition that is designed to solidify as ferrite (under low solidification velocities), the nominal composition can lie close to the transition in primary solidification mode so that dendrite tip undercooling can cause a shift in the primary solidification mode at higher cooling rates.

Fukumoto and Kurz (Ref 52) used a multi-component form of the KGT model to predict how solidification velocity and resultant tip undercooling affects primary phase stability in stainless steels. In this work, interface response functions were developed by calculating the tip temperature of the δ and γ phases as a function of solidification velocity. An example calculation for an Fe-18Cr-11.3Ni (wt%) alloy solidified with a temperature gradient of 400 K/mm is shown in Fig. 35. The primary solidification phase is identified by noting that the phase with the highest tip temperature is the one that will solidify first. Note that, for this alloy and temperature gradient, a shift in the primary solidification mode is expected at a solidification rate of 3.2×10^{-2} m/s, and such shifts have been observed experimentally.

Dilution in Fusion Welding

John N. DuPont, Lehigh University

Introduction

MANY APPLICATIONS EXIST in which alloys of differing compositions are joined by fusion welding. In these applications, the final fusion zone can potentially exhibit a composition that lies anywhere between that of each alloy. The final composition and corresponding microstructure and properties of the fusion zone will be determined by the dilution level. The dilution level is, in turn, strongly affected by the welding parameters. Thus, many dissimilar metal welding applications require careful control over the welding parameters and corresponding dilution level in order to produce welds with the proper microstructure and properties for the intended service. The objective of this article is to review the relation between dilution and bulk fusion-zone composition, describe the effect of welding parameters on dilution, and provide some typical examples of microstructure and property control in dissimilar weld applications.

Dilution and Fusion Zone Composition

Dilution can be understood with the schematic illustration provided in Fig. 1, which shows the amount of base metal melted (A_{bm}) and filler metal added (A_{fm}) in a typical fusion weld. The dilution is given by:

Fig. 1 Schematic illustration of dilution showing the amount of base metal melted (A_{bm}) and filler metal added (A_{fm}) in a typical fusion weld

$$D = \frac{A_{bm}}{A_{bm} + A_{fm}} \quad (\text{Eq 1})$$

Inspection of Eq 1 demonstrates that the dilution is simply a measure of the amount of base metal that mixes in with the fusion zone. In many applications, it is important to control the dilution level to provide the proper microstructure and properties for the intended service. For example, in cladding applications, the dilution is typically minimized in order to maintain the high alloy level and concomitant wear or corrosion resistance of the cladding. The concentration of any alloying element, i , in the fusion zone (C_{fz}^i) is determined by the dilution and concentrations of element i in the base metal (C_{bm}^i) and filler metal (C_{fm}^i) by:

$$C_{fz}^i = DC_{bm}^i + (1 - D)C_{fm}^i \quad (\text{Eq 2})$$

Equation 2 demonstrates that the weld-metal composition varies linearly with the dilution level. An example of Eq 2 is shown in Fig. 2, which shows the fusion-zone chromium concentration for a weld made on a carbon steel with no chromium ($C_{bm}^{Cr} = 0$) and a filler metal with 20 wt% Cr ($C_{fm}^{Cr} = 20$). Note that the fusion

Fig. 2 Calculated fusion-zone chromium concentration as a function of dilution for a weld made on a carbon steel with no chromium and a filler metal with 20 wt% Cr

composition varies linearly from the filler-metal chromium concentration at 0 dilution to the base-metal chromium concentration at a dilution value of unity. It is important to note that a dilution value of 0 does not actually represent a fusion weld, because no base metal has melted. This condition would produce lack of fusion between the base metal and fusion zone. Thus, although attempts are often made to minimize dilution (depending on the application), it is important to note that some finite dilution is required to induce mixing between the base and filler metal in the molten state in order to form the weld. A dilution value of unity (or 100%) represents an autogenous weld in which no filler metal is added. Thus, it is not possible to achieve 100% dilution when a filler metal with a composition different than that of the base metal is used.

Equations 1 and 2 assume that the chemical composition of the weld can be determined based solely on geometric information (i.e., the amount of base metal melted and filler metal added). Recent measurements have verified that this is generally accurate. Figure 3 compares the weld-metal dilution determined from both geometric measurements and direct chemical composition measurements made by electron probe microanalysis (EPMA) (Ref 1). These data were obtained on fusion welds made between alloy AL-6XN (a superaustenitic stainless steel) and nickel-base alloys IN625 and IN622. Note that there is good agreement between the weld-metal compositions measured with each technique, thus confirming that the fusion-zone composition can generally be determined accurately with geometrical measurements and knowledge of the base-metal and filler-metal compositions.

It should be noted that other factors can change the final fusion-zone composition in ways that are not accounted for in the simple geometrical dilution equations described previously. For example, elemental losses due to evaporation from the pool surface can occur during welding and lead to a reduction in alloying content in the fusion zone. An example of this is provided in Fig. 4, which shows the manganese content of the base metal and the fusion

zone for welds made on manganese-containing stainless steels (Ref 2). Note that the manganese content in the fusion zone is appreciably lower than that of the base metal, and this has been attributed to the relatively high vapor pressure of manganese. Similar effects have been reported for losses of magnesium in aluminum-magnesium alloys, and evaporative losses can also occur from the surface of hot molten droplets in the gas metal arc welding process (Ref 3). The effect of these losses can be important when the alloying element of interest plays an important role in controlling the strength in the alloy (i.e., by solid-solution hardening or precipitation strengthening). Additives made to the weld beyond the filler metal can also affect the weld-metal composition,

such as the addition of active fluxes that are used to promote good penetration. Similarly, the liquid pool can sometimes dissolve elements from the shielding gas, such as oxygen and nitrogen (Ref 4). This can lead to relatively minor changes in alloy compositions, but these changes can often have significant effects on the weld-metal microstructure and properties. In high-energy-density welds made at high welding speeds, the melting and solidification occur very rapidly so that there is often not sufficient time for uniform mixing in the melt pool, and macrosegregation exists in the fusion zone. These factors must be considered on an individual basis when using the expressions for fusion-zone composition described previously.

It is also important to note that the fusion-zone composition given by Eq 2 assumes there is uniform mixing of alloying elements in the liquid state, so that the composition is uniform on a macroscopic scale. This is also found to be generally true due to the rather aggressive liquid mixing that occurs in the weld due to the various forces that lead to fluid flow (i.e., buoyancy force, Lorentz force, surface-tension-driven force, and force from the impinging arc plasma, Ref 5). Figure 5 shows EPMA composition profiles for iron, nickel, and chromium acquired from a weld made with 308 stainless steel filler metal on A36 carbon steel with the gas metal arc welding process (Ref 6). The composition trace was made from the top surface of the weld to the fusion line. An expanded view of the composition profile near the fusion line is provided in Fig. 5(b). Note that the weld is over 3 mm (0.1 in.) in length from the fusion line to the weld surface, and the partially mixed zone (PMZ) is a very small fraction of this length (~50 μm, or 0.002 in.). While the PMZ is always present near the fusion line of dissimilar welds, the width of this zone is generally small in relation to the fusion-zone size. There are instances where the PMZ can become appreciable in size. Figure 6 shows composition profiles for claddings in which commercially pure aluminum was deposited onto a carbon steel using the gas tungsten arc welding process (Ref 7). Each cladding was prepared at similar values of heat input but increasing filler-metal feed speed, the values of which are indicated in the figure caption. Note that the PMZ becomes an appreciable size of the fusion zone as the filler-metal speed is increased. This effect can become important in gas tungsten arc welds but is generally not expected in welds made with consumable electrode processes due to the more aggressive mixing that occurs from the molten droplet transfer.

Influence of Welding Parameters on Dilution

The volumetric filler-metal feed rate (V_{fm}) and arc power (P) are the primary welding variables that control dilution. An example of this for gas tungsten arc welds made on alloy AL-6XN with IN625 filler metal is shown in Fig. 7. The plot shows a wide range of welds that were made at various values of filler-metal feed rate and arc power, and the number next to each data point represents the dilution level. The filler-metal feed rate controls the amount of filler metal added to the fusion zone, while the arc power generally controls the amount of base metal that is melted and mixed in with the fusion zone. For example, note in Fig. 7 that, for a fixed arc power, the dilution level decreases as the filler-metal feed rate increases. For a fixed arc power, the amount of melted

Fig. 7 Experimental matrix of fusion welds produced in which AL-6XN was the base metal and IN625 was the filler metal. Numbers to the right signify the dilution level.

base metal (i.e., the A_{bm} term in Eq 1) is fairly constant, but the increase in filler-metal feed rate causes the A_{fm} term to increase. As a result, the dilution decreases. Conversely, welds made with a fixed feed rate exhibit an increase in dilution with increasing arc power. In this case, the A_{fm} term is essentially constant, but the increase in arc power increases the amount of base metal melted, thus leading to an increase in the dilution level.

The qualitative effects of welding variables on dilution can be understood in a more quantitative fashion through the use of process efficiency factors. As shown in Fig. 1, dilution is typically determined by measurement of A_{fm} and A_{bm} using metallographic methods. However, dilution is actually the result of the volumetric quantities V_{fm} and V_{bm} , where V_{fm} is the volume of deposited filler metal and V_{bm} is the volume of melted base metal. These volumetric terms are simply reduced by one dimension into area terms when the sample is cross sectioned and the measurements of A_{fm} and A_{bm} are made. The assumption is made here that the cross-sectional areas do not vary along the length of the weld. Constant cross-sectional areas are produced along the weld length when the volumetric melting rate of the filler metal (V_{fm}) and the base metal (V_{bm}) are constant with travel speed. Under this assumption, dilution can also be expressed in terms of the volumetric melting rates of the base metal (V_{bm}) and the filler metal (V_{fm}) as:

$$D = \frac{V_{bm}}{V_{bm} + V_{fm}} \quad \text{(Eq 3)}$$

The volumetric melting rate of the filler metal is a controlled variable of the process. The implicit assumption in using the set value of volumetric filler-metal feed rate to represent the actual deposited volumetric filler-metal rate is that filler-metal losses due to spatter are negligible. An expression for V_{bm} can be obtained by considering a simplified balance of power

terms across the welding arc, which is facilitated by thermal efficiency factors (Ref 6, 8):

$$\eta_a \eta_m P = V_{fm} E_{fm} + V_{bm} E_{bm} \quad \text{(Eq 4)}$$

where η_a and η_m are the arc and melting efficiencies, respectively; P is the arc power; and E_{fm} and E_{bm} are the melting enthalpies of the filler metal and base metal, respectively. The left side of Eq 4 represents the melting power delivered by the arc, while the right side represents the power required for melting of the base metal and filler metal. The arc efficiency is essentially constant for a given process, while the melting efficiency can be estimated based on knowledge of the welding parameters (Ref 8). Thus, V_{bm} is the only unknown in Eq 4 and can be expressed as:

$$V_{bm} = \frac{\eta_a \eta_m P - V_{fm} E_{fm}}{E_{bm}} \quad \text{(Eq 5)}$$

Combining Eq 3 and 5 yields an expression for dilution in terms of the welding parameters, efficiency factors, and melting enthalpies of the filler metal and base metal:

$$D = \frac{1}{1 + \frac{\eta_a \eta_m P - V_{fm} E_{fm}}{V_{fm} E_{fm}}} \quad \text{(Eq 6)}$$

Note that both melting efficiency and dilution depend only on the volumetric quantities of the deposited filler metal and melted base metal. Thus, the shape of the weld does not need to be known to estimate these quantities.

It is interesting to note that the travel speed does not appear explicitly in Eq 6 when experience indicates that increases in travel speed will lead to increases in dilution (Ref 9). The relation between travel speed and dilution is readily apparent when the effect of travel speed on melting efficiency is considered. It is well known that increasing travel speed leads to an increase in the melting efficiency and a concomitant increase in the melting power (Ref 8). Inspection of Eq 5 indicates this will lead to an increase in V_{bm} with a corresponding increase in dilution. Therefore, the increase in dilution that is known to occur with travel speed is actually a direct result of the increase in melting efficiency.

Equation 6 demonstrates that dilution depends only on the ratio of volumetric filler-metal feed rate to melting power; that is, the individual values of V_{fm} and $\eta_a \eta_m P$ are not important. Figure 8 compares the measured and calculated dilution values as a function of the $V_{fm}/\eta_a \eta_m P$ ratio for dissimilar welds between alloy AL-6XN and IN625, and there is good agreement between the measured and calculated values. This validates the use of Eq 6 for estimating the weld-metal dilution from knowledge of the processing parameters, efficiency factors, and thermophysical properties and also demonstrates that dilution is generally controlled by the $V_{fm}/\eta_a \eta_m P$ ratio.

In many applications, it is often desirable to operate at high filler-metal feed rates (deposition rates) for economic reasons, while maintaining low dilution levels for corrosion resistance or avoidance of undesirable phase formation. In this regard, it is useful to develop a graphical display that reveals the effect of processing parameters on dilution. Equation 6 can be solved in terms of the deposition rate:

$$V_{fm} = \left(\frac{\gamma}{E_{bm} + \gamma E_{fm}} \right) \eta_a \eta_m P \tag{Eq 7}$$

$$\gamma = \frac{1}{D} - 1 \tag{Eq 8}$$

Equations 7 and 8 indicate that, for a given filler-metal/base-metal combination (i.e., E_{fm} and E_{bm} fixed), a plot of filler-metal feed rate (V_{fm}) against melting power ($\eta_a \eta_m P$) will yield various slopes that depend only on the dilution. An indication of the maximum filler-metal feed rate for a given melting power can be considered to be reached when the dilution is reduced to zero and the filler metal does not adequately fuse to the base metal. This occurs when the volumetric melting rate of the substrate is zero.

Figure 9 shows an example of a dilution diagram calculated for deposition of 308 stainless steel ($E_{fm} = 8.7 \text{ J/mm}^3$) onto A36 carbon steel ($E_{bm} = 10.5 \text{ J/mm}^3$). The filler-metal feed rate is plotted as a function of the melting power, and the slopes, which correspond to various calculated dilution levels, are plotted in 10% increments. Because the filler-metal/substrate combination is fixed here, the slopes are determined only by the dilution. A boundary between an inoperable range and an operable range is shown that describes the conditions for no dilution (i.e., a lack of fusion condition). Data for the submerged arc welding process are plotted on the diagram. The measured values of dilution are shown in the data points for comparison to the calculated isodilution lines, and the agreement is reasonable.

The effects of processing parameters are readily apparent on the diagram. For a fixed filler-metal feed rate, the dilution increases with increasing melting power. In this case, the extra melting power cannot be absorbed by the filler metal if the filler-metal feed rate is fixed, so the substrate absorbs the extra melting power, which results in an increase in the volumetric melting rate of the base metal and a concomitant increase in dilution. Note that a filler-metal feed rate of zero describes an autogenous weld that always has 100% dilution, as exhibited by the diagram. Conversely, for a given melting power, an increase in the filler-metal feed rate results in a decrease in dilution. In this case, additional filler metal is added without a significant change in the amount of melted base metal, leading to decreased dilution. When the filler-metal feed rate is increased beyond the

operable/inoperable boundary for a fixed melting power, the dilution reaches 0%, and lack of fusion is likely to result. The boundary between the inoperable and operable regimes simply represents the condition in which the

filler-metal feed rate is increased to the point in which all the melting power would be required to melt the filler metal, so that no power remains to melt the base metal. It is recognized that this somewhat oversimplifies

Fig. 8 Comparison of measured and calculated dilution values as a function of the $V_{fm} / \eta_a \eta_m P$ (where $P = VI$) ratio for dissimilar welds between alloy AL-6XN and IN625. Source: Ref 1

Fig. 9 Dilution diagram calculated for deposition of 308 stainless steel onto A36 carbon steel. Source: Ref 1

the problem, because it does not account for the relative rates of heat flow between the filler metal and base metal, but experimental results show this to be a reasonable approximation (Ref 10).

It should be recognized that the previous discussion pertains mainly to simple single-pass bead-on-plate welds. In more complex joint designs, other factors besides those described previously can also influence the dilution level. Figure 10 illustrates some examples. In an autogenous dissimilar weld, the placement of the heat source relative to the position of the seam in a square butt joint will influence the dilution, as shown in Fig. 10(a) and (b). In Fig. 10(a), the heat source is located to the left of the seam and will therefore melt more of alloy A, while Fig. 10(b) represents the reverse situation. In a multipass weld, the dilution can vary with position within the joint, as shown in Fig. 10(c). Here, the dilution may be high near the root of the weld, where a relatively large portion of base metal is melted. However, the dilution is minimized near the center of the cap pass, where the base-metal melting is minimized. Other welding parameter changes can also affect dilution. The heat balance and concomitant extent of melting between the electrode and base metal will be controlled by the polarity. For example, with the gas tungsten

arc welding process, a relatively deep weld pool will be created when the process is operated with electrode negative polarity, because a larger fraction of the thermal energy from the arc exists at the base metal. This will produce high dilution relative to electrode positive polarity, in which the weld pool is shallower due to a larger fraction of thermal energy at the electrode.

Influence of Dilution on Fusion-Zone Microstructure and Properties

The microstructure and corresponding properties of fusion welds are strongly controlled by the weld-metal composition. Wide variations in fusion-zone microstructure and properties are therefore possible in dissimilar welds that can exhibit large variations in dilution. Other articles in this Handbook provide detailed discussions on composition-microstructure-property relations in fusion welds that should be consulted when dissimilar welds are made between specific alloy systems. Only a few examples are provided here on common dissimilar welds of practical importance.

Deposition of Stainless Steel on Carbon or Low-Alloy Steel

Stainless steels are often deposited onto carbon and low-alloy steels for wear and/or corrosion resistance. In these applications, the final fusion-zone microstructure can be estimated fairly accurately with the Schaeffler diagram shown in Fig. 11. This diagram is used to estimate the final microstructure of steels and stainless steels based on the use of chromium equivalent (Cr_{eq}) and nickel equivalent (Ni_{eq}) values. Consider the deposition of 310 stainless steel with a typical composition of 0.05C-1.5Mn-25Cr-20Ni-0.5Si (all in weight percent) onto a low-alloy steel with a composition of 0.10C-1.0Mn-0.6Si-1.0Mo-2.25Cr. For the 310 stainless steel, $Cr_{eq} = 25.75$ and $Ni_{eq} = 22.25$. For the low-alloy steel, $Cr_{eq} = 4.15$ and $Ni_{eq} = 3.50$. These values are plotted on the diagram in Fig. 11. A fusion weld made between these two alloys can exhibit all possible Cr_{eq} and Ni_{eq} values that lie on a line connecting the two end points representing the individual alloys. Thus, depending on the dilution, the bulk fusion-zone microstructure can be fully austenitic, martensitic, or dual-phase martensite and austenite. A simple graphical procedure can be used to determine the dilution ranges that produce these corresponding microstructures. Note that the Cr_{eq} and Ni_{eq} values for 310 stainless steel represent 0% dilution, while the values for the low-alloy steel represent 100% dilution. The dilution level of any point along the line is given simply by the distance from the end point for 310 stainless steel to the point of interest, divided by the total distance of the line. For example, the phase boundary between the austenite and austenite plus martensite (A + M) regions occurs at 50% dilution, and the phase boundary between the A + M and martensite regions occurs at 67% dilution. These values are also noted on the diagram. This simple approach is convenient for setting dilution limits that are needed to produce a desired microstructure for a given application.

It should be noted that martensite will always form somewhere within the PMZ of dissimilar welds made between stainless steels and low-alloy or carbon steels. While the bulk Cr_{eq} and Ni_{eq} values of the fusion weld can be represented by any point along the line in Fig. 11, the PMZ will exhibit the entire range of Cr_{eq} and Ni_{eq} values that exist from the bulk weld to the low-alloy steel due to the composition gradients in the PMZ discussed previously. More detail on microstructural evolution near the fusion line of such dissimilar welds can be found in Ref 11 and 12.

Joining of Superaustenitic Stainless Steels

Another typical application of dissimilar welds involves the use of nickel-base filler metals (e.g., IN622, IN625, IN686) with

Fig. 10 Example of additional factors that can affect dilution. (a) and (b) Placement of the heat source relative to seam in a square butt weld. (c) Variation in dilution in a multipass butt weld

Fig. 11 Illustration of use of the Schaeffler diagram for estimating the microstructure for welds in which 310 stainless steel is deposited onto a low-alloy steel

relatively high molybdenum concentrations for joining of superaustenitic stainless steels. Superaustenitic stainless steels contain relatively high concentrations of nickel, chromium, nitrogen, and molybdenum for improved resistance to corrosion in a wide variety of aqueous media. However, the corrosion resistance of the weld can often be inferior to that of the base metal due to microsegregation of molybdenum (Ref 13). The microsegregation leaves the dendrite cores depleted in molybdenum, rendering them susceptible to accelerated corrosive attack (Ref 1, 13). In this case, nickel-base filler metals are used to enrich the molybdenum concentration of the weld as an aid to restoring the corrosion resistance. The use of nickel-base alloys does not prevent microsegregation of molybdenum, but the elevated molybdenum concentration in the weld helps counteract the negative effect due to microsegregation. For these applications, it is desirable to minimize the dilution level in order to maintain high concentrations of molybdenum in the weld zone for adequate corrosion resistance.

Figure 12 shows how dilution affects the corrosion resistance of welds made on alloy CN3MN (a cast superaustenitic stainless steel with a nominal molybdenum concentration of 6.2 wt%) using IN686 filler metal (approximately 16 wt% Mo). The plot shows the normalized mass loss as measured in the ASTM G48 test, which involves immersion in a 6 wt% solution of FeCl₃ at 75 °C (165 °F). The values next to each data point indicate the bulk molybdenum concentration in the weld. Also shown are the samples after each test in which the location of the weld and base metal are indicated. Note that, at the two highest dilution levels, the weight loss is relatively high, and extensive corrosion occurs in the weld. In contrast, dilution levels below approximately 50% lead to relatively low mass loss, and the weld exhibits less evidence of corrosion than the base metal. This improved corrosion resistance is attributed to the higher molybdenum concentration of the welds that were made with relatively low dilution values.

Solid-State Transformations in Weldments*

Revised by Mehran Maalekian, The University of British Columbia

SOLID-STATE TRANSFORMATIONS occurring in a weld are highly nonequilibrium in nature and differ distinctly from those experienced during casting, thermomechanical processing, and heat treatment. This discussion primarily focuses on the welding metallurgy of fusion welding of steels and attempts to highlight the fundamental principles that form the basis of many of the recent developments in steels and consumables for welding. Accordingly, examples are largely drawn from the well-known and relatively well-studied case of ferritic steel weldments to illustrate the special physical metallurgical considerations brought about by the weld thermal cycles and by the welding environment. Because of space limitations, only a very brief discussion is included on welds in other alloy systems, such as stainless steels and aluminum-base, nickel-base, and titanium-base alloys.

The metallurgy of the welded joint can be classified into two main regions: the fusion zone (FZ) and the heat-affected zone (HAZ). A series of transformations occur during both heating and cooling, and every aspect of phase transformations in steel is relevant to the welding. The typical transformations that take place in the FZ during welding of, for instance, low-carbon steels are ferrite (α) \rightarrow austenite (γ) \rightarrow ferrite (δ) \rightarrow liquid \rightarrow ferrite (δ) \rightarrow austenite (γ) \rightarrow ferrite (α), while that of the HAZ is $\alpha \rightarrow \gamma \rightarrow \alpha$. During heating in the HAZ, austenite begins to form at the temperature Ac_1 , and it becomes fully austenitic at Ac_3 . (Ac_1 and Ac_3 are the temperatures at which austenite begins to form and is completely transformed from ferrite upon heating, respectively.) The austenite grains grow above Ac_3 , and during cooling the austenite starts to decompose into various microconstituents below the Ar_3 temperature (that is, the temperature at which austenite begins to decompose upon cooling) (Fig. 1). To describe the microstructural development

under nonequilibrium conditions in steels, a continuous cooling transformation (CCT) diagram (Fig. 2) is a convenient method. However, a conventional CCT diagram like the one shown in Fig. 2 cannot be used to accurately describe the transformation behavior in a weldment of the same material, because weld thermal cycles are very different from those used for generating conventional CCT diagrams.

Special Factors Affecting Transformation Behavior in a Weldment

Several aspects of the weld thermal cycle and weld segregation should be considered because of their effect on the transformation upon cooling:

Fig. 1 Schematic illustration of typical microstructure history of the heat-affected zone that occurs during both heating and cooling of steel welds

Fig. 2 Conventional continuous cooling transformation (CCT) diagram for AISI 1541 (0.39C-1.56Mn-0.21Si-0.24S-0.010P) plain carbon steel with ASTM number 8 grain size and austenitization at 980 °C (1800 °F). For each of the cooling curves in the plot (given in terms of °C/min), the transformation start and end temperatures given by the CCT curves, the amount of each transformation product, and the hardness of the final structure are shown. Ac_3 , 788 °C (1450 °F); Ac_1 , 716 °C (1321 °F). F, ferrite; P, pearlite; B, bainite; M, martensite. Source: Ref 1

- Peak temperatures reached in the HAZ can be very much higher than the Ac_3 temperature. The heating rates are very high, and the times spent at high temperature are of the order of only a few seconds.
- The temperature gradient in the HAZ is very steep, and this complicates the problem of studying in situ transformations in the HAZ during welding (Ref 1).
- During solidification of the weld metal, alloying and impurity elements tend to segregate extensively to the interdendritic or intercellular regions under the conditions of rapid cooling. Also, the pickup of elements such as oxygen by the molten weld pool leads to the entrapment of oxide inclusions in the solidified weld. These inclusions then serve as heterogeneous nucleation sites and can substantially influence the kinetics of subsequent solid-state transformations. Accordingly, the weld-metal transformation behavior is quite different from that of the base metal, even though the nominal

chemical composition has not been significantly changed by the welding process (Ref 2). Most of the CCT diagrams (applicable to the weld metal) have been generated by reheating the as-deposited weld metal (Ref 3). One of the limitations of these diagrams is that they are strictly applicable only to the high-temperature reheated zone of multipass welds, because the initial microstructure at high temperatures is not characteristic of that developed from the liquid phase.

- Welding may be carried out in several passes, and this may result in the superposition of several different heating and cooling cycles at one point, each of these cycles having the characteristics noted earlier.
- Solidification of the weld metal is accompanied by shrinkage, and the anisothermal conditions already emphasized cause deformation. The thermal cycles are therefore acting on metal that is subjected to mechanical stresses at the same time.

The essential differences between weld thermal cycles and the thermal cycles used for generating a conventional CCT diagram are summarized in Fig. 3. Thermal cycles for conventional CCT diagrams involve a slow heating rate, soak at a temperature just above the Ac_3 temperature, and subsequent cooling rates, whereas a much higher peak temperature and heating rate as well as a very short soaking time at peak temperature are characteristics of a weld thermal cycle. Owing to these significant differences (Fig. 3), a conventional CCT diagram can give only an approximate idea of the transformation behavior in the HAZ of a weldment.

Heat-Affected Zone of a Single-Pass Weld

Microstructural Zones. In the HAZ, the material is not melted, but the microstructure

and mechanical properties are altered by the heat of welding. There is a well-defined gradient of microstructure in the HAZ that can be divided into a number of subzones as a function of the distance from the fusion line, as illustrated in Fig. 4 for a carbon steel. Very high peak temperatures (T_p) in the regions immediately adjacent to the fusion line cause coarsening of the austenite (γ) grains, and this in turn increases the hardenability of this region relative to the other subzones. The slower the heating rate, the longer the retention time above Ac_3 and thus the more severe the grain growth becomes. As the peak temperature decreases with distance from the fusion line, the austenite

Fig. 3 Schematic showing differences between weld thermal cycle and thermal cycle used to generate a conventional continuous cooling transformation (CCT) diagram. Note the much higher heating rate, higher temperature, and shorter time above Ac_3 temperature for welding. HAZ, heat-affected zone

grain size decreases sharply. Regions of the HAZ further away from the fusion line become only partially austenitic during the heating. Owing to the increase in the solubility of carbon in austenite with decreasing temperature, the austenite that forms will have a rather high carbon concentration (Ref 5). The part that does not transform into austenite becomes tempered. Table 1 summarizes the temperature ranges for the variety of microstructural zones within the HAZ of steel welds. Because each of the subzones shown in Fig. 4 occurs in a small volume, it is difficult to study the transformation behavior of individual regions by in situ methods (Ref 2). It is more convenient to obtain information about the microstructural and property changes in the HAZ by weld simulation (Ref 4, 6). A thermal cycle simulator (TCS) is used to reproduce the thermal cycle corresponding to a point in the HAZ in a large volume that is convenient for mechanical testing. It is possible to program the required thermal cycle in the TCS so that the peak temperature and the cooling rate can be varied independently. A TCS can be used in conjunction with a high-speed dilatometer to study phase transformations in welding and to construct welding CCT diagrams. It is thus possible to obtain information about the microstructural changes in the HAZ for a wide range of welding parameters. Nevertheless, it should be borne in mind that weld thermal simulators, although very useful, have some limitations. For instance, because of the limited cooling capacity, extremely high cooling rates during electron and laser beam welding cannot be replicated. Moreover, the

temperature gradient in the specimen of the TCS is much lower than that in the HAZ near to the fusion boundary, which makes the specimen microstructure differ from the HAZ microstructure (Ref 7).

Peak Temperature-Cooling Time Diagrams. Figure 5 shows how a change in the peak temperature of the thermal cycle affects the CCT characteristics of a steel. The well-known effect of a larger γ grain size (caused by a higher peak temperature) in increasing the hardenability of the steel is seen. To present the information about the CCT behavior for a number of peak temperatures (Fig. 3, 4), it is more convenient to adopt the scheme shown in Fig. 6. In this peak temperature-cooling time (PTCT) diagram (Ref 8, 9), each point represents a weld thermal cycle with a peak temperature, T_p , given by the ordinate and the cooling time, Δt_{8-5} (that is, required for cooling from 800 to 500 °C, or 1470 to 930 °F, see Fig. 1), given by the abscissa. A microstructural constituent or a combination of two or more constituents is shown to occur over an area in the diagram. The upward slope in the boundary between two areas is consistent with the information presented earlier in Fig. 5 that the hardenability increases with an increase in the peak temperature of the thermal cycle. Hardness and C_v transition temperatures are also shown in the diagram, corresponding to different thermal cycles.

The CCT diagram shown in Fig. 5 is plotted with Δt_{8-5} as the abscissa instead of time, as in Fig. 2. The Δt_{8-5} is a popular measure in welding, probably because solid-state transformations during cooling occur between Ar_3 and martensite-start temperature, and in most steels Ar_3 is approximately 800 °C (1470 °F). However, historically, the practice of thinking in terms of a cooling time began when a need was recognized (Ref 10) to compare the CCT behavior of specimens subjected to different types of cooling curves—Jominy specimens; cylindrical bars cooled in air, water, or oil; dilatometer specimens cooled at a constant or a Newtonian rate (i.e., $T \propto e^{-t}$, where t is the time); and so on. Initially, the cooling rate at 704 °C (1300 °F) was used as a criterion to judge the equivalency of these specimens in terms of microstructure and hardness. Because transformation takes place at lower

Table 1 Typical temperature ranges of the microstructural subzones within the heat-affected zone (HAZ) of steel welds

HAZ microstructure	Temperature range
Coarse-grained austenite	1500 °C > T_p > 1200 °C (2730 °F > T_p > 2190 °F)
Fine-grained austenite	1200 °C > T_p > Ac_3 (2190 °F > T_p > Ac_3)
Partially austenitized zone	Ac_3 > T_p > Ac_1
Tempered regions	Ac_1 > T_p

Source: Ref 5

temperatures in many steels, the half cooling time (Ref 10) was found to be a better equivalency criterion. The half cooling time was defined as the time to cool from A_{c3} to a temperature that lies midway between A_{c3} and room temperature. For the sake of general applicability, this was later modified to the $\Delta t_{8.5}$ criterion, and CCT diagrams began to be plotted with $\Delta t_{8.5}$ as the abscissa. It must be noted that using $\Delta t_{8.5}$ as an equivalency criterion is just an expedient solution that does not have strict theoretical justification (refer, for example, to the additivity principle in Ref 10).

A special significance of using $\Delta t_{8.5}$ as the abscissa in Fig. 6 is that it is almost constant (for $T_p > 900^\circ\text{C}$, or 1650°F) in the whole of the HAZ. This can be seen from Ref 4, where the expressions given for $\Delta t_{8.5}$ do not contain the distance from the weld centerline as a factor. The derivation of these expressions is based on the assumption that the time to cool to 800°C (1470°F) is far greater than the time to reach the peak temperature, so the $\Delta t_{8.5}$ can be taken to be the same for the whole of the weld and the HAZ. This assumption can be intuitively rationalized by observing that the

weld thermal cycles in Fig. 3 are such that the curves are approximately parallel below 800°C (1470°F). The constancy of $\Delta t_{8.5}$ in the HAZ means that the gradient in microstructure (in terms of the final transformation products from austenite) is mainly due to a variation in the peak temperature. By drawing a vertical line in Fig. 6 at a value of $\Delta t_{8.5}$ corresponding to a given heat input and preheating temperature, it is possible to obtain information about the type of microstructural gradient in the HAZ. A grasp of the changes in such properties as hardness and toughness can also be obtained from Fig. 6.

Continuous Heating Transformation Diagrams. The heating cycle in welding is also very important, because it influences the final microstructure and properties of the HAZ. For example, the heating rate to the peak temperature determines the degree of superheating, the rate of coarsening and dissolution temperature of carbides and nitrides, and the main proportion of austenite grain growth (Fig. 1, 4) (Ref 4). In fact, all of the aforementioned factors affect the degree of grain growth in the HAZ, which, in turn, will greatly influence the final properties of the weld.

The formation of austenite during heating is, in many respects, different from the transformations that occur during cooling. The formation of ferrite, for example, follows a "C-" curve kinetic form on a time-temperature transformation diagram. That is, the overall transformation rate goes through a maximum as a function of supercooling below the equilibrium temperature because of two opposing effects. As the temperature falls, the diffusion coefficient decreases, but the driving force for transformation increases (Ref 5). In contrast, during heating both the diffusion coefficient and the driving force increase with temperature. Thus, the overall rate of transformation increases continuously as the transformation temperature is raised, as shown in Fig. 7.

The heating rate in many welding processes can be very high, and considerable superheating may be required for the transformation to austenite on heating, because the A_{c1} and A_{c3} temperatures will be raised with an increase in the heating rate (Ref 11). For typical heating rates encountered in the region near the fusion line, the formation of austenite should be completed when the temperature has exceeded the A_{c3} by approximately 100°C (180°F) (Ref 5). This is seen in Fig. 8, a continuous heating transformation diagram, which is analogous to a CCT diagram. It is seen that grain growth begins only after the carbides have dissolved and after a homogeneous austenite (with respect to the distribution of carbon, at least) is formed.

Thermal Pinning. A fairly satisfactory correlation between real welds and simulation studies has been observed with respect to microstructure and property measurements. However, it has frequently been observed that the maximum austenite grain size in real welds is less than that in corresponding simulated

Fig. 5 Effect of a change in the peak temperature of the weld thermal cycle (from 1000 to 1400 °C, or 1830 to 2550 °F) on the continuous cooling transformation characteristics. M, martensite; B, bainite; F, ferrite; P, pearlite. Source: Ref 8

Source: Ref 9

weld specimens (Ref 2, 4, 6). The reason is attributed to the very steep temperature gradient in the HAZ, especially near to the fusion line where the grains are coarsest, the temperature gradient is steepest, and the temperature can vary across a single grain, as first reported in the HAZ of a Cr-Mo-V steel (Ref 13). The phenomenon, termed thermal pinning, causes grains to grow nonuniformly, resulting in a shape change from, for example, equiaxed to pear shaped, as shown in Fig. 9(a) (Ref 4).

Fig. 7 Schematic comparison of the $\gamma \rightarrow \alpha$ transformation (time-temperature transformation curve) and the reverse $\alpha \rightarrow \gamma$ transformation. ΔG is the driving force, and D is the diffusion coefficient. Adapted from Ref 5

The corresponding increase in surface-to-volume ratio effectively represents an increase in energy, thereby neutralizing the reduction in energy present in normal grain growth. Another explanation for thermal pinning is that the steep temperature gradients cause the atomic mobility to vary across a large grain, resulting in different growth propensities in different parts of the grain (Ref 14). Under the simulation conditions, the austenite grains grow in all directions, and the constraint arising from the thermal pinning effect in real welds is difficult to capture and quantify. However, the problem has been modeled numerically using Monte Carlo simulation by subdividing the grains into many discrete small units, each with its own atomic mobility depending on the local temperature (Ref 14, 15). Figure 9(b) shows that the kinetics of grain growth at the HAZ with gradient heating are lower than that for bulk heating using an identical thermal cycle, thus indicating grain-boundary pinning in the HAZ due to thermal pinning. However, under the weld simulation condition, the austenite grains can grow in all directions, so the previous discussion shows that the PTCT diagram (along with property measurements, as in Fig. 6) can alert the user to the possibility of local brittle zones in actual weldments, and that any error in the property being assessed will be on the conservative side.

Austenite Grain Growth and Grain-Boundary Pinning. Grain size is of paramount importance in steels as a key factor in determining their strength and toughness. It also has immense impact on the vulnerability of an alloy to cold cracking and reheat cracking in welds (Ref 4). Austenite grain growth influences the kinetics of phase transformation and may promote the formation of martensite and bainite, with adverse effects on the fracture toughness of the weld (Fig. 5). Further, it has an important effect on the grain size in the weld metal where the grains are grown epitaxially from the HAZ. Figure 10 shows that the crystals of the weld deposit (columnar δ -ferrite) have derived from the grains of the parent metal at the fusion surface, that is, epitaxial growth. Thus, the grain growth in the HAZ not only affects strength and toughness but also influences the grain size of the weld.

Traditional ways of improving the strength of steels had been to increase the carbon and manganese content. However, such steels, even with their higher carbon equivalent (CE), did not possess adequate toughness and were prone to weld cracking. The weldability of steels, which is usually expressed in terms of CE, is poor if the CE exceeds 0.4 wt%, because of their increased tendency to form martensite.

Fig. 8 Continuous heating transformation diagram for 34CrMo4 steel. In the region of homogeneous austenite there are lines of constant austenite grain size (ASTM numbers). Because of the measuring procedure, the diagrams can only be interpreted along lines of constant heating rate. To show the heating time more clearly, a time scale is added. Source: Ref 12

Fig. 9 (a) Steep temperature gradient in the heat-affected zone (HAZ) near the fusion line leads to a rapid change in grain size, which may tend to suppress grain growth due to grain shape changes. Arrows indicate direction of moving grain boundaries. Adapted from Ref 4. (b) Schematic kinetics of grain growth in the HAZ under steep temperature gradient (gradient heating) and corresponding uniform thermal cycle (bulk heating). The growth kinetics for the HAZ are much slower than that for the bulk heating. This can be seen in Ref 14 and 15.

Development of microalloyed or high-strength low-alloy (HSLA) steels through the last several decades made it possible to achieve higher strength levels with much lower carbon and manganese levels, thus improving weldability (Ref 16). In microalloyed steels, alloying additions are kept to a minimum, and higher strength is achieved primarily by a reduction in the grain size and by precipitation strengthening. A reduction in grain size is the only known method of increasing the strength and toughness at the same time. Because strengthening is obtained by other means, both carbon and the CE can be decreased and the susceptibility of HSLA steel to cold cracking thereby significantly reduced.

A fine ferrite grain size in these steels is achieved by controlled rolling in the austenitic condition (i.e., hot rolling). To obtain a fine austenite grain size before the $\gamma \rightarrow \alpha$ transformation, it is essential to add such grain-refining elements as niobium, titanium, vanadium, and aluminum. Such elements are strong carbide and nitride formers (except aluminum, which forms only nitrides); their addition to steels introduces fine precipitates to the austenitic matrix. The particles are usually found on grain boundaries, which are energetically more favorable formation sites. A short length of grain boundary is replaced by the precipitate, and the effective interfacial energy is lowered. When the grain boundary attempts to migrate away from the particles, the local energy increases, and a drag is exerted on the boundary by the particles. Therefore, the fine precipitates can pin the austenite grain boundaries and hinder grain coarsening (Fig. 11).

Fig. 10 Illustration of the epitaxial growth of columnar grains of the weld deposit from the fusion line of a stainless steel weld. After Honeycombe and Gooch, reprinted from Ref 5

In the HAZs of welds in these microalloyed steels, it is not possible to achieve the same optimal microstructure and microalloy precipitation obtained in the parent material by controlled thermomechanical processing. Because peak temperatures are much higher in the HAZ, the precipitate particles coarsen and dissolve, resulting in reduced pinning forces and therefore coarser austenite grains, as schematically shown in Fig. 11. This effect can be minimized by having precipitate particles that do not dissolve, even at higher temperatures. An idea of the stability of precipitate particles can be obtained from the solubility product shown in Fig. 12. It is seen that the nitrides compared with their respective carbides are more stable. Moreover, titanium nitride (TiN) has maximum stability, and this property has been used to advantage in many steels and has resulted in the development and extensive application of titanium technology (Ref 16). As shown in Fig. 13, the other carbides and nitrides are not as effective as titanium nitride in limiting the extent of grain coarsening; they play a bigger role during thermomechanical processing.

The austenite grain growth can be shown conveniently in the form of grain growth diagrams (Fig. 14), which illustrate contours of equal grain size as a function of the peak temperature and Δt_{8-5} (or input energy). In titanium-microalloyed steel (Fig. 14), it is seen that even in the presence of relatively stable

TiN precipitates, grain growth in the HAZ at high input energies can be considerable, which is attributed to the increase in the mean particle size, a process known as Ostwald ripening (Ref 16), as well as the partial dissolution of TiN. This means that it is not possible to stop, but only to limit, grain coarsening in the HAZ, especially in high-heat-input welds. This inevitable grain coarsening is actually used to advantage in titanium oxide steels (see the section "Titanium Oxide Steels" in this article). However, the grain growth can be made to cease after a certain time in the presence of a fine distribution of particles. Figure 15 shows that the limiting grain size (D_{lim}) is proportional to (r/f) with a constant of proportionality (k) that may be different for different materials. It also shows how a high volume fraction of fine precipitate particles is needed to maximize the pinning effect.

Unmixed and Partially Melted Zones in a Weldment. It is common to think of a single-pass weld as consisting of two zones: weld metal and HAZ. Careful metallographic examination has shown that a weld can, in fact, be divided into four regions (Fig. 16):

- *Composite zone:* A volume of base metal melted by the superheated filler metal experiences complete mixing to produce an alloy with nominal composition intermediate between that of the base metal and that of the filler metal.

Fig. 11 Schematic illustration of austenite grain size in the heat-affected zone (HAZ) of microalloyed steel with second-phase particles as a function of distance from the fusion line and associated thermal cycle. The movement of grain boundaries driven from the reduction of total surface energy (proportional to the inverse of grain size, D) is hindered by the precipitates that exert a pinning force proportional to the ratio of precipitate volume fraction, f , to their size, r (i.e., f/r). At regions near the fusion line, where the temperature is well above the dissolution temperature of carbonitrides (T_d), profound grain growth can occur as a result of dissolution and/or coarsening of precipitates and subsequent reduction in particle pinning effect (compare positions 1 and 2 in the HAZ).

- *Unmixed zone*: Forms from the stagnant molten boundary-layer region (approximately 100 to 1000 μm, or 0.004 to 0.040 in., thick) at the outer extremities of the composite region. Because no mechanical mixing with the filler metal occurs here, the composition of the metal in this region is identical to that of the base metal, except for minor changes produced by diffusion.
- *Partially melted zone*: A region at the fusion boundary where the peak temperatures fall between the liquidus and solidus so that melting is incomplete
- *True heat-affected zone*: That portion of the base metal where all microstructural changes induced by welding occur in the solid state

Fig. 12 Solubility products of carbides and nitrides in austenite. Adapted from Ref 17

Fig. 13 Effects of various microalloying additions on the grain-coarsening temperature of austenite. Grain-coarsening temperatures depend on the microalloying level, nitrogen and/or carbon contents, and size of the precipitates. Titanium is the most efficient microalloying element for grain refining due to the extremely low solubility of titanium nitride in austenite. Source: Ref 18

The width of the partially melted zone can be extended by a phenomenon known as constitutional liquation (Ref 23), a phenomenon of localized melting due to a nonequilibrium distribution of phases during rapid heating, in which melting can occur even when the peak temperature is less than the solidus temperature. This can be understood by referring to a phase diagram for a simple binary system A and B (Fig. 17). Consider an alloy of composition C. Its equilibrium structures at temperatures T_1 , T_2 , T_3 , and T_4 are $\alpha + \beta$, α , α , and $L + \alpha$, respectively (Fig. 17a). On heating from room temperature to T_3 and holding at this temperature for a long time, the β particles will dissolve and give a homogeneous α of composition C. However, under conditions of rapid heating in the HAZ, the dissolution of β will give rise to a solute concentration gradient around each particle, as shown in Fig. 17(b). In the region surrounding each particle, the concentration of the solute B will correspond to that of liquid because, as the phase diagram shows, a liquid phase must exist between α and β at T_3 .

The partially melted zone is the region where liquation cracks have been known to occur in maraging steels, austenitic stainless steels, heat treatable aluminum alloys, and nickel-base

superalloys. It can also be a site where hydrogen-induced cracking is initiated (Ref 21, 22), both because it can act as a pipeline for the diffusion of hydrogen picked up by the molten weld metal and because such segregated regions have higher hardenability.

Although the phenomenon of constitutional liquation is usually discussed in connection with liquation cracking of aluminum- and nickel-base alloys (Ref 7, 23, 24), a more dramatic example can be found in the case of cast iron welds (Ref 25). Figure 18(a) illustrates the temperature range over which the formation of a partially melted zone in a cast iron may occur. Figure 18 (b) shows the microstructure of the HAZ in a cast iron weld deposited using a quench welding technique (Ref 26). This procedure involves welding without any preheat by intermittently depositing a series of small stringer beads and strictly maintaining the interpass temperature below approximately 80 °C (175 °F). The idea is to limit the size of the hard and brittle white iron colonies that form by constitutional liquation around the graphite nodules, and to make sure that they do not interconnect. By contrast, a procedure involving a preheat of approximately 200 °C (390 °F) can prevent the formation

Fig. 14 Effect of peak temperature and precipitate (TiN) coarsening on austenite grain growth in the heat-affected zone of a titanium-microalloyed steel. The points in the diagram are experimental data, whereas the curves are calculated. Source: Ref 4

of martensite but not the formation of ledeburite (the structure of white iron). Because ledeburite forms at higher temperatures than martensite ($\approx 1100^\circ\text{C}$, or 2010°F), a much higher preheat temperature of approximately 600°C (1110°F) is required to reduce the cooling rate significantly and thereby prevent the formation of white iron. This high level of preheat is impractical. While cast iron appears to have been successfully welded with preheats of approximately 200°C (390°F), it has sometimes been found that weld repair is most effective when using the quench welding technique, by which it is possible to limit both the amount of ledeburite formed and the width of the HAZ.

Fusion Zone of a Single-Pass Weld

Transformations in Single-Pass Weld Metal. It is usually not necessary to select a filler metal that has exactly the same composition as the base metal; it is more important that the weld metal has the same strength and other properties (such as toughness or corrosion resistance). Because these properties are governed by the microstructure, it is important to understand the influence of different factors on phase

transformations in the weld metal. First, for a meaningful communication of the different features in a microstructure, the various phases and microconstituents must be identified using a system of nomenclature that is both widely accepted and well understood. In wrought steels, this need has been satisfied to a large degree by the Dubé scheme (Ref 27) for classifying the different morphologies of ferrite, as shown in Fig. 19. Similarly, confusion and controversy in the terminology for describing the microstructures in ferritic steel weld metals have been largely resolved by the classification scheme shown in Fig. 20. This scheme (Ref 28) was the result of several collaborative exercises undertaken under the auspices of the International Institute of Welding (IIW). It is worthwhile to note that the IIW approach to classifying microstructural elements is based on their appearance in the optical microscope. However, based on the knowledge of transformation behavior of various constituents, a different classification system has been proposed (Ref 29). Typical micrographs illustrating some of the microstructural constituents are shown in Fig. 21.

The transformation behavior in ferritic steel weld metals is best understood by first noting that ferrite is nucleated heterogeneously and that, for all practical purposes, it is necessary

to consider the competitive nucleation behavior only at grain boundaries and at inclusions. Figure 22 shows that inclusions must be larger than a certain size (0.2 to $0.5\ \mu\text{m}$, or 8 to $20\ \mu\text{in.}$, the typical size range of most weld-metal inclusions) for their potency as nucleation sites to reach a maximum. It also shows that nucleation of ferrite is always energetically more favorable at grain boundaries than at inclusions. Based on additional considerations, such as thermal contraction strains and lattice matching at inclusion-austenite-ferrite interfaces (not taken into account to obtain the results in Fig. 22), a discussion of why certain inclusions are more potent nucleation sites than others is found in Ref 3 and 30 to 32.

Broadly, the major factors affecting transformation behavior in ferritic steel weld metals are alloy composition, weld heat input (by its effect on γ grain size and $\Delta T_{(8-5)}$), oxygen content (that is, the inclusion content), and the nature of segregation in the weld metal. A typical weld CCT diagram is shown in Fig. 23. For the cooling curve shown in the figure, the first phase that forms is allotriomorphic ferrite, or grain-boundary ferrite in the IIW scheme. (The term *allotriomorphic* describes a particle of a phase that does not have a regular external shape; in

Fig. 15 Effect of particle radius (r) and volume fraction of precipitates (f) on the limiting (maximum) austenite grain size. The measured grain size data (symbols) reported for different steels (Ref 19, 20) are well represented by the equation $D_{\text{lim}} = k(r/f)$ (curves) using different k values.

Source: Ref 26

the present context it means that ferrite grows on the grain-boundary surfaces and does not have a regular faceted shape reflecting the symmetry of its internal crystalline structure.) At lower temperatures, the mobility of the curved or random γ/α -allotriomorph boundaries decreases, and Widmanstätten side plates (ferrite side plates in the IIW scheme) form. Growth of these side plates is rapid because carbon is efficiently redistributed to the sides of the growing tips, thus avoiding solute pile-up problems. In addition, substitutional atoms do not diffuse during the growth of Widmanstätten ferrite.

After all the grain-boundary sites are saturated with allotriomorphic or Widmanstätten ferrite and their growth rate is not sufficient to extend to the interior of the grains, the nucleation of ferrite at inclusions within the γ grains becomes competitive. Acicular ferrite forms, a structure resulting from ferrite laths growing in different directions from inclusions and from laths already nucleated. Upon impingement, high-angle grain boundaries and a very fine dispersion of microphases are obtained between ferrite laths. *Microphases* in this context means the transformation structures resulting from the

carbon-enriched regions between the ferrite laths; these could be the martensite-austenite constituent, bainite, or pearlite (see the section "Heat-Affected Zone in Multipass Weldments" in this article). An example of the microstructure of acicular ferrite is shown in Fig. 24. Acicular ferrite does not figure in the Dubé scheme because it is rarely observed in wrought steels. When the cooling rate is higher or when the inclusion content is very low, bainite can be nucleated directly at the γ grain boundaries. Bainite can form as upper or lower bainite; the difference between the two is illustrated in Fig. 25. Examination with transmission electron microscopy (TEM) is usually required for a firm identification of the type of bainite formed. In the case of the highest cooling rates, martensite is obtained.

Figure 26 shows the effect of alloying additions, Δt_{8-5} , oxygen content, and the γ grain size on the sequence and relative amounts of allotriomorphic ferrite, Widmanstätten ferrite, and bainite in the weld metal. Broadly, the trends shown can be understood in terms of the well-known observation that an increase in γ grain size, a decrease in inclusion content, and an increase in alloying additions will shift the CCT curves to lower temperatures and to longer times. While Fig. 26 can generally be interpreted by assuming that the individual factors act independently of each other, the transition from Fig. 26(b) to (a) with an increase in the inclusion content must be understood in terms of its effect of the γ grain size. It has been observed that the γ grain size decreases with an increase in the inclusion content, and this

Fig. 22 Effect of particle radius on energy barrier to ferrite nucleation at inclusions, ΔG^* (heterogeneous), normalized relative to the homogeneous nucleation barrier, ΔG^*_h (homogeneous). Corresponding energy barrier to nucleation of ferrite at austenite grain boundaries is indicated by horizontal broken line. Adapted from Ref 4

decrease has been explained by the higher magnitude of pinning forces at higher inclusion contents (Ref 31). The smaller grain size implies a greater grain-boundary surface area, which increases the amount of grain-boundary ferrite and side plate structures formed at the expense of acicular ferrite in Fig. 26(a). The role of the initial formation or nonformation of allotriomorphic ferrite at γ grain boundaries in bringing about the transition from Fig. 26 (b) to (c) is discussed in the next section of this article.

Although the IIW classification is the result of a consensus viewpoint, some researchers (Ref 30) still feel that it places an exaggerated emphasis on morphological features observed with the light microscope. They believe that it is more important that the terminology reflect the mechanism of transformation (Ref 29). For example, it can be difficult to differentiate between Widmanstätten ferrite and upper bainite when using the light microscope, and both are identified as "FS" in the IIW classification. For a more fundamental understanding for a clear interpretation of the trends in microstructural development, it is essential to make a distinction between the two. In addition, the subclassification of grain-boundary ferrite in the IIW classification is not unequivocal in its meaning: It could refer to ferrite that forms by diffusion, to Widmanstätten ferrite, or to the ferrite in upper bainite. In contrast, the term *allotriomorphic ferrite* clearly identifies the mechanism by which it is formed. On the other hand, the IIW classification is easy to use and

Fig. 23 Schematic of weld continuous cooling transformation diagram showing selected microstructures

Fig. 24 Replica transmission electron micrograph showing acicular ferrite in a steel weld deposit. Source: Ref 30

allows a more detailed identification, either by judgment or by further TEM examination—for example, to determine whether FS is FS (SP) or FS(UB). At least it decreases the tendency for a wrong identification of the transformation mechanism with insufficient data. For a microstructure-toughness correlation, it is

sufficient to characterize the morphological features.

Sensitivity to Carbon. Small variations in carbon concentration can have a major influence on the microstructure of the welds, particularly because the carbon content of a weld is normally kept very low. It is seen from Fig. 27 that the sensitivity of growth kinetics of allotriomorphic and Widmanstätten ferrite to carbon becomes larger as the concentration of carbon decreases (Ref 30). The growth rate of ferrite increases sharply as the carbon concentration of the steel approaches its solubility in ferrite, because there is no need for the carbon to diffuse ahead of the austenite/ferrite interface since it can all be accommodated in the ferrite (Ref 30). Hence, the effect of carbon is expected to be greater when its concentration changes, for example, from 0.03 to 0.05 wt%, when compared with the change from 0.09 to 0.11 wt% (Fig. 27). Changes in mechanical properties reflect this behavior, the strength of low-carbon steels being very sensitive to the carbon concentration. Figure 28 illustrates that both microstructure and mechanical properties change more rapidly at low carbon concentrations.

The high sensitivity of the α/γ transformation to carbon at low concentrations leads to a corresponding decreased sensitivity to substitutional alloying elements. Carbon essentially controls the kinetics of transformation. Hence, for the weldability of steels that is often expressed in terms of carbon equivalent (CE), there are logically two popular formulas for the CE for low- and high-carbon weldable steels (Ref 5):

Fig. 25 Schematic showing the differences in the transformation mechanism for upper and lower bainite and the effect of these mechanisms on the final morphology. Source: Ref 30

Fig. 26 Schematic showing the effect of alloy composition, $\Delta t_{b,5}$, oxygen content, and γ grain size on the development of microstructure in ferritic steel weld metals. The hexagons represent cross sections of columnar γ grains. (a) The γ grain boundaries become decorated first with a uniform, polycrystalline layer of allotriomorphic ferrite, followed by formation of Widmanstätten ferrite, and then by formation of acicular ferrite. (b) The growth rate of Widmanstätten ferrite is not sufficiently high to extend entirely across γ grains. Nucleation of ferrite at inclusions within the γ grains leads to an increase in the amount of acicular ferrite when compared with case (a). (c) The higher alloy content or the higher cooling rate suppresses the formation of allotriomorphic ferrite. This leaves the γ grain boundaries free to nucleate upper bainite. Source: Ref 30

Fig. 27 (a) Diagram illustrating the calculated thickening of allotriomorphic ferrite during isothermal transformation. The growth kinetics become sensitive to carbon concentration as the latter approaches the solubility of carbon in the ferrite. (b) Calculated isothermal growth rate of Widman-

IIW > 0.18wt%C : CE

$$= C + \frac{\text{Mn} + \text{Si}}{6} + \frac{\text{Ni} + \text{Cu}}{15} + \frac{\text{Cr} + \text{Mo} + \text{V}}{5} \text{ wt\%} \quad (\text{Eq 1})$$

Ito-Besseyo < 0.18wt%C : CE

$$= C + \frac{\text{Si}}{30} + \frac{\text{Mn} + \text{Cu} + \text{Cr}}{20} + \frac{\text{Ni}}{60} + \frac{\text{Mo}}{15} + \frac{\text{V}}{10} + 5B \text{ wt\%} \quad (\text{Eq 2})$$

The second equation (Ito-Besseyo) has smaller coefficients for the substitutional solutes compared with the IIW equation. This is, as already stated, because at low carbon concentrations the kinetics of transformation are more sensitive to carbon content than to substitutional solutes.

Relating Weld-Metal Toughness to the Microstructure. A good insight into the subject of toughness in ferrite steel weld metal is obtained by examining the data shown in Fig. 29. It is seen from Fig. 29(a) that the upper-shelf Charpy V-notch (CVN) energy

monotonically decreases with an increase in oxygen content. In the upper-shelf temperature region, ductile fracture occurs by a process of microvoid coalescence, and because microvoids are initiated at the inclusion-matrix interface, the upper-shelf impact energy decreases with an increase in the inclusion content. In contrast, from Fig. 29(b) it is seen that an optimal inclusion content is required to obtain the lowest CVN transition temperature. The transition temperature is governed mainly by cleavage fracture, which in turn depends on how effectively a propagating cleavage crack is forced to change direction as it traverses the microstructure. At low inclusion contents, an upper bainitic structure is obtained, consisting of parallel platelets of ferrite (in a single packet) growing from the grain-boundary surfaces. With an optimal inclusion content, a predominantly acicular ferrite structure is obtained, in which the adjacent ferrite platelets tend to radiate in many different directions from the inclusion nucleation site. At higher inclusion contents, the amount of ferrite side plate structures increases, again having nearly parallel ferrite platelets. The highest toughness (that is, the lowest transition temperature) is obtained only in the “chaotic” microstructure of acicular ferrite, because it has the smallest effective ferrite grain size.

In recognition of the latter fact, most of the work in consumables development in the recent past has concentrated on increasing the amount of acicular ferrite in the microstructure. In line with the trends shown in Fig. 26(a) and (b), it has been found that decreasing the amount of grain-boundary ferrite and ferrite side plate structures increases the acicular ferrite content. This is shown more clearly in Fig. 30.

Recent work (Ref 30, 31, 33–35), however, has shown that a 100% acicular ferritic structure is neither desirable nor, in most cases, achievable. Figure 31(a), for example, shows that, depending on the weld metals, the maximum amount of acicular ferrite (~70 to 80%) is achieved at different oxygen concentrations. The acceleration of CCT diagrams owing to oxygen in the weld metal (Fig. 32) is consistent with the decrease in weld-metal hardness shown in Fig. 31(b). The role of oxides in providing additional heterogeneous nucleation sites is indicated by the fact that both bainite and ferrite regions are accelerated as the oxygen content is increased (Ref 35). In other words, the hardenability of the weld is lowered as the oxygen is increased. Figure 33 shows that the impact toughness peaks at approximately 70% acicular ferrite. This phenomenon was attributed to the formation of segregated bands of brittle microphases in the alloy compositions giving the highest acicular ferrite contents. Moreover, when the alloying additions are increased still further, the transformation behavior becomes such that allotriomorphic

ferrite formation is totally suppressed, leaving the γ grain boundaries free to nucleate upper bainite at lower temperatures (Fig. 26c). It appears that a small layer of allotriomorphic ferrite is essential to obtain high acicular ferrite contents. When it forms, it saturates the γ grain-boundary sites, and bainite nucleation at the γ/α -allotriomorphic interface is inhibited by the high carbon content there as a result of its rejection from the ferrite (Ref 30). Conditions are then favorable for intragranular nucleation at inclusion sites and thus the formation of acicular ferrite.

For the welding of steels with yield strengths less than 600 MPa (85 ksi), it has been possible to develop weld metals with matching strength and toughness by giving them high acicular ferrite contents. A yield strength of approximately 600 MPa (85 ksi) seems to be the ceiling for weld metals based on acicular ferrite. Attempting to obtain additional strength by additional alloying to increase the amount of solid-solution hardening and precipitation hardening, in fact, results only in increasing amounts of martensite and bainite, structures that are associated with a lower toughness. This phenomenon was observed in HSLA-100 steels, for example, where attempts to obtain a matching strength in the weld metal resulted in a drop in toughness (Ref 31, 37). It should be noted that a slightly undermatching weld metal (in terms of strength) appeared to be favorable. Thus, the already available lower-strength, high-toughness consumables having high acicular ferrite contents can be used for high-strength steels (Ref 38). These weld-metal compositions have an additional benefit in that they do not require the most stringent measures for avoiding hydrogen-induced cracking. Work on consumables development for high-strength steels is still in progress to match the base metal in strength and toughness (Ref 38–41).

Titanium Oxide Steels. In the discussion of the role of pinning by precipitate particles (for example, TiN) in limiting grain growth in the HAZ (in the section “Austenite Grain Growth and Grain-Boundary Pinning” in this article), it was pointed out that at high heat inputs, the particles dissolve and are not able to prevent coarse γ grains from forming. The low toughness in these coarse-grained regions is of some concern. The fact that a coarse γ grain size will lead to a higher acicular ferrite content (Fig. 26b) with improved toughness has been used to advantage in the development of titanium-oxide-containing steels (Ref 42, 43). The compound Ti_2O_3 is more stable than titanium nitride and does not dissolve, even at the highest heat inputs. The undissolved Ti_2O_3 particles do not stop grain growth, but their survival after the heating cycle means that they can be effective in nucleating acicular ferrite within the coarse γ grains. The precise

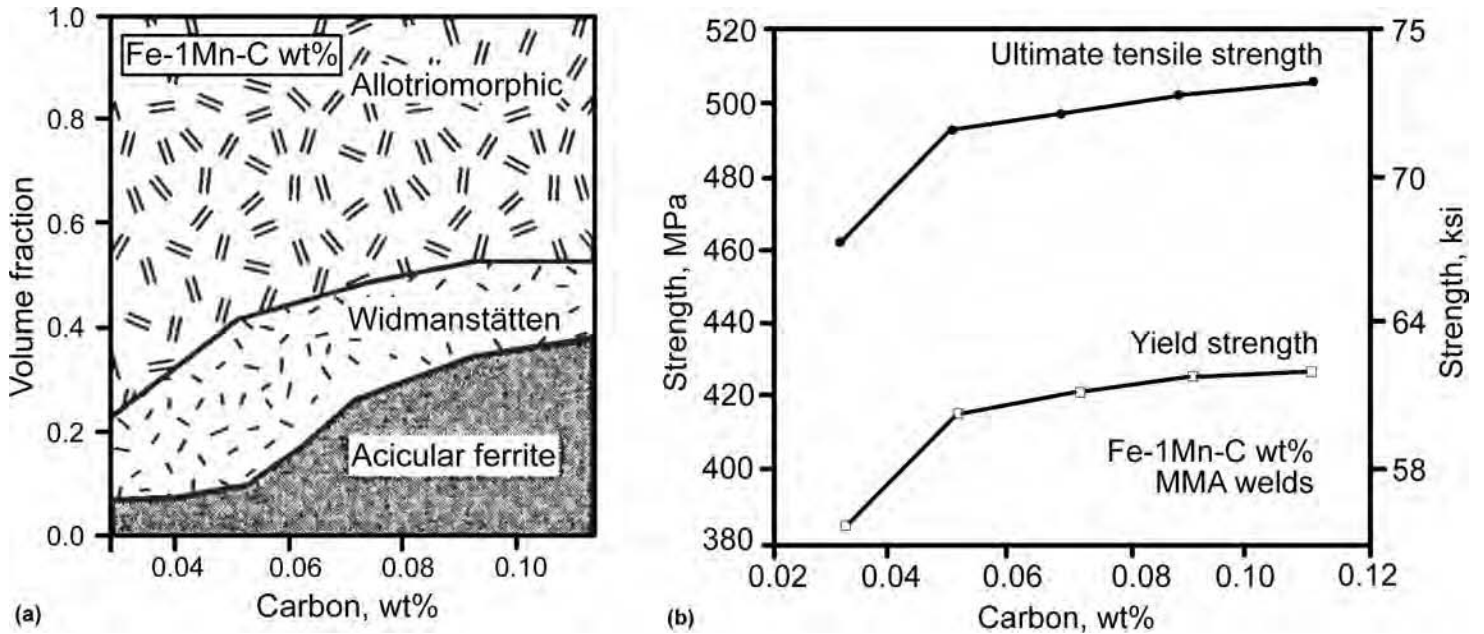

Fig. 28 Calculated variations in (a) microstructure (Ref 5) and (b) mechanical properties (adapted from Ref 5) as a function of carbon concentration in an Fe-1Mn-C wt% steel weld deposit using manual metal arc (MMA) welding (1 kJ/mm^{-1})

reasons why they are more effective than other undissolved inclusions (such as Al_2O_3) in nucleating acicular ferrite are not well understood (Ref 30). The improved HAZ microstructure and toughness obtained with titanium oxide steels over titanium nitride steels at high heat inputs are shown in Fig. 34 and 35, respectively.

Effect of Transformations on Transient Weld Stresses. The effect of transformations on weld stresses (and vice versa) is best illustrated by an old experiment known as the Satoh test (Ref 46). The method involves the cooling of a rigidly constrained steel tensile test sample from its austenitic state. During the test, the stress that accumulates is monitored. For uniaxial specimens using a HAZ simulation technique, the manner in which residual stress is accumulated during a weld thermal cycle was investigated for bainitic, martensitic, and stable austenitic steels (Ref 47). Initially, when a material is austenite at high temperature, its yield strength is low and only a small tensile stress can develop. On cooling, the tensile stress increases. When a phase transformation occurs, the resulting volume expansion opposes the contraction due to cooling and decreases the stress. When the transformation is complete, the tensile stress increases again (Fig. 36). As seen in Fig. 36, if the transformation occurs at a lower temperature (for example, in the case of 9CrMo steel), the magnitude of the final residual stress is less.

In contrast, the nontransforming austenitic steel exhibits a continuous increase in residual stress with decreasing temperature because of the thermal contraction of the constrained specimen. Moreover, the thermal expansion coefficient of austenite ($1.8 \times 10^{-6} / \text{K}$) is much larger than that of ferrite ($1.18 \times 10^{-6} / \text{K}$), and yet the slope of the line prior to transformation is smaller when compared with that after transformation is complete (Fig. 36) (Ref 48). This is because, at high temperatures, austenite has a low yield strength and can accommodate the thermal contraction by yielding. Ferrite is strong at low temperatures, so the slope of the stress/temperature curve is steeper.

By engineering the temperature regime over which phase changes occur, the pronounced effect of volume and shear strains of displacive transformation can be exploited to mitigate the development of welding residual stresses. In recent years, welding consumables with low austenite-to-martensite transformation temperatures (M_s) have been developed (Ref 49–51). By using the proposed welding electrodes that achieve M_s at or under 200°C (390°F) and martensite finish temperatures close to room temperature, it is possible to achieve near-zero or compressive residual stresses in the weld, as shown in Fig. 37. It has been shown that the fatigue limit of joints using the new low- M_s welding wire has been improved significantly (Ref 50). It should

be mentioned that the weld metal with fully martensitic structure is susceptible to hydrogen-induced cracking (HIC). This problem can be addressed by the use of a duplex martensite/retained austenite weld microstructure. Austenite can contribute by increasing the toughness and by minimizing the risk of HIC, because of the lower hardness and the higher hydrogen solubility of austenite compared to martensite. It has been shown that the resistance to cold cracking can be improved when the weld contains martensite with a small amount of retained austenite (Ref 41).

Heat-Affected Zone in Multipass Weldments

In the HAZ of a single-pass weld, the grain-coarsened zone (GC HAZ) is normally the region having the lowest toughness. Turning to a multipass weld, Fig. 38 (compare with Fig. 4) shows how the GC HAZ can be modified by subsequent passes and can be categorized into four regions, depending on the reheating temperature (Ref 52):

- *Subcritically reheated grain-coarsened (SCGC) zone:* The zone reheated below A_{c1}
- *Intercritically reheated grain-coarsened (ICGC) zone:* The zone reheated between A_{c1} and A_{c3}

Fig. 29 Typical variation of selected weld-metal properties with oxygen content in ferritic steel weld metals. (a) Plot of Charpy V-notch (CVN) impact test upper-shelf energy versus oxygen content. (b) Plot of CVN transition temperature versus oxygen content. HAZ, heat-affected zone. Source: Ref 33

- *Supercritically reheated grain-refined (SCGR) zone:* The zone reheated above A_{c3} and below approximately 1200 °C (2190 °F)
- *Unaltered grain-coarsened (UAGC) zone:* The zone that is not reheated above approximately 200 °C (390 °F) or the zone that is again reheated above approximately 1200 °C (2190 °F)

Figure 39 shows how the crack tip opening displacement (CTOD) value of simulated specimens varies with the peak temperature of the second thermal cycle, T_{p2} ($T_{p1} = 1400$ °C, or 2550 °F). It is seen that the ICGC, UAGC, and SCGC regions have CTOD values less than approximately 0.1 mm (0.004 in.). Similar low values have been obtained by locating the crack tip in the CTOD tests at corresponding locations in the HAZ of actual multipass weldments. These low-toughness regions are commonly known as local brittle zones (LBZs).

Fig. 30 Effect of manganese content of weld metal on the relative amounts of the microstructural constituents present. Carbon content maintained at 0.03%. Source: Ref 33

The low CTOD values have been obtained only in tests on modern structural steels, and no actual structural failure attributable to the LBZs has been reported so far (Ref 53). Because the structural significance of the low-toughness test results is still largely unresolved, the present conservative strategies are to choose a steel whose tendency to form LBZs is less and to choose a welding procedure by which the size of the LBZs can be reduced.

The ICGC HAZ usually has a lower toughness than the SCGC or UAGC regions, even though all of them have nearly the same γ grain size. This lower toughness is due to the higher amount of high-carbon martensite-austenite (M-A) constituent in the ICGC HAZ. When the GC HAZ is reheated to a temperature between A_{c1} and A_{c3} , austenite is nucleated at the high-carbon areas. Upon cooling, these local high-carbon areas can transform to give twinned martensite with very thin regions of retained austenite in between. (See Ref 54 for detailed metallographic procedures for identifying the M-A constituent.) The carbon content in the M-A islands can range from approximately 0.3 to 0.5% C. The significance of this is that, for a given nominal carbon content in the steel, the volume fraction of the M-A constituent will be much higher than it would be if most of the carbon formed carbides (by the lever rule). This fact will increase the number of crack nucleation sites and thereby contribute to the inferior toughness of ICGC HAZ. As is to be expected, the volume fraction of the M-A constituent also depends on the hardenability of the steel, which, in turn, depends on the alloying content. It has been shown that if the development of pearlitic microphases could be promoted instead of the development of M-A, by decreasing the alloy content, the toughness of the ICGC HAZ could be improved (Ref 55). However, this would have penalties in terms of achievement of parent plate strength. A more feasible solution would be to inhibit grain growth in the HAZ.

The multipass welding procedure can alternatively be controlled to limit the size of the LBZs. Figure 40 shows how this can be done with a tandem three-wire high-current gas metal arc welding procedure by adjusting the distances between the three arcs. Special “temper-bead” procedures (Ref 57) have been developed for controlling the microstructure in the HAZ, and a need for these procedures arises in the following way. Low-alloy steel weldments for critical applications (for example, pressure vessels) require a postweld heat treatment (PWHT) in a furnace in order to temper the hard regions in the HAZ and relieve

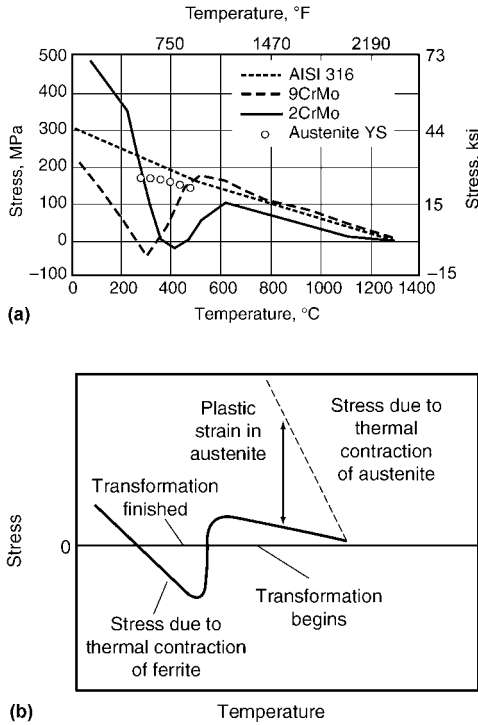

Fig. 36 (a) Axial stress accumulated in uniaxially constrained specimens during cooling of martensitic (9CrMo), bainitic (2CrMo), and austenitic (AISI 316) steels. Some experimental data are shown for yield strength (YS) of austenite in low-alloy steel. Adapted from Ref 47. (b) Schematic interpretation of the experiments shown in (a). Source: Ref 48

residual stresses. If on-site repairs become necessary after the component has been in service, PWHT is usually not feasible. The heat of the arc can then be used to achieve the tempering function of PWHT by suitable spatial positioning and sequencing of the individual passes. Grain refinement in the HAZ is also sought in order to increase the toughness and thereby offset the harmful effects of residual stresses that would remain in the absence of PWHT.

An example of a two-layer temper-bead procedure is shown in Fig. 41. The heat inputs of the first and second layer are carefully controlled, so that the heat from the second layer is used to refine the coarse-grained region in the HAZ of the base metal caused by the first layer. This idea can be extended one step further by using a pulsed gas tungsten arc welding procedure in which each pulse in a pulsed weldment successively refines and tempers the preceding pulse pitch region (Ref 11). The degree of microstructural refinement depends primarily on the welding speed and pulsing frequency, and these parameters can be controlled with great precision. In contrast,

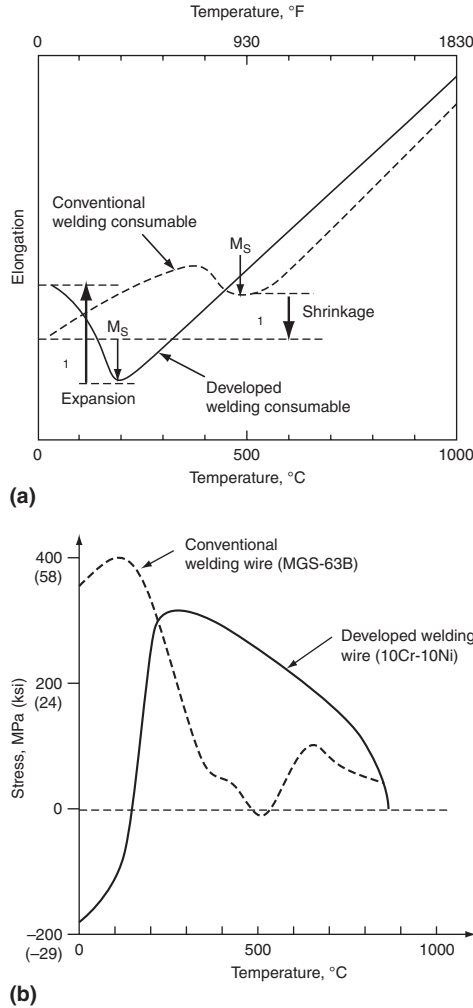

Fig. 37 Comparison between the low-transformation-temperature welding consumable and conventional steel wire. (a) Transformation strain developed during unconstrained cooling of welding

an important variable to be controlled in the temper-bead procedure is the weld-deposit height, and it is difficult to exercise the same degree of control on this variable. For this reason, it is argued that the maximum possible control on the microstructural changes in the repair weldment is possible with the pulsing procedure.

Fusion Zone in Multipass Weldments

In the weld metal of a multipass weld, reheating effects will lead to a gradient in microstructure similar to that in the HAZ. However, instead of a detailed classification, the multipass weld metal is usually considered to consist of just two regions (Fig. 42):

- *As-deposited or primary region:* Where the microstructure develops as the weld cools from the liquid phase to ambient temperature
- *Reheated or secondary region:* Where regions with the original primary microstructure are reheated to temperatures above the A_{c1} temperature. The tempered regions that are reheated to slightly lower temperatures are also generally considered to belong to this category.

The properties of the weld metal depend on the relative areas or volume fractions of the two regions, which, in turn, depend on the welding procedure; the properties are therefore procedure-specific. That is why it is necessary for welding procedures to be qualified according to codes and standards in addition to and separately from the qualification of consumables (for which a standard procedure is specified).

Weldments in Select Alloy Systems

Stainless Steels

It has long been known that solidification cracking can be avoided in austenitic stainless steel welds by having a small concentration of ferrite in them. Recent work has shown, however, that residual ferrite content at room temperature is no more than a symptom and that it is really the solidification mode (whether the weld metal solidifies as primary austenite or ferrite) that is the decisive criterion (Ref 58). It has been found that susceptibility to solidification cracking is least for a primary ferrite solidification mode (more specifically, when the solidification mode corresponds to the types shown in Fig. 43c and d). It is believed that low-melting-point liquid phases (formed by the segregation of impurities such as sulfur and phosphorus, for example) solidifying in the intercellular regions do not wet the δ - γ interphase boundaries as easily as they would δ - δ or γ - γ boundaries. In the ferritic-austenitic solidification mode (Fig. 43c, d), the δ - γ interphase boundary area is greater at temperatures just below the nominal solidus temperature, and this is the reason for a greater resistance to solidification cracking.

Information about the solidification mode can be obtained from the chemical composition of the weld metal by referring to the WRC-1992 diagram (Fig. 44a). It has been found that this diagram is more accurate than the Schaeffler (for duplex stainless steel welds) and Delong (for 300-series austenitic steel welds) diagrams developed earlier. These diagrams are strictly applicable only for the cooling rates obtained in manual metal arc (MMA) welding because the data for establishing the statistical correlations have been taken from MMA welds. The dotted lines in Fig. 44 are the demarcation

lines between the different solidification modes shown (that is, A, AF, FA, and F), corresponding to the types in Fig. 43(a to e), respectively. The AF-FA boundary in Fig. 44(a) (which, as discussed earlier, corresponds to the onset of cracking) intersects the iso-ferrite number lines at an angle. This is consistent with the findings of several investigators that the minimum ferrite content necessary to avoid hot cracking is different for different weld-metal compositions (that is, for weld metals deposited with E 316, E 308L, E 309, and so on).

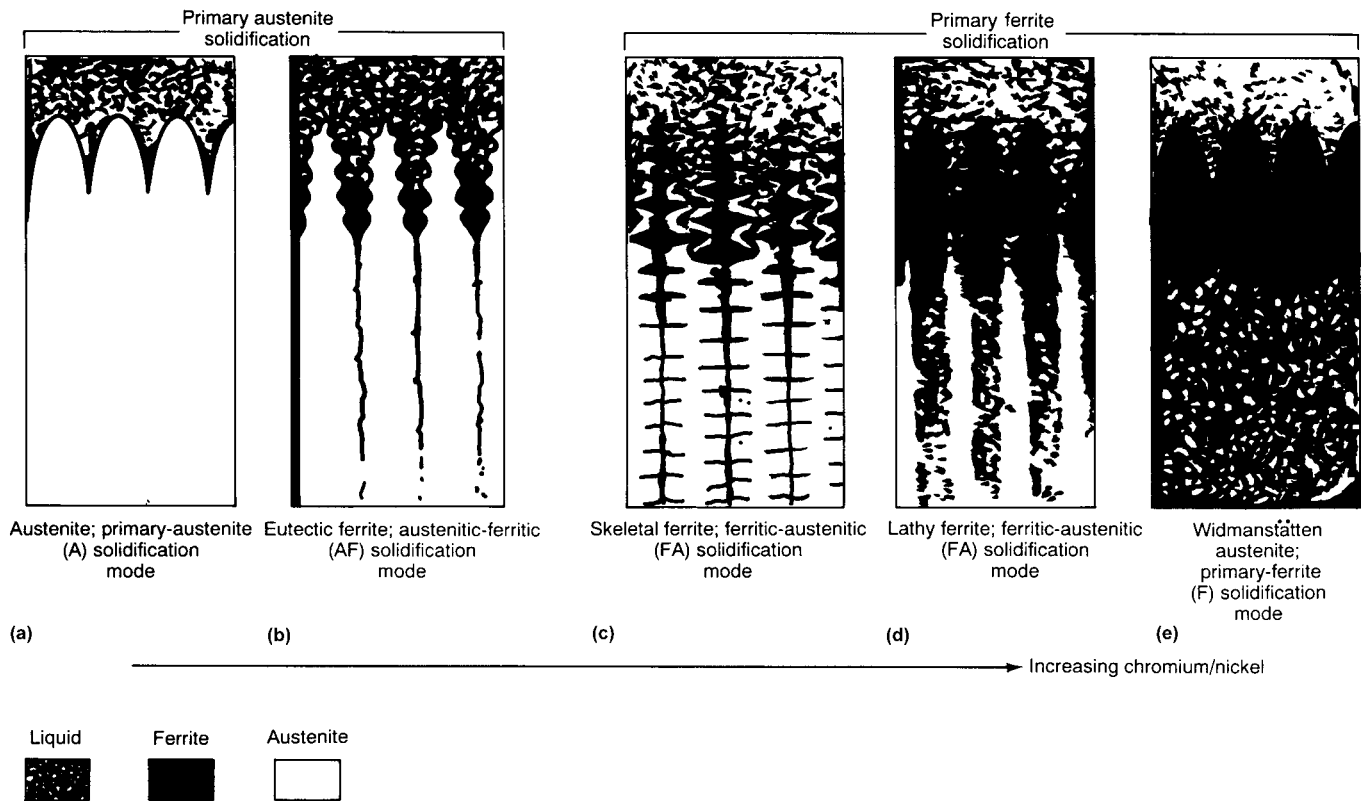

Fig. 43 Schematic showing solidification and transformation behavior resulting in a range of ferrite morphologies in austenitic stainless steel welds. Source: Ref 58

The utility of the WRC-1992 diagram has recently been expanded by adding martensite boundaries (Ref 60), as shown in Fig. 44(b). Using the modified WRC-1992 diagram, it is now possible to predict whether or not stainless steel clad layers, over nonalloy or low-alloy steel, will be free of martensite and will pass a 2T bend test (a bend test in which the bend specimen thickness, T , is twice the bending radius).

A discussion of weld decay due to sensitization and knife-line attack in the HAZ of austenitic stainless steels can be found in Ref 7, 61, and 62.

Aluminum Alloys

The main problems in the welding of heat treatable aluminum alloys are liquation cracking in the partially melted zone (PMZ) (see the section "Unmixed and Partially Melted Zones in a Weldment" in this article) and softening in the HAZ (Ref 7). Figure 45 shows, for example, the formation of liquation cracking in the PMZ of an aluminum alloy weld with partial penetration. A good discussion of how liquation cracking forms in aluminum alloys is found in Ref 63.

The softening in the HAZ means that the weld-joint strength can be reduced. Reasons for the softening can be understood by referring to Fig. 46. The parent material is assumed to be a 2000- or 6000-series aluminum alloy, artificially aged to contain the metastable phase of θ' (in aluminum-copper alloys), S' (in aluminum-copper-magnesium alloys), or β' (in aluminum-magnesium-silicon alloys). A very fine dispersion of precipitate particles is obtained in the parent material by a solution heat treatment followed by aging, and this is the reason for the high strength in the materials. Figure 46(b) shows that a gradient in hardness is obtained in the HAZ immediately after welding. At location 1, the high peak temperature causes the precipitate particles to go into solution, and the cooling rate is too high for reprecipitation. At locations 2 and 3, the precipitate particles partially dissolve and coarsen. After postweld artificial aging, fine precipitate particles are again formed at location 1, causing the hardness to increase to the level of the parent material. However, at locations 2 and 3, only a lower hardness can be obtained because of the formation of coarse precipitate particles. For increasing weld heat

inputs, the width of the softened zone increases. A good discussion of how the aforementioned phenomenon can be modeled is found in Ref 64.

Nickel-Base Superalloys

The high creep resistance of nickel-base superalloys makes them attractive for critical high-temperature applications such as gas turbines. Yet, it is this very characteristic that gives rise to the problem of strain age cracking in the weld HAZ (Ref 7, 24, 65). The high-temperature creep strength in the parent materials is obtained by forming fine precipitates of γ' ($\text{Ni}_3(\text{Al}, \text{Ti})$) or γ'' (Ni_3Nb) in them. In the region of the weld HAZ subjected to high peak temperatures, these precipitates dissolve, much as they do in aluminum alloys. After welding, the weldments are again solution heat treated and aged (note the difference between aluminum alloys and the nickel-base superalloys in this respect). The purposes of this treatment are to obtain the same uniform fine precipitation in the weld as in the parent material and to relieve the weld residual stresses.

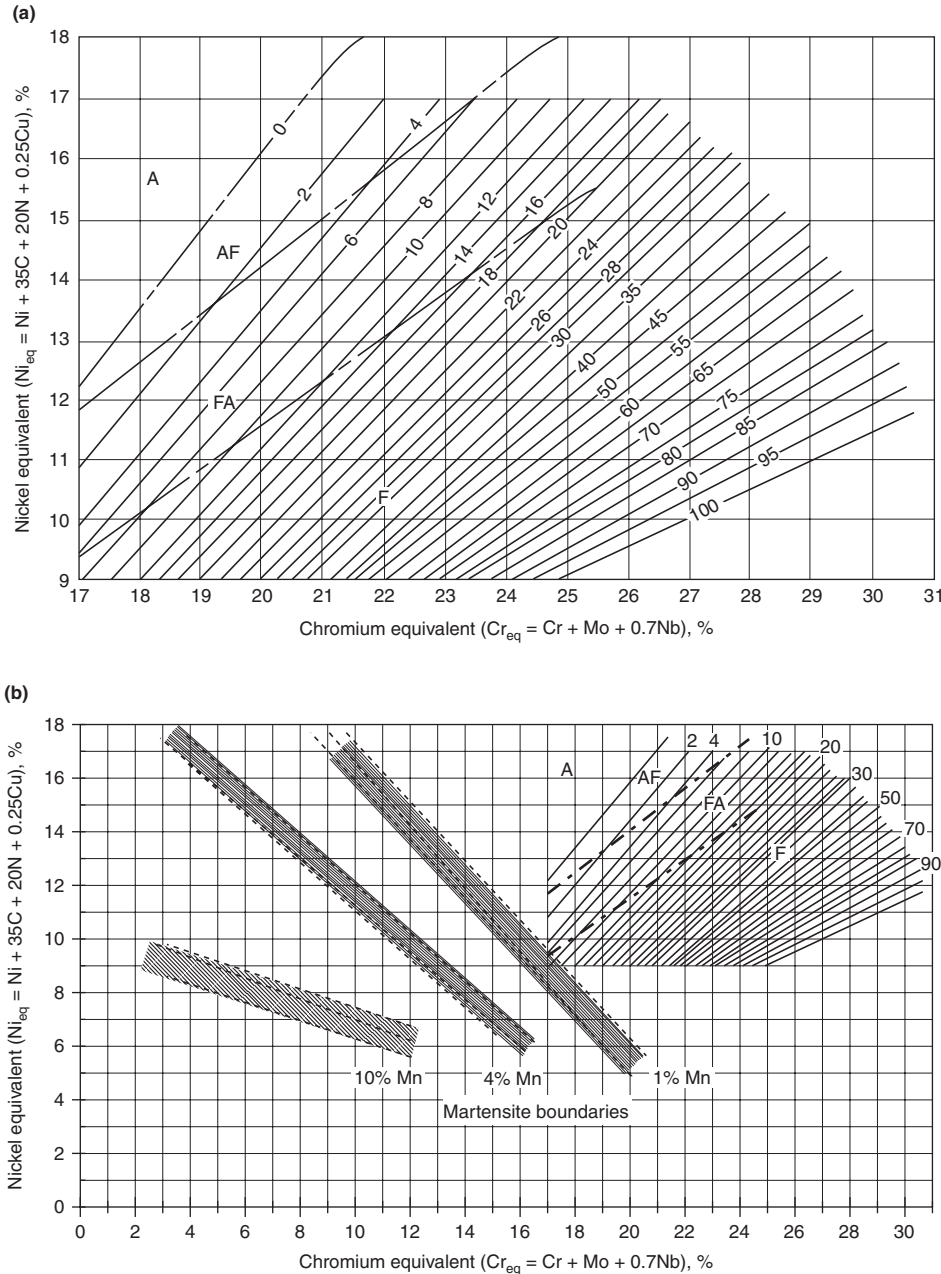

Fig. 44 (a) WRC-1992 diagram predicting ferrite content in stainless steels. Ferrite content is given by the ferrite number (FN), where 100 FN is approximately equal to 65 vol% ferrite. Boundaries denoting a change in solidification mode (A, AF, FA, and F in accordance with Fig. 43) are also shown (indicated by dotted lines). Source: Ref 59. (b) WRC-1992 diagram with martensite boundaries for 1, 4, and 10% Mn. Source: Ref 60

Normally (for example, in the case of low-alloy or carbon steel welds), PWHT in a furnace relieves the residual stresses because the yield stress at the PWHT temperature is very low. A residual stress greater than the yield stress cannot be supported, and stress relief is achieved by a process of creep and plastic deformation. This process is difficult in nickel-base superalloy weldments, however, because of their high creep strength and low creep

ductility. Reprecipitation in the solutionized regions of the HAZ (during the heating-up to the PWHT temperature) strengthens the matrix and does not allow any creep or plastic deformation (necessary for the relief of residual stress) to take place. Cracking can occur in this condition at the grain boundaries in the grain-coarsened region of the HAZ. Cracks initiated here have been known to run far into the base material. Figure 47 shows the development of

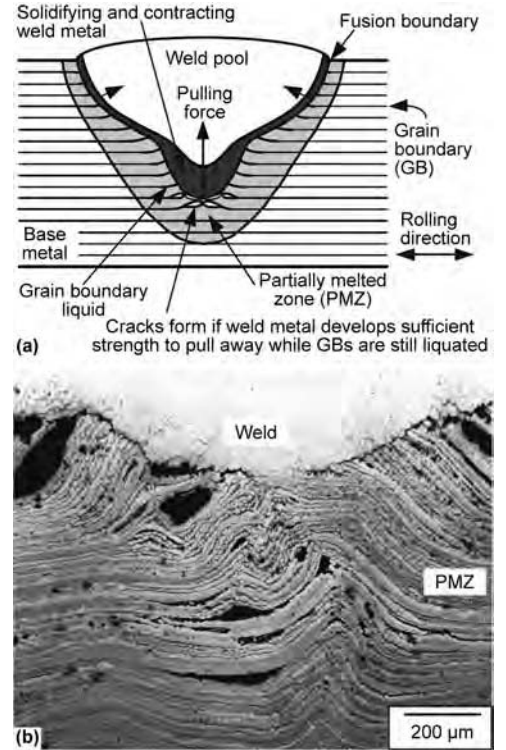

Fig. 45 Weld metal pulling and tearing the partially melted zone (PMZ). (a) Schematic showing the formation of liquation cracking in the PMZ of a partial-penetration gas metal arc weld of an aluminum alloy. The welding direction is perpendicular to the rolling direction. The weld metal in the papillary penetration solidifies rapidly. This pulls the PMZ that is weakened by grain-boundary (GB) liquation. (b) Microstructure near the weld root of 7075 aluminum made with filler wire of aluminum 1100. The weld metal pulls and tears the PMZ near the tip of the papillary penetration. Source: Ref 63

PWHT cracking. This problem is very difficult to solve, and the best solution has been found to be to switch over to materials such as Inconel 718 alloy that are inherently less susceptible to cracking, even though their creep strength is somewhat lower. Inconel 718 alloy contains γ'' precipitate, and the slow kinetics of precipitation in this alloy allow substantial stress relief to be achieved before precipitation increases the creep strength in the HAZ.

A more detailed discussion of the welding metallurgy and weldability of nickel-base superalloys can be found in Ref 24, 65, and 66.

Titanium Alloys

Titanium alloys find use in aerospace applications, pressure vessels, and so on because of their high strength-to-weight ratio, high corrosion resistance, and high fracture toughness. Pure titanium has two allotropic forms: low-temperature hexagonal close-packed (hcp) α phase and elevated-temperature body-centered

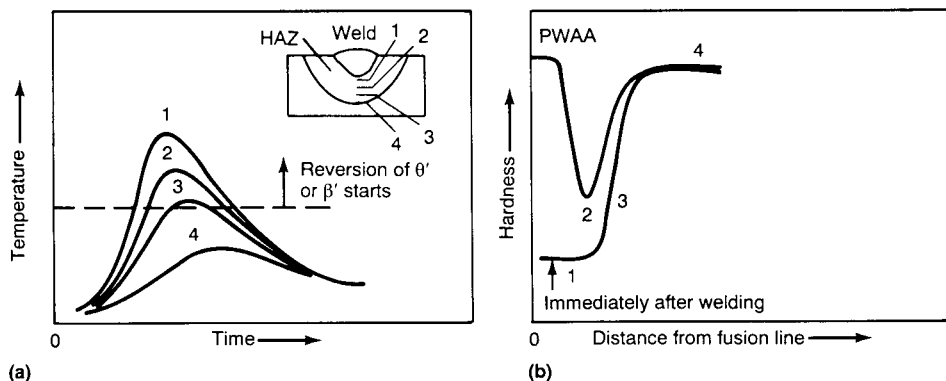

Fig. 46 Schematics showing the effect of weld thermal cycles on the softening in the heat-affected zone (HAZ) in age-hardenable aluminum alloys. cubic (bcc) β phase. Various alloying elements preferentially stabilize one or the other of these phases. As a result, titanium alloys are generally classified as α , $\alpha + \beta$, metastable β , and β alloys (Fig. 48).

The α alloys are not heat treatable (that is, it is not possible to obtain a significant increase

in strength and toughness by heat treatment), and they have the lowest strength of the four titanium alloy families. Interestingly, these alloys are thus considered to have excellent weldability—which means, in practice, that the weld thermal cycles cause no significant degradation in the properties of the weld and

HAZ relative to the parent material. Also, the $\beta \leftrightarrow \alpha$ transformation in the weld and near HAZ means that the extent of grain coarsening will not be as high as in other single-phase materials in which no phase transformation occurs upon heating or cooling, such as stabilized ferritic stainless steels (Ref 68), pure aluminum, and so on.

In the $\alpha + \beta$ alloys, a higher strength is obtained with a higher volume fraction of the β phase, which, in turn, is obtained with a higher β -stabilizing alloy content (Fig. 48). The effect of cooling rate on the phase transformations in two $\alpha + \beta$ alloys is shown schematically in Fig. 49. As in the case of steels, it is seen that the $\beta \leftrightarrow \alpha$ transformation can occur either by nucleation and growth at slower cooling rates or martensitically at higher cooling rates. The martensitic product in the lean $\alpha + \beta$ alloys has an hcp crystal structure (designated as α') or an orthorhombic one (designated as α'') in the β -stabilized $\alpha + \beta$ alloys. It is seen that the C-curve for the $\beta \leftrightarrow \alpha$ intergranular transformation is shifted to the right for alloys with increasing β -stabilizing alloy content, while that for the allotriomorphic α (more commonly referred to as grain-boundary, or GB, α) is relatively insensitive to alloy concentration (Ref 69). As a result, alloys that are fairly rich in β -stabilizing additions exhibit a stronger tendency to form a continuous network of GB α than do leaner $\alpha + \beta$ alloys.

The morphology of the α and β phases in the $\alpha + \beta$ base materials is strongly dependent on thermomechanical processing (TMP) and heat treatment, which are performed either in the β -phase field or in the two-phase $\alpha + \beta$ -phase field. When TMP is done in the $\alpha + \beta$ -phase field, the α that forms on cooling is continuously deformed. After recrystallization, a near-equiaxed α structure is obtained. Very little GB α is formed, because deformation introduces sufficient alternate heterogeneous nucleation sites in the form of dislocations. On the other hand, if TMP is done above the β -transus temperature (β -processing) and cooled, α forms at grain boundaries (giving GB α) and in the interior of grains as a Widmanstätten structure (also referred to as an acicular, lenticular, or basketweave structure). The microstructure in the weld and near the HAZ is closer to that obtained after β -processing.

Figure 50 shows the effect of $\alpha + \beta$ -processing and β -processing on the strength and toughness of $\alpha + \beta$ alloys with increasing β -stabilizing alloy content. At the lower strength levels obtained with a lower β -stabilizing alloy content (because of a lower volume fraction of β -phase present), the finer Widmanstätten structure obtained after β -processing has a higher toughness than the coarser structure obtained by $\alpha + \beta$ -processing. At

Fig. 48 Hypothetical β isomorphous phase diagram that shows relation between β -stabilizer solute content and titanium alloy family description. Selected common alloys are listed along the x-axis of the diagram based on their compositions. Source: Ref 67

higher strength levels, the trend reverses, with the $\alpha + \beta$ -processed structure having a higher toughness. This result can be understood in terms of the strength differences between GB α and the interior of the prior- β grains (Fig. 51). At lower strengths, when the grain interiors are relatively weak, the crack tip plastic zone is distributed between the GB α and the grain interiors. However, as the α -phase precipitates are refined by lower aging temperatures, as in the case of the metastable β alloys, the grain interiors are strengthened considerably. Under such circumstances, the cracks are essentially constrained to follow the GB α layer. This results in a contraction of the plastic zone, a reduction in the crack tip opening displacement for crack extension, and an attendant drop in the toughness.

The microstructures in the weld metal and the near HAZ (the region where the peak temperature exceeds the β -transus temperature) resemble those obtained after β -processing. This means that it is easier to obtain a matching toughness in the weld metal at the lower strength levels referred to in Fig. 50. However, even this result is made somewhat difficult to achieve by the coarser β grain size in the weld and HAZ. Grain coarsening in the HAZ induces coarse β grains to form in the weld too, because solidification in the weld metal occurs by epitaxial growth from the HAZ. The extent of grain coarsening is such that it is not uncommon to find a single columnar β grain traversing the entire thickness in gas tungsten arc welds on thin sheet (Ref 70). If high-energy-density welding processes are used (for example, electron beam welding or laser beam welding), it is possible to limit the extent of β grain coarsening. However, the high cooling rates in

Fig. 49 Schematic continuous cooling transformation diagrams for two $\alpha + \beta$ titanium alloys with different β -stabilizer solute contents. (a) Lean $\alpha + \beta$ alloy (for example, Ti-6Al-4V). (b) $\alpha + \beta$ alloy (for example, Corona 5 [Ti-4.5Al-5Mo-1.5Cr]) richer in β -stabilizing solute content. GB, grain boundary

Fig. 50 Schematic plot of toughness versus yield strength for $\alpha + \beta$ - and β -processed structures. Approximate locations of lean (for example, Ti-6Al-4V) and richer β -stabilized $\alpha + \beta$ alloys (for example, Corona 5 [Ti-4.5Al-5Mo-1.5Cr]) are shown. GB, grain boundary. Source: Ref 69

the weld and HAZ will mean that a martensitic structure will be obtained.

To obtain adequate ductility and toughness, PWHT must be performed at temperatures close to the β -transus temperature. This can be a problem because the low strength at these

temperatures can cause sagging in large welded structures, and complex fixturing will be necessary to maintain dimensional tolerances. It can also be expensive, because inert gas shielding is required for almost the entire time of PWHT. (It is assumed in the present discussion that adequate care is taken to maintain proper shielding during welding.) Moreover, it can be difficult to increase the ductility in the weld metal and HAZ to a level equal to that in an $\alpha + \beta$ -processed base material (Fig. 52). The trends seen in Fig. 50 and 52 can be understood by noting that crack nucleation is more difficult in an equiaxed structure (because the strain concentration effects are less) and that the

plastic zone sizes are bigger (Table 2). This results in a higher tensile ductility. However, because crack propagation follows a less tortuous path, the toughness is lower. The reverse is true for a Widmanstätten structure (referred to as a lenticular structure in Table 2). Table 2 explains the apparently strange observation in titanium alloys that a structure having a high strength and toughness is not necessarily the one having a high tensile ductility. The implication of this observation for weldments is that, for many applications, it may be more important to optimize the welding and PWHT procedure with respect to the toughness than with respect to the ductility.

A more detailed discussion of the welding metallurgy of titanium alloys can be found in Ref 70, 72, and 73.

ACKNOWLEDGMENTS

The author would like to express his sincere gratitude to Professor Emeritus Horst Cerjak, Graz University of Technology, Austria, for the opportunity to contribute to this article and for his constant support and encouragement. The author would also like to thank Professor Bruno Buchmayr, University of Leoben, Austria, and Professor Sudarsanam Suresh Babu, The Ohio State University, for their encouragement.

Thermomechanical Effects of Fusion Welding

P. Michaleris, Pennsylvania State University

APPLICATION OF WELDING in fabricating large structures offers several advantages over mechanical joining methods, such as improved structural performance, weight and cost savings, and flexibility of design. However, welding induces residual stresses and distortion, which may result in loss of dimensional control, costly rework, and production delays. Welding may also introduce such defects as inclusions and lack of penetration, leading to reduced fatigue life.

Modeling of welding distortion and residual stress has been an active research area since the late 1970s. Some of the first publications in weld modeling include Ref 1 to 3. Significant research in the 1980s includes the development of the double-ellipsoid heat-input model by Goldak et al. (Ref 4) and the modeling of phase transformations (Ref 5–7). Most of the weld modeling in the 1970s and 1980s involved two-dimensional (2-D) models transverse to the welding direction using either plane-strain or generalized plane-strain conditions. These models demonstrated good correlations with experimental measurements for residual stress. However, these models were not capable of predicting the magnitudes of angular distortion (Ref 8) or of longitudinal buckling and bowing (Ref 9). Developments in weld modeling in the 1990s included the use of three-dimensional (3-D) moving-source models (Ref 10–12), the development of sensitivity formulations (Ref 13, 14), and the development of the applied plastic strain method (Ref 9, 15, 16). The 3-D moving-source models demonstrated the capability to model all distortion modes.

A detailed review of finite-element modeling for welding residual stress and distortion modeling is available in Ref 17 to 20. Typically, modeling of welding residual stress and distortion involves one-way coupled thermomechanical analyses. In thermal analysis, conductive heat transfer is considered through the use of empirical models that provide values for the applied welding heat input. Some researchers, in order to consider the effect of the convective heat flow in the molten metal, have used

artificially high thermal conductivity values for temperatures that exceed the melting point (Ref 11). However, this approach may lead to slower numerical convergence. In mechanical analysis, rate-independent elastoplastic material response is considered, using the results of the thermal analysis as thermal load. Both thermal and mechanical analyses are typically performed using the finite-element method in a Lagrangian reference frame. Although thermoelastoplastic modeling of welding is reportedly providing computed values of residual stress that agree closely with experimental measurements (Ref 15, 17–19), it is difficult to correlate the computed and measured fusion zones, especially for high-energy-intensity processes such as laser and hybrid welding (Ref 21–23).

Formation of Residual Stress: Three-Bar Analogy

The three-bar analogy is commonly used to illustrate the formation of welding residual stress. Figure 1 illustrates three bars of equal length connected at the ends. The shade of the bars correlates to their temperature, with dark representing hot and light representing cold.

The symbol S denotes their stress state. For thin plates, the stress correlates to the longitudinal stress component, and the middle bar corresponds to the welding region. The middle bar is considered to have a smaller diameter than the side bars, which correspond to the remaining part of the plate. Before welding, all bars are at room temperature and under zero stress (Fig. 1a). When the middle bar is heated (Fig. 1b), it expands and pulls along the side bars. The middle bar is under compression and the side bars are in tension. If the temperature is high, as in welding, the yield strength of the material drops, and the middle bar permanently deforms due to plasticity. When the middle bar returns to room temperature, it contracts. If the bar had not been connected (Fig. 1c) at room temperature, it would now be shorter than the side bars due to plastic deformation. However, because it is connected (Fig. 1d), it pushes the side bars into a state of compression. The middle bar is now in tension. Therefore, after welding, the welding region is expected to be in tension and the base material in compression. Figure 2 illustrates the computed temperatures and corresponding longitudinal stress across a plate before, during, and after welding (Ref 24). Before welding, the plate has zero stress. During welding, the welding region (center of the plate) is under compression and

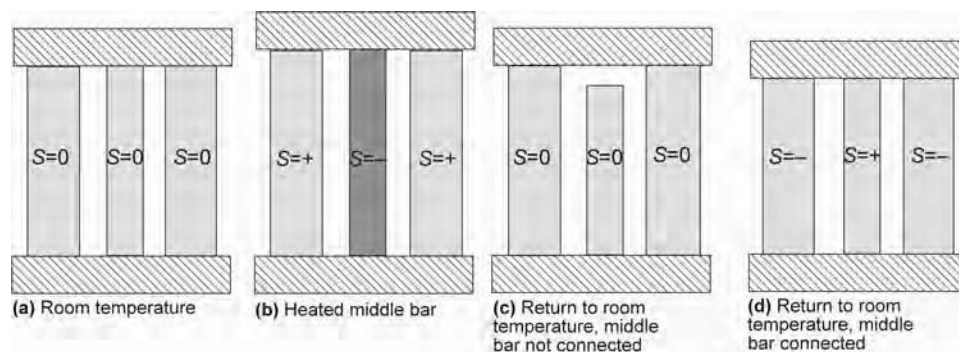

Fig. 1 Formation of welding residual stress

Fig. 2 Temperature and corresponding longitudinal residual stress before, during, and after welding. Source: Ref 24

the edges of the plate under tension. After cooling, the stresses reverse, resulting in tension at the welding region and compression elsewhere.

Volumetric solid-state phase transformations during the welding thermal cycle may also contribute to the generation of welding residual stress and consequently distortion (Ref 5, 7, 25–29). The section “Solid-State Transformations” in this article discusses the effect of solid-state phase transformation in further detail.

Mathematical Formulations

Thermal Transport

Thermal transport models of welding typically involve coupled heat and mass transfer and typically use computational fluid dynamics (CFD) solution methods in Eulerian reference frames (for more about fundamental principles of CFD, see Ref 30). A viscoplastic material

response is assumed in most thermal transport analyses of welding in order to eliminate the need for tracing and integrating the material response; this being the case, thermal transport analyses of welding compute the resulting residual stress to be zero. Such analyses have primarily been used to model the temperature field and physical shape of the weld pool (Ref 31–35), the interaction between arc and material (Ref 36), buoyancy, surface tension, and magneto-hydrodynamic effects (Ref 3).

Accurate material property data are lacking for metal alloys at extremely high temperatures (Ref 3). Currently, these material properties are available only in specific published cases (Ref 3). Parameters describing the arc (such as efficiency and other weighting factors) are also difficult to model accurately, as shown by the wide range of values chosen in studies for apparently similar conditions (Ref 31). Because of the difficulties of knowing all the material and arc variables in modeling, Mishra and

DebRoy introduced an identification method for these uncertain variables that combines experimental data with thermofluid modeling to obtain exceptional correlation with experimental data (Ref 31).

Thermal transport analyses of welding involve solving for the mass conservation, momentum balance, and energy balance simultaneously. The analysis is typically performed in a Eulerian reference frame centered on the welding torch, with material flowing through the control volume (Fig. 3). The analysis is further simplified by assuming steady-state conditions and thus eliminating dependence on time. The mass conservation equation (continuity equation) is given by:

$$\nabla \cdot (\rho v) = 0 \tag{Eq 1}$$

where ρ is the density, v is the velocity, and ∇ is the spatial gradient operator.

The conservation of momentum equation is as follows:

$$\nabla \cdot (\rho v) = -\nabla p + \nabla \cdot \boldsymbol{\sigma}' + \rho g \tag{Eq 2}$$

where p is the pressure, $\boldsymbol{\sigma}'$ is the deviatoric stress tensor, g is the acceleration due to gravity, and v is the velocity.

Newtonian material response is assumed, and the deviatoric stress, $\boldsymbol{\sigma}'$, is calculated as follows:

$$\sigma'_{ij} = \mu \left[\frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right] \tag{Eq 3}$$

where μ is the viscosity.

The energy conservation equation is written in terms of enthalpy, H , as follows:

$$\nabla \cdot (\rho v H) = \nabla \cdot (k \nabla T) + Q \tag{Eq 4}$$

where k is the temperature-dependent thermal conductivity, and Q is the volumetric energy source.

As mentioned previously, the assumption of pure viscoplastic behavior (Eq 3) in thermal transport models of welding results in a computed value of zero residual stress, and the reason is shown in Eq 3. Once the velocity becomes zero, Eq 3 determines that the deviatoric stress is also zero. Computing residual stress requires modification of the constitutive model to account for the elastic component of stress, which depends on the deformation history of each particle. Furthermore, if material evolution (via, for example, hardening or transformations) is also to be considered in the computation of residual stress, the temperature, stress, strain, and internal variable history of each material particle must be computed. In a Eulerian reference frame, this computation can be accomplished by computing backward the streamline of each particle and then integrating the material evolution along the streamline (Ref 40–42). Another approach is to use a mixed finite-element analysis formulation and enforce the evolution in a weak form (Ref 43–46). Both approaches are quite specialized and require custom computer programming.

Fig. 3 Eulerian versus Lagrangian models in welding

Thermoelastoplasticity

Welding residual-stress analyses typically involve solving the energy and momentum balance sequentially in a Lagrangian reference frame. The material is attached to the mesh, and the welding torch travels with time (Fig. 3). The thermal analysis assumes conductive heat transfer only, but convective energy transfer is indirectly simulated by using artificially high thermal conductivity for temperatures above melting. The energy balance equation is as follows:

$$\rho C_p \frac{dT}{dt} = -\nabla \cdot \mathbf{q}(r,t) + Q(r,t) \tag{Eq 5}$$

where C_p is the specific heat capacity, T is the temperature, \mathbf{q} is the heat flux vector, t is the time, and r is the coordinate in the reference configuration.

The momentum balance equation is further simplified by assuming negligible inertia and body forces as follows:

$$\nabla \cdot \boldsymbol{\sigma} = 0 \tag{Eq 6}$$

where $\boldsymbol{\sigma}$ is the stress. Typically, a rate-independent elastoplastic material response is assumed in the mechanical analysis, allowing for the computation of residual stress due to plastic deformation during the welding heat cycle. Then, stress is computed as follows:

$$\boldsymbol{\sigma} = \mathbf{C} \boldsymbol{\varepsilon}_e \tag{Eq 7}$$

$$\boldsymbol{\varepsilon}_e = \boldsymbol{\varepsilon} - \boldsymbol{\varepsilon}_p - \boldsymbol{\varepsilon}_t - \boldsymbol{\varepsilon}_v - \boldsymbol{\varepsilon}_{tr} \tag{Eq 8}$$

$$\boldsymbol{\varepsilon}_p = \boldsymbol{\varepsilon}_q \cdot \mathbf{a}(\boldsymbol{\sigma}, \boldsymbol{\varepsilon}_q, T) \tag{Eq 9}$$

$$f = \sigma_e - \sigma_y \leq 0 \tag{Eq 10}$$

where T is temperature; \mathbf{C} is the material stiffness tensor; \mathbf{a} is the plastic flow vector; $\boldsymbol{\varepsilon}$, $\boldsymbol{\varepsilon}_p$, and $\boldsymbol{\varepsilon}_t$ are the total, plastic, and thermal strains, respectively; $\boldsymbol{\varepsilon}_q$ is the equivalent plastic strain; and $\boldsymbol{\varepsilon}_v$ and $\boldsymbol{\varepsilon}_{tr}$ are the volumetric change and transformation plasticity strain components, respectively (Ref 7, 28, 29). Equation 10 is the equation for isotropic hardening, where f is the yield function, σ_e is the von Mises stress, and σ_y is the yield stress. Active yielding occurs when $f = 0$.

The thermomechanical simulations of welding processes are further simplified by recognizing that the mechanical work is negligible compared to the heat input, and therefore, the unique coupling between thermal and mechanical behavior is the thermal expansion. On this understanding, a thermal simulation is performed first and a mechanical simulation afterward. However, when the components to be welded are unrestrained from rigid movements, large distortions may lead to a full thermomechanical coupling, because the fit-up and weld location may be altered (Ref 12).

Figure 4 illustrates a typical thermomechanical welding simulation. The welding conditions and joint configuration are the input to the thermal analysis, in which the heat flow, molten metal flow, and phase transformations are analyzed. The output from these analyses is the temperature history and microstructure. In the mechanical analysis, which may either follow or be coupled with the thermal analysis, the elastic-plastic deformation, creep, and transformation plasticity are analyzed. The distortion and residual stresses are the output of the mechanical analyses.

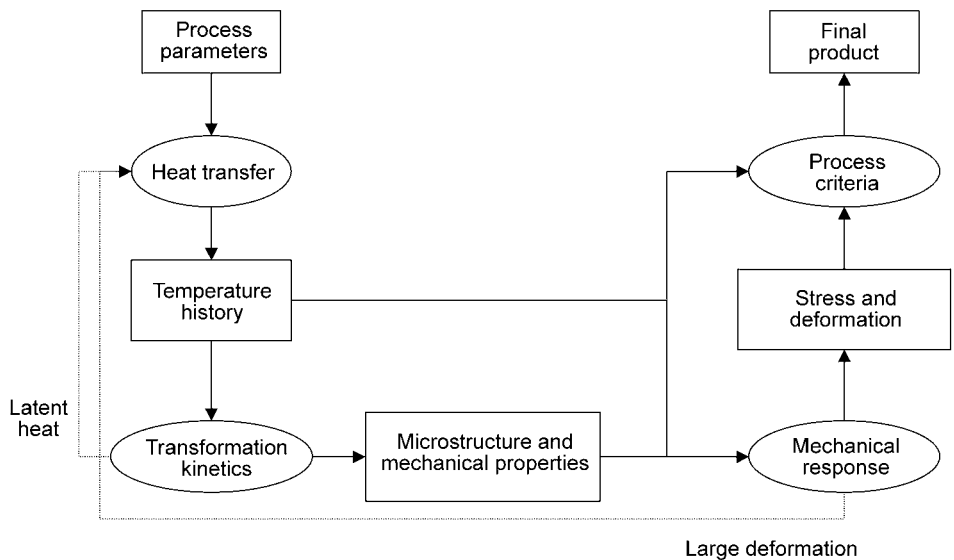

Fig. 4 Outline of thermomechanical weld modeling

Heat-Input Models

Depending on the process, different types of physics take place to generate the welding heat and fuse the material. For example, arc physics take place in arc welding, electric current flow takes place in arc and spot welding, and electron diffraction takes place in electron beam welding. Most commonly, in welding process modeling, the physics that account for the heat generation are not analyzed. Empirical heat-generation models are used instead.

A review of empirical models used to represent the heat generated in the welding process is presented in Ref 4 and 47 to 50. Early simulations of welding implemented simple point-and-line heat-source models as well as combinations of them (Ref 51–53). These simple heat-input models, in conjunction with the assumption of steady-state conditions and temperature-independent material properties, led to analytical solutions of the temperature field. These solutions provide a good approximation in regions far from the weld zone. However, the predicted infinite temperatures at the weld source are unrealistic. The availability of computational resources at low cost leads to the implementation of more accurate heat-input models for welding simulations. Papazoglou and Masubuchi (Ref 3) used a uniform density surface heat flux over the weld to simulate the welding heat input. Argyris et al. (Ref 2) and Tekriwal and Mazumder (Ref 11) used a surface heat flux with a Gaussian density distribution. Goldak et al. (Ref 4) proposed the double-ellipsoid heat-source model, where the heat generated by welding is simulated with a power density moving along with the torch. Other heat-input models impose a time-dependent temperature-boundary condition (frequently called ramp temperature-boundary condition) at selected points or regions of the weld pool (Ref 2, 54). The surface flux and volume heat-source models are directly derived from welding conditions and therefore are predictive. The ramp temperature models do not provide a direct relation to the actual weld parameters and thus require temperature measurements to determine the imposed conditions.

The most commonly used welding heat-input model is the double-ellipsoid model proposed by Goldak (Ref 4), in which the welding heat input is represented by a volumetric heat source, Q , as follows:

$$Q = \frac{6\sqrt{3}Q_w\eta f}{abc\pi\sqrt{\pi}} e^{-\left[\frac{3x^2}{a^2} + \frac{3y^2}{b^2} + \frac{3(z+vt)^2}{c^2}\right]} \quad (\text{W/mm}^3) \quad (\text{Eq 11})$$

where Q_w is the welding heat input; η is the welding efficiency; x , y , and z are the local coordinates of the double-ellipsoid model aligned with the weld fillet; a is the weld width; b is the weld penetration; c is the weld ellipsoid length; f is a scaling factor; v_w is the torch travel speed; and t is time. (Typically, different values are used for c and f in front of and

behind the weld.) An illustration of the energy density of the double-ellipsoid model is presented in Fig. 5.

Material Models

The rate-independent, deviatoric plasticity model with the von Mises yield condition and the associated flow rule has been used with success in many welding simulations (Ref 18). Some work has also used viscoplastic models (Ref 2, 55, 56) or combined rate-independent plasticity models at lower temperatures with viscoplastic models at higher temperatures (Ref 57). The hardening behavior at lower temperature is important in the computation of the residual stresses; the material near the weld undergoes cyclic loading, and choosing between isotropic or kinematic hardening will affect the stresses calculated from the model for this region (Ref 58).

For temperatures that exceed the melting point, the modulus of elasticity and yield limit have zero value. Viscous flow models are more appropriate at these temperatures. However, elastoplastic or elastoviscoplastic models may still be used in conjunction with a cut-off temperature. This technique is used for two reasons: The properties at high temperatures are usually unknown, and a too-soft weld metal in the model may cause numerical problems. In this technique, during the mechanical analysis, temperatures that exceed a cut-off value are reset to the cut-off temperature. An appropriate choice of cut-off temperature will not affect the residual stresses (Ref 3, 11, 18).

The very low value of yield strength along with the use of elastoplastic models may result in artificial hardening and lead to computed values that exceed the actual residual stresses. To account for the annealing effect that naturally occurs in metals, either a creep model may be used or all accumulated plastic strains may set to zero above a critical temperature (Ref 8).

Solid-State Transformations

Solid-phase transformations that occur during the thermal cycle produced by welding lead to irreversible plastic deformation known as transformation plasticity. This phenomenon can be driven either by volume change during phase transformations (Greenwood-Johnson effect) or by martensitic transformations in which, under external loading, martensite plates are formed with preferred orientation (Magee effect) (Ref 5, 7, 25–28). Oddy et al. (Ref 10, 59) decomposed the total strain into its elastic, plastic, thermal, volumetric change, and transformation plasticity (which is proportional to the deviatoric stress tensor) components. The authors report that transformation plasticity significantly affects longitudinal and transverse residual-stress distributions. Early work on weld modeling in which the thermal expansion coefficient is modified to take into account the

volumetric change during phase transformations is found in Ref 2 and 3. Argyris et al. (Ref 2) also modified the yield strength during cooling to reflect the formation of austenite, ferrite, and pearlite. From their numerical simulations, they conclude that the individual stress components are affected by the phase transformations during the heat cycle, but that the effects of phase transformations are dampened upon cooling of the weld. They also conclude that the equivalent von Mises stress is not affected by the phase transformations.

Multipass Welding

The simulation of multipass welding requires additional care (Ref 60). Early attempts involved lump weld passes (Ref 52, 53); however, this procedure should be performed with care (Ref 17). Two approaches, namely the use of quiet elements or inactive elements, are available for modeling of multipass welding. Quiet elements are present in the analysis but are given properties that prevent them from affecting the analysis. Inactive elements are not included at all until the corresponding filler material has been added. Both methods require special attention when large deformations occur. Quiet elements can accumulate excessive strains that must be reset during activation, and inactive elements can be severely distorted before activation, requiring the use of additional nodes and constraint equations. Both methods can give the same results (Ref 61). Methods and issues for obtaining correct sizes and shapes of the elements corresponding to the filler metal are described in Ref 60.

Residual Stress

In Michaleris et al. (Ref 15), the effectiveness of 2-D and 3-D small- and large-deformation analyses was investigated in the computation of welding distortion. Experimental testing was used for verification purposes. Fillet welding was performed on panels of various sizes, and residual-stress and distortion measurements were obtained and used as a

Fig. 5 Illustration of double-ellipsoid heat-input model. Source: Ref 4

benchmark to evaluate the accuracy of the various modeling methods. The panel thickness and welding conditions were kept the same in all experiments.

A schematic of the panel geometry and welding configuration is shown in Fig. 6. Three panels with dimensions (width by length) 255 by 255 mm (10 by 10 in.), 310 by 310 mm (12 by 12 in.), and 310 by 610 mm (12 by 24 in.) and a thickness of 3.2 mm (1/8 in.) are investigated. A stiffener with a height of 50 mm (2 in.) and thickness of 3.2 mm (1/8 in.) is fillet welded at the centerline of the panels.

255 by 255 mm (10 by 10 in.) Plate.

Figure 7 depicts the longitudinal residual-stress distribution for the 255 by 255 mm (10 by 10 in.) plate. Identical results are obtained for the longitudinal stress distribution from the small- and large-deformation analyses.

310 by 310 mm (12 by 12 in.) Plate.

Figure 8 shows the longitudinal residual-stress distribution computed using 2-D analysis (case B1) for a 310 mm (12 in.) wide panel. The 2-D analysis predicts constant compressive longitudinal stress away from the weld region. Figures 9 and 10 show the longitudinal residual-stress distribution computed using 3-D small- and large-deformation analyses, respectively. The large-deformation analysis shows slightly lower residual stress, which is attributed to relaxation due to buckling.

Longitudinal residual-stress measurements are carried out at seven locations along the transverse axis of the welded panel (Fig. 6). Figure 11 shows the comparison of the computed longitudinal residual stress and the experimental results along the transverse axis. The 2-D analysis cannot predict the longitudinal stress correctly at the ends of the plate. Both the 3-D small- and large-deformation analysis results compare well with the experimental results.

310 by 610 mm (12 by 24 in.) Plate.

Figures 12 and 13 show the distribution of longitudinal residual stress in the 310 by 610 mm (12 by 24 in.) plate computed by the 3-D small- (case C1) and 3-D large- (case C2) deformation

analyses, respectively. The plots show that the small-deformation analysis predicts a high compressive stress zone that stretches from a distance away from the weld centerline to the ends of the plate. The large-deformation analysis predicts a longitudinal stress distribution that is compressive away from the weld and decreases toward the ends. The difference is attributed to relaxation due to buckling.

Figure 14 compares the longitudinal residual-stress distribution along the transverse axis for the 2-D, 3-D small-, and 3-D large-deformation analyses with experimental results. The 3-D large-deformation analysis shows good correlation. The 2-D and the 3-D large-deformation analysis results are in close agreement but do not agree with the experimental results at the ends of the plate. The difference is attributed

to stress relaxation due to buckling, which only the 3-D large-deformation analysis can capture.

Figure 15 shows the longitudinal residual-stress distribution along the transverse axis for 2-D and 3-D small-deformation analyses of models of varying lengths. The figure shows that the longitudinal stress distributions from the 2-D analysis approach the curve predicted by the 3-D small-deformation analysis as the panel becomes longer. This phenomenon is

attributed to the fact that the 3-D small-deformation analysis corresponds to the unstable equilibrium condition under no imperfections.

The following conclusions are drawn from Fig. 7 to 15 (Ref 15):

- The 3-D small-deformation analysis predicts correct values of longitudinal residual stress and distortion if there is no buckling. When buckling occurs, the 3-D small-deformation

analysis corresponds to the unstable equilibrium state.

- As panel length increases, the longitudinal stress distribution predicted by the 2-D analysis approaches a state corresponding to the unstable equilibrium state of long panels in the 3-D small-deformation results.
- The 3-D large-deformation analysis predicts the correct residual-stress distribution. It also captures end effects.

Distortion

Masubuchi (Ref 62) classified welding distortion into six types (modes), as illustrated in Fig. 16. In transverse shrinkage, the parts shrink transverse to the weld. Angular change is a distortion that manifests in fillet and butt welds, where the plates change angle as compared to the configuration prior to welding. In rotational distortion, the parts open as the welding progresses. In longitudinal shrinkage, the parts shrink in the welding direction. Welding-induced buckling is elastic instability caused by compressive residual stress. Longitudinal bending, also known as bowing or camber distortion, is bending caused by nonbalanced residual stresses with respect to the neutral axis of the part.

The welding distortion modes can be further classified into in-plane and out-of-plane modes. Transverse shrinkage, longitudinal shrinkage, and rotational distortion are in-plane modes, and buckling, longitudinal bending (bowing), and angular change are out-of-plane modes. In general, in-plane distortion is negligible in small parts and receives little attention. In large components (such as those used in shipbuilding), in-plane distortion can be significant, and manufacturers compensate by starting with bigger parts. Out-of-plane distortion modes are very common and sometimes difficult to control. When welding results in buckling distortion, the magnitude of distortion is very large, and distortion control methods should be implemented to remove the source of buckling. Structures with thick sections are more resistant to buckling and usually distort via the bowing and angular out-of-plane modes.

Most of the weld modeling in the 1970s and 1980s involved 2-D models transverse to the welding direction using either plane-strain or generalized plane-strain conditions. These models demonstrated good correlations with experimental measurements for residual stress. However, these models were not capable of predicting the magnitudes of angular distortion (Ref 8) or longitudinal buckling and bowing (Ref 9).

Large and complex structures such as ship panels generally have various types of welding-induced distortions, including angular deformation, longitudinal bending, and buckling. Conventional transient moving-source analyses on 3-D finite-element models, where millions of degrees of freedom and thousands

Fig. 11 Comparison of predicted longitudinal stress distribution with measured experimental stress values for 310 × 310 mm (12 × 12 in.) panel. Source: Ref 15

components were simplified as two normal components—longitudinal plastic strain and transverse plastic strain—and the shear components were neglected. They determined the plastic strain distributions by both empirical and analytical methods.

2-D/3-D Applied Plastic Strain Methods.

Michaleris et al. developed a 2-D/3-D applied plastic strain approach to capture welding-induced buckling distortion in large ship panels (Ref 9). Because the buckling was caused mainly by longitudinal stress, they mapped only the longitudinal plastic strain component. The plastic strain field was computed by a 2-D generalized plane-strain thermoelastoplastic welding simulation and was applied as a thermal load in a structural 3-D analysis. Solid elements were used in the structural analysis in Ref 9 and shell for the plates and truss for the welds in Ref 72. Michaleris et al. (Ref 9) report that the method can successfully predict buckling distortion. However, it does not account for angular distortion or welding sequencing effects.

The longitudinal component of plastic strain is applied as an orthotropic thermal load on the structural model. A unit thermal load is applied on the structural model, and then the load is scaled up by a factor γ computed as:

$$\gamma = \sigma_{res} / \sigma_1 \quad (\text{Eq 12})$$

where, σ_{res} is the computed residual stress in the 2-D model, and σ_1 is the stress resulting from the unit thermal load ($\Delta T_1 = -1.0$) in the structural model.

The structural analysis may consist of an eigenvalue analysis to compute the buckling stress and mode (Ref 73, 74):

$$\det(\mathbf{K} + \lambda_i \mathbf{K}_{G1}) = 0 \quad (\text{Eq 13})$$

where \mathbf{K}_{G1} is the nonlinear (stress stiffening) stress stiffness matrix for a unit negative thermal load applied in the weld region ($\Delta T_1 = -1.0$). In shell-truss models, the thermal load is applied to the truss elements only (Ref 72). The eigenvalues (λ_i) represent the multipliers (scaling factors) to the unit thermal load that will result in buckling. The structural analysis may also involve an incremental large-deformation analysis to compute the magnitude of distortion by applying a negative thermal load ($\Delta T = -\gamma$) at the weld region in the structural model.

A comparison of the 2-D/3-D applied plastic strain method and a direct 3-D thermoelastoplastic welding simulation against experimental measurements is presented in Ref 15. Figure 17 shows a 310 by 610 mm (12 by 24 in.) stiffened panel after welding. Excessive buckling distortion is visible. Figures 18 and 19 show the computed distortion using 3-D large-deformation thermoelastoplastic and 2-D/3-D applied plastic strain methods, respectively. Both analyses compute the buckling distortion accurately.

Fig. 12 Longitudinal residual-stress distribution computed by three-dimensional small-deformation analysis for 310 × 610 mm (12 × 24 in.) panel. Source: Ref 15

of time increments are involved, have been shown to be able to capture all types of welding distortions, but at great computational cost (Ref 63). A variety of simplified methods (inherent strain, applied plastic strain, fictitious loads) have been proposed over the years for modeling welding distortion in large structures (Ref 50).

Applied Plastic Strain Methods

The concept of applied plastic (inherent) strain was originally proposed by Ueda et al. (Ref 64) for determining the residual stresses and distortions of welded structures (Ref 65–71). In their approach, six plastic strain

Fig. 13 Longitudinal residual-stress distribution computed by three-dimensional large-deformation analysis for 310 × 610 mm (12 × 24 in.) panel. Source: Ref 15

Fig. 14 Comparison of predicted longitudinal stress distribution with measured experimental stress values for 310 × 610 mm (12 × 24 in.) panel. Source: Ref 15

3-D/3-D Applied Plastic Strain Methods. Tsai et al. (Ref 75, 76) developed a 3-D plasticity-based applied approach to compute angular welding distortions in panels and T-joints. Their model demonstrated the relationship between cumulative plastic strains and angular distortions and reported that angular distortion is mainly induced by shear plastic strain (Ref 76, 77).

Michaleris et al. (Ref 16) developed a 3-D applied plastic strain method for computing welding distortion in large and complex structures. In this method, the six components of plastic strain of each weld are calculated in two steps. First, a 3-D moving-source analysis is performed on a small 3-D model with a shorter length, and then the plastic strain components of the small models are mapped and

superposed onto a large 3-D structural model to obtain the final distortion results. An interpolation algorithm was also developed for mapping between meshes with different densities. The effectiveness of the 3-D applied plastic strain method was evaluated by comparing to the distortion results from 3-D moving-source simulations. Figure 20 shows a comparison of the computed distortion using the applied plastic strain method and a direct moving-source thermoelastoplastic simulation on the entire structure. The numerical results show that the applied plastic strain method accounts for all distortion modes but is only qualitatively accurate for the prediction of angular distortion.

Effect of Initial Plate Straightness

The initial plate straightness can have a significant effect on the resulting welding distortion. Michaleris et al. (Ref 15) evaluated this effect using the applied plastic strain method by seeding the structural model with geometric imperfections of the first buckling mode, as follows:

$$x_i = x + \alpha_{imp} \cdot x_e \tag{Eq 14}$$

where x is the original node coordinates, x_i is the perturbed node coordinates, x_e is the normalized eigenmode solution for the first mode, and α_{imp} is the imperfection magnitude.

Figure 21 illustrates the computed buckling distortion for various magnitudes of imperfections for a 310 by 610 mm (12 by 24 in.) panel. The analyses show the computed buckling norm for increasing residual stress for several different values of imperfection magnitude, α_{imp} . For welds resulting in low residual stress (low magnitude of thermal load), the results are insensitive to imperfections. When the residual stress is close to the critical buckling stress, the onset of buckling is hastened, and its magnitude increases with increasing imperfection size. The critical thermal load computed by the eigenvalue analysis is illustrated in the figure by a vertical dotted line. At postbuckling residual stresses, there is no sensitivity. The results also demonstrate the highly nonlinear nature of distortion near the onset of buckling. A 10% change in the loading causes two to three times as great a change in distortion values.

2-D versus 3-D Analyses

Michaleris et al. (Ref 15) performed a comparison of 2-D, 3-D small-deformation, 3-D large-deformation, and 2-D/3-D decoupled applied plastic strain analyses for computing welding-induced distortion. Experimental out-of-plane distortion measurements were used as a reference. The following conclusions are drawn based on the results obtained:

Fig. 15 Comparison of longitudinal stress predicted by two- and three-dimensional small-deformation analyses. Source: Ref 15

Fig. 16 Types of welding distortion. Source: Ref 62

- The 2-D generalized plane-strain analysis cannot capture welding distortion accurately. In thin plates, it does account for longitudinal buckling. In thick plates, it results in incorrect predictions of angular distortion.
- The 2-D/3-D applied plastic strain method predicts the onset and magnitude of buckling distortion accurately. However, it is not suitable for computing angular distortion.
- The 3-D large-deformation analysis predicts the correct magnitude of distortion in case of both angular and buckling distortion. It also captures end effects.
- Geometric or load imperfections are needed in large-deformation buckling analysis. In thermoelastoplastic analyses, the torch offset acts as load imperfection. Additional geometric imperfections are needed in the structural analyses of the applied plastic strain method.
- The distortion magnitude has a high sensitivity to the imperfection magnitude for residual stresses near the critical buckling stress.

Fig. 17 Experimental 310 × 610 mm (12 × 24 in.) panel. Source: Ref 15

Fig. 18 Computed distortion by three-dimensional large-deformation analysis of a 310 × 610 mm (12 × 24 in.) panel. Original magnification: 2×. Source: Ref 15

Fig. 19 Computed distortion by two- and three-dimensional decoupled analysis of a 310 × 610 mm (12 × 24 in.) panel. Original magnification: 2×. Source: Ref 15

- When buckling occurs, the residual stresses relax and reduce in magnitude.
- There are multiple equilibrium configurations in a buckled panel. In computational models, the configuration can be switched by switching the imperfection sign. The configuration of the experimental panels can be switched by applications of momentary external forces. Therefore, when buckling occurs, the buckling mode and absolute value of distortion magnitude are of significance.
- The 3-D large-deformation method becomes computationally very expensive as the problem size becomes large. Thus, the 2-D/3-D

Fig. 20 Distortion results of the large structural model, large-deformation analysis. From Viewpoint 2. Original magnification: 50×

Fig. 21 Imperfection sensitivity for 310 × 610 mm (12 × 24 in.) plate. Source: Ref 15

applied plastic strain approach may be used as an effective tool to predict buckling-induced welding distortion instead of the 3-D large-deformation method.

Residual Stresses and Distortion*

Koichi Masubuchi, Massachusetts Institute of Technology

COMPLEX THERMAL STRESSES occur in parts during welding due to the localized application of heat. Residual stresses and distortion remain after welding is completed. Transient thermal stresses, residual stresses, and distortion sometimes cause cracking and mismatching of joints. High tensile residual stresses in areas near the weld can cause premature failures of welded structures under certain conditions. Distortion, especially out-of-plane distortion, and compressive residual stresses in the base plate can reduce the buckling strength of a structural member subjected to compressive loading. Correction of unacceptable distortion is costly and, in some cases, impossible. The subjects related to residual stresses, distortion, and their consequences are too broad to be discussed in depth in this article. Those who need more detailed information are advised to refer to the references, especially Ref 1 to 8.

Formation of Residual Stresses and Distortion

Residual stresses, also referred to as internal stresses, initial stresses, inherent stresses, and locked-in stresses, are stresses that exist in a body after all external loads are removed. Residual stresses also occur when a body is subjected to nonuniform temperature changes; these stresses are called thermal stresses. The intensity of stress is usually expressed in load or force per unit area, such as newtons per square meter (N/m^2) or pascals (Pa), kilograms force per square millimeter (kg/mm^2), or pounds per square inch (psi).

Residual stresses in metal structures occur for many reasons during various manufacturing stages, including casting, rolling, bending, flame cutting, forging, machining, and grinding. Heat treatments at various stages also influence residual stresses. For example, quenching treatments produce residual stresses, while stress-relieving heat treatments may reduce such stresses. Areas in which residual stresses exist vary greatly—from microscopic areas to large sections of the metal structure. This article focuses primarily on macroscopic residual stresses. Residual stresses can be classified into two groups according to the mechanisms that produce them:

- Stresses produced by structural mismatch
- Stresses produced by an uneven distribution of nonelastic strains, including plastic and thermal strains

Thermal Stresses and Metal Movement during Welding

Because a weldment is locally heated by the welding heat source, the temperature distribution is not uniform and changes as welding progresses. During the welding thermal cycle, complex transient thermal stresses are produced in the weldment and the surrounding joint. The

weldment also undergoes shrinkage and deformation during solidification and cooling.

Thermal Stresses during Welding. Figure 1 schematically shows changes in temperature and resulting stresses that occur during welding by examining a bead-on-plate weld of a thin plate made along the x -axis. The welding arc, which is moving at a speed v , is presently located at the origin, O , as shown in Fig. 1(a). The area where plastic deformation occurs during the welding thermal cycle is shown by the shaded area, $M-M'$, in Fig. 1(a). The region where the metal is molten is indicated by the ellipse near O . The region outside the shaded area remains elastic throughout the entire welding thermal cycle.

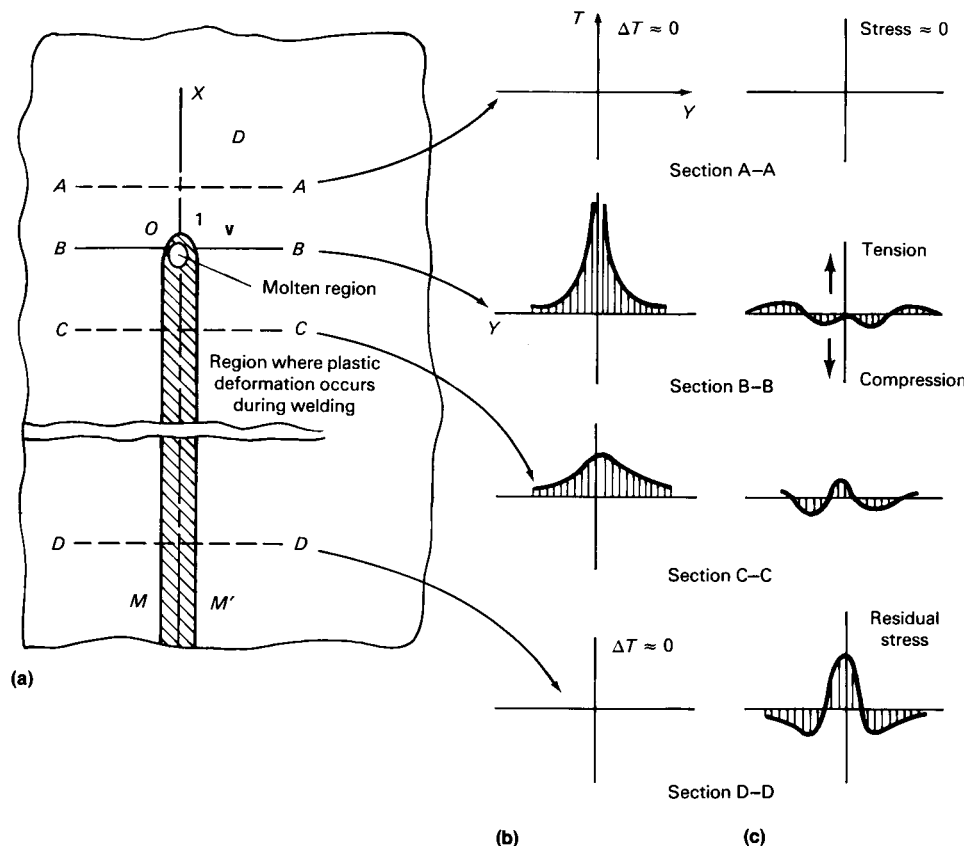

Fig. 1 Schematic representation of changes in temperature and stresses during welding. (a) Weld. (b) Temperature change. (c) Stress, σ_x . Stress distribution is shown in the plane stress condition. Therefore, stresses are regarded as being uniform in the thickness direction. Source: Welding Research Council

Temperature gradients along several cross sections through the weld bead path are indicated in Fig. 1(b). In the base metal ahead of the welding arc (denoted as section A-A), the slope of the temperature gradient due to welding ($\Delta T/\Delta Y$) is almost zero. However, along section B-B, which crosses the welding arc, the slope becomes very steep. Along section C-C, somewhat behind the welding arc, the slope becomes less steep. The slope of the temperature gradient due to welding once again approaches zero along section D-D, which is some distance behind the welding arc. Figure 1(c) shows the distribution of normal stress in the x -direction (σ_x) along the cross sections. Normal stress in the y -direction (σ_y) and shearing stress (τ_{xy}) also exist in a two-dimensional stress field. In a three-dimensional stress field, six stress components exist: σ_x , σ_y , σ_z , τ_{xy} , τ_{yz} , and τ_{zx} .

Figure 1(c) shows the distribution (along the y -axis) of normal stress in the x -direction (σ_x) due to welding (that is, thermal stress). Along section A-A, the stresses are almost zero. The stress distribution along section B-B is complicated. Beneath the welding arc, stresses are close to zero, because molten metal does not support shear loading. Moving away from the arc, stresses become compressive, because expansion of the metal surrounding the weld pool is restrained by the base metal. Because the temperatures of these areas are quite high, the yield stress of the material becomes quite low. In other words, a situation occurs in which stresses in these areas are as high as the yield stress of the base metal at corresponding temperatures. The magnitude of compressive stress passes through a maximum with increasing distance from the weld or with decreasing temperature. However, stresses occurring in regions farther away from the welding arc are tensile in nature and balance with compressive stresses in areas near the weld pool.

Figure 1(b) shows that along section C-C the weld-metal and base-metal regions have cooled. As they shrink, tensile stresses are caused in regions in and adjacent to the weld (Fig. 1c). As the distance from the weld increases, stresses become compressive. High tensile stresses exist along section D-D in and adjacent to the weld. Compressive stresses are produced in areas away from the weld.

Equilibrium Condition of Residual Stresses. Because residual stresses exist without external forces, the resultant force and the resultant moment produced by the residual stresses must vanish on any plane section:

$$\int \sigma \cdot dA = 0 \quad (\text{Eq 1})$$

$$\int dM = 0 \quad (\text{Eq 2})$$

where dA is area and dM is the resultant moment. Residual stress data must be checked in any experiment to ensure that they satisfy the above condition.

Metal Movement during Welding. During welding, the weldment undergoes shrinkage and deformation. The transient deformation,

or metal movement, is most evident when the weld line is away from the neutral axis of the weldment, causing a large amount of bending moment. Figure 2 schematically shows how a rectangular plate distorts when its longitudinal edge is heated by a welding arc or an oxyacetylene torch (for cutting, welding, or flame heating). Areas near the heat source, or the upper regions of the rectangular plate, are heated to higher temperatures and thus expand more than areas away from the heat source, or the lower regions of the plate. Therefore, the plate first deforms as shown by curve AB .

If all the parts of the material remained completely elastic during the entire thermal cycle, thermal stresses produced during the heating and cooling cycle would disappear when the temperature returned to the initial temperature. Deformation of the plate during the welding process would be indicated by curve $AB'C'D'$, resulting in no deformation after the thermal cycle. However, in most practical materials, plastic strains are produced in areas heated to elevated temperatures, causing plastic upsetting. The thermal stresses do not disappear when the temperature returns to the initial temperature, causing residual stresses. Transient deformation of the plate during heating and cooling is shown by curve $ABCD$. After the plate cools to the initial temperature, final deformation in the amount δ_f remains, which also is called distortion. The metal movement (that is, transient distortion or transient deformation) during welding and the distortion after welding is completed occur in opposite directions, generally with the same order of magnitude.

In summary, some basic characteristics of residual stresses and distortion are (Ref 9):

- The metal movement during welding (expansion) is opposite to the distortion that remains after welding.
- Although welding is completed in a short period (in a few minutes, for example), residual stresses and distortion take a relatively long time to develop completely (30 min to 1h)
- Because most of the nonelastic strains that cause residual stresses and distortions are produced during welding, necessary actions must be performed during welding to effectively control and reduce residual stresses and distortion.

Analyses of Residual Stresses and Distortion in Weldments

Residual stresses and distortion in welded structures have been recognized and studied since the 1930s. Analyses of these subjects require complex computation; therefore, most early studies were primarily empirical or limited to the analysis of simple cases. With the advancement of modern computers and computational techniques (for example, the finite-element and finite-difference method), a renewed effort has been made in recent years to study residual stresses and related phenomena. Therefore, it is now possible using computer programs to simulate the transient thermal stresses and metal movement during welding as

well as the residual stresses and distortion that remain after welding is completed (Ref 10–14). However, because these analysis methods are very complex, most are not practical for analyzing and controlling residual stresses and distortion in weldments.

Techniques for Measuring Residual Stresses

Many techniques have been used to measure residual stresses in metals (Ref 6, 15, 16). Table 1 lists most of the presently available measurement techniques and classifies them as follows:

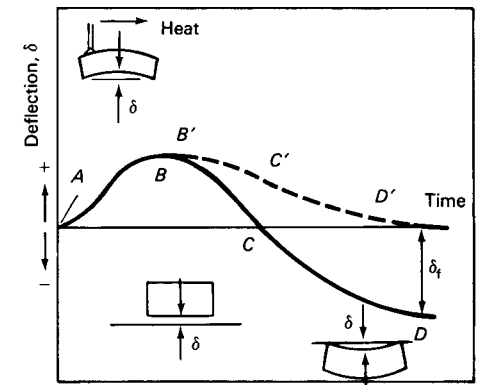

Fig. 2 Changes of deflection at the center of the lower edge of a rectangular plate due to heating by a heat source moving along the upper edge and subsequent cooling

Table 1 Classification of techniques for measuring residual stress

A-1 Stress-relaxation techniques using electric and mechanical strain gages	
Plate	Sectioning technique using electric resistance strain gages
	Gunnert technique
	Mathar-Soete drilling technique
	Stäblein successive milling technique
Solid cylinders and tubes	Heyn-Bauer successive machining technique

	Hydrogen-induced cracking technique
	Stress-corrosion cracking technique

Source: Ref 17

- Stress-relaxation techniques
- X-ray diffraction techniques
- Techniques using stress-sensitive properties
- Cracking techniques

In the stress-relaxation technique, residual stress is determined by measuring the elastic-strain release that takes place when a specimen is cut into pieces or has a piece removed. In most cases, electric or mechanical gages are used for measuring this strain release (group A-1 in Table 1). A variety of such techniques exist (that is, there are many ways to section a specimen to determine residual stresses). Certain techniques are used to study stresses in a plate, while others are used for cylinders, tubes, or three-dimensional solids. Strain release caused by stress relaxation can also be determined by using grid systems, brittle coatings, or photoelastic coatings (group A-2 in Table 1). An inherent disadvantage of stress-relaxation techniques is that they are destructive (that is, the specimen must be partially or entirely sectioned). Nevertheless, the stress-relaxation techniques provide reliable quantitative data and are the most widely used method for measuring residual stresses in weldments.

In metals with crystalline structures, elastic strains can also be determined by using x-ray diffraction to measure the lattice parameter. Because the lattice parameter of a metal in the unstressed state is known or can be determined separately, elastic strain in the metal can be measured nondestructively without machining or drilling. Two methods are presently available: the x-ray film technique and the x-ray diffractometer technique. With x-ray diffraction, surface strains can be determined within a small area—for example, to a depth of 0.025 mm (0.001 in.) and a diameter of 0.0025 mm (0.0001 in.). Modern x-ray diffraction stress-measurement instrumentation can provide one complete measurement in time scales as short as a fraction of a second, and typically less than 1 min. However, x-ray diffraction techniques have some disadvantages. They are time-consuming, and they are not accurate, especially in situations where high temperatures have distorted the atomic structure of the material. Studies have recently been made using diffraction of neutrons, which can penetrate deeper into the metal than x-rays (Ref 18).

Attempts have been made to determine the residual stresses in metals by measuring their stress-sensitive properties. The following stress-measurement techniques have been proposed:

- Ultrasonic techniques, such as the polarized ultrasonic wave technique (which makes use of stress-induced changes in the angle of polarization of polarized ultrasonic waves) and the ultrasonic attenuation technique (which makes use of stress-induced changes in the rate of absorption of ultrasonic waves)
- Hardness techniques, which make use of stress-induced changes in hardness

However, none of these techniques has been developed beyond the laboratory stage, and

they have not been used successfully for the measurement of residual stresses in weldments.

Another technique developed for the study of residual stresses involves the close observation of cracks induced in the specimen by hydrogen embrittlement or stress-corrosion cracking (SCC). Cracking techniques are useful when studying residual stresses in complex structural models in which the distribution of residual stresses is complicated, but these techniques provide only qualitative, not quantitative, data.

Magnitude and Distribution of Residual Stresses in Weldments

A number of investigators have studied distributions of residual stresses in various types of weldments. Most of the data presented in this section relates to single welds as opposed to multipass welds. References 6 to 8 present detailed information.

Residual Welding Stresses, Reaction Stresses, and Stress Distributions in a Groove Weld. As stated earlier, residual stresses can be classified as (1) stresses produced by structural mismatch or displacement and (2) stresses produced by uneven distribution of nonelastic strains. The same method of classification is applicable to residual stresses in weldments: (1) reaction stresses caused when the weldment is restrained externally and (2) residual stresses produced in an unrestrained weldment.

Figure 3 shows a typical distribution of residual stresses in a groove weld. The significant stresses are those parallel to the weld direction, designated σ_x , which are usually called the longitudinal stresses, and those transverse to σ_x , designated σ_y , which are called the transverse stresses. The distribution of the longitudinal stress is shown in Fig. 3(b). Near the weld, tensile stresses of high magnitude are produced. These taper off quickly and become compressive at a distance equal to several times the width of the weld metal. The stress distribution is characterized by two parameters:

- The maximum stress at the weld region, σ_m
- The width of the tension zone of residual stress, b

The distribution of longitudinal residual stress, σ_x , can be approximated by:

$$\sigma_x(y) = \sigma_m \left[1 - \left(\frac{y}{b} \right)^2 \right] e^{-[1/2(y/b)^2]} \quad (\text{Eq 3})$$

Equation 3 satisfies the equilibrium conditions given in Eq 1 and 2.

Curve 1 of Fig. 3(c) shows the distribution of transverse stress, σ_y , along the length of the weld. In the center of the joint, tensile stresses of relatively low magnitude are produced. Compressive stresses are produced at the ends of the joint. If an external constraint is used to restrain the lateral contraction of the joint, approximately uniform tensile stresses along the weld are added, resulting in curve 2 of Fig. 3(c). However, an

external constraint has little influence on the distribution of residual stress (σ_x).

Residual Stresses in a Plug Weld. Figure 4 shows the distribution of both the theoretical and experimental residual stresses in a circular plug weld (Ref 19). Tensile stresses, as high as the yield stress of the material, are produced in both radial and tangential directions in the weld and adjacent areas. In areas away from the weld, radial stresses (σ_r) are tensile, and tangential stresses (σ_θ) are compressive; both stresses decrease with increasing distance from the weld (r).

Residual Stresses in a Welded Shape and a Column. Figure 5 shows typical distributions of residual stresses and distortion in various welded shapes (Ref 20). As shown in section xx of Fig. 5 (a), high tensile residual stresses are produced in areas near the weld, in the direction parallel to the weld line (axis). In the flange, longitudinal stresses are compressive (−) in areas away from the weld and tensile (+) in areas near the weld. Tensile stresses in areas near the upper edge of the web are caused by longitudinal bending distortion of the T-shape, which are caused by the longitudinal shrinkage of the weld. Angular distortion also is produced.

Figures 5(b) and 5(c) show typical distributions of residual stress in H-shapes (I-beams)

Fig. 3 Typical distributions of residual stresses in a groove weld. (a) Groove weld. (b) Distribution of σ_x along YY. (c) Distribution of σ_y along XX. Source: Welding Research Council

Fig. 4 Theoretical and experimental distributions of residual stresses in a plug weld

and in a welded box shape, respectively. Residual stresses are shown parallel to the weld line (axis); they are compressive in areas away from the welds and tensile in areas near the welds.

Residual Stresses in Weldments of Selected Materials. Distributions of residual stresses in welds in various metals are similar to those in low-carbon steel welds, discussed previously. In most cases, the maximum residual stresses are as high as the yield stress of the material. One exception is ultrahigh-strength steels, such as 4130, D-6a, and H13 (Ref 6). For such steels, peak values of residual stresses in some areas can be as high as the yield stress (or even higher in the case of triaxiality); however, average values of residual stresses in the weld metal are considerably lower than the yield stress.

Distortion in Weldments

Distortions found in fabricating structures are caused by three fundamental dimensional changes:

- Transverse shrinkage
- Longitudinal shrinkage parallel to the weld line
- Angular distortion around the weld line

These dimensional changes are shown in Fig. 6. The shrinkage and distortion that occur during fabrication of actual structures are far more complex than those shown in Fig. 6. For example, when longitudinal shrinkage occurs in a fillet joint,

Fig. 5 Typical residual stresses in welded shapes. (a) T-shapes. (b) H-shapes. (c) Box shapes. Compressive stress, -; tensile strength, +

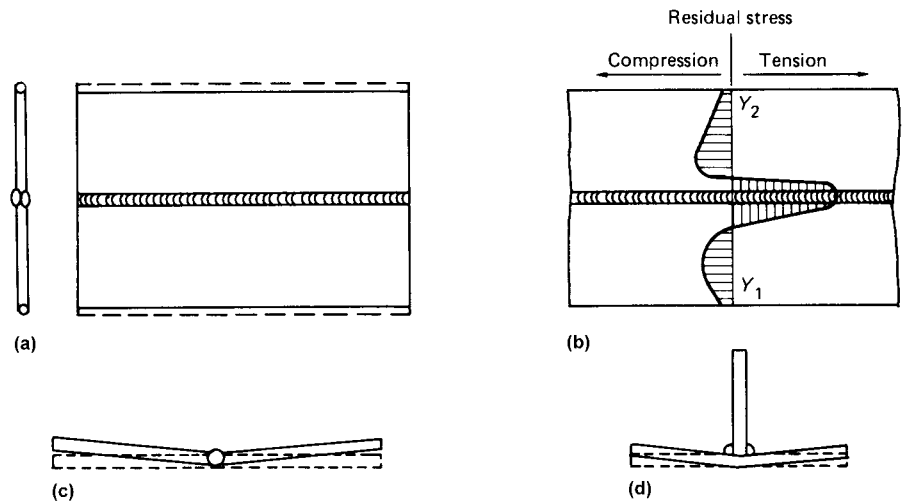

Fig. 6 Dimensional changes occurring in weldments. (a) Transverse shrinkage in a groove weld. (b) Longitudinal shrinkage in a groove weld. Distribution of longitudinal residual stress, σ_x , is also shown. (c) Angular change in a groove weld. (d) Angular change in a fillet weld. Source: Welding Research Council

the joint bends longitudinally unless the weld line is located along the neutral axis of the joint. A common structural element is a stiffened panel structure in which longitudinal and transverse stiffeners are fillet welded to a flat plate. Angular changes that occur in the fillet welds cause out-of-plane distortion in the plate, resulting in a shape which looks like a "hungry horse." Presented subsequently are brief discussions of:

- Transverse shrinkage of groove welds
- Angular distortion of groove welds
- Out-of-plane distortion caused by angular distortion of fillet welds
- Longitudinal distortion of built-up beams
- Buckling distortion

Transverse Shrinkage of Square-Groove Welds. In Fig. 6(a), shrinkage is uniform along the weld; however, transverse shrinkage that occurs in a groove weld, especially in a long groove weld, is not uniform and is typically much more complex. The major factors causing nonuniform transverse shrinkage in a groove weld are rotational distortion and joint restraint. When two separate planes are joined progressively from one end to the other, the plate edges of the unwelded portion of the joint move, causing a rotational distortion. This can be understood from Fig. 2. The rotational distortion is affected by welding conditions and the location of tack welds. In many practical joints, the degree of joint restraint is not uniform along the weld. Because the amount of transverse shrinkage is less when the joint is more severely restrained, nonuniform distribution of the magnitude of restraint results in an uneven distribution of transverse shrinkage.

Mechanisms of Transverse Shrinkage. The most important finding of mathematical analyses of mechanisms of transverse shrinkage is that the major portion of the transverse shrinkage of a groove joint is caused by contraction of the base plate adjacent to the weld. The base plate near the weld expands during welding. When the weld metal solidifies, the expanded base metal must shrink; this shrinkage accounts for the major part of transverse shrinkage. Shrinkage of the weld metal accounts for approximately 10% of the actual total shrinkage. Therefore, most formulas developed for computing transverse shrinkage of a square groove weld are composed of two parts:

- Shrinkage of the adjacent base plate
- Shrinkage of the weld metal

Transverse Shrinkage during Multipass Welding. Welding of a square-groove joint in a thick plate commonly requires a number of passes. Figure 7 shows how transverse shrinkage increases during multipass welding of a groove joint in 19 mm (3/4 in.) thick low-carbon steel plates. Shrinkage is pronounced during the early weld passes but diminishes during later passes because of the resistance to shrinkage that increases as the weld metal is increased. The effects of transverse shrinkage on various factors, including root opening, joint design,

electrode diameter, and degree of restraint, have been studied extensively (Ref 6).

Transverse Shrinkage in a Square-Groove Weld in Aluminum. As stated earlier, the major portion of transverse shrinkage of a square-groove weld is caused by contraction of the base plate adjacent to the weld. Compared with steel, aluminum has a much higher heat conductivity and coefficient of thermal expansion; therefore, transverse shrinkage of an aluminum groove weld is approximately three times greater than that of a steel groove weld of similar dimensions (Ref 6). Because the value of thermal conductivity of aluminum is much greater than that of steel, heat generated by the welding arc dissipates faster in aluminum than in steel, resulting in a broader heat-affected zone (HAZ) (Ref 7).

Angular Distortion of Groove Welds. In a groove weld, when transverse shrinkage is not uniform in the thickness direction, angular distortion often occurs. The angular change of a weld in a thick plate can be minimized by properly selecting the ratio of the size of the weld groove on the front surface to that of the back surface (Ref 6).

Out-of-Plane Distortion Caused by Angular Distortion in Fillet Welds. A stiffened panel composed of a flat plate with longitudinal and transverse stiffeners fillet welded to the plate is widely used for many structures. Angular changes that occur at fillet welds cause out-of-plane distortion of the flat plate (Ref 6). Figure 8 compares values of distortion at the panel center (δ_m) for steel and aluminum welded structures on the basis of the same fillet size (D_f) for selected plate thicknesses. Distortion in aluminum structures is less than in steel structures because the temperature distribution in the thickness direction is more uniform in an aluminum weld than in a steel weld (Ref 7).

Longitudinal Distortion of Built-Up Beams. Figure 9 compares values of longitudinal distortion expressed in terms of the radius of curvature of built-up beams in steel and aluminum. In this instance, aluminum welds distorted less than steel welds, perhaps because the temperature distribution in the z -direction is more uniform in an aluminum weld than in a steel weld.

Buckling Distortion. In any weldment, longitudinal residual stresses are compressive in areas away from the weld, as shown in Fig. 3. When the plate is thin, it may buckle due to these compressive residual stresses. Buckling distortion differs from bending distortion in that the amount of distortion in buckling is much greater. Also, there may be more than one stable deformed shape in buckling distortion. The most effective method for dealing with buckling distortion is prevention by proper selection of plate thickness, length of free span, and welding heat input.

When stiffeners are fillet welded to thin plate, the plate may buckle because of the compressive residual stresses that occur in the plate. Figure 10 shows relationships between distortion at the center of the panel and heat

input for square panels 500 mm (20 in.) long made with plates 4.6 to 10 mm (0.18 to 0.4 in.) thick. For example, in the case of a 500 by 500 mm (20 by 20 in.) panel with a plate 6 mm (0.24 in.) thick, the plate deflection increases suddenly when the heat input exceeds approximately 3700 cal/cm². This indicates that the critical heat input is approximately 3700 cal/cm². When the plate is 4.6 mm (0.18 in.) thick, this critical heat input is only approximately 2000 cal/cm². The following formula can be used to determine the critical heat input, H_{cr} , above which excessive buckling distortion occurs:

$$H_{cr} = \frac{Q}{t^3} \quad b \geq \sim 4 \times 10^5 \text{ cal/cm}^3 \quad (\text{Eq 4})$$

where b is the length of the panel, and t is the plate thickness, both in millimeters. The aforementioned parameter, H_{cr} , is also called the critical heat input index.

Effects of Residual Stresses and Distortion on the Service Behavior of Welded Structures

High tensile residual stresses in areas near the weld can cause premature failures of welded structures under certain conditions. Distortion, especially out-of-plane distortion, and compressive residual stresses in the base plate can reduce the buckling strength of a structural member subjected to compressive loading.

Changes in Residual Stresses

Changes in residual stresses when a groove-welded joint is subjected to tensile loading is shown in Fig. 11. Curve 0 shows the lateral distribution of longitudinal residual stresses in the as-welded condition. When uniform tensile stress, σ_1 , is applied, the stress distribution will be shown by curve 1. The stresses near the weld reach the yield stress, and most of the stress increase occurs in areas away from the weld. When the tensile applied stress increases to σ_2 , the stress distribution will be as shown by curve 2. As the level of

Weight of weld metal per unit weld length, w

Fig. 7 Increase of transverse shrinkage during multipass welding of a groove joint. Specimens were 19 mm (3/4 in.) thick low-carbon steel plates.

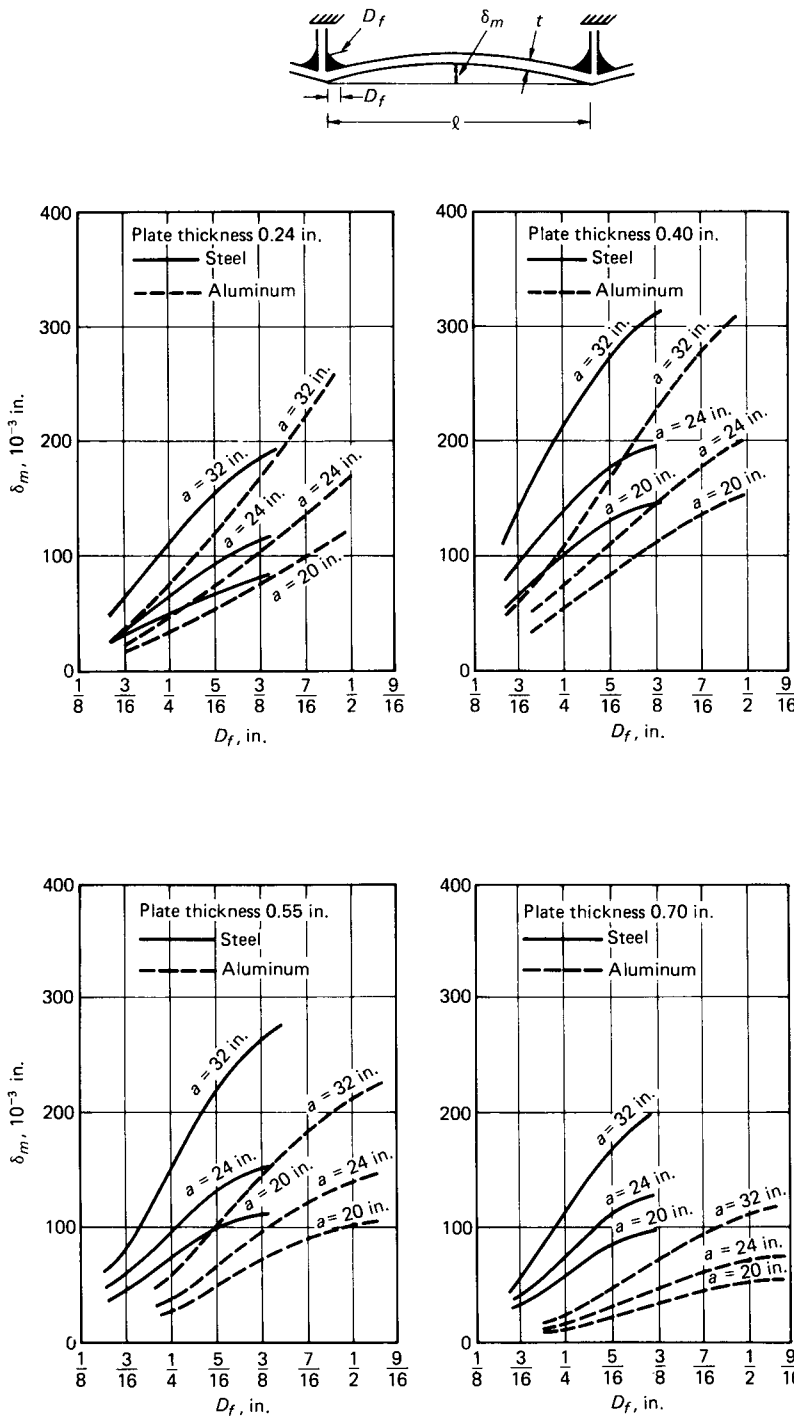

Fig. 8 Out-of-plane distortion (δ_m) as a function of plate thickness (t), span length (l), and the size of the fillet weld (D_f) for steel and aluminum. Relation of l to a in graphs: $a = l$

applied stress increases, the stress distribution across the weld becomes even more (that is, the effect of welding residual stresses on the stress distribution decreases). When the level of applied stress is further increased, general yielding takes place (that is, yielding occurs across the entire cross section). The stress distribution at general yielding is shown by curve 3. Beyond general

yielding, the effect of residual stress on the stress distribution virtually disappears.

The next consideration is the distribution of residual stresses after the tensile loads are released. Curve 1' shows the residual stress that remains after unloading when the tensile stress σ_1 is applied to the weld and then released. Curve 2' shows the residual stress distribution

Fig. 9 Relationship between length of leg and curvature of longitudinal deflection in T-section beam. Source: Ref 6, 21

when the tensile stress σ_2 is applied and then released. Compared with the original residual stress distribution, curve 0, residual stress distributions after loading and unloading are less severe. As the level of loading increases, the residual stress distribution after unloading becomes more uniform (that is, the effect of welding residual stress on the overall stress distribution across the welded joint decreases). This phenomenon is called mechanical stress relieving.

Based on this analysis, the effects of residual welding stresses can be summarized as follows:

- The effect of residual welding stresses on the performance of welded structures is significant only for phenomena that occur under low applied stress, such as brittle fracture and SCC.
- As the level of applied stress increases, the effect of residual stresses decreases.
- The effect of residual stress on the performance of welded structures is negligible under applied stresses greater than the yield stress.
- The effect of residual stresses tends to decrease after repeated loading (that is, the reduction of residual stresses will be greater as the level of service load increases).

Effects of Residual Stresses on the Brittle Fracture of Welded Structures

Extensive studies have been conducted on the effects of residual stresses on the

Fig. 10 Plot of heat input versus deflection for 500 × 500 mm (20 × 20 in.) low-carbon steel panels as a function of panel thickness

brittle fracture of welded steel constructions (Ref 6, 19). Investigators have observed differences between data obtained from brittle fractures in ships and other structures and experimental data obtained with notched specimens. Actual structural fractures were observed to occur at stresses far below the yield stress of the material; however, even when experimental test specimens contain very sharp cracks, the nominal applied fracture stress of a notched laboratory specimen is as high as the yield stress. A number of research studies have been carried out on low-applied-stress fractures of weldments in service. Under certain test conditions, complete fracture of a specimen occurred even though the magnitude of applied stress was considerably below the yield stress of the material.

Figure 12 shows the general fracture strength tendencies of welded low-carbon steel specimens at various temperatures and the effects of a sharp notch and residual stress on fracture strength (Ref 6, 23). When a specimen does not contain a sharp notch, fracture occurs

at the ultimate tensile strength of the material at the test temperature, as shown by curve *PQR*. When a specimen contains a sharp notch (but no residual stress), fracture occurs at the stresses shown by curve *PQST*. When the temperature is higher than the fracture transition temperature (T_f), a high-energy (shear-type) fracture occurs at high stress. When the temperature is below T_f , the fracture appearance changes to a low-energy (cleavage) type, and the stress at fracture decreases to near the yield stress.

These various fractures can occur when a notch is located in areas where high residual tensile stresses exist. At temperatures higher than T_f , fracture stress is equal to the ultimate tensile strength (curve *PQR*). Residual stress has no effect on fracture strength. At temperatures lower than T_f , but higher than the crack-arrest temperature (T_a), a crack may initiate at a low stress but will be arrested. At temperatures lower than T_a , one of two phenomena can occur, depending on the stress level at fracture initiation:

Fig. 11 Schematic showing distribution of stresses in a groove weld when uniform tensile loads are applied and the residual stresses that result after the loads are released. Curve 0, residual-stresses in the as-welded condition; curve 1, stress distribution at $\sigma = \sigma_y$; curve 2, stress distribution at $\sigma = \sigma_u$; curve 3, distribution of stresses at general yielding; curve 1', distribution of residual stress after $\sigma = \sigma_y$ is applied and then released; curve 2', distribution of residual stress after $\sigma = \sigma_u$ is applied and then released

- If the stress is below the critical stress (*VW*), the crack will be arrested after running a short distance; complete fracture will occur at the yield stress (*ST*).
- If the fracture initiation stress is higher than *VW*, complete fracture of the weldment will occur.

Effect of Stress-Relieving Treatments.

Residual stresses in weldments can be reduced by production of plastic deformation in proper amounts and distribution. This deformation can be applied mechanically, thermally, or by a combination of methods. In the most frequently used technique, called a stress-relieving treatment, a weldment is placed in a furnace or surrounded by local heaters for a certain period of time at a specific temperature, depending on the type of material and thickness, and then is cooled slowly. Typically, low-carbon steels are stress relieved at 595 to 650 °C (1100 to 1200 °F). Also, when a load is applied to a weldment, residual stresses are redistributed because of local plastic deformation. Residual stresses are reduced when the load is removed, as discussed previously (see Fig. 11).

In a series of tests, external loads were applied to different stress levels—50, 100, 150, 200, and 230 MPa (7, 15, 20, 30, and 35 ksi)—at 20 °C (68 °F), which was above the critical temperature for crack initiation (T_c).

The load was then reduced. After mechanical stress-relieving treatments, specimens were cooled to temperatures below $-30\text{ }^{\circ}\text{C}$ ($22\text{ }^{\circ}\text{F}$) and tensile loads were applied. For these specimens, fractures occurred only after the pre-loaded stresses were exceeded, even at this low temperature, as shown in Fig. 13(a). In another series of tests, specimens were thermally stress relieved by placing them in a furnace for 1 h at 320, 420, 520, and $620\text{ }^{\circ}\text{C}$ (610, 790, 970, and $1150\text{ }^{\circ}\text{F}$). Fracture stresses for these specimens were higher when welds were heat treated at higher temperatures, indicating that more stresses were relieved by heating at higher temperatures (see Fig. 13).

Effects of Residual Stresses on Fatigue Fracture of Welded Structures

Effects of residual stresses on the fatigue strength of weldments have been studied extensively (Ref 4, 25–27). Fatigue strength increases when a specimen has compressive residual stresses, especially on the specimen surface. Many investigators have reported that fatigue strength (the number of cycles to fracture under a given load, or the endurance limit) increased when the specimens had compressive residual stresses. Conversely, tensile surface residual stresses are expected to reduce fatigue strength. In conducting experiments to determine the effects of residual stresses on the fatigue strength of weldments, the surface conditions of specimens must be carefully considered. Because most fatigue cracks originate at the surface, surface smoothness is very important in obtaining high fatigue strength. For example, removing weld reinforcement, grinding surface irregularities, and other treatments are effective in reducing stress concentrations and increasing fatigue strength. In other words, although a specimen that has compressive residual stresses is expected to have a high fatigue strength, the specimen may yield poor results if it contains a sharp notch that initiates a fatigue crack.

Effects of Environment

Even without external loading, cracking can occur in weldments when the material is embrittled by exposure to certain environments and residual stresses are present. Stress-corrosion cracking is a brittle type of fracture that occurs in a material exposed to a certain environment; it should not be confused with other types of localized attack, such as pitting, galvanic attack, intergranular corrosion, or cavitation (Ref 1, 6, 27). Stress-corrosion cracking has been observed in a number of ferrous and nonferrous alloys exposed to certain environments (Table 2).

High-strength alloys are sensitive to atomic hydrogen. Many cracks in weldments are caused by hydrogen that is introduced

Fig. 12 Effects of sharp notch and residual stress on fracture strength. Source: Ref 22

during the welding process or that is present in the base metal. Hydrogen-induced cracking of weldments in various steels has been studied, and attempts have been made to develop a technique for determining the distribution of residual stresses in a weldment by observing the pattern of hydrogen-induced cracks (Ref 6).

Buckling Under Compressive Loading

Failures caused by instability or buckling sometimes occur in metal structures composed of slender bars or thin plates, when subjected to compressive axial loading, bending, or torsional loading. Residual compressive stresses decrease the buckling strength of a metal structure. In addition, out-of-shape (out-of-plane, out-of-circularity, and so forth) distortion caused by residual stresses also decreases buckling strength. Reference 6 discusses various subjects related to the effects of residual stresses and distortion on the buckling strength of structures of different shapes.

Thermal Treatments of Weldments

Thermal treatments are often necessary to maintain or restore the properties of base metal affected by the heat of welding. Thermal treatment may also affect the properties of the weld metal. The extent of changes in the properties of the base metal, weld metal, and HAZ are determined by several factors, including the soaking temperature, time, cooling rate, and material thickness. Further detailed information is available in Ref 7 and 8.

Preheat is the most common thermal treatment applied to weldments. Proper use of preheat can minimize residual stresses and distortion that would normally occur during welding as a result of lower thermal gradients around the weld. Preheat also has the beneficial effect in steels of reducing the tendency for the formation of a HAZ and weld-metal cracking.

Postweld Thermal Treatments. A properly executed postweld heat treatment results in uniform mechanical properties and reduced residual stresses. The effects of time at

temperature and the stress-relieving temperature on residual stresses are shown in Fig. 14(a) and (b), respectively (Ref 8). When thick weldments require a postweld machining operation, a stress-relief treatment is usually necessary to achieve normal machining tolerance.

Mechanisms of Bonding for Solid-State Welding Processes

Jerry E. Gould, Edison Welding Institute

SOLID-STATE WELDING PROCESSES encompass all the methods in which metallic bonding occurs without the presence of resolidified liquid metal. These processes range from cold methods (cold-pressure welding) to hot upset processes (forge processes) to diffusion processes (diffusion bonding). Typically, these processes take advantage of applied strain and/or heat to facilitate joining. Joining is largely the result of intimate intermetallic contact in the absence of local protective films.

This article focuses on the underlying mechanisms of bonding for these processes, with particular emphasis on mechanisms for the forge-type processes, while mechanisms for both the cold and the diffusion processes are considered in other articles. Specific mechanisms for different stages of these processes are identified and quantified using best-available theory. Further, these mechanisms are used to understand the roles of temperature and strain in facilitating bonding with these classes of joining technologies.

There are three categories of bonding mechanisms for the forge welding processes to be considered:

- Contaminant displacement/interatomic bonding
- Dissociation of retained oxides
- Decomposition of the interfacial structure

Modeling of contaminant displacement/interatomic bonding is largely taken from the cold-pressure literature and adapted to the forge welding processes. This modeling suggests that with increasing surface strain, bond strengths can asymptotically approach that of the base metal. The cold-pressure models can be adapted to forge welding processes by considering the role that the developing temperature field has on the distribution of strain. Generally, however, after the surface strain is applied (upset), there are still residual oxide particles trapped in the bondline, and thermal dissolution of these particles can further improve joint performance.

Thermal dissolution modeling has been adapted from the carbide dissolution (in steels) literature, with stability data collected from

the diffusion bonding literature. Resulting models show the importance of the size and distribution of the residual oxide particles, as well as the role of the thermal cycle.

Finally, the third underlying mechanism of forge welding processes is the decomposition of the interfacial structure. Following the forging required to displace contaminants, the bondline can be characterized as a highly dislocated, high-energy structure. Improvements in weld performance can be made by decomposing this structure and reducing the residual bondline strain energy. Decomposition can occur either by recovery or recrystallization, depending on the thermal cycle employed. There is evidence to suggest that decomposition by recrystallization gives better bond performance. Decomposition by recrystallization can be promoted by appropriate thermal cycles as well as appropriate distributions of strain following upsetting.

Solid-State Welding Processes

Solid-state welding processes are the oldest of welding processes, with the official American Welding Society definition of forge welding requiring an anvil and a hammer (Ref 1). Solid-state welding processes have proliferated, particularly over the last several decades, as new power systems have developed. General classifications of these processes include cold-pressure welding, externally heated hot-pressure processes, resistance processes, friction processes, arc-heated processes, and diffusion processes. In this article, mechanisms of bonding are described for those processes using both mechanically applied straining and heating. Detailed examinations of bonding mechanisms of the other processes are available in the literature. These include the cold-pressure welding processes (Ref 2–8) and the diffusion bonding processes (Ref 9–12). Specific variants of the other bonding processes are as follows:

- Externally heated hot-pressure processes
 - a. Forge welding
 - b. Gas pressure welding
 - c. Induction hot-pressure welding

- Resistance processes
 - a. Flash butt welding
 - b. Resistance butt welding
 - c. Projection welding
 - d. Mash seam welding
- Friction processes
 - a. Inertia welding
 - b. Continuous-drive friction welding
 - c. Linear friction welding
 - d. Friction stir welding
- Arc processes
 - a. Percussive welding
 - b. Magnetically impelled arc butt welding

These processes can be thought of as having two generally separable stages. These include a heating stage and an upsetting stage. As such, these welding methods can be generally classified as heat and forge processes. Distinctions between these processes then are largely in how heat and forging are applied. Inevitably, however, heat is first applied. Mechanistically, this heat is used for two purposes. First, heating the workpieces reduces the yield strengths of the base materials and permits forging to occur with high degrees of strain at reduced upsetting forces. Second, if heating is properly applied, upsetting creates high degrees of strain over a very localized area (at the bonding surface). Once the appropriate heating has been accomplished, forging (or upsetting) commences. Upsetting also has two major functions. These include collapsing asperities to create intimate contact, and displacing/dispersing protective oxides and films to facilitate metal-to-metal bonding. Residual heat content/heating is also considered advantageous, to further consolidate/homogenize the joint.

Mechanisms of Solid-State Bonding

To attempt to define the specific mechanisms of bonding for solid-state welding processes, it is first necessary to have an understanding about the microstructural and surface conditions of the workpieces planned for joining. On a microscopic scale, the surfaces for

bonding have been well categorized as irregular and covered with various oxide and contaminant films (Ref 2–12). In addition, there may be microstructural/compositional irregularities, which further complicate the joining process. A typical representation of the prebond surface condition is presented in Fig. 1. This surface is generally characterized as three layers: the base material, a layer of mechanically and/or chemically affected metal, and surface oxides/contaminant films.

There are a number of mechanisms that can proceed to form a bond between such surfaces. The most important of these is that asperities on the surfaces must be collapsed to form intimate contact between materials. In forge welding processes, creation of this intimate contact is done mechanically; that is, local yield stresses are exceeded on the contacting surfaces, and surface deformation is used to create the contact. For diffusion bonding processes (not covered extensively in this article), such surface collapse is done under relatively low forces and relies on creep and surface diffusional mechanisms to consolidate the surfaces.

Once the surfaces have come under intimate contact, bonding still cannot initiate until a number of other criteria are met. The most important of these is how oxide and surface contaminant films can be affected to allow intimate contact of the underlying virgin materials. Generally, there are two mechanisms for this. For forge welding processes, contaminant films can be broken up as a result of mechanical action. In addition, it is also possible to break down metal oxides by dissolution into the matrix. This is a mechanism particularly important in diffusion bonding (Ref 13) but also plays a role in other thermally assisted forge processes.

Even when base materials are in intimate contact, there are additional changes that must occur to facilitate an adequate joint. First, crystallographic matching across the boundary must occur (Ref 14). Obviously, most forge welding applications are between parent materials with randomly oriented grain structures, and so, this bond surface must take on the characteristic of a series of high-angle grain boundaries. Generation of this dislocation structure can occur mechanically (Ref 6) thermally (Ref 9, 10), or by a combination of the two. At this stage of the process, intimate solid-state bonding has undoubtedly occurred; however, the localized high-angle grain-boundary structure is

Fig. 1 Schematic representation of workpiece surface conditions in the prebonded state

relatively unstable and is unlikely to yield an adequate joint. As a result, the last stage of the process is to relieve these local bondline stresses, typically with some sort of thermal assist. Depending on the treatment, this local concentration of strain energy can result in a final bond structure ranging from local recovery to recrystallization (Ref 15).

As mentioned, these mechanisms collectively permit solid-state bonding between metallic materials, although not all mechanisms are used by all solid-state welding processes. Generally, these mechanisms, particularly as they operate within the group of forge welding processes, can be classified in three general areas. These include surface deformation mechanisms, contaminant dissolution mechanisms, and interfacial structure homogenization mechanisms. These are described in detail, including their direct relationship to the forge welding processes, in subsequent sections.

Contaminant Displacement/Interatomic Bonding. As briefly described previously, surface deformation mechanisms have two functions: to collapse surface asperities and to displace surface contaminants. It is of interest that the best information on the role of surface strain and its effect on the extent of solid-state bonding is available in the cold-pressure welding literature (Ref 2–8). Several authors have examined the roles of surface condition, mechanisms of interfacial breakdown, and degrees of subsequent bonding for cold-pressure welding applications. Collectively, initial bonding, related to surface straining, appears to progress through the following stages.

Extension of the Contacting Surfaces

For any bonding to occur, it is essential that contaminating oxides/films be disrupted. This is, of course, accomplished by application of contact surface strains. It is equally important, however, that surface oxides/films be in a condition in which they can be readily broken up when the surface strain is applied. Table 1 lists hardnesses for some common oxides. Of interest here is the difference between the hardnesses of the aluminum or copper oxides. Figure 2 shows some fractographs of bond surfaces for cold-pressure welds below critical bonding deformation for aluminum, copper, and silver. It is clear from these results that the aluminum oxide fails in a brittle manner, while the copper oxide fails in a shear manner.

Table 1 Representative hardnesses of some metal oxides at room temperature

Metal	Hardness, HV	Oxide	Hardness, HV
Al	15	Al ₂ O ₃	1800
Cu	40	Cu ₂ O	160
Ag	26	Ag ₂ O	135
Au	20

Source: Ref 6, Table 1

A more general plot showing the relationship between oxide/metal hardness ratio and required deformation for bonding is presented in Fig. 3. One method of improving the characteristics of surface film fracture is to locally cold work the base metal. It has been demonstrated that cold working the surface using scratch brushing both minimizes the extent of contaminant films and creates a local layer of heavily cold-worked material, which, on straining, can fracture and carry more ductile oxide films (Ref 6).

For most conventional forge welding processes, extension of the contacting surfaces is done with a combination of heat and force. For this stage of the process, local strain is the most important factor. However, how that strain is distributed is a strong function of how the thermal field is applied. Figure 4 shows some results from numerical simulations of the flash-butt welding process (Ref 16). This plot shows how contact surface strain is affected both by the amount of upset used and the level of flashing acceleration employed. Flashing acceleration directly controls the heat distribution in the workpiece, with higher flashing accelerations indicating steeper, higher thermal gradients (Ref 17, 18). For conductivity materials, particularly aluminum and copper, strain location provided simply by the thermal gradient is difficult. In such cases, pinch-off dies are recommended (Ref 19). Pinch-off dies simply use the constraint of the die (rather than the thermal profile) to create localization of forging. The function of pinch-off dies is shown schematically in Fig. 5.

Separation of the Contaminated Areas

It is established that the onset of bonding occurs with applied surface strain as surface contaminants are separated and virgin base materials are allowed to contact. Considerable work has been done, again largely in the cold-pressure welding area, attempting to quantify the separation of these contaminants and the resulting bond quality. In examining the role of contaminated surfaces, all workers agree that a critical strain must first be achieved that this surface ruptures (Ref 2–8). There are discrepancies, however, on how this rupture occurs. Mohamed and Washburn (Ref 6) suggest that separations of the two contaminated surfaces are unrelated, while Wright et al. (Ref 7) and later Bay (Ref 8) suggest that surface contaminants impinge on either side of the joining and therefore separate as pairs. Local bonding is then accomplished by extrusion of virgin material into the spaces between the separated contaminated surfaces. Each set of authors has developed models based on their assumption of interfacial breakdown. In each case, the underlying assumption is that the strength of the joint is a direct function of the fraction of

Fig. 2 Fractographs showing the faying surfaces of cold-pressure-welded aluminum, copper, and silver at subbonding strains. (a) Aluminum, 3% deformation. (b) Aluminum, 6% deformation. (c) Copper, 5% deformation. (d) Copper, 23% deformation. (e) Silver, 25% deformation. Source: Ref 6, Fig. 1

Fig. 3 Relationship between oxide/metal hardness ratio and the critical deformation for bonding during cold-pressure welding. Source: Ref 3

Fig. 4 Thermomechanical modeling results showing the relationship between flashing acceleration, upset distance, and contact surface strain for flash-butt welding mild steel

the bond area converted by actual base material/base material bonds.

The simplest of these models is that developed by Mohamed and Washburn (Ref 6). This model assumes a completely brittle contamination layer and no coordination of contaminants on either side of the bondline. The physical representation of this model is presented in Fig. 6. The resulting equation for strength is:

$$f = C \left(\frac{R}{R + 1} \right)^2 \quad (\text{Eq 1})$$

where f is the ratio of the joint strength to the parent material strength, R is the surface strain, and C is a constant to incorporate contaminant mismatches and contaminant hardness.

The model proposed by Wright et al. is slightly more complex. This model was generated for roll-bonding applications, so largely plain-strain conditions exist. The physical representation of this model is presented in Fig. 7. This model assumes matchup of contaminants across the bondline and attempts to account for a degree of prebonding deformation. The resulting equation for joint strength is:

$$f = C \left[1 - \frac{(1 - R_f)^2}{(1 - R_t)^2} \right] \quad (\text{Eq 2})$$

In this case, C is considered an empirical hardening factor, R_t is the threshold deformation for bonding, and R_f is the total deformation of the process. Equations 1 and 2 are similar, asymptotically approaching a maximum bond strength as the total deformation (R or R_f) approaches 1. The most complex analysis is provided by Bay. This model includes the effects of contaminant films and subsurface hardened layers and is diagramed in Fig. 8. The resulting equation for joint strength is:

$$f = (1 - \beta)Y \frac{p - p_e}{\sigma_o} + \beta \frac{Y - Y'}{1 - Y'} \frac{p}{\sigma_o} \quad (\text{Eq 3})$$

where f is now the ratio of weld tensile strength to base material tensile strength, β is the fraction area covered by contaminant films, p is the applied pressure, p_e is the threshold pressure

for bonding (extrusion pressure), and σ_o is the yield strength of the base material. Y and Y' are the surface exposure and threshold surface exposure, where the surface exposure is defined by:

$$Y = 1 - \frac{1}{1 + X} \quad (\text{Eq 4})$$

where X is the degree of expansion of the contact area.

These models, of course, show a greater degree of complexity, because a greater number of bonding factors are included. It is important to recall, however, that these models have been developed for cold-pressure processes, and these complexities may be more or less relevant for conventional forge welding processes. One factor of note is the extrusion pressure (described as p_e in Eq 3). This factor is included either directly or indirectly in each of these models. However, for conventional forge welding processes, extrusion pressures will fall dramatically with temperature and may be less of a factor. Also to be questioned is the role of subsurface cold-worked layers, which, in conventional forge welding processes, will probably anneal substantially before any macroscopic deformation occurs.

Realignment of the Grain Structures for Bonding

There is considerable evidence that crystallographic matchup across the bondline is also important at this stage of bonding (Ref 3, 6, 14). Detailed work (Ref 3) suggests that contact between similarly oriented close-packed or near-close-packed planes most readily bonds. For aluminum, (111) to (111) and (110) to (110) were found to bond readily, while (111) to (100) were found difficult to bond. However, most structural materials are polycrystalline, so such ideal crystallographic matchups are relatively uncommon. To accomplish bonding requires some localized crystallographic reorientation. The model here is the one of a series of grain boundaries. Grain boundaries can be thought of as a complex dislocation pileup, accommodating the misorientation between grains over a very small distance. The types of macroscopic surface strains and local intercontaminant extrusion described here are ideal sources for dislocation generation and undoubtedly contribute to the generation of this bondline structure. An example of this dislocated structure is presented in Fig. 9. This particular example is a resistance butt weld on steel, showing evidence of a residual bondline. This region is characterized by relatively high internal strain energy and may be a quality concern. Reactions of this region to the applied thermal fields typical of the forge welding processes are described in a subsequent section.

Thermal Dissolution of Oxides/Contaminants

The preceding discussion indicates the degrees to which bondline strain can be used to create a solid-state bond. However, implicit in that discussion and related modeling were two related facts: some level of contamination was always present in the joint area, and joint strengths could only asymptotically approach parent material strengths. The relationship here is straightforward. As long as contaminants exist in the joint, they reduce effective bond area and act as initiation sites for subsequent mechanical failures (Ref 20).

To achieve improved joint properties, particularly in industrial applications, some further reduction in the residual bondline contaminant content is advantageous. Fortunately, for many metallic systems, oxides are soluble in the matrix at elevated temperatures. The degree of solubility of a specific oxide in M_xO_y in a matrix of metal "A" at equilibrium can be defined by the solubility product:

$$K_{eq} = Z(C_M)^x(C_O)^y \quad (\text{Eq 5})$$

where K_{eq} is the equilibrium solubility product, C_M and C_O are the compositions of the metal "M" and oxygen in the matrix metal "A," and Z is a proportionality constant relevant to the activity coefficient. If the oxide is of the matrix metal, this expression reduces to:

$$K_{eq} = Z(C_O)^y \quad (\text{Eq 6})$$

with Z a different proportionality constant. This suggests that the solubility product is similarly a power function of the maximum soluble oxygen content in the base material. For oxides of the base materials, Eq 6 suggests that the solubility product can be estimated from the maximum solubility of oxygen in the matrix as taken from the appropriate phase diagram. In addition, the shape of the oxygen solvus provides some indication of the temperature dependence for the solubility product. In a similar manner, Eq 5 suggests that

Fig. 9 Resistance butt weld on mild steel indicating a highly deformed zone down the bondline

the solubility product for non-base-material metal oxides relative to the base metal (as well as the temperature dependence) can also be estimated from the phase diagram. Here, the solubility product is estimated from the maximum solubilities of the secondary metal and oxygen in the base material.

If Raoultian behavior of oxygen in the base material is assumed, the proportionality constants in Eq 5 and 6 become equal to 1. Then, knowing the stoichiometry of the oxide present and using the appropriate phase diagram, approximate solubility products for some different metals can be done directly. Table 2 lists approximate solubility products for some standard engineering materials with their most common oxide. These solubility products are calculated for approximately bonding temperatures estimated for forge welding processes ($0.9 T_m$). Materials shown include aluminum, iron, and titanium. These solubility products cover approximately 30 orders of magnitude, indicating, on one extreme, the difficulty of dissolving aluminum oxide into an aluminum matrix as well as the relative ease with which titanium can dissolve its own oxide.

Similar calculations can be done for nonmatrix metal oxides. The approximately solubility product for Al_2O_3 on iron is calculated and compared to the similar calculation for the oxide of iron (Fe_2O_3) in Table 3. These calculations were done at the approximate bonding temperature for forge welding iron. In this case, the stoichiometry for the two oxides is similar ($x = 2, y = 3$), so the difference between the two solubility products is directly related to the solubility of the aluminum in the steel. This fact appears to account for the relatively low solubility of Al_2O_3 in iron.

Such solubility products and diffusivities of oxygen in the matrix have been used as a basis

Table 2 Estimated solubility products for oxides present on some common engineering materials assuming Raoultian behavior of oxygen in solution in the parent material

Metal	Oxide	K_{eq}
Al	Al_2O_3	3×10^{-29}
Fe	Fe_2O_3	1×10^{-15}
Ti	TiO_2	1×10^{-1}

Calculations are done for temperatures approximately representing bonding temperatures for forge welding processes ($0.9 T_m$) (internally generated).

Table 3 Comparison of solubility products for Al_2O_3 and Fe_2O_3 in an iron matrix at the appropriate bonding temperature for forge welding iron ($0.9 T_m$)

Base material	Oxide	K_{eq}
Fe	Al_2O_3	1.8×10^{-19}
Fe	Fe_2O_3	1.0×10^{-15}

Internally generated

for modeling oxide dissolution during diffusion bonding (Ref 21). However, this analysis was largely based on continuous oxide films and focused on the maximum thickness of these films for relatively long (diffusion bonding) heating cycles. Such an analysis does not take into account the breakup of the oxide film into discrete particles caused by the applied surface strain during forge welding processes, or the relatively short heating times.

A better analysis can parallel that done by Ashby and Easterling for the dissolution of carbide particles during welding (Ref 22). That analysis examines the dissolution of discrete particles. The approach used attempts to estimate the roles of both the solubility of the carbide constituents into the matrix and diffusion of these constituents away from the decomposing carbide. The approach is based on the assumption that distinct spherical particles can be dissociated completely into a volume of matrix with radius l . Further, the particle will dissociate into this volume at a locus of times and temperatures defined by:

$$l = (D^*t^*)^{1/2} \quad (\text{Eq 7})$$

where D^* and t^* are the combinations of the diffusivities (D , a function of temperature, defined at T^*) and times (t^*) over which the particle can be completely dissolved into the volume matrix defined by l . Combining this approach for examining the role of diffusion can be combined with an expression for the temperature dependence of the solubility product of the particle, to examine particle dissolution behavior. The discussions on solubility products for oxides detailed previously can be used to adapt these equations for oxide particle dissolution. The resulting governing equations include for base-metal oxide particles:

$$T_s = \frac{B}{A - \ln \left[\frac{(O)^y}{f} \right]} \quad (\text{Eq 8})$$

and for non-base-metal oxides:

$$T_s = \frac{B}{A - \ln \left[\frac{(M)^x(O)^y}{f} \right]} \quad (\text{Eq 9})$$

where T_s is the dissolution temperature, A and B are the temperature coefficients for the appropriate solubility product, and f is the matrix volume fraction affected by the decaying oxide, defined by:

$$f = \frac{1}{1 + \left[\frac{t}{\tau} \exp - \frac{Q_2}{R} \left(\frac{1}{T^*} - \frac{1}{T_s} \right) \right]^{3/2}} \quad (\text{Eq 10})$$

In this expression, Q_2 is the activation energy associated with the appropriate diffusivity (oxygen or metal + oxygen), and R is the ideal gas constant. With some estimate of t^* and T^* , Eq 10 combined with either Eq 8 or 9

(as appropriate) defines an implicit relationship between the time/temperature profile for the process and the degree of oxide dissolution.

In these expressions, t^* and T^* are direct functions of the oxide particle size and distribution. Values for these can presumably be estimated from the original distribution of oxides on the bonding surfaces and estimations of surface strain, as described previously.

From these equations, some qualitative estimate can be made of the role of both the degree of forging and time-temperature profile on bond quality. With increasing strain applied to the contacting surface, both particle size and density will inevitably fall. These factors reduce amounts of oxygen (and potentially second metal) that must be diffused and increase the kinetics of oxide dissolution. Extended heating (welding) times are important in that, again, diffusion is promoted. Increasing welding temperatures are not only advantageous for increasing rates of diffusion but also for increasing the solubility product for the dissolution reaction.

Breakdown of the Interfacial Structure

A third mechanism of bonding results from the decomposition of any interfacial structure. As described previously, straining of the bond surface, extrusion of material around residual oxide particles, and matching crystallographic structures across the bondline result in a highly dislocated bondline structure. This highly dislocated structure is of relatively high energy as well as planar. An example of such a highly dislocated bond is shown in Fig. 10. This structure obviously develops during straining the contact surface. However, the presence of various particulates from the contaminated bond surfaces may also stabilize this structure.

Decomposition of this structure is largely a thermally assisted process. To develop this highly dislocated structure, considerable energy for deformation is required. Much of this energy is stored in the interfacial structure itself. With varying degrees of activation

energy, this structure can quickly decompose to a lower energy variant. Parks (Ref 15) has done considerable work to understand the breakdown of contacting interfaces. In his work, he suggests two regimes for breakdown of this interfacial structure. These parallel the concepts of recovery and recrystallization. Recovery of the interface implies a realignment of the dislocated structure to reduce the overall strain energy of the system. This is typically done at relatively low temperatures, permitting only local movement of the dislocations that make up the boundary structure (Ref 23–25). During recovery, these dislocations realign themselves into dislocation cells. An example of such cells is shown in Fig. 11 (Ref 26). Parks found that very little effective bonding occurred if interfacial decomposition was limited to recovery. Rather, substantial bond strengths were found if higher annealing temperatures were used, resulting in bondline recrystallization. This is shown in Fig. 12. Recrystallization is essentially the nucleation and growth of new grains. Provided activation energies are high enough, this mechanism of interfacial decomposition shows the greatest reduction in bondline energy and is suggested by Parks as essential for forming high-integrity bonds.

During welding, residual stored energy (as local deformation) can play a role in the kinetics of recovery and/or recrystallization. Parks has demonstrated that actual bonding temperatures can be reduced depending on the degree of deformation in the material. Required recrystallization temperatures as a function of the degree of deformation for a range of materials are shown in Fig. 13.

Obviously, the extent to which this interfacial structure can decompose is a function of both the amount of strain applied and the temperature cycle experienced. Increasing amounts of strain (upset) obviously increase the amount of work in the material and promote subsequent breakdown of the interfacial structure. Time at temperature, however, provides the activation energy to allow this aspect of the bonding process to proceed. It is interesting from this discussion that greater levels of upset may permit bonding at shorter times and lower temperatures. However, in practice, extended times

and temperatures are almost always advantageous, permitting maximum homogenization of the joint microstructure.

Comparison of Solid-State Bonding Processes

The above discussion suggests that, in summary, solid state processes employ one or more of three mechanisms to accomplish bonding. These include disruption of contacting interfaces for nascent metal contact, diffusion related dissociation of residual contaminants, and breakdown of the remaining interfacial structure. These fundamental mechanisms, are driven by process mechanisms, specifically temperature, time, and deformation. Obviously, temperature and time both drive diffusion reactions (promoting both contaminant dissolution and breakdown of the interfacial structure), while deformation promotes interfacial disruption. This approach was used by Fenn (Ref 27). In the developed construct, Fenn created a ternary diagram with axes of temperature, time, and deformation. For this diagram, the axes are represented as conceptual fractional values. Here, temperature can be considered as the fraction of the absolute melting temperature, time as a dimensionless fraction, and deformation as the relative collapse of the two components. On this diagram, Fenn then placed hypothetical ranges for a number of solid state processes. The resulting diagram is shown in Fig. 14. Limits of the diagram include diffusion bonding (all time and temperature) and, cold welding (all deformation). Of note, most conventional solid state welding processes (flash welding, friction welding, upset (or forge) welding) fall toward the middle of the diagram, utilizing components of all the mechanisms described above. Of note, the diagram is not material specific. As a result, how individual processes fall on this diagram will be strongly affected by the substrate welded, shifting to match the specific combination of mechanisms most advantageous to individual material systems.

Summary

This article provides a systematic look at mechanisms of bond formation during solid-state (forge) welding processes. Discussions have been limited to those processes that can be characterized as having two stages: heating and forging. Explicitly excluded were those processes that do not use heating (cold-pressure welding processes) or forging (diffusion bonding processes). For the forge welding processes, three distinct mechanisms of bonding have been discussed. These include contaminant displacement/interatomic bonding, dissociation of retained oxides, and decomposition of the interfacial structure.

Contaminant Displacement/Interatomic Bonding. This mechanism of bonding relates to displacement of contaminants by local strain at the contacting surface. Displacement of these

Fig. 10 Interfacial structure on resistance-projection-welded mild steel

Fig. 12 Weld strengths as a function of annealing temperature for a range of materials. Source: Ref 15

contaminants allows exposure of clean surfaces for direct interatomic bonding. The basics for modeling this mechanism were largely taken from the cold-pressure literature. Although several models are available with increasing levels of complexity, all predict that bond strengths asymptotically approach that of the base metal with increasing surface strain. For the forge welding processes, the developed temperature distribution also plays a role, increasing metal plasticity, assisting in localizing strain at the bondline, and reducing required upset loads.

Thermal Dissolution of Oxides/Contaminants. The applied surface strains described previously permit considerable bonding but leave a residue of oxide/contaminant particles dispersed over the bond surface. As a mechanism for further facilitating bonding, many of

these particles can be thermally dissolved in the matrix. The relative solubility of specific types of particles can be assessed directly by examining solubility products between the constituent elements of the particle compared with solution in the base material. For base-material oxides, this solubility product is only a function of the solubility limit of oxygen in the matrix. This analysis was used to indicate relative stability of a range of base-metal oxides. This examination was extended, using previous work done for dissolution of carbide particles in steel, to examine the kinetics of dissolution. This analysis incorporates both solubility product and diffusivity factors. The results indicate the effects of residual oxide particle size as well as the role of the severity of the thermal cycle for dissolving these oxide particles.

Breakdown of the Interfacial Structure.

The side result of the first two mechanisms is a highly dislocated interfacial bond structure. This structure results largely from the application of bondline strain but can be stabilized by the presence of discrete oxide particles. This structure is of relatively high energy and can be a detriment to weld quality. Decomposition of this structure does improve bond quality. The mechanism of decomposition, however, depends on the thermal cycle employed. For relatively short or low-temperature cycles, the structure may only recover, resulting in a series of dislocation cells. At higher temperatures and longer times, recrystallization of the metal at the bondline can also occur. Some results suggest that recrystallization of the bondline structure results in better weld properties. Increasing stored energy at the bondline (caused by higher levels of strain) also appears to aid the kinetics of recrystallization and improve weld quality.

Fundamentals of Friction Welding*

Revised by D.D. Kautz, Los Alamos National Laboratory

FRICION WELDING (FRW) is a solid-state welding process in which the heat for welding is produced by the relative motion of the two interfaces being joined. This method relies on the direct conversion of mechanical energy to thermal energy to form the weld, without the application of heat from any other source. Under normal conditions, no melting occurs at the interface.

Figure 1 shows a typical friction weld, in which a nonrotating workpiece is held in contact with a rotating workpiece under constant or gradually increasing pressure until the interface reaches the welding temperature. The rotational speed, the axial pressure, and the welding time are the principal variables that are controlled in order to provide the necessary combination of heat and pressure to form the weldment. These parameters are adjusted so that the interface is heated into the plastic temperature range where welding can take place. Once the interface is heated, axial pressure is used to bring the weld interfaces into intimate contact. During this last stage of the welding process, atomic diffusion occurs while the

interfaces are in contact, allowing a metallurgical bond to form between the two materials.

Friction welding involves heat generation through frictional abrasion (Ref 1–3), heat dissipation, plastic deformation, and chemical interdiffusion. The interrelation among these factors during FRW complicates development of predictive models for the friction welding process. However, from a qualitative standpoint, the process is well understood through empirical FRW studies that have been performed on a wide variety of materials. Five qualitative factors influence the quality of a friction weld (Ref 4):

- Relative velocity of the surfaces
- Applied pressure
- Surface temperature
- Bulk material properties
- Surface condition and presence of surface films

The first two factors are related to FRW, the last two are related to the properties of the materials being joined, while the temperature achieved is a combination of process parameters and material properties.

Commercial FRW applications employ a number of variations on the basic FRW concepts. These variations were developed to accommodate different part geometries and to produce different metallurgical effects (Ref 5) and are not discussed in this article.

Process Parameters

During FRW, the relative velocity, the applied pressure, and the duration of the force are the three variables that are controlled. The effect of these variables on weld quality is discussed for the two basic friction welding processes: direct-drive welding and inertia-drive welding. The surface temperature is the critical parameter for ensuring good welds and is dependent on the processing conditions and the materials being joined.

Although the surface temperature is not measured or directly controlled, the effects of insufficient or excessive temperature are generally apparent through visual examination of the finished weld. The bulk material properties and the condition of the surfaces being joined affect both the frictional forces and the forging characteristics of the materials being joined. These factors are discussed for the friction welding of both similar-material and dissimilar-material combinations.

Mechanisms of Friction Heating. The mechanism of heat generation during friction welding is complex. Studies in assessing the effective coefficients of friction for continuous-drive friction welding processes (Ref 6–8) have shown coefficient values considerably larger than normal values of sliding friction, typically found in the range of 0.15 to 0.3. These works define equilibrium coefficients of friction when friction welding steels as roughly equal to 2 over a wide range of processing conditions.

To understand the utility of this effective coefficient of friction and its suitability to the FSW process, it is useful to understand the variations in frictional behavior occurring during conventional friction welding. These mechanisms can be summarized from other works (Ref 7, 8). The typical coefficient of friction heating is diagrammed in Fig. 2. At the beginning of the process, the coefficient of friction is defined by the sliding friction, with values in the 0.15 to 0.30 range. Quickly, however, the contacting surface heats sufficiently to allow some instantaneous bonding, with subsequent shearing or tearing. This period of bonding and tearing is characterized by a rapidly rising coefficient of friction. It is during this period that the friction peak is often observed. The exact magnitude of this friction peak is difficult to characterize, because this stage of friction heating is so rapid.

During the friction peak stage, the very high effective coefficient of friction results in considerable generation of heat. This heat allows the material in the region of the bondline to

Fig. 1 Schematic showing fundamental steps in the friction welding process. (a) One workpiece is rotated, and the other workpiece is held stationary. (b) Both workpieces are brought together, and axial force is applied to begin the upsetting process. (c) Workpiece rotation is stopped, and the upsetting process is completed.

increasingly plasticize. The increasing thickness of the plastic layers then results in a final transition, during which bonding and shearing is replaced by a continuous working and recovery of the material. This is sometimes referred to as a viscoelastic condition. In this third stage, the effective coefficient of friction is defined by the temperature and extent of this plasticized region. During this time, the temperature profiles become relatively stable (Ref 7, 8), resulting in an equilibrium condition. It is in this stage that effective coefficients of friction in the range of 2 are observed.

The effectiveness of this model suggests that such equilibrium friction conditions exist between the tool and the workpiece. Given the highly differing plasticization temperatures between the steel tool and the aluminum workpiece, such equilibrium conditions must be restricted to the aluminum substrate. This can only occur if, in the preliminary stages of the process, aluminum is deposited onto the working surfaces of the tool. Once material is deposited onto the surface of the tool, the necessary plasticized region is now defined between this deposited material and the substrate itself. This is consistent with observations of aluminum deposits onto the surface of FSW tools (Ref 9). For FSW purposes, enhanced heat generation can be said to occur through metallurgical coupling between the tool and the workpiece.

It is clear that such metallurgical coupling brings into question the applicability of a coefficient of friction. In such cases, heat generation is more properly related to material working (Ref 10). However, for inclusion into the simplified modeling described in this work, an interpretive coefficient of friction term, incorporating these strain heat effects, is used. This means that the heating occurs only at the surface, which is reasonable, because the plastic deformation is very localized just beneath the shoulder.

Friction Welding Technology

There are two principal FRW methods: direct-drive welding and inertia-drive welding.

Fig. 2 Schematic representation of the coefficient of friction variations during direct-drive friction welding

Direct-drive FRW, sometimes called conventional friction welding, uses a motor running at constant speed to input energy to the weld. Inertia-drive friction welding, sometimes called flywheel friction welding, uses the energy stored in a flywheel to input energy to the weld. These two FRW technologies produce inherently different metallurgical effects at the joint interface.

Both FRW technologies can be applied through different types of relative motion to generate the friction necessary to form the weld. The most common FRW geometry is that shown in Fig. 1, in which one cylindrical component is held stationary and the other is rotated. However, in other methods, both components are rotated in opposite directions, or two stationary components are pushed against a rotating piece positioned between them. Additional forms of FRW, such as radial, orbital, and linear reciprocating motions, have been developed for special part geometries. These alternate methods are discussed elsewhere (Ref 5, 11).

Direct Drive Welding

In direct-drive FRW, a machine resembling a lathe is equipped with a brake and clutch, a means of applying and controlling axial pressure, and a weld-cycle timer and displacement controller. The operation of a direct-drive machine consists of a friction phase where heat is generated, a stopping phase where the rotation is terminated, and a forging phase where the pressure is applied to join the pieces. The relationships among the process variables are shown in Fig. 3, which plots the rotational speed and the axial pressure as a function of time for a typical weld. The time required to stop the spindle is also an important variable, because it affects the weld temperature and the timing of the forging force.

The forging phase starts at the instant when higher pressure (that is, a larger forging force)

is applied in the weld cycle. Thus, the forging phase actually starts during the stopping phase. In general, the larger forging force is applied (case 1) while the spindle is decelerating in the stopping phase (Fig. 3) or (case 2) after the spindle has stopped rotating at the end of the stopping phase. The difference between the two cases is the presence of a second friction peak. In case 1, the torque will rise again to reach a second peak before dropping. This produces a torsional force. In case 2, especially when the stopping phase is very short due to rapid braking, frictional torque does not rise but actually starts to decrease at the onset of the forging phase. In this case, there is no torsional force, and forging is affected only by the upsetting force.

The speed of rotation is the least sensitive process variable in that it can be varied over a wide range if heating time and pressure are properly controlled. For steels, the recommended peripheral velocity varies from 75 to 215 m/min (250 to 700 ft/min) (Ref 12). In general, higher speeds correspond to low weld heat inputs and are used to weld heat-sensitive materials such as hardenable steels.

The friction force is generally applied gradually to the weld to help overcome the initial contact-torque peak. For carbon steels, a friction pressure of approximately 70 MPa (10 ksi) at the interface area is required to form a good joint. After the drive motor is disengaged from the workpiece, the forging force is applied to complete the weld. Typical forging forces for carbon steel are of 140 MPa (20 ksi) at the weld interface.

Inertia-Drive Welding

The inertia-drive FRW method uses a similar type of machine except that the spindle holding the rotating piece is attached to a flywheel. The flywheel controls the energy input to the weld. The moment of inertia of the flywheel is an important variable that is adjusted by adding

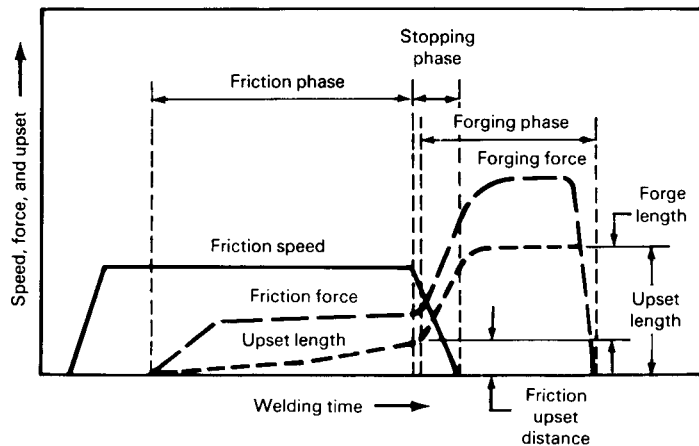

Fig. 3 Plot of selected parameters versus time relative to the three phases of the direct-drive friction welding process

or removing flywheel mass and diameter. The amount of energy stored in the flywheel is controlled by its speed. Once the spindle is at the correct speed, the drive system is disengaged, leaving a rotating flywheel mass. Axial pressure is then applied and held constant throughout the welding process. The applied pressure results in a decrease in the rotational speed, typically referred to as deceleration. In some cases, when the spindle has either nearly stopped or come to a complete stop, a higher forging force may be used.

Figure 4 illustrates the inertia-drive FRW process, which is similar to the direct-drive method in that the weld typically takes place in two stages: friction and forging. However, some weld schedules do not require a forging stage.

The major difference between the direct-drive and inertia-drive methods is the speed during the friction stage. In inertia welding, the speed continuously decreases during the friction stage, while in direct welding the speed remains constant.

The heat generated by the plastic deformation of materials at the faying surfaces during the forging phase, not the heat generated by friction in the friction phase, prevents rapid decrease of the temperature at the interface.

The process variables that control the characteristics of an inertia weld are the flywheel size (moment of inertia), the flywheel speed, and the axial pressure. The weld energy is related to the first two variables and is a fixed quantity once they have been determined. The kinetic energy in the flywheel at any time during the weld is given by:

$$E = \frac{S^2 \cdot I}{C}$$

where E is the energy (ft · lbf, or J), I is the moment of inertia (lb/ft², or kg/m²), S is the flywheel speed (rev/min), and C is a conversion constant that is equal to 5873 for English units or 182.4 for metric units.

The constant C is derived from:

$$E = \frac{1}{2}mv^2$$

where $v = \omega r$. Because $\omega = 2\pi S$, $v = 2\pi Sr$:

$$E = \frac{1}{2}m(2\pi)^2 S^2 r^2$$

$$E = \frac{1}{2}mr^2(2\pi)^2 S^2$$

Since $mr^2 = I$, the previous equation becomes:

$$E = \frac{1}{2}I(2\pi)^2 S^2$$

In SI units, the previous equation becomes:

$$E \left[\frac{\text{m}^2 \cdot \text{kg}}{\text{s}^2} \right] = \frac{1}{2}(2\pi)^2 S^2 \left[\frac{1}{\text{min}^2} \right] / [\text{m}^2 \cdot \text{kg}] \left[\frac{\text{min}}{60\text{s}} \right]^2$$

$$E = \frac{1}{2} \frac{(2\pi)^2}{60^2} S^2 I$$

$$E = \frac{I S^2}{C}$$

Solving for C in the previous equation:

$$C = \frac{2 \cdot 60^2}{(2\pi)^2}$$

$$= \frac{60^2}{2\pi^2}$$

$$= 182.378$$

The energy stored in the flywheel is proportional to its speed of rotation squared, S^2 . Therefore, a wide range of energy levels can be obtained without changing the flywheel to accommodate changes in part geometries. For large changes in the parts being joined, the capacity of an inertia welding machine can be modified by changing the flywheel moment of inertia if necessary.

Flywheel Energy. The moment of inertia of the flywheel is selected to produce both the desired amount of kinetic energy and the

desired amount of forging. Forging results from the characteristic increase in torque that occurs at the weld interface as the flywheel slows and comes to rest. This increased torque, in combination with the axial pressure, produces forging. Because forging begins at some critical velocity, the amount of forging depends on the amount of energy remaining in the flywheel, which is a linear function of the flywheel moment of inertia. Large, low-speed flywheels produce greater forging force than small, high-speed flywheels even though they contain the same amount of kinetic energy. Although small, medium, and large amounts of flywheel energy produce similar heating patterns, the amount of energy greatly affects the size and shape of the weld upset, as shown in Fig. 5(a) for similar-metal joints.

Peripheral Velocities. There is an optimum range of peripheral or linear surface velocities for each combination of metals being joined. For welding steel to steel, the recommended initial peripheral velocity ranges from 90 to 460 m/min (300 to 1500 ft/min). However, welds can be made at velocities as low as 85 m/min (275 ft/min). Figure 5(b) shows the effect of initial peripheral velocity on weld shape for similar-metal welds.

Axial Pressure versus Peripheral Velocities. The effect of varying the axial pressure is opposite to the effect of varying the velocity. Welds made at low axial pressure resemble welds made at medium velocity relative to the formation of weld upset and heat-affected zones (HAZ), as shown in Fig. 5(c). Excessive pressure produces a weld that has poor quality at the center and has a large amount of weld upset, similar to a weld made at a low velocity.

Metallurgical Parameters

Friction welding can be used to join a wide range of similar and dissimilar materials. Metals, ceramics, metal-matrix composites (MMCs), and polymers have been joined by FRW, and many of the dissimilar-metal combinations that cannot be joined by conventional fusion welding techniques are readily joined by FRW methods. This section summarizes some of the metals that have been joined by FRW and discusses the metallurgical considerations that govern the properties of the resulting weld.

Joining of Similar Materials

The two general requirements for forming good friction welds are, first, that the materials to be joined can be forged and, second, that the materials can generate friction at the weld interface. The first requirement eliminates similar-material welds in brittle materials such as ceramics, cast irons, and cemented carbides. However, ductile materials can sometimes be joined to these materials. The second

Fig. 4 Plot of selected parameters versus time relative to the two phases of the inertia-drive friction welding process

requirement eliminates materials that contain alloying additions that provide dry lubrication to the joint interface. Free-machining additives to steel, graphite-containing alloys such as cast iron, and lead alloys may be difficult to weld due to this requirement.

Almost all other metal alloys can be welded to themselves by FRW techniques. Table 1 summarizes a number of common similar-metal weld joints that have been made using inertia-

drive FRW. Metallic alloys known to form high-quality FRW joints include alloys based on aluminum, copper (copper-nickel, brass, bronze), iron (low-alloy steel, tool steel, stainless steel, maraging steel), nickel, titanium, tantalum, and many others (Ref 5, 11). Near full-strength metallurgical bonds can be produced for a very wide range of similar-metal alloy friction welds. The microstructure and mechanical properties of inertia-welded similar-metal

joints for the following alloys can be found in the sources listed:

Alloy	Ref
Low-alloy steels	13, 14
Austenitic stainless steels	15
Aluminum alloys	16-18
Titanium alloys	19

The relative ease of friction welding metals to themselves is related to the matching properties at the weld interface. Because the materials properties are matched, heat is distributed uniformly on both sides of the joint, and the deformation characteristics are identical on both sides of the joint. This results in symmetric welds with good properties. In general, the process variables do not vary significantly for different alloys within a given class of materials. However, there can be a significant variation in processing variables between different classes of materials (Table 1).

Because FRW generates localized heating at the interface, the HAZ is subject to rapid cooling due to heat transfer to the cold base metal. This rapid quenching may sufficiently alter the mechanical properties of the base metal in the HAZ region to require postweld heat treatment. For example, to restore ductility, stress relieving or tempering may be required to friction weld steels with hardenability greater than that of AISI 1035 (Ref 5, 11). In addition, age-hardenable alloys will lose strength in the HAZ during welding and may require postweld solution heat treating and/or postweld aging to restore their strength. Other alloys, such as those that obtain their strength from cold working, will lose strength in the HAZ of the weld, and their properties cannot be restored with postweld treatments.

Joining of Dissimilar Metals

While many similar-metal FRW joints are produced because of economic considerations, many dissimilar-metal FRW joints are produced because there are no alternative welding methods available. Examples of these types of joints include dissimilar-metal combinations with widely different melting points and

dissimilar-metal combinations that form incompatible phases when fusion welded. Table 2 gives parameters used for inertia welding several common dissimilar-material combinations.

Carbon Steels and Alloy Steels. In general, low- and medium-carbon steels are joined to each other under a wide range of conditions, and high-carbon steels are readily joined to alloy steels (Ref 12) using friction welding. High-speed tool steels are welded to alloy steel shanks for numerous machine-tool applications. Steel with carbon contents as high as 1.0%, such as 52100 steel, can be joined to lower-carbon alloys. Preweld heat treating may be required in some cases to better match the properties at the interface, and post-weld heat treatment may be required in some cases to temper the interface region of the high-carbon steel grades.

Stainless Steels to Other Selected Metals. Stainless steel alloys are comparatively easy to friction weld to other metals. For example, austenitic stainless steel to low-alloy steel (Ref 20), titanium and copper to stainless steel (Ref 21), and 1100 aluminum to stainless steel (Ref 22) are examples of transition joints that are made by FRW.

Titanium can be welded to stainless steel with extreme care (Ref 23), and other incompatible dissimilar combinations may be successfully welded using interlayer techniques (Ref 24). Figure 6 shows a micrograph of the interfacial region of an inertia weld between Monel 400 and 21-6-9 stainless steel. The joint properties are excellent, with plastic flow

occurring in Monel 400 before joint failure during bend testing.

Such transition joints can often be used as interlayers for the friction welding of incompatible materials. For example, it is difficult to weld 5083 aluminum directly to stainless steel. However, by first friction welding aluminum alloy 1100 to the stainless steel and machining the 1100 aluminum alloy back to an interlayer thickness of approximately 1 mm (0.04 in.), the 5083 aluminum alloy can be joined to the stainless steel via this 1100 interlayer with high joint efficiencies (Ref 25).

Figure 7(a) shows an example of an aluminum-base MMC that was friction welded to 1100 aluminum. The MMC is a 2024 aluminum alloy with 15 vol% Al_2O_3 particles. The interface region between these materials is shown at higher magnification in Fig. 7(b), where intermixing of both the materials is shown to occur.

Problems Common to Welding of Dissimilar Materials. In general, the same problems encountered when welding similar materials must be addressed when welding dissimilar materials. However, some problems are associated only with the welding of dissimilar materials or are greatly magnified during the welding of dissimilar materials. These factors include joint interfaces, low-melting phases, brittle phases, and different thermal expansions.

Joint Interfaces. While most similar-material welds are made with little concern for surface preparation, highly dissimilar-metal combinations are more sensitive. This happens for vari-

ous reasons. In stainless steel to aluminum alloy welds, the oxide surface that forms on the aluminum picks up contaminants such as water and hydrocarbons, forming extremely tenacious surface layers (Ref 26). If this layer is not removed prior to welding, poor structural welds may occur. In stainless steel to refractory metal alloy welds, the oxide on the faying surfaces again may contain contaminants such as water and hydrocarbons. The contaminants in this case are likely to alloy into the finished weldment. This alloying causes a reduction of structural integrity through the formation of low-melting or brittle phases at the weld interface.

Surface-treated interfaces frequently cause problems during FRW. Steels that have been carburized or nitrided, titanium alloys that have been nitrided, and other hardfaced alloys are difficult to friction weld due to the inherently low friction coefficient and low forgeability. The repeatability of welds made on materials with hard surface layers is difficult to characterize due to several factors, including coating thickness, coating quality, and physical properties of the coating. In most instances, weldability is improved if the surface-treated area is removed from the faying surface(s) before welding.

Low-Melting-Phase Formation. Some material combinations have very low-melting-point phases associated with mixing of constituents at the weld interface. The formation of these phases during the welding cycle is deleterious to the finished weld properties. Examples of combinations that fall into this category include

Table 2 Parameters for inertia-drive friction welding of two 25 mm (1 in.) diameter bars made of dissimilar metals

iron-base alloys to titanium alloys and aluminum alloys to magnesium alloys. Low-melting-point eutectics are found in both of these metallurgical systems, and great care must be exercised during parameter development to prevent the formation of liquid phases during the completion of successful welds.

Other weld combinations may be affected by contaminants at the weld interface. Examples include sulfur and phosphorus in iron-base alloys and bismuth in copper alloys. These contaminants may cause problems with hot shortness in very low concentrations. It is imperative that good cleaning practices be implemented when materials may have been contaminated with these elements or with material containing these elements.

Brittle-Phase Formation. Many materials, when combined, are susceptible to the formation of brittle phases. In some combinations, this occurs during the welding cycle; in others, service conditions after welding cause the problem. Two main reasons exist for brittle-phase formation in friction welds:

- Surface contaminants that embrittle the weld interface (see the section “Joint Interfaces” in this article)
- Formation of intermetallic phases between normal constituents of the alloys being welded

Intermetallic phase formation is common when welding refractory metal alloys to stainless steel alloys and in several other systems. In the case of stainless steels to refractory metals, σ phase or similar phases may occur at the interface upon welding. Proper weld procedure development reduces the amount of brittle phases that are formed but typically does not eliminate their formation completely.

Properly developed welds have satisfactory structural properties, because only small, non-continuous areas of the brittle phase are present at the weld interface. Figure 8(a) shows an inertia-drive welded joint between vanadium and 21-6-9 stainless steel. The interface is smooth and shows no areas of brittle phases. Electron microscopy techniques are needed to find the small areas of σ phase that could be present at the weld interface for this weld or for other deleterious phases in other material combinations.

Caution must be used when designing components for use at elevated-temperature extremes. In many instances, material combinations in which no brittle phases form during welding are susceptible to brittle-phase formation at the interface during high-temperature use. This is not a design issue when the welds are used for near-room-temperature applications. Figure 8(b) shows the vanadium to 21-6-9 stainless steel inertia-drive weld after a severe thermal cycle of 1000 °C (1830 °F) for 2 h with σ -phase and solid-solution growth at the weld interface. The thick layer next to the stainless steel is a solid solution of iron and vanadium. The thin layer next to the vanadium is σ phase and forms a continuous brittle fracture path across the weld interface.

Differential Thermal Expansion. Some material combinations are difficult to weld because of the large differences in thermal expansion. Low-expansion materials, such as refractory metals, ceramics, and low-expansion iron-nickel and iron-nickel-cobalt alloys, may fail or be highly stressed during cooling when welded to high-expansion material, such as austenitic stainless steels and nickel- and cobalt-base superalloys. Use of these combinations requires the designer to consider the large

stresses or metal fatigue developed within the fabricated structure if the welds are restrained when exposed to large temperature changes. Intermediate-expansion materials and multiple friction welds may be required to allow for the transition from high to low thermal expansion materials.

Fundamentals of Friction Stir Welding

P.S. De, N. Kumar, J.Q. Su, and R.S. Mishra, Missouri University of Science and Technology

TRADITIONALLY, WELDING OF METALS AND ALLOYS has been a fusion-based process where a filler metal is used for joining. The approach, although applicable to a wide variety of commercial alloys, has its own specific limitations due to the nature of the process. As an example, high-strength precipitation-strengthened aluminum alloys are nonweldable by fusion techniques due to problems of liquation cracking and porosity. Friction stir welding (FSW) techniques, invented at The Welding Institute of the United Kingdom in 1991, have successfully overcome these drawbacks of fusion welding methods (Ref 1, 2). The concept is remarkably straightforward: a cylindrical tool with a pinlike attachment is rotated and slowly inserted into the rigidly clamped joint to be welded (Fig. 1a). The frictional and deformational effects due to the rotating tool surface in contact with the workpiece cause plasticization of the metals to be joined. Translational movement of the rotating tool (actual or relative to the workpiece) results in the mixing of plasticized metal volumes, leading to joining (Fig. 1b). Control of the FSW process is currently thought of in terms of process parameters and is not related directly to fundamental deformation mechanisms. Friction stir welding can be viewed as a deformation process used to join metals rather than a joining process that involves deformation.

Figure 2 shows the schematic section of a friction stir welded workpiece with its different zones after macroetching. The microstructural particulars are explained in more details later in this article. In this context, the advancing and retreating side of a friction stir weld needs further explanation. As already mentioned, during FSW the tool rotates as well as translates along the joint to be welded. Half of the weld, where the tool rotation direction has similar sense to the tool translation direction, is known as the advancing side of the weld. The other half, where the tool rotation direction is opposite to the tool translation direction, is known as the retreating side of the weld. The macrostructures in the advancing/retreating sides are significantly different, particularly in their shape and microstructure, and are explained later in this article. Subsequent sections present the link between deformation and FSW process parameters in more details.

Thermal Aspects

As previously indicated, FSW involves plastic deformation at high strain rates and elevated temperatures, with resultant microstructural changes leading to joining. The heat generated in FSW is primarily from two sources: frictional and plastic deformation. The frictional component is an outcome of the rotational movement of the tool shoulder and pin surfaces with respect to the stationary

Fig. 1 (a) Schematic of a friction stir tool being inserted into the workpiece. The process is also sometimes called the plunge period of welding. The workpiece is clamped firmly to prevent any movement. The tool rotation direction and the pin thread handedness are adjusted such that material is pushed downward. (b) The tool fully plunged into the workpiece is moved along the seam while it is rotating, which consequently leads to welding due to mixing of metals in a plasticized state.

workpiece and is the primary heat source at the start of the process (i.e., the plunge period). The frictional heat generation causes a localized softening of the metal, which causes plastic deformation. During the pseudo-steady-state welding process, both frictional and plastic deformation contribute to the overall heat generation. Unlike other fusion welding techniques, in FSW no melting occurs (other than localized extreme parameters). In the next section, the results of experimental temperature measurements during FSW of various metals are summarized.

Temperature Measurement

The temperature generated during FSW is an important process variable and plays a vital role in determining the weld microstructure. Consequently, numerous experimental measurements of temperature around the weld zone have been reported. Figure 3 shows the peak temperatures measured around the welded region during a friction stir butt weld. It should be noted that no measurement in the actual welded region has been performed. This is primarily due to the experimental limitation imposed by the moving tool during the actual welding process. Table 1 summarizes a few examples of the maximum temperature measured in various metals during FSW, along with their locations (Ref 3–9). The first observation is that, regardless of the material welded, the temperatures measured were well below the

Fig. 2 Schematic macroetched section of a general friction stir welded microstructure with its different zones. TMAZ, thermomechanically affected zone; HAZ, heat-affected zone

solidus temperatures of the corresponding alloys. In addition, the microstructural features showed no obvious indication of melting. In fact, a detailed microstructural analysis of the weld nugget indicates the occurrence of a solid-state recrystallization type of phenomenon (see the section “Dynamic Recrystallization and Microstructural Evolution” in this article).

The temperatures reported in Table 1 were typical for the corresponding welding parameters. Thus, for the same welding setup, different FSW parameters result in different thermal cycles. Again, use of a different welding tool or weld backing plate will result in alterations of the thermal cycle. To predict and understand such changes, a thorough understanding of the factors controlling weld temperature is therefore essential. In the next sections, physical explanation of the heat input during FSW and the possible methods of their estimation are considered.

Heat-Source Estimation

Although heat-source estimation during FSW continues to be a topic of active research, this section covers the most common approaches adopted. One of the methods consists of measuring the power consumed by the machine during the welding process. Thus, Khandkar et al. (Ref 10) measured the torque and the

rotation rate during welding, from which the radial heat flux $\dot{q}(r)$ was calculated as:

$$\dot{q}(r) = \frac{P_{av}r}{\frac{2}{3}\pi R_{Shoulder}^3 + 2\pi R_{Pin}^2 H_{Pin}} \quad (Eq 1)$$

where P_{av} is the average power input calculated from the measured torque and rotation rate, $R_{Shoulder}$ is the shoulder radius, R_{Pin} is the pin radius, and H_{Pin} is the pin height. However, this method is limited by its inability to predict temperatures for unknown welding conditions. Moreover, the technique was based on the premise that heat generated during FSW was transferred fully to the workpiece, and it neglected any heat transferred to the tool and machine components. Schmidt and Hattel (Ref 11) proposed an alternative analytical model of heat generation where both the tool/workpiece contact condition and tool geometry were considered. According to this model, the total heat generated during the rotation of the tool can be expressed as:

$$Q_{total} = \frac{2}{3}\pi(\delta\tau_{yield} + (1 - \delta)\mu p) \cdot \omega \cdot [(R_{Shoulder}^3 - R_{Pin}^3)(1 + \tan \alpha) + 3R_{Pin}^3 H_{Pin}] \quad (Eq 2)$$

where δ is a dimensionless factor defining the contact conditions, τ_{yield} is the yield stress at the welding temperature and strain rates, μ is the

coefficient of friction, p is the contact pressure, ω is the tool rotation rate, and α is the tool shoulder cone angle. However, in this model Q_{total} is an implicit function of δ , τ_{yield} , μ , and p . Consequently, as in Eq 1, this restricts the prediction of weld temperature for cases where experimental measurements are unavailable (Ref 12). Because of the fully coupled thermomechanical nature of the friction stir process, temperature predictions for unknown weld conditions are possible only for models where both thermal and material flow equations are solved simultaneously. In fact, even in such coupled simulations, an appropriate model for heat generation is critical. A common approach adopted for this is an assumption that a finite fraction of the plastic work done during FSW is converted into heat. The plastic work done can then be calculated as:

$$\dot{q} = \beta \sigma \cdot \dot{\epsilon} \quad (Eq 3)$$

where β is the fraction of plastic work converted, σ is the stress, and $\dot{\epsilon}$ is the strain rate.

Alternatively, considering material to be a viscous fluid, the work done is calculated as a product of material viscosity (η) and strain rate and is given as:

$$\dot{q} = \beta \eta \cdot \dot{\epsilon} \quad (Eq 4)$$

The frictional heat contribution is generally regarded as a boundary condition and is expressed as:

$$\dot{q} = \mu p \dot{\gamma} \quad (Eq 5)$$

where $\dot{\gamma}$ is the slip rate, defined as the difference in velocity between tool surface and matrix. With a suitable heat-source model, the FSW temperatures can then be approximated using analytical/numerical methods.

Temperature Prediction: Analytical Approach

Any weld temperature prediction is based on the basic energy conservation equation, which can be schematically presented as (Ref 13):

$$\begin{aligned} \{ \text{Net rate of internal and kinetic energy stored} \} \\ = \{ \text{Net rate of internal and kinetic energy} \\ \text{flow by convection} \} \\ + \{ \text{Net rate of heat addition by conduction} \} \\ + \{ \text{Rate of heat generation} \} \end{aligned} \quad (Eq 6)$$

During FSW, the kinetic energy contribution is generally neglected, and the energy equation is adapted as:

$$\frac{\partial}{\partial t} \rho(C_p T) = -\vec{\nabla} \cdot \rho \vec{u}(C_p T) - \vec{\nabla} \cdot (k \vec{\nabla} T) + \dot{q} \quad (Eq 7)$$

where ρ is the material density, C_p is the specific heat capacity, T is the temperature, \vec{u} is the velocity, and k the thermal conductivity. Neglecting convective energy transport in Eq 7, analytical expressions for steady-state conditions can then be obtained by approximating the heat

Fig. 3 Peak temperature distribution around the friction stir weld (FSW) region of a 6.35 mm (0.25 in.) thick butt-welded AA7075-T651 alloy. Source: Ref 3

Table 1 Summary of temperatures measured during friction stir welding of various metals

Serial	Alloy	Location measured	Temperature, K	Ref
1	AA6061-T6	Top surface and weld center	698	4
2	AA7075-T651	~0.6 mm (0.02 in.) below top adjacent to stir zone	748	3
3	AA6061-T6	...	810	5
4	AA1050	Close to stir zone bottom	583	6
5	AISI-1018	Shoulder-workpiece interface	1263	7
6	AA2195-T8	Adjacent to pin edge at plate middle	723	8
7	AZ-31	Measured in heat-affected zone	633	9

source as a line or point geometry. Thus, for point heat-source geometry, the pseudo-steady-state temperature distribution (Rosenthal's thick plate solution) is given as (Ref 14):

$$T - T_0 = \frac{q_0}{2\pi k} \left(\frac{1}{R} \right) \exp\left[-\frac{v}{2a}(R+x)\right] \quad (\text{Eq 8})$$

where T_0 is the initial plate temperature, v is the welding velocity, $a (= k/\rho C_p)$ is the thermal diffusivity, R is the distance from the source to the point of measurement, and x is the X -coordinate in the moving reference axis system (located at the source). For line heat-source geometry, the pseudo-steady-state temperature (Rosenthal's thin plate solution) distribution is given as (Ref 14):

$$T - T_0 = \frac{q_0/d}{2\pi k} \exp\left(\frac{vx}{2a}\right) K_0\left(\frac{vr}{2a}\right) \quad (\text{Eq 9})$$

where $K_0(vr/2a)$ is the modified Bessel function of the second kind and zero order. In fact, the first assessments of FSW temperature done by Gould and Feng (Ref 15) and Feng et al. (Ref 16) used Rosenthal's model. However, such analytical models are applicable only for very specific boundary conditions. Thus, in practical welding situations, heat loss through the tool and backing plate limits the applicability of such analytical models. In such instances, numerical solution to the problem is expected to give a better prediction. The next section discusses the results of such numerical models on FSW in more detail.

Temperature Prediction: Numerical Approach

As mentioned previously, a thorough analysis of temperature requires a simultaneous

solution of thermal and material flow equations. However, solving such coupled equations is exceedingly complex and is associated with specific limitations. In this section, temperature prediction by the solution of Eq 7 alone is discussed. The approach for such temperature prediction is based on numerical methods such as the finite-difference and finite-element methods.

However, subtle differences exist between the works of various authors. Thus, Song and Kovacevic (Ref 5) considered \dot{q} as a boundary condition with heat generation due to friction at the shoulder/matrix interfaces. Both friction and shear were considered to be the heat-generation source at the pin/matrix interface. The coefficient of friction was assumed to be a constant value (~ 0.4). On the other hand, Khandkar et al. (Ref 10) assumed the existence of a uniform shear stress at the entire tool/matrix interface. The total heat input was derived from the torque measurements obtained from actual FSW experiments. The simulated time-temperature profile obtained was then matched with the experimental data by assuming an appropriate conductance value of the base plate. Frigaard et al. (Ref 17) calculated the temperature profile by using an adjustable friction coefficient. The friction coefficient was adjusted such that the peak processing temperature never exceeded the liquation temperature. However, during the initial plunge period, the coefficient of friction was assumed to be a constant with an approximate value of 0.4. The pressure (P) during FSW was assumed to be constant. Similar simulations done by Khandkar and Khan (Ref 18) resulted in a friction factor value of only 0.15. As can be noted, although the predicted

temperature profiles matched with the measurements, the coefficient of friction assumed by various authors was inconsistent. The results clearly indicate that using friction as the sole heat-generation source is unrealistic and does not simulate the actual process occurring during FSW.

Material Flow

The discussion on thermal aspects of FSW and the variation in friction coefficients clearly indicates that plastic flow plays a crucial role during heat generation. In the next section, the experimental results on material flow during FSW are presented.

Experimental Aspects

Experiments on material flow in FSW can be categorized into two main groups: marker studies and dissimilar welding. In the marker studies, small, undissolvable material such as steel balls or SiC particles (in aluminum) are inserted in grooves machined along the welding path. The passage of the FSW tool and accompanying material flow displaces the markers, from which the material movement during FSW is reconstructed. In the dissimilar-welding technique, materials that etch differently are welded together, with the material flow reconstructed by postweld chemical etching. Alternatively, microtextural changes after FSW have also been used to understand the material movement. A more detailed discussion on texture evolution during FSW is given in the section "Texture" in this article. In Table 2, the results

Table 2 Summary of marker study results by various authors

Study type	Ref	Flow pattern
Steel shots in AA6061-T6 and AA7075-T6	19	(a) Steel shots affected by shoulder deposited chaotically and moved downward (b) Steel shots in pin front deposited continuously behind pin and moved up
AA5454-H32 marker in AA2195-T8	20	(a) Material stirring occurs only at shoulder-affected zone. (b) In pin-affected zone, material moves behind its original position. (c) For threaded pins, a secondary vertical flow exists.
Radioactive Ni tracer in AA2219-T8	21	Metal rotated around tool in a thin sliver just beneath shear surface ("wiping flow") in last-in/first-out mode.
Microtexture study in AA6063-T5	22	(a) Transverse weld section microtexture shows {111} planes as roughly parallel to pin surface. (b) The <110> directions were parallel to transverse direction. (c) Shear type of plastic flow along pin surface
Microtexture study in AA1100, AA6061-T6, and C458 alloy	23	(a) Dominant shear direction is aligned tangent to rotating tool. (b) Secondary shear direction along tool such that {111} planes are inclined 70° from the dominant shear direction
Cu foil along faying surface in AA6061-T6	24	(a) Advancing-side material deposits behind pin on advancing side. (b) Retreating-side material stays on retreating side. (c) Vortex movement within rotational zone associated with the pin
Microtexture study in AZ-61 alloy	25	(a) Prominent basal texture (0002) of base material traced an ellipsoid surrounding the pin column. (b) The effect was not noticed near the shoulder region. (c) Onion-ring structure and nugget shape associated with the elliptical trace of (0002) texture
Al-30vol%SiC and Al-20vol%W markers in AA7050 alloy	26	(a) Upward movement of material ahead of pin (b) Markers at advancing side distributed over a much wider region in the wake of weld compared to weld centerline (c) Downward movement of material due to tool threads
Microstructural studies on AA2024-T3/2524-T3	27	(a) Metallurgical bands (low-strain and high-strain alternating bands observed on etching) form, which correspond closely to tool marks. (b) Variation in secondary particle segregation and grain size along bands
Microstructure studies on AA2024-T3/2524-T3	28	(a) Strong correspondence between strain response and metallurgical bands (b) High-strain bands correspond to lower particle density, larger grain size. Reverse is true for lower-strain bands.
Textural studies on AA2195-T8 alloy	29	(a) The {111} planes are aligned with the tool rotation axis. (b) Randomly oriented grains in nugget
Cu as marker in AA2024-T3 alloys	30	(a) Average material flow velocity 0.1–0.3 times the tool rotation speed (b) Three different zones of rotation around the pin are proposed: rotation, transition, and deflection. (c) In rotational zone, material sticks to tool and undergoes multiple rotations.

of some marker and microtextural studies done in FSW have been summarized (Ref 19–33), and a typical example is presented in Fig. 4. The basic material flow characteristics obtained from experiments can therefore be summarized as follows (Ref 31):

- Near the shoulder region, material from the retreating side is dragged across the weld centerline and deposited on the advancing side.
- Material intersecting the pin travels around the retreating side and is deposited behind the tool, being moved backward from the original position by no more than one pin diameter, except for welds where shoulder flow dominates (e.g., in thin-sheet welding).
- Flow pattern similar to that of the shoulder is seen near the pin bottom, but on a much smaller scale.
- Tool runout can affect the material flow in addition to causing periodic variation in welding forces.

Although the aforementioned flow features were obtained mostly from FSW of aluminum alloys, similar studies on magnesium alloys and steels reveal identical material flow characteristics (Ref 25, 32). Therefore, the material flow characteristics mentioned previously holds true regardless of the crystal structure of the metal considered.

Another typical flow characteristic observed in FSW is the banded feature, which is observed on etching of FSW cross sections, as seen in Fig. 5 (see also the discussion on “onion rings” in the section “Cross Section of FSW Material” in this article). These bands are characterized by alternating microstructures with different grain and particle size distributions in the weld nugget, where the individual bands are separated by a distance equal to or less than the tool advance per revolution

(i.e., v/ω). Recent experiments by Yan et al. (Ref 35) indicate that the banding is associated with periodic oscillations in force that occur during each tool revolution in FSW and are unaffected by tool runout. However, at present no definite explanation for this periodic metallurgical feature is established, although broadly, material flow has been accepted to be behind its genesis.

Analytical Modeling

In this section, two analytical models, supplemented by experimental/numerical flow models, are described. In Nune’s (Ref 21) rotating plug model, the flow in the proximity of the tool pin was approximated by a rotating disc that is superimposed on a continuum moving at the speed of welding. The particle trajectory during FSW was therefore expressed as (Ref 21):

$$x^2 + \left(y + \frac{v}{\omega}\right)^2 = \text{Constant} \quad (\text{Eq 10})$$

The boundary of the rotating disc was considered to be a region of velocity discontinuity, that is, the shearing surface. Additionally, a vortex flow due to tool thread action was also incorporated where the radial velocity of material was assumed to vary sinusoidally with the weld depth. Although Nune’s (Ref 21) model partially simulated the material flow as observed by nickel tracer distribution, it is inapplicable for unthreaded tools and lacks physical explanation, particularly for the shoulder-affected region of FSW.

Schmidt and Hattel (Ref 36), on the other hand, proposed a two-dimensional analytical model to determine the material shear layer thickness located around the rotating tool (Fig. 6). This model explains the shear layer asymmetry observed in FSW experiments

and assimilates the rotation and transition zone concepts proposed by Guerra et al. (Ref 24). Schmidt et al. (Ref 30) further used this model to calculate the material flow velocity during FSW in a separate experimental paper published later. The width of the shear layer (w_θ) variation as a function of angle, θ (Fig. 6), calculated from the centerline of the weld (positive toward retreating side and negative toward advancing), was expressed as (Ref 36):

$$w_\theta = \frac{2R_{\text{pin}}v(\sin\theta + 1) + w_{\text{adv}}\omega}{\omega R_{\text{pin}} - v\sin\theta} \quad (\text{Eq 11})$$

Although the aforementioned analytical models provide valuable insight into the material flow mechanisms, they have a limited practical use. Consequently, numerical simulations are assuming a more significant role in extending the current understanding about the processes that occur during FSW.

Numerical Modeling

Standalone material flow models, although physically inaccurate, do provide significant insight into the process when done in tandem with experimental results. The mass and momentum balance equations form the basic building block for such simulations, where the mass balance equation is given as:

$$\frac{\partial \rho}{\partial t} = - \left[\frac{\partial(\rho u_x)}{\partial x} + \frac{\partial(\rho u_y)}{\partial y} + \frac{\partial(\rho u_z)}{\partial z} \right] \quad (\text{Eq 12})$$

with the density, ρ , remaining constant for all practical purposes. The momentum balance equation is expressed as (Ref 13):

Fig. 4 Distribution showing the position of AA5454-O markers (white region) in AA2195-T8 alloy after the passage of friction stir tool pin. The markers placed perpendicular to the weld path moved backward by a distance equal to the chord length intersecting the pin circle, and oriented parallel to welding direction. The double arrow gives a measure of the pin diameter used. Source: Ref 31

Fig. 5 Difference in grain size within the ring patterns observed in the horizontal-section microstructure of a bead-on-plate run of cast A356 alloy. The tool advance per revolution (APR) was 0.1 mm (0.004 in.). Note that the gap between the bands matches the APR from Ref 34.

Fig. 6 Various layers in friction stir welding nugget as proposed by Schmidt and Hattel (Ref 36). The streamlines (ψ) of material flow are also depicted, along with the shear layer variation with θ . Source: Ref 30

 & + \{\text{Gravitational force on element per unit volume}\} \\
 & + \{\text{Body forces}\} \qquad \qquad \qquad \text{(Eq 13)}
 \end{aligned}$$

Schmidt and Hattel (Ref 37) used a two-dimensional version of Eq 13 to model the material flow around the pin, where the material during FSW was assumed to follow a non-Newtonian power law equation. These simulations showed the presence of a rotational and transition zone, as proposed by Guerra et al. (Ref 24). Similar material flow simulations in two dimensions conducted by Xu et al. (Ref 38) used an adaptive Lagrangian-Eulerian technique (ALE) in combination with the experimental temperature measurements from a previous work. The results showed that material flow in FSW occurs along the retreating side, replicating the general flow feature observed during experiments. A complete understanding of material flow, however, requires three-dimensional simulations with simultaneous consideration of both thermal and material flow models. In the next section, a brief discussion on coupled modeling in FSW is presented.

Coupled Numerical Modeling

The principal intent of coupled numerical modeling using finite-element modeling (FEM) is to solve the energy and momentum partial differential equations (i.e., Eq 6 and 13) simultaneously. Depending on the approach taken, the heat source is modeled on the basis of Eq 3 and 5 or Eq 4 and 5. Thus, when material flow is considered to be a plastic deformation problem, Eq 3 and 5 are used, and when in the fluid dynamic approach, Eq 4 and 5 are adopted. However, in both cases, the stress response variation of the metal to changing temperatures and strain rate, that is, the choice of constitutive equation, determines the accuracy of the simulations.

Table 3 summarizes the constitutive equations adopted by various authors during FSW simulations, where the equation constants are obtained from isothermal hot compression experiments or torsion experiments. During hot compression experiments, the levels of strain achieved are much lower compared to those estimated for FSW. On the other hand, in torsion experiments, although levels of strains achieved are higher than in the hot compression case, the strain distribution is nonuniform, being highest at the surface and zero at the specimen center. Thus, the strain rate and temperature regimes during such experiments are significantly different from that of FSW, which introduces inherent uncertainties into the constitutive equations adopted.

Another important difference is the capability of the simulations to reproduce different welding defects (see the section “Simulation of Defect Formation” in this article) that occur during FSW. To understand the complexities of such simulation, the difference between Lagrangian and Eulerian representation in kinematics needs further

elucidation. In Lagrangian representation, the flow path of individually identifiable material volumes is traced with respect to their initial position. The Eulerian flow representation, on the other hand, tracks the material velocity at fixed locations in the space. Plastic deformation modeling uses the Lagrangian representation, while fluid dynamics modeling uses the Eulerian representation. In other words, the finite-element mesh during plastic deformation modeling distorts with the progression of the simulation, while in the fluid dynamics approach, the finite-element mesh remains undistorted. This, along with the contact surface requirements during FEM-based modeling, makes defect simulation using the fluid dynamics approach unachievable. Again, excessive mesh deformation during plastic-deformation-based FSW simulation creates numerical instabilities, causing Lagrangian representations to be inherently difficult to simulate. Currently, attempts are being made to address this issue by using more complex numerical methods, such as the ALE technique (Ref 39). In fact, Schmidt and Hattel (Ref 39) have shown that defect simulation using the ALE technique is numerically achievable (see the section “Simulation of Defect Formation” in this article). In Table 4, a summary of the different coupled numerical approaches used by various authors is presented.

Friction

As discussed previously, frictional heat generation is a major part of the FSW process.

Table 3 Constitutive models adopted in friction stir welding simulations published in literature.

Here, Z denotes the Zener-Holloman parameter, and σ , $\dot{\epsilon}$, and $\bar{\epsilon}$ are the average stress, strain rate, and strains, respectively. T_M is the melting point, and T_{ref} is a reference temperature. Remaining variables are material constants and are obtained experimentally.

Ref	Constitutive model used
39	$\sigma = (A + B[\dot{\epsilon}]^n) \left(1 + C \ln \frac{\dot{\epsilon}}{\dot{\epsilon}_0}\right) \left(1 - \left(\frac{T - T_{ref}}{T_M - T_{ref}}\right)^m\right)$
40	$\sigma(T, \dot{\epsilon}) = \frac{1}{2} \ln \left(\left[\frac{Z}{A}\right]^{1/n} + \left\{ \left[\frac{Z}{A}\right]^{2/n} + 1 \right\}^{1/2} \right)$
41	$\sigma_e = \frac{1}{2} \sinh^{-1} \left[\left(\frac{Z}{A}\right)^{1/n} \right]$
42	Extrapolation from experimental data
43	$\sigma = KT^A (\dot{\epsilon})^B (\bar{\epsilon})^C$
44	$\sigma_e = \frac{1}{2} \sinh^{-1} \left[\left(\frac{Z}{A}\right)^{1/n} \right]$
45	$Z = A(\sinh \alpha \sigma)^n$

Table 4 Summary of coupled simulations in friction stir welding as published in literature

Simulations are differentiated on the basis of modeling approach used: ALE, adaptive Lagrangian-Eulerian; CFD, computational fluid dynamics; and LM, Lagrangian method. The temperatures mentioned in column 4 are the peak simulation temperatures.

Ref	Approach	Material	Temperature, K	Other variables predicted
39	ALE	AA2024-T3	773	Deformation field, plunge force
40	CFD	AA6061-T4	Isothermal	Material flow, power, X-force
41	CFD	AA7075-T7	701	Material flow, pin forces
42	LM	AA6061-T6	773	Residual stress
43	LM	AA7075	731	Strain distribution, material flow
44	CFD	AISI-1018	1100	Strain rate, tool torque, material flow
45	CFD	AA5083 and AA7075-T6	1133	Material flow, transverse force, power

The frictional heat generated at the tool/work-piece interface is considered to be particularly important at the beginning of the process (plunge portion) and was also observed in the simulations of Schmidt and Hattel (Ref 39). According to Schmidt and Hattel’s simulation, during the pseudo-steady-state period of actual welding, the contribution of heat generated due to frictional forces decreases to ~25% of the total heat generated (Ref 39). Nonetheless, for accurate FSW process simulation, a proper assessment of frictional heat contribution is essential.

Frictional forces can be classified mainly into two types: Coulomb’s and constant shear. For Coulomb’s friction, the frictional force is expressed as:

$$\sigma = \mu p \qquad \qquad \qquad \text{(Eq 14)}$$

where μ is the Coulomb’s coefficient of friction, and p is the pressure applied. The frictional stress for the constant shear model is given as:

$$\sigma = m \frac{\sigma_0}{\sqrt{3}} \qquad \qquad \qquad \text{(Eq 15)}$$

where m is the friction factor, and σ_0 is the flow stress of the material. Schmidt and Hattel (Ref 11) proposed a modified description for the frictional forces during FSW, where three different conditions were assumed to exist. They are sticking condition, sliding condition, and partial sliding/sticking condition. A modified contact variable, δ , was proposed (see the

section “Heat-Source Estimation” in this article), which was defined as (Ref 11):

$$\delta = \frac{U_{\text{matrix}}}{U_{\text{tool}}} \quad (\text{Eq 16})$$

where U_{matrix} is the linear matrix velocity, and U_{tool} is the corresponding linear tool velocity at that position. This was subsequently used to develop an analytical model for heat generation in FSW (Eq 2). Thus, for the sliding condition, the value of m in Eq 15 is 0, while for sticking friction, m assumes a value of 1. It should be noted that in FSW, coefficient of friction values greater than 1 have also been reported. Colligan and Mishra (Ref 46) have reported coefficient of friction values as high as 1.3 (Fig. 7). This relates to the complexity of the frictional conditions during FSW. The experimental and theoretical approaches so far try to obtain or use a value of coefficient of friction for a particular run. However, the coefficient of friction would vary across the tool shoulder and pin surface because the pressure and temperature is location-specific. A fundamental understanding of this is lacking.

Defects

Improper processing leads to defects in the welded zone in all joining processes, and FSW is no exception. The defects have been found

in butt joints as well as lap joints. Material flow and heat-generation patterns have been attributed to the creation of defective welds. In this section, types of defects, processing parameters affecting the generation of these defects, and results of theoretical models and simulations to understand the formation and control of defects during FSW are discussed.

Types of Defects

Arbegas (Ref 47) reported various types of defects (wormhole or voids, lack of penetration, lack of fusion, surface lack of fill, root-flow defect, nugget collapse, surface galling, and scalloping), and representative examples of these are shown in Fig. 8. These defects are either flow related or geometric. Also shown in Fig. 8 is a processing map correlating the tool rotational rate and tool traverse speed and the impact of these parameters on the generation and control of these defects. In flow-related defects, processing of a material outside the processing window leads to defect generation due to unbalanced material flow. Improper tool selection, insufficient plunge depth, unequal thicknesses of joining materials, or improper seam tracking lead to geometric defect formation.

Among all, the most commonly encountered defects are voids, joint-line remnants, and improper root penetration (Ref 48). Voids have been reported to form on the advancing side of

the welds. Some of the voids formed during FSW are shown in Fig. 9. Figure 9(a) shows a predominantly surface-breaking void (Ref 49). A tunnel type of void is shown in Fig. 9(b) (Ref 50).

A joint-line remnant (JLR) defect is also termed a lazy “S” or zigzag line (Ref 51). If processing parameters or surface conditions at the interface of the materials being joined are such that, during processing, oxide layers cannot be disrupted, it leads to formation of a JLR. The oxide layers are present at the faying surface of the workpieces to be joined. A representative example is shown in Fig. 10 (Ref 48). Like other defects, JLR is also dependent on processing and geometric conditions.

Among many parameters, a considerably smaller pin height compared to the thickness of the plates to be joined and positioning of the tool relative to the joint interface are the main reasons for incomplete root penetration. Local thickness variation of plates may also lead to this defect (Ref 48).

Kim et al. (Ref 52) discussed three other types of defects: excess heat input resulting in flash formation, cavity- or groove-like defects, and abnormal stirring that leads to cavity formation. The groove and channel defects have also been reported by Chen et al. (Ref 53).

Parameters Affecting Defect Formation

Tool rotational rate, tool traverse speed, axial pressure, tool tilt angle, tool geometry, and gap between plates are a few important processing parameters determining the quality of the weld. Tool rotational rate affects the formation of defects in two ways. Low rotational rate causes lower heat input and hence less softening of the materials being joined, and very high rotational rate causes abnormal stirring. Kim et al. (Ref 52) have addressed these two aspects of the effects of rotational rate on the formation of weld defects. Figure 11 shows the effect of rotational rate on void formation. As can be noted, lower rotational rate led to insufficient heat input and resulted in defect formation. On increasing the rotational rate from 1250 to 1500 rpm and keeping the tool traverse speed the same (250 and 500 rpm) in the first two cases, sound FSW welds were obtained. On further increasing the rotational rate, defects appeared again due to abnormal stirring of the processed material. Kim et al. (Ref 52) suggested that the abnormal stirring was a result of a difference in temperatures between the upper and lower parts of the weld. In Fig. 11, the effect of axial pressure can be noted as well. For the defects arising due to insufficient heat input, increasing axial pressure reduced the size of the void. The effect of increase in axial pressure on the defects generated due to abnormal stirring was marginal.

In a study to show the effect of welding speed, Zhang et al. (Ref 54) changed welding speed from 40 mm/min (1.6 in./min) to 600

mm/min (24 in./min) at a constant rotation rate of 1000 rpm. The micrographs from their study demonstrating the effect of welding speed on defect formation are shown in Fig. 12. It can be noted that voids formed at a welding speed of 200 mm/min (8 in./min).

The effect of tool geometry has been studied by Elangovan and Balasubramanian (Ref 55, 56). Five different pin profiles (straight cylindrical, threaded cylindrical, tapered cylindrical, square, and triangle) were used by these

researchers, and the formation of a sound weld was discussed in terms of the effect of pin profiles on material flow. The material flow was explained on the basis of the relationship between the static and dynamic volume defining the zone of thermomechanically plasticized material flow. The effect of shoulder diameter on defect formation has also been addressed (Ref 55). Using a larger-diameter tool resulted in formation of sound welds due to sufficient heat input compared to tools with smaller diameters.

Tool tilt angle also has an influence on defect formation. Chen et al. (Ref 53) studied the effect of tool tilt angle on the formation of weld defects. The formation of groove-type defects was reported by these authors at a very small tool tilt angle (1°) on the advancing side of the weld. At a tool tilt angle of 3.5° , a sound weld formed. However, on further increase of the tilt angle $\geq 4.5^\circ$, void formation was observed again.

Leal and Loureiro (Ref 50) have studied the effect of alloys on the formation of defects. Three alloys, 5083-O, 2024-T3, and 6063-T6, were used in that study. Under the processing conditions used, 6063-T6 did not show any defects, whereas defects were observed in the remaining two alloys. This shows the link between the flow behavior of the material and defect formation.

Leonard and Lockyer (Ref 49) have shown the effect of the presence of joint gap on weld formation. A joint gap of 3.2 mm (0.13 in.), which corresponded to 50% of the plate thickness, resulted in a defective weld, and the presence of a cavity was reported on the advancing side of the weld.

Theoretical Models of Defect Formation

To develop a physical understanding of the defect formation process, efforts have been made to develop theoretical models by various researchers (Ref 52, 54, 57). Here, the model developed by Arbegast (Ref 57), based on a flow-partitioned deformation zone, is discussed. (Refer to Ref 52 and 54 for more details.)

Arbegast (Ref 57) divided the material flow process during FSW into four zones, as shown in Fig. 13. In accordance with this model, material passing through zone III on the retreating side is dragged toward the advancing side. It is interleaved with the material flowing from

the advancing side and is pushed vertically downward, entering zone I. Part of the material flowing in zone II may enter zone IV under the pin before entering into zone I from zone IV.

This model is based on the criterion of mass balance; material entering the cavity on the

trailing side created by the tool movement per revolution should be exactly balanced by the material flowing from the leading side of the tool. It was defined as the critical total mass flux of material, M_T^{cr} , and this is given as:

$$M_T^{cr} = \rho(\alpha \cdot \beta \cdot \phi^2)^{-1} \tag{Eq 17}$$

where ρ , α , β , and ϕ are the density of the material, the pin shape factor (mm^{-1}), the shoulder shape factor (mm^2), and the processing parameters (defined as tool rotational rate/tool traverse speed), respectively. For the extrusion zone, Eq 17 can be rewritten for a specific location (i) as:

$$M_T^{cr} = \sum \rho_i \left(\alpha \cdot \beta \cdot \left(\frac{\omega_i}{v_i} \right)^2 \right)^{-1} \tag{Eq 18}$$

In Eq 18, ω_i and v_i are the tool rotational rate and tool traverse speed, respectively. The whole process of welding is divided into three zones in terms of material flow: initial deformation zone (M_T^i), extrusion zone (M_T^e), and forging zone (M_T^f). The variables M_T^i , M_T^e , and M_T^f are given as:

$$M_T^i = M_I^i + M_{II}^i + M_{III}^i + M_{IV}^i = \sum_{j=I}^{IV} M_j^i \tag{Eq 19}$$

$$M_T^e = M_T^i + M_T^{XS} = \sum_{j=I}^{IV} M_j^i + \sum_{j=I}^{IV} M_j^{XS} \tag{Eq 20}$$

$$M_T^f = M_I^f + M_{II}^f + M_{III}^f + M_{IV}^f = \sum_{j=I}^{IV} M_j^f \tag{Eq 21}$$

For a defect-free weld, balanced material flow should take place, and this criterion is met when $M_T^f = M_T^{cr}$. For defect formation, $M_T^f < M_T^{cr}$. In such cases, $M_T^e = M_T^e + M_T^{wh}$ and M_T^{wh} is termed as wormhole mass deficiency and defined as:

Fig. 12 Friction stir weld regions at tool traverse speed of (a) 40 mm/min (1.6 in./min), (b) 120 mm/min (4.7 in./min), (c) 150 mm/min (6.0 in./min), and (d) 200 mm/min (8.0 in./min). Processed region corresponding to 200 mm/min shows void. Source: Ref 54

Fig. 13 Flow-partitioned zone model showing the flow of material during friction stir welding. Source: Ref 57

$$M_T^{wh} = M_T^{cr} - \sum_{j=1}^{IV} M_j^i - \sum_{j=1}^{IV} \psi_j(\alpha, \beta, \phi^2) \quad (\text{Eq 22})$$

where $\psi_j(\alpha, \beta, \phi^2)$ is an excess material factor that takes the excess material entering the extrusion zone into account. Hence, the flow-partitioned zone model represents formation of the defect in terms of an imbalance created by material flow from one zone to another.

Some of the defects shown in Fig. 8 can be explained using Arbegast's flow-partitioned model. Inadequate flow of materials to zone I from zones II, III, and/or IV would cause a third term on the right side of Eq 22 to be less than needed for mass balance. Consequently, it will result in formation of defects such as lack of fill, wormholes, or lack of consolidation. If there is very little or no flow of materials from zone II to zone IV, it will again create mass imbalance in zone IV and may result in a root-flow defect.

Simulation of Defect Formation

Despite availability of a large volume of experimental and theoretical data to understand the material flow during the FSW process, the exact nature of material flow is not known due to the complex nature of thermomechanical conditions during welding. Consequently, the formation of defects is not properly understood. Due to improved computational capability and the availability of commercial codes to simulate large deformation, efforts have been made to simulate the material flow process during FSW. Schmidt and Hattel (Ref 39) used fully coupled three-dimensional thermomechanical finite-element models using ABAQUS/Explicit to study the material flow during FSW. An ALE formulation and Johnson-Cook material model was used to model the system. The output of their simulation study leading to the prediction of void formation is shown in Fig. 14. It shows the formation of a void on the trailing side of the lower advancing side at the pin/matrix interface.

Strain and Strain Rate in FSW

For a severe plastic deformation process such as FSW, knowledge of the strain and strain rate experienced during processing is essential to understand the microstructural evolution. Such strain and strain-rate estimations have been carried out by various researchers using experimental, analytical, and simulation techniques. In some cases, a combined approach was also adopted. These efforts are summarized in Table 5.

A more simple and elegant way of estimating the strain and strain rates during FSW is the analytical approach, some of which is discussed further. Chang et al. (Ref 63) assumed the deformation process during FSW to be of the torsion type, which led to an expression for

strain rate. (Note: The texture observed after FSW is similar to torsional deformation; see the section "Texture" in this article.):

$$\dot{\epsilon} = \frac{\omega \pi r_e}{L_e} \quad (\text{Eq 23})$$

where r_e is the radius of the dynamically recrystallized zone, and L_e is the depth of the dynamically recrystallized zone. Long et al. (Ref 64) used the two-dimensional material flow field observed around the tool pin during experiments and simulations to propose a model for calculating strain and strain rate (Fig. 15). In this model, it was assumed that each streamline intersecting the pin on the leading side of the tool was transported to the trailing side at a position equal to the respective chord length. Based on this assumption, the expression to calculate strain in the FSW shear zone was given as:

$$\epsilon = \ln\left(\frac{l}{APR}\right) + \left| \ln\left(\frac{APR}{l}\right) \right| \quad (\text{Eq 24})$$

$$l = 2r \cos^{-1}\left(\frac{r-x}{r}\right) \quad (\text{Eq 25})$$

where APR is defined as the advance per revolution of the tool, l is the maximum stretched

length of a material in the shear zone of an initial length equal to APR, and r and x are the radius of the pin and the distance of the streamline from the retreating side of the tool, respectively. An estimate of the strain distribution in the processed zone for an APR = 0.5 mm/rev (0.02 in./rev) and a pin diameter of 10 mm (0.4 in.) is shown in Fig. 16 (Ref 64). It can be noted from Fig. 16 that, on the retreating side, strain is zero, while a maximum in strain is observed (in this case, ~8) on the advancing side. This is consistent with the experimental observations during FSW. A sharp transition from the base material to the advancing side of the processed zone and a gradual transition from the retreating side to the base metal are also observed. The average strain rate was calculated by obtaining the average strain from Eq 24 and 25, which was divided by the time per revolution (Ref 64). A typical result of this model is presented in Fig. 17.

The estimates for strain and strain rate discussed previously involve considerable simplification and assumptions. Hence, the actual strain and strain rate involved may be different from the values reported. A better understanding of the material flow process in the future is therefore expected to result in more comprehensive theoretical and computational models.

Overall Microstructural Feature

Cross Section of FSW Material

The microstructure and its distribution produced during FSW are dependent on several factors. The contributing factors include alloy composition, initial material temper, welding parameter, tool geometry, and cooling rate. Based on microstructural characterization of grains and precipitates, a typical cross section of an FSW joint can be identified by three distinct zones: stirred (nugget) zone, thermomechanically affected zone (TMAZ), and heat-affected zone (HAZ) (Ref 67, 68). The HAZ is similar to that in conventional welds, although the maximum peak temperature is significantly lower than the solidus temperature. This zone experiences a thermal cycle but does not undergo any plastic deformation. Unique to the FSW process is the creation

of a transition zone, the TMAZ, between the HAZ and the nugget zone. The TMAZ experiences both temperature and deformation during FSW. The central stir region experiences the most severe deformation and is a consequence of the way in which a rotating tool deposits material from the front to the back of the weld. This region is usually referred to as the nugget zone (or weld nugget). Under some processing conditions, an “onion-ring” structure develops in the nugget zone. This has been linked to the nature of material flow during FSW (Ref 29, 69, 70). Depending on processing parameters, tool geometry, temperature of workpiece, and thermal conductivity of the material, various shapes of the nugget zone have been observed. Basically, the nugget zone can be classified into two types: a basin-shaped nugget that widens near the upper surface, and an elliptical nugget

(Ref 3, 71, 72). The interface between the nugget zone and the parent metal is relatively diffuse on the retreating side of the tool but quite sharp on the advancing side of the tool (Ref 73). Figure 18 shows the macroscopic features in a transverse section of an FSW 7075Al-T651 alloy.

The grain structure in the HAZ remains similar to the parent material. The TMAZ is characterized by a highly deformed structure. The grains of the original microstructure deform in this region in an upward flowing pattern around the nugget zone. Although the TMAZ undergoes plastic deformation, full recrystallization does not occur in this zone due to insufficient deformation strain. Grains in the TMAZ usually contain a high density of subboundaries (Ref 71). Within the nugget zone, intense plastic deformation at elevated temperatures during FSW results in generation of a recrystallized fine-grained microstructure. This region is also referred to as the dynamically recrystallized zone. It is well accepted that dynamic recrystallization during FSW results in generation of fine and equiaxed grains in the nugget zone. Figure 19 shows typical grain structures in different regions in an FSW 7050-T651 aluminum alloy. In some instances, where the dislocation recovery rate in a particular alloy is sufficiently high, the grain structure in the nugget region can remain unrecrystallized.

Grain Size in the Nugget Zone

Grain size in the nugget zone in FSW materials can be affected by various factors, including processing parameters, tool geometry, composition of workpiece, temperature of the workpiece, vertical pressure, and active cooling. Typical recrystallized grain size in FSW aluminum and magnesium alloys is in the micrometer range, although ultrafine-grained microstructures (average grain size <1 μm) can be achieved by using external cooling or smaller tool geometries. Table 6 gives a summary of the grain size values obtained during FSW for a few aluminum and magnesium alloys.

Generally, FSW results in equiaxed fine-grained structures in the nugget zone. However, grain size is not uniform across the weld nugget. In FSW of aluminum alloys, the grain size tends to increase near the top of the weld zone, and it decreases with distance on either side of the weld-zone centerline. This corresponds roughly to the temperature variation within the weld zone (Ref 3, 105, 106). Figure 20 shows the distribution of the grain sizes in different locations of the nugget zone in FSW 7050Al (Ref 107). The average grain size ranges from 3.2 μm (126 μin.) at the bottom to 5.3 μm (207 μin.) at the top and 3.5 μm (138 μin.) from the retreating side to 5.1 μm (201 μin.) on the advancing side.

Precipitate Distribution

The temperature during FSW increases up to 400 to 550 °C (752 to 1022 °F) within the nugget zone in aluminum alloys (Ref 3, 6, 72, 79, 80, 108–111). The temperature gradually decreases from the nugget zone to the TMAZ to the HAZ. In the HAZ, the temperature rises above 250 °C (482 °F) for aluminum alloys (Ref 109), which exerts a significant effect on the precipitate structure. At such temperatures, precipitates in aluminum alloys can coarsen or dissolve into aluminum matrix, depending on alloy type and maximum temperature. Figure 21 shows the change of strengthening precipitates in an FSW 7050-T651 aluminum alloy (Ref 74). Precipitates in 7050-T651 base alloy predominantly consist of intragranular fine η' less than 50 nm (2 μin.), along with coarser η precipitates along grain boundaries. Following FSW, the precipitates coarsen and the precipitate-free zone increases in width along the grain boundary in the HAZ. In the TMAZ, strengthening precipitates underwent severe coarsening and partly dissolved, while a small amount of very fine η particles reprecipitated. The temperature in the nugget zone reaches the solution heat treatment temperature. Strengthening precipitates in this region go into solution and reprecipitate during cooling.

Texture

In FSW, each zone has a different thermomechanical history. What is even more complicated for FSW is that the nugget region consists of subdomains. For example, the top layer undergoes deformation by shoulder after the pin has passed through. In addition, depending on the tool rotation rate and traverse speed, the nugget region can contain ring patterns or other microstructural variations. Such deformation features can cause complex texture patterns in FSW materials. For example, in an FSW AA6063 alloy, the Goss orientation in the parent material changed to a shear texture component containing both {110} <001> and {114} <221> orientations, and these components rotated around the pin axis (Ref 22). Both these components were also observed in FSW AA1100 and AA6061 alloys, including the rotational aspect of the texture component from the advancing side to the retreating side (Ref 23). In FSW AA2195 alloy, B-fiber shear (torsion) textures were reported as the main textural components, with the shear plane normal and shear directions aligned approximately perpendicular to and tangential with the flow lines in the weld (Ref 112–114). It is also noted that in an FSW AA7075 alloy, no strong texture was detected (Ref 115). In general, the texture evolution in FSW of aluminum alloys can be classified into two types. One is a shear texture with easy slip plane(s) roughly parallel to the cylindrical pin surface. The other is the severe gradient in crystallographic texture through the

Fig. 20 Grain size distribution in various locations of a 7050Al weld nugget. Source: Ref 107

Fig. 21 Precipitate microstructures in a friction stir welded 7050Al-T651. (a) Base metal. (b) Heat-affected zone. (c) Thermomechanically affected zone. (d) Nugget zone. Source: Ref 74

thickness of the stir zone due to the complicated material flow. Severe plastic deformation has been considered as the main source for texture evolution during FSW.

Dynamic Recrystallization and Microstructural Evolution

Microstructural examinations of FSW aluminum alloys have shown a typically fine equiaxed grain structure in the stir zone. The fine-grained structure observed in the nugget has usually been attributed to dynamic recrystallization. Several recrystallization theories, including continuous dynamic recrystallization (CDRX) (Ref 59, 74, 81), discontinuous dynamic recrystallization (DDRX) (Ref 78, 80, 116), geometric dynamic recrystallization (Ref 17, 117), dynamic recrystallization in the adiabatic shear bands (Ref 118), and recrystallization via particle-stimulated nucleation (Ref 119) (which were developed to account for grain size control during conventional thermo-mechanical processing), have been used to explain the formation of grain structures during FSW/friction stir processing. In FSW Al-Li-Cu alloy (Ref 59), it was suggested that low-angle boundaries in the parent metal are replaced by high-angle boundaries in the nugget zone by means of a continuous rotation of the original low-angle boundaries during FSW. In this model, dislocation glide gives rise to a gradual relative rotation of adjacent subgrains. On the basis of microstructural observations in FSW 7050Al-T651 (Ref 74), it is proposed that the dynamic recrystallization in the nugget zone can be considered as CDRX on the basis of dynamic recovery. Subgrain growth associated with absorption of dislocation into the boundaries is the CDRX mechanism. Repeated absorption of dislocations into subgrain boundaries is the dominant mechanism for increasing the misorientation between adjacent subgrains during CDRX. Alternatively, DDRX has been proposed as an operative mechanism for the formation of very small grains in friction stir processed aluminum alloys. Using friction stir processing with rapid cooling, nanocrystalline structure was obtained in 7075Al and 7050Al-T76 alloys (Ref 78, 116). These recrystallized grains were significantly smaller than the pre-existing subgrains in the parent alloy and were identified as nonequilibrium in nature, predominantly high-angled, and relatively dislocation-free. Although the exact formation mechanism of the nanocrystalline structure is still not clear, the DDRX mechanism has been proposed for the nanostructure evolution (Ref 78).

During FSW, materials are heavily deformed at high temperatures. Material nearest to the tool pin experiences the largest strain and highest peak temperature. The resulting microstructures around the tool pin further evolve to form final grain structures under a thermomechanical deformation of decreasing strain, strain rate,

and temperature behind the pin tool. It is noted, however, that the formation of the final grain structure is unlikely to be a result of a single mechanism. In a study of friction stir processed 7075Al (Ref 120), multimechanisms, including DDRX, grain growth, dislocation introduction, dynamic recovery (DRV), and CDRX, were proposed to be inherent at different stages of microstructure evolution. The final grain structure contains of a range of microstructure/grains developed via different paths, either from initial recrystallized grains or subgrains formed from DRV. The grains have different densities of dislocations and are in various degrees of recovery. A complex microstructure evolution was also reported in FSW AZ31 magnesium alloy (Ref 101). The grain structure development was dictated not only by the texture evolution but also involved twinning, geometrical effects of strain, and limited discontinuous recrystallization.

Fundamentals of Ultrasonic Welding

Leijun Li and Chunbo (Sam) Zhang, Utah State University

ULTRASONIC WELDING (UW), as a solid-state joining process, uses an ultrasonic energy source and pressure to induce oscillating shears between the faying surfaces to produce metallurgical bonds between a wide range of metal sheets (Ref 1, 2), thin foils (Ref 3), and wires. Besides joining metals, UW has been used to join semiconductors (Ref 4), plastics (Ref 5), glass (Ref 6), and ceramics (Ref 7). In contrast to fusion welding processes, UW has several inherent advantages (Ref 3, 8) derived from its solid-state process characteristics and has been used as a versatile joining method in the electronics, automotive, and aerospace industries since the 1950s.

Although numerous researchers have been studying the bonding mechanisms of UW for over 50 years, the process is still arguably the least understood welding process. Various mechanisms have been proposed for UW, including interdiffusion, recrystallization, plastic deformation, work hardening, breaking of contaminant, generation of heat by friction, and even melting (Ref 9, 10).

Diffusion has been observed at the interface between copper and aluminum welds for an extended period of welding time (Ref 11, 12). It has also been found that diffusion occurs along grain boundaries rather than in the bulk of the material in ultrasonic welding (Ref 13). Kreye et al. (Ref 14) examined the microstructure at the weld interface with transmission electron microscopy and claimed that the very small grain size observed in a thin layer could only be explained by melting and solidification. However, others (Ref 15, 16) concluded that neither diffusion nor recrystallization could be responsible for the joint formation of UW after comparing low-frequency vibration welding with UW of aluminum and examining the copper and soft iron UW. A great degree of plastic deformation and metal flow occur across the interface, and flow lines, evidence of extensive plastic deformation, are visible in the bond zone (Ref 17, 18). For the UW of aluminum foil, plastic flow occurs in a narrow interfacial zone approximately 10 to 20 μm (0.0004 to 0.0008 in.) in width (Ref 19). In this region, new subgrain structures form across the bond zone. When the relative motion at the beginning of the welding cycle cleans the surfaces

and plastically deforms asperities, micro-welds—areas in which the friction exceeds the flow stress level of the material and plastic metal flow has started—occur immediately between points of contact of the adjacent surfaces (Ref 9, 10, 20). Zhou et al. have used scanning electron microscopy to investigate the effects of process parameters on bond formation in thermosonic gold ball bonding on a copper substrate at ambient temperatures (Ref 21). They concluded that relative motion existed at the bonding interface as microslip at lower powers, transitioning into gross sliding at higher powers. Researchers in a variety of fields have observed that ultrasonic excitation of metals can produce an apparent reduction in the yield strength and an enhancement in the plastic flow behavior of metals (Ref 22, 23).

Due to the difficulties in definitively characterizing the UW process, the mechanism(s) for bond formation in the UW process are still under debate. The challenges for process measurement and instrumentation come from:

- The contact surface, where the bonding that occurs is invisible to observers
- The measurement devices or sensors, which tend to damage the contact surface and interfere with the bonding process
- The highly localized (a few micrometers) and transient (typically 20 kHz vibration) nature of ultrasonic bonding
- The necessity of a high spatial resolution (micrometer-scale vibration amplitude)

To overcome these obstacles and to gain insights into the UW process, numerous researchers have developed analytical (Ref 2, 17, 18) and numerical models (Ref 24–32).

During the last decade, UW has become a popular technique for joining thermoplastic polymers. Many studies were conducted in modeling the process. Senchenkov et al. (Ref 33, 34) studied the problem of vibrations and the dissipative heating of a viscoelastic prism by a waveguide. Benatar and Gutowski (Ref 35) modeled the UW of thermoplastics using a five-part model that included mechanics and vibration of the parts, viscoelastic heating, heat transfer, flow and wetting, and intermolecular diffusion. Roylance et al. (Ref 36)

outlined numerical simulation methods useful in understanding and developing UW for polymers. Verderber (Ref 37) implemented algorithms in an explicit finite-element (FE) analysis code applicable to the unique features of UW analysis. Senchenkov and Zhuk (Ref 38) studied the two-dimensional (2-D) problem of planar oscillations of plates under cyclic loading. The model developed was applied to the simulation of vibration of sonotrodes for UW of plastics. A similar study by Mikhailenko and Franovskii (Ref 39) proposed a two-dimensional FE model that linked thermo-electric processes in acoustic systems.

A recent combination of ultrasonic metal seam welding and computer numerical control milling has resulted in a new additive manufacturing process known as ultrasonic consolidation (UC). By continuously welding layers of metal foil to previously deposited material, during which the profile for each layer is created by contour milling, UC is able to build up complex, multifunctional, three-dimensional (3-D) objects. Objects with internal features, objects made up of multiple materials, and objects integrated with wiring, fiber optics, sensors, and instruments can thus be directly fabricated (Ref 3, 40, 41).

Numerical modeling of UW of metals and alloys began recently, with the development of emerging new technologies that employ UW in UC (Ref 3, 42, 43). Compared with UW of polymers, UW of metals seems to be more challenging to model. In metals, vibration and heat have effects on dislocation dynamics, metallurgical transformations, and associated variations in thermomechanical properties (Ref 44).

Gao and Doumanidis (Ref 17, 18) analyzed the mechanics of metal UW. They developed a 2-D, quasi-static/dynamic, elasto-plastic numerical model of the stress/strain field through FE analysis. In the study by de Vries (Ref 2), mechanics-based models were developed, along with a model for temperature generation and effect on mechanical properties of welded material. His models were capable of calculating the interface forces that were verified experimentally. Siddiq and Ghassemieh (Ref 31, 32) studied the changes in the friction work at the weld interface by simulating UW of metals based on a phenomenological material model, which incorporated both surface (friction) and volume (plasticity) “softening” effects.

Focusing on the contribution of friction to bond formation in UW, Zhang and Li developed a 3-D thermomechanical FE model (Ref 25). The model predicted a saturation of plastic deformation at the bond interface after a certain number of vibration cycles. Ding et al. (Ref 29, 30) analyzed deformation and stress distributions in the wire and bond pad during ultrasonic wire bonding using 2-D and 3-D FE models. A coupled temperature-displacement FE analysis performed by Huang and Ghassemieh (Ref 26) found the oscillation of stress in the substrate to lag behind the ultrasonic vibration by approximately 0.1 cycle of ultrasonic wave. Yadav and Domanidis (Ref 27) performed an FE analysis of two layers of aluminum foil subjected to certain welding conditions, with surface contact resistance calibrated by experiments. The results revealed a moderate temperature rise that was believed to be sufficient for metal bonding via vacancy diffusion. The fully coupling effects of thermal field (friction and plastic heat generation) and structural field (stress/strain, slide distance, and temperature-dependent material properties) were studied by Zhang and Li (Ref 24). In an effort to verify the model, plastic deformation was correlated with the bond area of welded joints.

Models

Governing Equations of Thermomechanical Processes

In modeling the UW process, the governing dynamic equation of displacement (u) for a linear structure (Ref 45) is:

$$[M]\{\ddot{u}\} + [C]\{\dot{u}\} + [K]\{u\} = \{L\} \quad (\text{Eq 1})$$

where (M) is the structural mass matrix, (C) is the structural damping matrix, (K) is the structural stiffness matrix, \ddot{u} is the nodal acceleration vector, \dot{u} is the nodal velocity vector, u is the nodal displacement vector, and $\{L\}$ is the applied load vector.

The basic constitutive equations between stress (σ) and strain (ϵ) are as follows:

$$\{\sigma\} = [D]\{\epsilon^{\text{el}}\} \quad (\text{Eq 2})$$

$$\{\epsilon^{\text{el}}\} = \{\epsilon\} - \{\epsilon^{\text{pl}}\} - \{\epsilon^{\text{th}}\} \quad (\text{Eq 3})$$

where $\{\sigma\}$ is the stress vector, (D) is the elastic stiffness matrix that is a function of temperature, $\{\epsilon^{\text{el}}\}$ is the elastic strain vector, $\{\epsilon\}$ is the total strain vector, $\{\epsilon^{\text{pl}}\}$ is the plastic strain vector, and $\{\epsilon^{\text{th}}\}$ is the thermal strain vector.

Conductive heat transfer can be considered using the following governing equation:

$$\rho c \left(\frac{\partial T}{\partial t} + (\vec{v} \cdot \nabla) T \right) = \dot{q} + \nabla \cdot ((\vec{K} \cdot \nabla) T) \quad (\text{Eq 4})$$

where ρ is the density, c is the specific heat, T is the temperature, t is the time, \vec{v} is the velocity vector for mass transport of heat, \dot{q} is the heat

generation rate per unit volume, \vec{K} is the conductivity vector, and:

$$\nabla = \frac{\partial}{\partial x} + \frac{\partial}{\partial y} + \frac{\partial}{\partial z}$$

Ultrasonic welding has been identified as a two-way coupled thermomechanical problem:

- The thermal field affects the mechanical field, because most of the material properties, such as modulus of elasticity, yield strength, and friction coefficient, are temperature sensitive.
- The mechanical field (friction and plastic deformation) generates heat, which affects the thermal field.

Therefore, modeling of the UW process demands a coupled-field analysis method. Because closed-form solutions for coupled-field equations are difficult to obtain, structural and thermal fields are generally treated separately in analytical modeling of UW (Ref 2, 17, 18).

Recently, commercial FE packages have expanded their capabilities in solving complex multiphysics problems. Many researchers found it convenient to study involved processes that are not solvable analytically. In the thermomechanical-coupled analysis, the FE matrix equation for mechanical and thermal fields, coupled by the thermoelastic constitutive equations, is (Ref 45):

$$\begin{aligned} & \begin{bmatrix} [M][0] \\ [0][0] \end{bmatrix} \begin{Bmatrix} \{\ddot{u}\} \\ \{\dot{T}\} \end{Bmatrix} + \begin{bmatrix} [C][0] \\ [C^{\text{th}}][C^{\text{t}}] \end{bmatrix} \begin{Bmatrix} \{\dot{u}\} \\ \{\dot{T}\} \end{Bmatrix} \\ & + \begin{bmatrix} [K][K^{\text{th}}] \\ [0][K^{\text{t}}] \end{bmatrix} \begin{Bmatrix} \{u\} \\ \{T\} \end{Bmatrix} \\ & = \begin{Bmatrix} \{L\} \\ \{Q\} \end{Bmatrix} \quad (\text{Eq 5}) \end{aligned}$$

where $[M]$ is the element mass matrix, $[C]$ is the element structural damping matrix, $[K]$ is the element stiffness matrix, $\{u\}$ is the displacement vector, $\{F\}$ is the sum of the element nodal force, $[C^{\text{t}}]$ is the element specific heat matrix, $[K^{\text{t}}]$ is the element diffusion conductivity matrix, $\{T\}$ is the temperature, $\{Q\}$ is the sum of the element heat-generation load and element convection surface heat-flow vectors, and $[K^{\text{th}}]$ is the element thermoelastic stiffness matrix:

$$([K^{\text{th}}]) = - \int_{\text{vol}} [B]^T \{ \beta \} \{ \nabla \{ N \} \}^T d\{\text{vol}\}$$

where $[B]$ is the strain-displacement matrix, N is the element shape function, and β is the vector of thermoelastic coefficients. For $[C^{\text{th}}]$, which is the element thermoelastic damping matrix, $[C^{\text{th}}] = -T_0[K^{\text{th}}]^T$, and T_0 is the absolute reference temperature.

Material Behavior in UW

Yield Rule and Plastic Deformation. The von Mises yield criterion has been widely applied in plastic analysis (Ref 24, 27). If the von Mises equivalent stress is lower than the material yield strength at temperature, the stress

state is elastic and no plastic strain is computed. If the stress exceeds the material yield strength, the plastic strain, ϵ^{pl} , is calculated by:

$$\{d\epsilon^{\text{pl}}\} = \lambda \left\{ \frac{\partial F}{\partial \sigma} \right\} \quad (\text{Eq 6})$$

where λ determines the amount of plastic straining, and F (yield function) is given by:

$$F = |\underline{\sigma} - \underline{\alpha}| - (\sigma^0 + R) = 0 \quad (\text{Eq 7})$$

where $\underline{\sigma}$ is the stress tensor, $\underline{\alpha}$ is the back stress tensor due to kinematic hardening, R is the isotropic hardening term, and σ^0 is the initial yield stress.

Thermomechanical Hardening Rules.

The nonlinear isotropic hardening rule was presented by Lemaitre and Chaboche (Ref 46) and Huber and Tsakmakis (Ref 47). The isotropic hardening (R), which describes the expansion of the yield surface, is defined as an exponential function of accumulated plastic strain:

$$R = A(1 - e^{-b\bar{\epsilon}^{\text{pl}}}) \quad (\text{Eq 8})$$

where $\bar{\epsilon}^{\text{pl}}$ is the equivalent plastic strain, while A and b are material parameters to be identified. A is the maximum change in the size of the yield surface, and b is the rate at which the size of the yield surface changes with changing plastic strains.

A nonlinear kinematic hardening rule proposed by Armstrong and Frederick (Ref 48) has been used to capture nonlinear hardening behavior and the smooth transition from elastic to plastic deformation. The evolution of back stress tensor ($\underline{\alpha}$) is given by:

$$\dot{\underline{\alpha}} = \frac{S}{\gamma} (\underline{\sigma} - \underline{\alpha}) \bar{\epsilon}^{\text{pl}} - \gamma \underline{\alpha} \bar{\epsilon}^{\text{pl}} \quad (\text{Eq 9})$$

where S and γ are the material parameters, which can be identified from cyclic testing. The γ term determines the rate at which the saturation value of kinematic hardening decreases with increasing plastic deformation. S is the kinematic shift of the yield surface.

Adopted from the hardening model by Johnson and Cook (Ref 49), the temperature term $(1 - T^m)$ can be embedded in the nonlinear isotropic and kinematic hardening model. The thermally modified nonlinear isotropic hardening law is given by:

$$R_{\text{th}} = A(1 - e^{-b\bar{\epsilon}^{\text{pl}}}) \cdot (1 - T^m) \quad (\text{Eq 10})$$

where m is a material parameter, and T is the nondimensional temperature given by:

$$T = \frac{T - T_{\text{transition}}}{T_{\text{melt}} - T_{\text{transition}}} \quad (\text{Eq 11})$$

Similarly, the modified nonlinear kinematic hardening law is given by:

$$\alpha_{th} = \alpha_{isothermal} (1 - T^m) \tag{Eq 12}$$

where $\alpha_{isothermal}$ is obtained from the numerical integration of Eq (Ref 50).

Siddiq and Ghassemieh (Ref 31, 32) introduced a phenomenological softening term, dependent on the ultrasonic energy density per unit time, in the isotropic and kinematic hardening terms (Eq 10 and 12). They have implemented these hardening models in user-defined ABAQUS subroutines and identified six parameters (Q, b, C, γ, m, d) using an inverse method from cyclic stress-strain data, thermal softening data, and acoustic (ultrasonic) softening data. The modified equations of isotropic and kinematic hardening are given by:

$$R_{ultrasonic} = R_{th} \cdot (1 - d \cdot E_{ultrasonic})^2 \tag{Eq 13}$$

$$\alpha_{ultrasonic} = \alpha_{th} \cdot (1 - d \cdot E_{ultrasonic})^2 \tag{Eq 14}$$

where R_{th} is defined in Eq 10, d must be identified from deformation behavior of the material in the presence of ultrasonic energy, $E_{ultrasonic}$ is the ultrasonic energy transferred from the sonotrode to the material, and α_{th} is defined in Eq 12.

Heat Generation in UW

Surface and Volume Heat Generation.

The ultrasonic mechanical energy, subsequently converted to thermal energy, can be determined by the local cyclic stress (σ), strain (ϵ), friction shear (τ_x), and component slip (e_x) near the faying interface. Heat is generated locally in the control volume, ($Q_v(x, y, z)$), by inelastic hysteresis and plastic deformation, and at the interface surfaces, ($Q_s(x, y)$), by friction during each cycle at the ultrasonic frequency, f , as shown in Fig. 1 (Ref 2, 27, 29):

$$Q_v(x, y, z) = f \oint \sigma_{eq}(\epsilon) d\epsilon_{eq} \tag{Eq 15}$$

$$Q_s(x, y) = f \oint \tau_x(\epsilon_x) de_x = N \oint \mu \sigma_z(\epsilon_x) de_x \tag{Eq 16}$$

where σ_{eq} and ϵ_{eq} are equivalent stress and strain, and σ_z is normal compressive stress.

Fig. 1 Mechanical work done during each vibration cycle of ultrasonic welding. Source: Ref 27

The previous equations for calculating heat generation assume the mechanical state as a function of location only, without considering time and temperature influences. Zhang and Li (Ref 24) have proposed a plastic work rate (\dot{W}^{pl}), proportional to the plastic strain rate, to account for the effects of location, temperature, and time in UW:

$$\dot{W}^{pl}(x, y, z, t, T) = \sigma_j(x, y, z, t, T) \cdot \dot{\epsilon}_j^{pl}(x, y, z, t, T) \tag{Eq 17}$$

where $j = 1,2,3$. It is assumed that some of the plastic work converts to heat, while the rest is stored as energy of crystal defects accompanying plastic deformation. The fraction of the plastic work ($\dot{Q}^{pl}/\dot{W}^{pl}$) that is converted to thermoplastic heating (\dot{Q}^{pl}) is 0.33 for aluminum (Ref 51).

Friction Coefficient. As a friction-based welding process, there is no doubt that the friction coefficient at the faying interfaces plays a key role in UW by affecting the stress/strain state and surface heat generation. Gao and Domanidis (Ref 17) experimentally determined the friction-efficient history of aluminum 1100 foils during one cycle (Fig. 2). Zhang and Li (Ref 25) measured the aluminum-aluminum friction coefficient varying with temperature (Fig. 3) at a slide speed corresponding to UW conditions. Siddiq and Ghassemieh (Ref 31, 32) numerically described the friction coefficient varying with temperature and vibration cycle by curve-fitting the published experimental data. Based on Coulomb's friction law, the stick-slip contact condition can be identified with the relation of $|\tau_{fric}|$ and $\mu \cdot p$. If $|\tau_{fric}| < \mu \cdot p$, the friction is of the stick type, and if $|\tau_{fric}| = \mu \cdot p$, the friction is of the slip type.

Results

Vibration

The vibration of the sonotrode under a constant pressure produces a cyclic sliding at the bonding interface, along with periodic variation of the elastic/plastic strain/stress state, as

Fig. 2 Experimentally identified history of friction coefficient of aluminum 1100 foils during one cycle of weld. Source: Ref 17

illustrated in Fig. 4. The resultant shear stress at the interface is helpful to break the oxides/contaminants and to generate intimate contact between the faying surfaces. The overall effect of ultrasonic vibration of the bonding interface can be summarized by the so-called ‘‘acoustic softening’’ of metals. Based on a phenomenological model, the stress required to initiate metal plastic deformation decreased significantly with ultrasonic excitation. The material softening effect has been studied by evaluating the sonotrode displacement in the height direction, as illustrated in Fig. 5 (Ref 26). It is found

Fig. 3 Measured aluminum 3003-H18 friction coefficient varying with temperature. Source: Ref 25

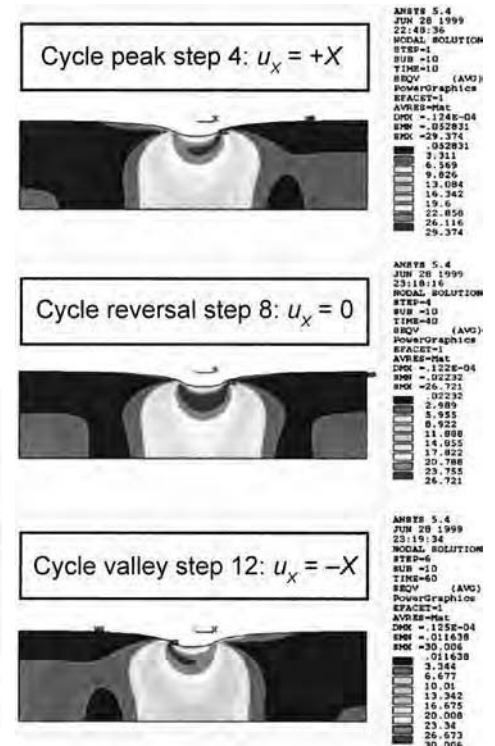

Fig. 4 Equivalent stress field, σ_{eq} , at three steps of one ultrasonic cycle. Source: Ref 17

that the sonotrode moves downward continuously during the entire UW process, under a constant load on the sonotrode. This softening effect becomes significant for a higher friction coefficient.

Friction

For those areas with the slipping contact condition, the shear stress results in the generation of friction heat. The friction work is affected by the vibration amplitude, as illustrated in Fig. 6, but has a nonlinear relation with the applied pressure. Higher pressure elevates the shear stress level but decreases both the overall slipping areas and distances of contact interface. Better ultrasonic bonds can be formed by greater friction work, because more ultrasonic energy is brought into the bonding interface. These results agree well with the experimental data of bond strength with amplitude and pressure (Ref 52).

Fig. 5 Simulated displacements of the sonotrode versus time in height direction using different friction models. The external force applied on the sonotrode is 80 N (18 lb). The friction coefficient equation is defined as $\mu = E/p[\epsilon_{xx}(t) + \nu]$, where E and ν are the modulus and Poisson's ratio, respectively, and p is the constant pressure. Source: Ref 26

Fig. 6 Simulated friction work at foil/substrate interface. Velocity = 27.8 mm/s (1.1 in./s). Source: Ref 32

Temperature

Due to the heat generation from friction and plastic deformation, the temperature on the bonding interface increases during UW. Higher temperature occurs along the boundary of the foil/substrate contact area (Fig. 7). The generated heat can dissipate quickly across the entire contact surface for aluminum alloys. Some simulation results show the maximum temperature to be located at the foil/sonotrode interface (Fig. 8), resulting from severe plastic deformation. These simulation results seem to match the experimental observation of temperature measurement by high-speed thermal camera (Ref 2). The consequence of temperature rise is to reduce the stress state of the contact interface by decreasing the material properties and the friction coefficient. Thus, the friction work decreases with temperature rise, and the final

Fig. 7 Simulated three-dimensional temperature distribution at the 50th vibration cycle. Unit: °C (°F), 20 kHz frequency. Source: Ref 24

Fig. 8 Simulated temperature in the weld specimen. Amplitude = 8.4 μm (330 μin.), velocity = 27.8 mm/s (1.1 in./s), and pressure = 125 MPa (18 ksi). Source: Ref 32

temperature level is determined by the competition between friction and plastic deformation work. When only the friction heat generation is considered, the temperature rise is slowed down and seems to approach a steady state (Fig. 9). The increase of interface temperature is determined by $q_{friction} - q_{loss}$, where $q_{friction}$ is the friction heat-generation rate, and q_{loss} is the heat-dissipation rate by conduction. A balance between $q_{friction}$ and q_{loss} will be achieved eventually, because once the heat loss is greater than the friction heat generation and the interface temperature drops, the higher values of material properties in the lower temperature will automatically increase the $q_{friction}$ until a new thermal balance is achieved.

Plastic Deformation

A strong linear correlation between the plastic strain and bond area ratio, which reflects the bond strength level (Ref 52), is shown in Fig. 10. A large von Mises plastic strain will result in more bonded areas. Plastic

Fig. 8 Simulated temperature in the weld specimen. Amplitude = 8.4 μm (330 μin.), velocity = 27.8 mm/s (1.1 in./s), and pressure = 125 MPa (18 ksi). Source: Ref 32

deformation affects the bond formation in the following ways:

- It disperses the surface oxide layer.
- It generates heat to make the atoms more thermally active.
- It deforms the crystals and grains on the interfaces and generates a high dislocation density, which also provides potential energy for dynamic grain-boundary migration.

Therefore, the plastic deformation from the simulation model can be quantitatively correlated with the bonded area (bond strength) from experiments.

Another quantitative approach for building the relationship between the simulated and experimental data is to measure the dimension of dynamic recrystallized grains. From experiments, it is found that the crystals have been dynamically recrystallized into nanosized grains during processing (Fig. 11). From simulation data (Fig. 12), the plastic strain is relatively small at the beginning of bonding. The highest plastic strain occurs at the edge of the contact surface. Subsequently, the plastic deformation at the center of the contact surface exceeds the level of plastic strain at the edge and becomes the highest.

Bond Strength

The peeling test has been widely used to measure the bond strength of UW-made parts with laminated structure by examining the peak load (Ref 54). A novel push-pin-type test was developed as a general test for bond strength evaluation normal to bonded areas for laminated structures (Ref 52). This evaluation method includes both experiment—obtaining a load-displacement response—and elastic-plastic FE simulation, fitting the experimental load-displacement response by adjusting the material property coefficient for the bond zone to find the maximum stress normal to bonded areas from simulation results.

The bond strength is significantly influenced by process parameters. The bond strength

Fig. 12 Distribution of plastic strain as a function of location and vibration cycle. The X-direction is parallel to the sonotrode vibration direction. The origin is the center of the contact surface. Source: Ref 25

increases with the vibration amplitude and pre-heat temperature, decreases with the sonotrode traveling speed, but shows a nonlinear relation with normal pressure (Ref 52, 55). It is believed a high normal pressure will decrease bond strength, because the vibrational motion of the parts is constrained, and not enough friction heat will be generated. Indicators from both experiment and simulation are employed to predict the true bond strength. Linear weld density (LWD), defined as the length of the bonded interface divided by the total interface length under consideration (expressed in percentage), has a good linear relation with bond strength (Fig. 13), but a significant increase of LWD results in only a small increase in the bond strength. A 2-D experimental indicator, bond area percentage measured from the entire fracture surface, shows a more significant correlation with bond strength (Fig. 14). Friction

Fig. 14 Bond strength versus percentage of bonded area for aluminum 3003-H18. Source: Ref 52

Fig. 13 Correlation of weld strength with linear weld density of welded aluminum 6061 specimens. Source: Ref 54

work and plastic deformation (Fig. 10) from simulation have also been used to estimate the bond strength of UW parts (Ref 24, 31, 52). The limitation of friction work as a bond strength indicator results from the neglect of contributions of plastic heat and vibration energy.

Geometry Effect (Height-to-Width Ratio of Build)

In ultrasonic consolidation, the geometry of buildup, specifically referring to the height-to-width ratio, influences the bond formation and results in different bond quality across the bonding interface and inside the substrate, although the same process parameters are used. The simulation shows that for a given vibration condition, with the increased substrate height, the amplitude of contact frictional strain decreases (Fig. 15), while that of contact interface displacement increases (Fig. 16). The reason for the decrease in the frictional stress at the contact interface for certain substrate heights is the complicated wave interference

occurring in the substrate (Ref 56). From experiments, parts with a height-to-width ratio of approximately 1.0 are not feasible to build (Ref 57). At this particular substrate height, the wave superposition produces a minimum interface relative displacement. The displacement on the contact interface is found to be a critical parameter for bond formation (Ref 25). The minimal displacement and relatively low friction stress are the reasons why a height-to-width ratio equal to 1.0 is a critical height for defects to occur in ultrasonic bonding. By using support materials for tall structures, resonant vibration of the UW part is constrained, and good bonding is possible. Figure 17 illustrates the cross-sectional view of a typical vibration pattern for a substrate with a height-to-width ratio of 1:1. The vibration pattern is believed to be closely related with those observed in fractography of ultrasonic welded joints (Fig. 18). The distribution of defects (unbonded areas) can be correlated with the saturated vibration patterns of strain/stress and displacement.

Mechanisms for Bond Formation

The temperature and microstructure of the bonding interface have been examined by researchers to identify the melting phenomenon in UW (Ref 2, 13, 58, 59). In most cases, no evidence of metal melting has been found. Diffusion has been observed at the interface between copper and aluminum welds for an extended period of welding time (Ref 11, 12). However, the relatively low temperature and short time during the rapid bonding process seems to make diffusion insignificant for bond formation. A very small grain size has been observed in a thin layer, and the interface region is believed to have experienced dynamic recrystallization (Ref 14, 53). The role of the recrystallization phenomenon in UW and its contribution to the ultrasonic bond is currently being investigated. Severe plastic deformation and metal turbulent flow occur across the interface, and flow lines, evidence of extensive plastic deformation, are visible in the bond zone (Ref 3, 17, 18). The severe, localized plastic

Fig. 18 Typical features of fractured surfaces. (a) 87.4% bonded. (b) 76.4% bonded. Source: Ref 24

deformation at the bond region is believed to be the major phenomenon in UW by establishing a metallurgical bond via atomic forces at those intimate contact areas (Ref 24, 53). Plastic deformation and metal flow at the bonded regions result in displacement of oxide films and flow of metal into the voids between the faying surfaces. Plastic deformation also provides the driving force for subsequent dynamic recrystallization, which may be the process through which the bond forms.

Fundamentals of Solid-State Resistance Welding

Jerry E. Gould, Edison Welding Institute

RESISTANCE WELDING PROCESSES are those which incorporate electric currents to facilitate Joule heating. This heating is then used to promote the metallurgical mechanisms that result in formation of a joint. The most common resistance processes nominally result in melting and resolidification of metal. These processes typically create weld “nuggets” as described in the article on “Resistance Welding” included in this volume. Joule (or resistance) heating can also be used to foster the necessary mechanisms for solid-state joining. Variants of solid-state resistance welding include flash-butt, upset-butt, mash-seam, etc. This article provides a fundamentals-based description of these approaches through one specific process variant. This is termed as solid-state resistance projection welding.

The underlying mechanisms of thermally assisted solid-state welding include displacement of bond line contaminants and thermal dissolution of contact surface oxides (see the article “Mechanisms of Bonding for Solid-State Welding Processes” in this Volume). Projection welding is a resistance welding process which uses geometric discontinuities to create highly localized heating. The approach can produce solid-state or fusion welds, and allows highly localized welds to be produced in predefined locations of components.

Solid-state projection welding is closely related to other solid-state processes, and it provides a good example in describing the mechanisms of solid-state welding with resistance heating. In this article, simple analytical tools are described to help understand the variety of mechanisms that occur during resistance projection welding. Factors relating to the quality of solid projection are discussed, including an explanation of the mechanisms of bonding for solid projection welding. This is followed by a review of how these mechanisms are affected by heat balance, current profile, mechanical characteristics of the welding equipment, and finally, the design of the projection itself.

The analysis is done in five parts, as described in the section “Summary of Analysis” in this article. It is shown that when projection welding is properly done, the results are solid state in character and incorporate both bond-line strain and thermal cycle components. Bond-line strain has the effect of disrupting surface contaminants and revealing the underlying clean material for bonding.

Projection Welding

Projection welding is one of the oldest variations of the resistance processes. Projection welding is defined by using a geometric feature as a current concentrator during resistance welding (Ref 1). The use of the projection allows highly localized welds in predefined locations based on the design of the component(s) (Ref 2). The resulting joints can be formed either as solid-state or fusion processes. Two categories of projections are typically used with these processes (Ref 2). These include embossed and solid projection welding.

Embossed projections are often used with sheet components. The projections are then stamped into one of the two components. Embossed projection welding has been studied extensively (Ref 3–7). These studies have included basic process dynamics (Ref 3), design guidelines for projections (Ref 3–6), process optimization studies (Ref 3–6), and the mechanics of bonding (Ref 3–7). Such welds using embossed projections accomplish bonding progressively, first through solid-state mechanisms and then through formation of weld nuggets.

These studies have shown that solid-state bonds can be accomplished at extremely short times (milliseconds), with weld nuggets forming at longer weld times (hundreds of milliseconds). With embossed projections, the maximum solid-state weld sizes are on the order of the projection size itself. Alternately,

if nuggets are allowed to grow, the weld size can exceed that of the projection by many times. These studies have led to the development of recommended practices for projection designs that are widely published (Ref 1, 8, 9).

Solid projection welding is used for machined or cold-headed components. This class of projection welding includes all those where the basic geometry of the components results in localized contact that can be used for current concentration (Ref 9). Geometries included in this class of projection welding vary widely. These include those with designed projections (e.g., annular projection welding) as well as those where the contact points are implied (edge projection welding, cross-wire welding). This class of projection welds (when done properly) typically results in solid-state joints (Ref 10–12). Because solid projection welding applications vary so broadly, there is little research or standardization for resulting designs. One area where some information is available is annular projection welds (Ref 10–12). These studies have evaluated projection designs for a number of different power supply types. Generally, the best weld quality is associated with balanced projection designs (forging will occur equally to the inside and outside diameters of the projection), and the projection will have a 90° included angle.

Projection welding is generally considered a reliable and robust process. However, given the variety of projection designs, the complexity of the stack-ups, and the number of material combinations with which the process is used, there are some chronic concerns. These include the presence of expulsion (melting and expelling of material), modes of projection collapse, consistency of the joint, and so on. The underlying causes of these problems can be multifold and include projection design, type of power supply used, mechanical system, and so on.

Bonding Mechanisms during Solid-State Projection Welding

As mentioned previously, solid projection welding generally results in solid-state joints. Fusion welds (indicated by the formation of a weld nugget) are not possible in these applications, because the solid projection geometry does not allow constraint of the weld nugget. Essentially, as the solid projection collapses, it must form laterally (or circumferentially). Because there are generally no provisions to allow flow of this displaced material, the individual component surfaces cannot make an enclosing contact, allowing formation of a weld nugget. Bonding, then, for solid projection welds is closely related to other solid-state processes. The mechanisms of solid-state bonding for thermally assisted processes are described in the article "Mechanisms of Bonding for Solid-State Welding Processes" in this Volume (Ref 13). During solid-state welding, two mechanisms predominate. These include surface disruption by the application of strain, and thermal dissolution of contact surface oxides.

Surface strain is an artifact of projection collapse. As the projection collapses, there is both deformation in that component as well as on the opposing surface. This deformation results in surface strains that act to disrupt the oxides resident on the contacting surfaces. As those oxides fracture, clean surface is exposed. Clean surfaces on the opposing parts, when brought into intimate contact, then share electrons and become bonded.

As suggested previously, the second mechanism of interest for projection welding is the thermal dissolution of any remaining oxides. Projection welding thermal cycles can be estimated from actual current flow times. These times range from a few to as many as several hundred milliseconds. Clearly, such short times require high temperatures for dissociation of residual oxides. This fact also suggests that degrees of residual oxides must be reduced through forging action (as described previously) for the mechanism to be effective. It is generally observed that both forging (i.e., surface strains) and thermal cycles (i.e., oxide dissociation) are required for effective projection welding.

A third mechanism is also often involved in solid projection welding. This mechanism is associated with localized melting and resolidification of metal. As mentioned earlier, melting is often associated with projection welding. Melting during solid projection welding is caused by overheating the part for the force applied. The balance between mechanical and thermal responses in projection welding is discussed in subsequent sections. When melting occurs, there is little constraint to contain this material. As a result, the liquid is typically both expelled (defined as weld expulsion) and retained along the bond line.

Liquid metal can be advantageous for projection welding, in that material solidifying along the bond line can facilitate a joint. This bonding mechanism is commonly used in percussion welding (Ref 14). Allowing such expulsion, however, has a number of drawbacks. One issue is the expelled metal itself. For projection welding applications, the resulting distribution of expelled material may be detrimental to the application (e.g., where sealing is required). In such cases, the lost material (due to localized melting) cannot be replaced in subsequent forging. This can result in porosity along the weld. In addition, a specific type of weld defect, so-called flat spots, can be related to this resolidified material.

The relationship between flat spots and liquid metal in otherwise solid-state welds has been well investigated with respect to flash butt welding (Ref 15–17). The problem is predominantly related to carbon segregation to this liquid material. Carbon at high temperatures is well known to segregate to liquid steel if it is present. The result is a local depletion of carbon from the working surfaces during processing. As forging occurs, the liquid is typically squeezed out. However, the thin layers of decarburized solid steel are then forged over the contact surface, leaving a so-called decarburized band across the interface. This band is typically only a few micrometers wide but can have hardnesses on the order of one-half that of the surrounding material.

Flat spots can then occur when there are residual discontinuities at the bond line. For the projection welding application, the most likely such discontinuities are residual oxides. Such discontinuities are inherently located in

this low-strength interface. The difference in yield strengths between the matrix and decarburized band can result in high triaxial stresses during cooling. Under such conditions, the defects can expand into planar cracks or so-called flat spots. These defects occur irregularly and can be the source of intermittent failures on projection-welded components.

Mechanical/Heat-Transfer Balances

Ideal projection welds show a number of underlying process characteristics. These include localized heating (and subsequent forging), stable applied forces to prevent expulsion, and a balanced forging profile. Achieving localized heating is typically a balance between the rates of heating and thermal conduction. Rapid heating rates (or alternately poor thermal conduction through the projection) result in steep thermal profiles in the projection itself. The temperature profile can be related to the forge depth through the temperature-dependent yield strength of the base material. A characteristic profile for 1015 steel is shown in Fig. 1 (Ref 18). This plot shows a rapid plunge in yield strength with increasing temperature. For an applied force, the band of material that is sufficiently soft to forge is clearly temperature dependent.

The thermal profile (and subsequently the forge depth) is strongly a function of both heating time and projection geometry. The latter is discussed in the section "Geometric Effects" in this article. The effect of heating time on the thermal profile can be estimated through a simple one-dimensional analysis. By looking

Fig. 1 Yield strength as a function of temperature for 1015 steel. Data taken from Ref 18

at essentially a straight-sided projection subjected to a heating pulse of duration t , the peak temperature profile in the part can be defined by the following equation (Ref 19):

$$T(x, t) = T_p - (T_p - T_o) \operatorname{erf}\left(\frac{x}{2\sqrt{\alpha t}}\right) \quad (\text{Eq 1})$$

where T_p and T_o are the peak (in the welding cycle) and room temperatures, respectively; α is the thermal diffusivity of the projection material; t is the effective width of the heat (weld) pulse; and x is the distance back into the projection. Characteristic results from this equation are shown in Fig. 2. This plot is based on a steel projection, using the thermal diffusivity at high temperatures ($\sim 0.1 \text{ mm}^2/\text{ms}$). These results show that for increasing heat pulse (weld) time, thermal gradients progressively decrease. Of particular interest is the effect such thermal gradients have on the forge depth in the projection. This can be assessed by determining the depth of material that is above some forging temperature in Fig. 2. Such a forge temperature for steels can be taken directly from Fig. 1. Here, it is estimated that $900 \text{ }^\circ\text{C}$ ($1650 \text{ }^\circ\text{F}$) is typical (although dependent on projection geometry and applied force) for forging this material. Using this as an approximate forging temperature, forge depths can then be taken directly from Fig. 2. These data have been replotted as forge depth as a function of heat time in Fig. 3.

For steep temperature profiles, the shallow forging depths suggest highly localized deformation. Such localized deformation implies progressively higher degrees of surface strain and improved weld quality. It is of note that processing requirements, particularly current on-times to achieve best surface strains, are contrary to those necessary for thermal dissolution of residual oxides along the bond line. That is, rapid thermal cycles tend to improve surface strains, while long times provide a good thermal profile for diffusion. Generally, balancing these two competing mechanisms is application dependent. Limited experimental data (Ref 10, 11, 20) show that biasing the process toward maximizing surface strains (short times, high currents) is typically beneficial. This is believed to be related to two factors. First, maximizing surface strains has the effect of minimizing the degree of residual oxides for thermal dissolution. It appears that shorter thermal cycles for dissociating fewer and smaller residual oxides is beneficial. Second, rapid thermal cycles reduce the tendency to form oxides on the surface of the projection prior to collapse. This appears again to reduce the size and distribution of these residual oxides, again minimizing the extent of the thermal cycle necessary for dissolution.

As mentioned, applied welding force may also be a concern. Low welding forces prohibit forging except at high temperatures. The effect, then, is twofold. First, because the difference between the forging and melting temperatures is reduced, unstable expulsion can result.

Fig. 2 Peak temperature profiles as a function of heat (weld) time for a straight-sided projection. Results are calculated from Eq 1.

Fig. 3 Calculated forge depths on a straight-sided steel projection. Results are based on a $900 \text{ }^\circ\text{C}$ ($1650 \text{ }^\circ\text{F}$) forge temperature and the data shown in Fig. 2.

Second, because the interfacial temperatures are inherently higher, the driving forces for extended heat soak-back are increased. As a result, lower forces inherently result in shallower thermal gradients, with subsequent declines in weld quality. Similar problems are experienced with poor mechanical follow-up. The issue of mechanical follow-up is addressed in the next section. However, the implication of poor mechanical follow-up is a loss of welding force as the projection collapses. This dynamic variation in welding force has the same

influence as low welding force on such aspects as incidences of expulsion and reduced thermal gradients in the projection.

Effect of System Mechanical Dynamics on Projection Welds

As discussed previously, system mechanical dynamics play an important role in projection weld quality. Specifically, proper forging of

projections requires that the force consolidating the weld be maintained throughout the heating cycle. Otherwise, force dips will result, leading to heat soak and expulsion-related problems, as described in the previous section. The relationship between applied weld force, system mechanical inertia, collapse distance, and collapse time is demonstrated in the following equation (Ref 21):

$$\frac{W_{\text{head}}}{F_{\text{app}}} \leq \frac{g(f t)^2}{20x} \quad (\text{Eq 2})$$

where W_{head} is the weight of the welding head, F_{app} is the applied welding force, g is the acceleration due to gravity, t is the welding time, f is the fraction of the weld time over which projection collapse occurs, and x is the projection collapse distance. The equation is based on the assumptions of constant weld head acceleration, and that 95% of the applied welding force should be maintained for adequate welding. The results of this plot are presented graphically for a range of projection collapse distances, collapse times, and resultant head weight/applied force ratios in Fig. 4. This plot shows that for projection collapse times and distances on the order of 10 ms and 0.5 mm, respectively, the head weight must be less than 10% of the applied welding force. However, if for the same application the collapse time dropped to 5 ms, the critical head weight/applied force ratio would drop to 2.5%.

For larger-scale projection welding systems, the weld force is typically applied by a cylinder behind the ram and tooling. The weight of the

head then includes all those components. As a result $W_{\text{head}}/F_{\text{app}}$ can easily rise and fail the criterion described in Eq 2. This, however, can be compensated for by using so-called fast follow-up heads. These heads are spring loaded and act as a buffer between the main ram and the platen holding the electrode. Such springs can be made from steel (both coil and Bellville washer variations) or from various polymers. The use of these springs essentially reduces the moving weight in the process. In effect, the controlling head weight for Eq 2 then becomes that of the moving assembly below the springs. A typical fast follow-up head assembly is shown in Fig. 5. For this head, a spring is used for follow-up. In addition, the cavity holding the spring (in the center of the unit) is actually a bearing surface, providing alignment between the fast follow-up platen and the primary ram of the machine. With such an assembly, the moving weight in the system can be readily sized to match Eq 2.

Critical to any fast follow-up head is the design of the spring itself. The designs of such springs are usually bounded by geometric considerations and the required spring constant. The governing equation here is that for force supplied by a spring (Ref 22):

$$F_{\text{app}} = -kx_{\text{total}} \quad (\text{Eq 3})$$

where k is the spring constant, and x_{total} is the total displacement of the spring. This equation basically can be used to define spring collapse requirements to applied and relative forces. Similar to the analysis for mechanical follow-up, it is recommended that springs be designed

to maintain 95% of the applied weld force through the collapse distance of the projection. In terms of displacements, this can be expressed as:

$$\frac{x_{\text{precomp}} + x_{\text{comp}} - x}{x_{\text{precomp}} + x_{\text{comp}}} \geq 95\% \quad (\text{Eq 4})$$

where x_{precomp} and x_{comp} are the precompression (preload) and compression distances of the spring, and x is the collapse distance of the projection, as defined previously. Of note, $x_{\text{precomp}} + x_{\text{comp}}$ is equal to x_{total} in Eq 3. Also, x_{comp} must always be greater than x (with a margin) for the head to function properly. For steel springs, the constant k is a design characteristic of the unit. For polymer springs, this constant is defined by the modulus and the spring geometry through the following relationship:

$$k = E \frac{\text{area}}{L} \quad (\text{Eq 5})$$

In this equation, E is the material modulus, while L and “area” are the length and cross-sectional area of the spring itself. Springs for a specific application can then be designed iterating Eq 3 and 4 with the spring constant (for steel springs) or Eq 3 to 5 (for polymer springs). Heads are available in an array of configurations, matching both the requirements of the application and geometry of the welding equipment. When properly designed, projection welding mechanical systems can generally maintain 90% of the weld force throughout the projection collapse cycle.

Fig. 4 Relationship between projection collapse distance, projection collapse time, and the head weight/weld force ratio

Fig. 5 Typical fast follow-up head for resistance welding. The spring is located in the body of the assembly. Note the shunts providing a current flow path around the spring.

Effect of Electrical Characteristics on Projection Welds

The thermal cycle of the projection welding process is, to a large degree, defined by the current waveform. As described previously, short cycles and fast rise times suggest localized deformation of the projection and improved weld quality. Longer weld cycles and faster rise times suggest more delocalized forging and subsequent reductions in quality. An example is provided here for the capacitive discharge (CD) variant of projection welding. While this is just one variant of power supplies used for this process, the analysis provides insight into how heat is generated for this class of welding methods. The schematic for the power circuit in CD welding systems is shown in Fig. 6. For operation, the switch on the left is used to charge the capacitor, while the switch on the right discharges the capacitor energy into the welding circuit. Characteristic values for the circuit include the capacitor charge voltage (V_c), the system capacitance (C), the turns ratio of the transformer (N), and the inductance and resistance of the secondary circuit (L_s and R_s). The L_s is usually defined by the secondary geometry (larger loops imply larger inductances), while the R_s is associated with the workpiece resistance. The secondary current waveform for this circuit is characterized in the following equations (Ref 23):

$$I_s(t) \approx V_c \sqrt{\frac{C}{L_s}} e^{-\zeta \omega t} \sin(\omega t) \tag{Eq 6}$$

where:

$$\omega = \frac{1}{N} \sqrt{\frac{1}{L_s C}} \tag{Eq 7}$$

and:

$$\zeta = \frac{NR_s}{2} \sqrt{\frac{C}{L_s}} \tag{Eq 8}$$

These equations are based on treating the secondary (output) as an inductance resistance capacitance circuit. The capacitance and charge voltage have been incorporated into these equations through the windings ratio expressions $V_s = V_c/N$ and $C_s = N^{1/2} C$, where V_s and C_s are the charge voltage and capacitance when reflected to the secondary of the transformer.

These equations allow current profiles to be estimated from process inputs (charge voltages), machine configurations (capacitances, transformer windings ratios), and workpiece arrangements (component resistances, secondary inductances). A characteristic waveform for a CD projection weld is shown in Fig. 7. This waveform was generated using conditions for a nominal 15 mm (0.6 in.) diameter steel annular projection weld. This included a capacitance of 2400 μ Fd, a charge voltage of 2000 V, a

transformer windings ratio of 100 to 1, a secondary inductance of 0.27 μ H, and a secondary resistance of 175 $\mu\Omega$. The waveform shows a characteristic shape, including a fast rise time and subsequent exponential decay of the current. For this waveform, the peak current obtained is approximately 70 kA, with an associated rise time of 2.3 ms.

Geometric Effects

As mentioned previously, solid projection welding can be accomplished with a wide variation of included geometries (Ref 10–12). As suggested by the results of the analyses provided earlier, the best designs of projections are those that optimize surface strains during welding. These projections are

typically geometrically symmetric, allowing uniform deformation in all unconstrained directions. For single-point projections, this is generally either a radiused or cone geometry. For annular projections, the desired cross-sectional geometry is typically an isosceles triangle. This triangle may also include a flat or radius at the tip. This projection is designed to forge equally to the inside and outside diameters of the component during welding.

For such projection designs, two variables are dominant. The first of these is the projection width. Projection widths are largely selected based on the strength requirements of the joint. Previous work (Ref 11) has based the width of the projection on the thickness of the opposing material in the application. This decision was largely based on achieving parent-material failure (in the opposing workpiece) during

Fig. 6 Schematic representation of the power circuit for a capacitive discharge projection welding system. V_c , charge voltage; C , capacitance; N , windings ratio in the transformer; L_s , inductance in the secondary; R_s , resistance in the secondary

Fig. 7 Current waveform for a capacitive discharge projection welding system. Plot is generated using Eq 6 to 8, with a capacitance of 2400 μ Fd, a charge voltage of 2000 V, a transformer windings ratio of 100:1, a secondary inductance of 0.27 μ H, and a secondary resistance of 175 $\mu\Omega$.

destructive testing for welds on steels. The second of these is the included angle in the projection itself.

Included projection angle has effects on heat transfer during welding as well as the resultant profile of the forged material. The heat-transfer effects can be understood by conducting a simple one-dimensional thermal analysis incorporating the included angle of the projection. For simplicity, this analysis is conducted assuming steady-state conditions. In addition, it is assumed that the process is heat-sunk by the mass of the component at the base of the projection. The analysis here parallels that for truncated cone-style resistance welding electrodes (Ref 24). For an annular projection, the governing equation is then:

$$\frac{d^2T}{dx^2} + \frac{2 \tan \phi}{w + 2x \tan \phi} \frac{dT}{dx} = 0 \tag{Eq 9}$$

where ϕ is the included angle, w is the face width, and x is the distance back into the projection. Assuming a maximum temperature at the projection tip (similar to the approach used for Eq 1), the solution to this equation can be expressed as:

$$T = (T_p - T_o) \left[\frac{\ln \left(\frac{1 + \frac{2x}{w} \tan \phi}{1 + \frac{2h}{w} \tan \phi} \right)}{\ln \left(1 + \frac{2h}{w} \tan \phi \right)} \right] + T_o \tag{Eq 10}$$

where h is the height of the projection. Using this equation, the effect of the included projection angle on the resulting temperature profile is shown in Fig. 8. The plot is based on an annular projection with a 2 mm (0.08 in.) height and a 0.2 mm (0.008 in.) flat on the tip. As when examining the effects of heat (weld) time, a peak temperature at the projection tip of 1400 °C (2550 °F) is assumed. In general, the results show a progressively decreasing thermal gradient away from the projection tip. This is the result of change in projection cross section associated with the included angle. It is noted from this plot that the degree of heat penetration varies inversely with the included angle. That is, the narrowest included angles result in the deepest (into the projection) heat penetrations. This variation in heat penetration can again be used to examine the forge depths, as was done when considering heat (weld) times. These forge depths can be calculated by rearranging Eq 10. The resulting equation is:

$$x_f = \frac{w}{2 \tan \phi} \left[\left(1 + \frac{2h}{w} \tan \phi \right)^{1 - \frac{T_f - T_o}{T_p - T_o}} - 1 \right] \tag{Eq 11}$$

where x_f is the forge depth, and T_f is the forge temperature. Again, using a forge temperature of 900 °C (1650 °F), the variation in forge depths as a function of projection included angle is given in Fig. 9. The plot shows that the forge depth decreases monotonically with increasing angle. This again shows the heat-

sinking capability associated with changes in projection angle.

It has been documented that for annular projection welding, a 90° included angle appears to be optimal (Ref 11, 20). Both too-small (Ref 20) and too-large (Ref 11) included angles have been shown to be detrimental to weld performance. A too-small included angle inevitably leads to a too-wide forge zone. This, as described previously, leads to delocalized forging and reduced effective surface strains. The concerns with a too-large included angle

can be related to effective stresses during forging. Essentially, the increase in contact area during forging with a large included angle reduces effective stresses, limiting material deformation and effective strain.

Actual thermal cycles and forge depths are actually a combination of the effects of weld time and included projection angle. The effects have been described separately previously, with the time-based analysis done with a straight-sided projection and the geometric analysis done assuming steady-state conditions (long

Fig. 8 Temperature profiles near the tip for an array of included projection angles. Data generated from Eq 10

Fig. 9 Forge depth as a function of projection angle. Data generated from Eq 11, assuming a forge temperature of 900 °C (1650 °F)

heat times). Proper optimization requires balances of these two effects to achieve the best possible forging characteristic.

While the analysis done earlier assumes balanced projections, many applications use asymmetric profiles. Such asymmetric profiles tend to heat on the side with less material. This has been seen to result in, at a minimum, asymmetric set-down. This, in turn, has the effect of trapping material in the bond line, reducing weld quality. In addition, such asymmetric set-down can easily result in overheating on one side of the joint, resulting in expulsion. As mentioned earlier, expulsion is typically detrimental to solid projection welds, so joint quality is inevitably compromised. When using such unbalanced projections, shorter weld times tend to improve weld quality. This can be implied from Eq 1 as well as Fig. 2 and 3. Short weld times have the effect of minimizing thermal soak-backs (and forge depths), minimizing complex heating profiles associated with the specific projection design and the resultant quality variations. In general, however, balanced projection designs will yield better weld quality.

All the equations defining the temperature profiles for included-angle projections include flats at the tip. Flats at the tip are essential in these analyses, because a sharp tip implies a local heat-transfer discontinuity. Such a point contact would result in excessive current densities and essentially no heat flux into the projection. The second implication is that the tip of the component would reach temperature nearly instantaneously, causing follow-up problems for the application. In practice, no projection is absolutely sharp, in that the applied welding force would cause yielding at the tip. This would then dull the projection, creating a flat that matches the geometry and the applied welding force. In practice, flats are often used to compensate for follow-up in the welding machine. Recent work has shown that the use of a small flat (~0.2 mm, or 0.008 in.) can minimize weld defects and improve weld strengths, particularly for CD systems.

Finally, it is of note that annular projection welds are often made into holes (Ref 2, 9). These types of joints are referred to as edge-projection welds. Such welds use the geometry of the hole and component to imply a projection for resistance heating. Typical examples include a squared-off bar/tube into a tapered hole, and a tapered section into a straight hole. In both cases, the implied projection forges into and slides across the opposing working surface. The key factors described earlier for annular welds are equally valid for edge welds. These include mechanical balance of the (implied) projection, matching weld times to the desired set-down, and so on. One additional note is to address the motion of the projection across the mating surface. Generally, if the contact angle is too steep, the projection will experience too much lateral motion during forging. This has the effect of bringing contaminants into the

bond area (as the projection slides), reducing bond quality. As discussed earlier for unbalanced projections, shortening the weld times to minimize the forge depths can again be helpful in these applications.

Summary of Analysis

The foregoing analysis was done in five parts. First, efforts were made to define the basic mechanisms of bonding in projection welding. Thermal cycles can be used as a measure of oxide dissolution in the bond line. Basic theory, originally developed for particle dissolution during such thermal cycles, was reviewed in this context. It was noted that most studies suggest that surface-strain effects dominate those from thermal cycles in most projection welding applications. Some discussion was also provided regarding the influence of expulsion on subsequent weld quality.

The second stage of the analysis considered thermal and mechanical balances during projection welding. Thermal balances were analyzed by examining a defined heat pulse into a parallel-sided projection. From the resulting analysis, the concept of forge depth was defined. Forge depth compared the temperature-dependent yield strength to the thermal gradient in the projection. Generally, the greater the forge depth, the more delocalized the forging action and the lower the effective strains for bonding. The analysis showed that forge depths are strongly dependent on heat time. For projection welding, this is closely analogous to the current rise time. Narrower forge depths (with improved effective surface strains) are accomplished through shorter and shorter heat times. Short heat times, however, then require improved mechanical follow-up to prevent expulsion.

The third stage considered mechanical follow-up and related design issues. The relationships between forge distances, collapse times, welding forces, and necessary head weights were discussed, and a defining quantitative relationship was presented. This was followed by design criteria for spring-assisted fast follow-up systems.

The fourth step addressed current (and therefore heating) cycles associated with resistance projection welding. An example was provided by examining the CD process. A relationship was developed based on a simple inductance resistance capacitance circuit, combined with a constancy-of-energy relationship across the transformer. The resulting equations allowed details of the waveform to be predicted based on welding parameters (charge voltage) and process characteristics (system capacitances, transformer windings ratios, and both secondary resistances and impedances). Rise times from this analysis could be used to provide heating information for the various other analyses discussed in this work.

Finally, some consideration was given to the influences of projection geometry. A quantitative analysis was presented relating included projection angle, projection height, and the width of any flat on the projection tip to thermal profiles in the part during joining. These were then converted to forge depths using an approach similar to that described previously for heat times. These results suggest that wider included angles in the projection resulted in shallower forge depths. It is noted that previous experimental results suggested 90° as an optimal included angle for projection welding. At sharper projections, the wider forge depths correlated with reduced weld performance. For angles greater than 90°, it was speculated that the increase in projection cross section (with increasing forge depth) reduced stresses and effectively minimized any forging that would occur. This, in effect, again reduced weld performance. These results (collectively) were then discussed regarding nonsymmetric and edge-style projections. For such configurations, the use of short pulse times (with associated shallow forge depths) offered a way of mitigating the thermal imbalances associated with these designs.

Conclusions

In this work, the mechanisms of bonding for resistance projection welding have been examined in detail. These mechanisms were broken into several components. These included a review of the basic mechanisms of solid-state bonding, an analysis of the mechanical and heat-transfer characteristics of projection welding, assessments of weld head follow-up requirements, examinations of current waveforms, and influence of projection/workpiece geometries. Where possible, simplified mathematical solutions were developed to quantify the phenomena described. From these analyses, several conclusions were drawn:

- Bond-line quality is largely defined by contact surface strains and thermal cycles. Two metallurgical mechanisms are active during projection welding. These include surface strains for fracture and separation of oxide particles, and thermal cycles for particle dissolution. Surface strain effects appear to be dominant for achieving the best projection weld quality.
- Expulsion is generally detrimental to projection weld quality. Expulsion is the formation of liquid metal in the joint, and it implies poor welding practice. In particular, expulsion can lead to loss of metal in the weld and formation of soft zones. The former can lead to porosity and lack of bonding. The latter can cause softened layers along the bond line, leading to intermittent interfacial failures.
- Metal yield strengths typically decrease with increasing temperature and assist in

projection forging. In general, most metals show precipitous drops in yield strengths with increases in temperature. This softening with heating creates forge depths in the projection. These forge depths are defined by the temperature-dependent yield strength and the resulting thermal gradient in the projection.

- Forge depths during projection welding are a strong function of the heat pulse width. Longer heat pulse widths (or weld times) result in shallower thermal gradients in the projection. Such shallower thermal gradients increase forge depths and thus decrease effective strains at the bond line. This, in turn, can result in a reduction in weld quality.
- Proper mechanical follow-up is essential to achieving solid-state projection welds. Proper forging is accomplished by assuring that the applied force can be maintained at the contact surfaces throughout the welding process. This is accomplished by assuring that the weld head can accelerate at a sufficient rate to maintain force as the projection collapses. A criterion for head weight/weld force was developed based on the height of the projection and the effective collapse time.
- Application-specific spring-loaded fast follow-up heads can be defined through some simple design rules. Fast follow-up heads are typically designed with springs. The springs in these heads can be designed based on the load range of interest, the effective spring constant, and the availability of space within the welding machine.
- Current pulse profiles can be defined from process inputs and basic machine characteristics. Current pulse profiles can be defined by a simple analysis of the welding circuit. An example was provided for CD projection welding. Current response was calculated from basic process inputs (charge voltage) and machine characteristics (capacitance, transformer windings ratio, secondary inductance, and secondary resistance).
- Thermal profiles and effective forge depths are strongly affected by the projection design. Thermal profiles in projections during welding are strongly affected by local geometry, particularly the included projection angle. Results show that thermal gradients increase (and forge depths decrease) with increasing included projection angle. Experimental results have shown that weld quality does increase with included

projection angle, but only to a point. Above angles of 90°, the increase in contact area (with collapse of the projection) rapidly reduces the applied stresses (for a given weld force), minimizing deformation and surface strains and reducing joint quality.

- Rapid heat pulses can compensate for unbalanced and edge-style projection designs. Both heat pulse width and projection geometry affect forge depths in welded components. As the projection geometry becomes less optimal (unbalanced and edge-style projections), short pulse widths can be used to control effective temperature profiles and to create stabilized forging profiles.

Fundamentals of Diffusion Bonding*

DIFFUSION BONDING is only one of many solid-state joining processes wherein joining is accomplished without the need for a liquid interface (brazing) or the creation of a cast product via melting and resolidification (welding). In its most narrow definition, which is used to differentiate it from other joining processes such as deformation bonding or transient liquid-phase joining, diffusion bonding (DB) is a process that produces solid-state coalescence between two materials under the following conditions:

- Joining occurs at a temperature below the melting point, T_m , of the materials to be joined (usually $>1/2T_m$).
- Coalescence of contacting surfaces is produced with loads below those that would cause macroscopic deformation to the part.
- A bonding aid can be used, such as an interface foil or coating, to either facilitate bonding or prevent the creation of brittle phases between dissimilar materials, but the material should not produce a low-temperature liquid eutectic upon reaction with the materials to be joined.

Thus, diffusion bonding facilitates the joining of materials to produce components with no abrupt discontinuity in the microstructure and with a minimum of deformation. Within the confines of this definition, the DB process, in practice, is limited to either press or gas pressure or bonding approaches. It is also noted that the preferred term for this process, according to the American Welding Society, is diffusion *welding*. However, because diffusion *bonding* is used more commonly in industry, it is the term that is used in this article.

This article provides a qualitative summary of the theory of diffusion bonding, as distinguished from the mechanisms of other solid-state welding processes (see the article “Mechanisms of Bonding for Solid-State Welding Processes” in this Volume). Additional details on the fundamentals of diffusion bonding can be found in the article “Modeling of Diffusion Bonding” (Ref 1) and in the Selected References at the end of this article.

Applications details for both metals and oxide ceramics are in the article “Diffusion Bonding” in this Volume. It is also well established that diffusion bonding can be combined with superplastic forming (SPF); these processes are generally referred to as SPF/DB processes. Diffusion bonding in conjunction with superplastic forming is addressed in *ASM Handbook* articles “Superplastic Sheet Forming” (Ref 2) and “Forming of Titanium and Titanium Alloys” (Ref 3).

Diffusion Bonding Process

The DB process, that is, the application of pressure and temperature to an interface for a prescribed period of time, is generally considered complete when cavities fully close at the faying surfaces. Relative agreement is found for the mechanisms and sequence of events that lead to the collapse of interface voids, and the following discussion describes these metallurgical processes. Although this theoretical understanding of the DB process is universally applicable, it should be understood that parent metal strength is only approached for materials with surface conditions that do not have barriers to impede atomic bonding, such as the absence of surface oxides or adsorbed gases at the bonding interface.

In practice, oxide-free conditions exist only for a limited number of materials. Accordingly, the properties of real surfaces limit and impede the extent of diffusion bonding. The most notable exception is titanium alloys, which, at DB temperatures greater than 850 °C (1560 °F), can readily dissolve minor amounts of adsorbed gases and thin surface oxide films and diffuse them away from the bonding surfaces, so that they will not impede the formation of the required metallic bonds across the bond interface, as shown in Fig. 1(a). An example of a successful diffusion bond in a titanium alloy is illustrated in Fig. 1(b), where the integrity of the bonded interfaces was demonstrated with subsequent superplastic expansion without interface failure.

* Reaffirmed in 2011 and reprinted from M.W. Mahoney and C.C. Bampton, Fundamentals of Diffusion Bonding, *Welding, Brazing, and Soldering*, Vol 6, *ASM Handbook*, ASM International, 1993, p 156-159

Similarly, the joining of silver at 200 °C (390 °F) requires no deformation to break up and disperse oxides, because silver oxide dissociates completely at 190 °C (375 °F). Above this temperature, silver dissolves its oxide and also scavenges many surface contaminants. Other examples of metals that have a high solubility for interstitial contaminants include tantalum, tungsten, copper, iron, zirconium, and niobium. Accordingly, this class of alloy is easiest to diffusion bond.

A second class of material, that is, metals and alloys that exhibit very low solubility for interstitials (such as aluminum-, iron-, nickel-, and cobalt-base alloys), is not readily diffusion bondable. Special consideration must be given to remove surface barriers to atomic diffusion prior to joining and subsequently prevent their reformation during the joining process. This is not an easy processing matter. Accordingly, the potential for high-strength bond interfaces for alloys with low interstitial solubility should be considered on an individual alloy basis.

Bonding Surfaces Containing Oxides

Diffusion bonding can be achieved for materials with adherent surface oxides, but the resultant interface strengths of these materials are considerably less than that measured for the parent material. Aluminum alloys are prime examples of this class of material. Research since 1960 has demonstrated only limited diffusion bond properties. Although interface strength can be increased for oxide-bearing materials, it requires considerable surface extension of the faying interfaces to create localized plastic flow of the metal and concurrent oxide breakage. This introduces an increased number of locations for metal-to-metal contact via plastic flow around or micro-extrusion through the broken oxide. In general, the oxide is not removed but is simply dispersed over a greater surface area in an enclosed environment, in which oxidation cannot recur. Thus, even with significant surface deformation, only a fraction of the interface area contributes to the strength of the bond. The proportion of oxide-free metallic area revealed is dependent on the relative hardness of the metal and its oxide film, as well as on the mechanical properties of the oxide. This type of bonding, although often considered as diffusion bonding, is better described as deformation bonding and does not fit within the strict definition of the low deformation associated with diffusion bonding.

Factors that affect the relative difficulty of diffusion bonding oxide-bearing surfaces include:

- *Surface roughness prior to welding:* A rougher surface will result in greater shear deformation.

- *Mechanical properties of the oxide:* The more brittle the oxide, the greater the dispersion for a given level of deformation.
- *Relative hardness of the metal and its oxide film:* Because plastic flow controls the amount of bonding area, large differences in their hardness should facilitate bonding.
- *Prestraining or work hardening of the material:* Initiation of bonding will occur at lower deformations for prestrained or work-hardened materials, and the degree of surface extension in the central region of the interface is considerably greater for cold-worked material. Thus, annealed material requires a larger total deformation before bonding will initiate.

It is clear that with the appropriate information, sufficient experiments can be performed to determine the diffusion bondability of most materials. Parent metal strength will not always be attained using the DB approach, particularly for materials with adherent oxides, but interface strength can be maximized if the fundamentals of the process are understood.

Mechanism of Diffusion Bonding

In diffusion bonding, the nature of the joining process is essentially the coalescence of two atomically clean solid surfaces. Complete coalescence comes about through a three-stage metallurgical sequence of events. Each stage, as shown in Fig. 2, is associated with a particular metallurgical mechanism that makes the dominant contribution to the bonding process. Consequently, the stages are not discretely defined but begin and end gradually, because the metallurgical mechanisms overlap in time. During the first stage, the contact area grows to a large fraction of the joint area by localized deformation of the contacting surface asperities. Factors such as surface roughness, yield strength, work hardening, temperature, and pressure are of primary importance during this stage of bonding. At the completion of this stage, the interface boundary is no longer a planar interface but consists of voids separated by areas of intimate contact. In these areas of contact, the joint becomes equivalent to a grain boundary between the grains on each surface. The first stage is usually of short duration for the common case of relatively high-pressure diffusion bonding.

During the second stage of joint formation, two changes occur simultaneously. All of the voids in the joints shrink, and most are eliminated. In addition, the interfacial grain boundary migrates out of the plane of the joint to a lower-energy equilibrium. Creep and diffusion mechanisms are important during the second stage of bonding and for most, if not all, practical applications, bonding would be considered essentially complete following this stage. As the boundary moves, any remaining voids are engulfed within grains where they are no longer

in contact with a grain boundary. During this third stage of bonding, the voids are very small and very likely have no impact on interface strength. Again, diffusional processes cause the shrinkage and elimination of voids, but the only possible diffusion path is now through the volume of the grains themselves.

Stage I—Microasperity Deformation

The nature of the starting surface is of considerable importance, because of the small macroscopic deformation allowed during diffusion bonding. A real surface is never perfectly clean or perfectly smooth, and the area of metal-to-metal contact between faying surfaces is a very small fraction of the area of joint contact. Contact is limited to a relatively few microasperities. At room temperature and under load, these asperities deform as long as the surface area of contact is such that the yield strength of the material is exceeded. The extent of this deformation is limited at room temperature and is even more limited for work-hardenable

Fig. 2 Sequence of metallurgical stages in diffusion bonding process. (a) Initial contact: limited to a few asperities (room temperature). (b) First stage: deformation of surface asperities by plastic flow and creep. (c) Second stage: grain-boundary diffusion of atoms to the voids and grain-boundary migration. (d) Third stage: volume diffusion of atoms to the voids

materials. As temperature increases to the diffusion bonding temperature, the flow stress of the material decreases and additional asperity deformation occurs through plastic flow. Again, flow occurs until the area of contact increases to an extent that the yield strength of the material is exceeded. If the temperature is above the recrystallization temperature of the material, then work hardening is no longer a consideration. With time at temperature, creep mechanisms now control the rate of asperity deformation, and the area of contact or bond continues to grow. As the area of contact grows, the stress acting on the surface asperities decreases. Consequently, creep deformation progressively slows and diminishes in significance.

The contributions of temperature and pressure to both plastic and creep deformation during this initial stage of diffusion bonding are synergistic; that is, at higher temperatures, less pressure is required and vice versa. However, for any combination of temperature and pressure, bulk deformation to the part is limited to a small percentage (<2 to 3%). Ideally, at the completion of the first stage, the extent of asperity collapse should result in a planar area of contacting surfaces with individually dispersed voids. It is necessary to achieve this extent of contact in order to complete the final stages of diffusion bonding in a reasonable period of time.

For example, Fig. 3 illustrates the influence of pressure on the bond-line morphology for a titanium alloy. At lower pressures, where surface asperity deformation is less during the first stage of bonding, large voids remain at the interface, even after a reasonable time at temperature. Conversely with a higher applied pressure and a correspondingly greater initial

interface deformation, the bond interface becomes indistinguishable from the matrix alloy. It should be remembered that, by definition, very little bulk deformation is allowed and that only interface microdeformation contributes to the growth in contact area of the faying surfaces.

Surface Roughness. When considering the sequences in the stages of diffusion bonding, it is clear that the original surface finish plays a significant role in the time dependency for the completion of the different stages. The surfaces that are mated at the bond line are usually rather irregular, as a result of the machining or other surface-preparation steps. As shown in Fig. 4, the surface roughness can be viewed as a bimodal distribution of asperities; that is, small, short-wavelength asperities (surface roughness) arrange on larger, long-wavelength asperities (surfaces waviness).

It is expected that during the first bonding stage, a more uneven initial surface that is due to either roughness or waviness would produce more large voids than would a smooth initial surface. For example, as load is applied, asperities on rough surfaces will experience higher stresses on the points of contact. Plastic flow will occur at a lower load, and greater interface shear will occur. Although first-stage plastic flow and creep will create more localized interface deformation for a rough surface, fewer but larger voids will remain at the interface (the contact area should approach an equilibrium value independent of the initial surface roughness). In addition to size, the shape and curvature of the voids would be considerably different, with higher-aspect-ratio voids for the rougher starting surfaces. For the subsequent

diffusion-controlled collapse of interface voids during second-stage bonding, an initially rough surface will require a longer time or higher temperatures for the mass-transport processes to shrink and eliminate the voids.

Conversely, because real surfaces are not perfectly clean, some limited degree of interface deformation is necessary for the diffusion bonding of even oxide-free materials. Experimental evidence has demonstrated that even gold is not joined unless some shear displacement occurs as the two faying surfaces come into contact. It seems that the importance of the shear displacement, besides increasing the contact area, is that it destroys the continuity of any adsorbed oxygen layer that can contaminate the oxide-free area because of trapped air at the interface. Procedures as simple as wire brushing have been shown to be a particularly effective surface preparation. This can be partly attributed to the creation of rough layers on the surface.

Stage II—Diffusion-Controlled Mass Transport

The densification or collapse of interface cavities during the second stage of diffusion bonding is attributable to the lowering of the surface free energy by the decrease in surface area. This takes place with the formation of new, but lower-energy, solid-solid interfaces. Because the driving force is the same (reduction of surface energy) for all systems, the considerable differences in behavior in various types of systems are related to the different mechanisms of material transfer.

In diffusion bonding, a number of mass-transport processes are operative simultaneously, including time-dependent plastic flow, diffusion from the interface to the cavity via the lattice and the interface and grain boundaries, and diffusive flow around the surface of the void via the lattice and vapor phase. These different paths of mass transfer are illustrated in Fig. 5 and include:

- Plastic yielding that deforms an original contacting asperity
- Surface diffusion from a surface source to a neck
- Volume diffusion from a surface source to a neck
- Evaporation from a surface source to condensation at a neck

- Grain-boundary diffusion from an interfacial source to a neck
- Volume diffusion from an interfacial source to a neck
- Power-law creep

Although vapor transport and surface transport of matter change the shape of the void, they do not directly alter the volume. Thus, these transport paths have only a secondary influence on the rate of void collapse indirectly, through a change in void curvature. Only the transfer of matter from the matrix volume or from grain boundaries causes shrinkage and pore elimination. Thus, only the first two mechanisms, plastic flow and interface diffusion, actually reduce the volume of the interfacial voids. The dominance of either of these two processes is dependent on many inseparable factors, including material system, void geometry, microstructure, and bonding parameters.

When considering diffusion, evidence seems to suggest that the most efficient path for atom flow and counterdiffusing vacancies is along the interfacial grain boundary and along grain boundaries that intersect the void when the grain size is less than the pore size. Although the area of a grain boundary is small in comparison to the void surface, this high-diffusivity path has been shown to dominate. For example, bonding has been shown to be enhanced by first blasting the faying surfaces with chilled iron grit. This treatment promoted recrystallization and thus a finer grain size across the interface, creating additional high-diffusivity paths. In a related process (the sintering of Al_2O_3), porosity was shown to be eliminated next to grain boundaries, with residual porosity remaining at grain centers. Similarly, fine grain size, as exists in superplastic alloys, should create higher rates of void coalescence via grain-boundary diffusion. However, because the chemical potential driving force for grain-boundary diffusion mechanisms is partly dependent on the angle between the applied pressure and a particular grain boundary, its actual contribution will be dependent on its precise

orientation with respect to the applied pressure. The driving force will be maximal when the two are perpendicular and minimal when they are parallel.

Although there is insufficient evidence for generalization, evidence also exists to illustrate that diffusion is, at times, the rate-controlling factor for void coalescence. For example, maintaining temperature while removing pressure following the first bonding stage was shown to not significantly impede the joining process. The rate of void elimination was only slightly slower without the applied pressure. However, this change in rate could be due to either the lost contribution that deformation makes to void coalescence or a reduction in efficiency of the stress-enhanced grain-boundary contribution.

Stage III—Interface Migration

During the second stage of diffusion bonding, voids become much smaller and many are eliminated. Their grain-boundary pinning influence decreases, so that interfacial grain boundary migrates toward an equilibrium configuration, which is indistinguishable from the other grain boundaries in the microstructure. The driving force for the boundary migration is the reduction in grain-boundary area. The initially straight interfacial bond line becomes distorted with local penetrations of a few micrometers of one material into the other at triple points. As the boundary moves, any remaining voids become enclosed within grains where they are no longer in contact with a grain boundary. Diffusional processes continue to shrink and eliminate these cavities, but the diffusion path is now restricted to volume diffusion through the matrix lattice. Accordingly, the elimination of this final small volume of porosity would be likely to contribute an inordinate time to the bonding process for any interface strength benefits that may be achieved.

Diffusion Bonding with Interface Aids

Additional layers of material in the form of coatings or foils are often used as bonding aids for a variety of reasons. For example, an intermediate material can be used when joining dissimilar materials where a brittle intermetallic would otherwise form. In this case, the interfacial material would be selected for its compatibility with each of the materials to be joined and for its ability to prevent the creation of a brittle reaction layer. To promote diffusion in materials that contain elements with low diffusivities, the interfacial material should contain an element with a higher mobility than elements found in the joined materials. A common material for such applications is electroless nickel, which contains phosphorus. (Phosphorus has been shown to have a high diffusivity in other metallic systems.) However, caution should be exercised when

considering the addition of high-diffusivity elements, because of their potential for accumulation at grain boundaries and their resultant influence on mechanical properties.

Another approach is to add an interfacial material that will scavenge impurity elements at the interface and thus produce clean surfaces in situ. Materials with high solubilities for interstitial elements, such as titanium alloys, can be appropriate for this purpose. Because of the importance of localized plastic flow at the interface, a soft material addition can also be of benefit to maximize interfacial contact during the first bonding stage, where deformation mechanisms dominate.

With the addition of interfacial materials, geometric as well as metallurgical considerations become important. The mechanical strength of solid-state metallic bonds achieved with a thin interfacial layer of bonding material goes through a maximum, with decreasing joint thickness. For thick joints, tensile strength is directly related to the bulk properties of the interfacial layer material. As joint thickness decreases, the tensile strength of these joints increases, because of the matrix material restraint on the plastic flow of the interfacial layer. However, for very thin joints, the problems of surface roughness and cleanliness start to diminish the contact area and thus effectively reduce the joint tensile strength. Experimental studies should be performed for individual materials. In general, thicknesses of approximately 0.025 mm (0.00098 in.) yield maximum interface strengths.

Nondestructive Evaluation of Solid-State Welds

Jeong Na, Roger Spencer, Evgeni Todorov, Sean Gleeson, and Perry White, Edison Welding Institute

A NUMBER OF NONDESTRUCTIVE EVALUATION (NDE) methods, such as visual, liquid penetrant, magnetic particle, radiography, ultrasound, and eddy current, are available to detect flaws in solid materials. In general, the first three methods are for inspecting surface discontinuities such as cracks or cavities. For detection of surface and subsurface flaws, radiography, ultrasound, and eddy current are more suitable methods. Because most solid-state welds deal with internal flaws rather than surface-oriented ones, only radiography, ultrasound, and eddy current methods are discussed in this article. First, fundamental aspects of these three NDE methods are briefly described in terms of operation principles; second, some examples are discussed of NDE techniques performed on various types of flaws resulting from solid-state welding processes.

Nondestructive Evaluation Fundamentals

Radiography

Radiography is one of the most widely used volumetric NDE methods. This method is based on differential absorption of penetrating radiation by the material. X-rays or gamma rays are the two types of waves used for this process. The radiography method works well for detecting and sizing volumetric flaws such as pores, voids, and inclusions. With the radiographic method, it is possible to examine a wide variety of materials ranging from light to heavy elements, components of different sizes and shapes ranging from miniature electronics parts to large vessels, and different product forms such as castings, weldments, composites, and so on. For welding inspection applications, the rays pass through the weld and onto a sensitized film that is in direct contact with the back of the weld. When the film is developed, gas pockets, slag inclusions, cracks, or poor penetration are visible on the film. Conventional radiography, which uses x-ray machines or

radioactive isotopes such as iridium-192 and cobalt-60 for generating penetrating radiation, is used to record the internal flaws of the object on a radiographic film. Because of the danger of these rays, only qualified personnel are authorized to perform these tests.

As one of the recently developed radiography methods, digital x-ray radiography using cadmium telluride (CdTe) detectors provides the capability to detect small flaws that require very little inherent unsharpness. The main advantage of using a CdTe detector is its sensitivity when used with low-power microfocus generators (Ref 1). The following are some of the main advantages of digital radiography over conventional film radiography:

- Digital detectors require less radiation to create an image, typically only 1 to 4% of that normally required for a fine-grained, high-contrast, high-speed film (Ref 1).
- Image processing and computer-aided detection and diagnosis algorithms are available for image enhancement and analysis.
- The ability to transmit data to remote sites for consultation, review, or formal interpretation (Ref 2).
- Dark-room facilities are no longer required.
- There are no environmental issues with film and chemical disposal.

However, one of the biggest drawbacks with the radiography method over other NDE methods is the requirement for accessibility to both surfaces of the material to be tested.

Ultrasound

The ultrasonic method uses high-frequency sound waves to locate and measure flaws in welds. It can be used to inspect various materials such as metals, plastics, composites, ceramics, and others. This is an extremely sensitive method, and it can locate very fine surface and subsurface cracks as well as many other types of internal flaws. All types of joints can be tested. As the sound wave passes through the weld zone, flaws cause some of the sound energy to be

reflected back to the probe. By calibrating on known standards, the depth of flaws can be accurately determined. One of the advantages of the ultrasonic method is that only one side of the weld needs to be exposed for inspection.

The amount of ultrasonic energy reflected and transmitted through an interface can be related to the difference in the acoustic impedance, Z , which is defined by the multiplication of the density, ρ , of the medium and the sound velocity, v , in the medium, $Z = \rho \cdot v$. When an ultrasonic wave travels through an interface separated by two media having different acoustic impedances, Z_1 and Z_2 , as shown in Fig. 1, the reflection, R , and transmission, T , coefficients are defined by:

$$R = \left(\frac{Z_2 - Z_1}{Z_1 + Z_2} \right)^2 \quad (\text{Eq 1})$$

and

$$T = 1 - R \quad (\text{Eq 2})$$

where $Z_1 = \rho_1 \cdot v_1$ and $Z_2 = \rho_2 \cdot v_2$. As an example, for a longitudinal wave traveling in an aluminum alloy that interacts with a void filled with air, the reflection coefficient R is almost 1, because air has an acoustic impedance of $0.0004 \text{ g/cm}^2\text{-s}$ ($8 \times 10^{-4} \text{ lb/ft}^2\text{-s}$), while aluminum has approximately $17 \times 10^5 \text{ g/cm}^2\text{-s}$ ($35 \times 10^5 \text{ lb/ft}^2\text{-s}$). This means that the bigger the difference in the acoustic impedance, the stronger the reflection at the interface. This is why it is relatively easier

Fig. 1 Reflection and transmission of ultrasound at an interface separated by two different media

to detect voids in a solid material than it is to detect solid inclusions having an acoustic impedance value similar to the surrounding medium.

Other factors that must be considered when an ultrasonic technique is used are the frequency and the attenuation. In general, the minimum flaw size that would be detected by ultrasound is approximately one-half of the wavelength. The wavelength of ultrasound is determined by dividing the sound velocity of a material by the sound wave frequency; therefore, the higher the frequency, the smaller the flaw size that can be detected. However, a majority of materials have some levels of attenuation at a high frequency. The ultrasonic attenuation coefficient, α , represents how much ultrasonic energy is absorbed and scattered in the material. For metals, the value of α is proportional to the square of the frequency, that is, $\alpha \propto f^2$. It is common to consider both the minimum flaw size and the attenuation coefficient in the material at the frequency being considered. Especially for welded joints, the scattering portion of the attenuation due to a complex microstructure can be a major concern when a high-frequency signal is considered for a small flaw.

Recently, more advanced ultrasonic methods, such as linear phased array and matrix phased array, have been used for weld inspections. Phased array probes consist of multiple transducer elements within a single probe housing that can be grouped to form a desired aperture size and then pulsed in different timing sequences. By varying the timing sequences, the ultrasonic beam can be electronically scanned, steered, and focused to provide quicker coverage of a weld zone. Illustrations in Fig. 2 show how the linear phased array technique is used to focus or steer an ultrasonic beam for better detection. In both cases, the amount and sequence of delay in firing of each element determine the effects. For beam focusing, the midcentral section of the elements has more delay than the outer-edge elements, so the waves generated from the side elements converge into the central beam to create a focusing effect. In contrast, for the beam steering effect, one side of the elements has a longer delay time than the other side, as illustrated in Fig. 2(b). It is also possible to combine beam steering and beam focusing effects. This beam-manipulation capability with the linear phased array technique makes it possible to inspect parts and components with complicated geometries that are not easily inspected with conventional single-element transducers.

Eddy Current

The eddy current inspection method is based on the principle of electromagnetic induction, where eddy currents are induced in a conductive material when the material is placed in a changing magnetic field. It can be used for both ferrous and nonferrous materials. Usually, a drive coil carrying an alternating current induces a swirl of circulating electrical currents, called eddy currents, as shown in Fig. 3 (Ref 3). The eddy current

Fig. 2 (a) Beam focusing and (b) beam steering effects of a linear phased array

Fig. 3 Principle for inducing eddy currents in a conducting material. (a) Without defect. (b) With flaw

contours in the tested material are approximately similar in shape to the shape of the coil that generates the alternating field, especially on the material surface facing the coil. After eddy currents are induced in the material, a secondary magnetic field is formed to interact with the primary magnetic field of the drive coil. This mutual magnetic field interaction causes a change in the drive coil electrical impedance, which has two components: one is called the resistance, and the other is called the reactance. An eddy current instrument monitors and displays changes in the electrical impedance, which can be correlated to the surface or subsurface flaws in the specimen under test. The strength of eddy currents normally depends on the material electrical conductivity, magnetic permeability, frequency of drive signal, and distance between the coil and the material (referred to as the lift-off distance).

One of the most important parameters in the eddy current method is the depth of penetration, δ , as defined by:

$$\delta = \frac{1}{\sqrt{\pi f \mu_0 \mu_r \sigma}} \tag{Eq 3}$$

where f is the frequency of alternating current applied to the drive coil, μ_0 is the constant magnetic permeability of air or free space ($4\pi \times 10^{-7}$ H/m), μ_r is the relative magnetic permeability of the material, and σ is the electrical conductivity of the material. In general, the depth of penetration has a strong relationship with the detectability and sizing of flaws.

The eddy current techniques may be used to detect changes in metallurgical phase and chemical composition, hardness, residual stresses, and others that would affect the electrical conductivity and magnetic permeability distribution in the material (Ref 3). One of the main applications of eddy current is for surface and subsurface flaws and material discontinuities.

Examples of NDE of Solid-State Welds

Radiography (X-Ray)

One of the most common flaws resulting from solid-state welding processes is incomplete consolidation. For cold welding and

diffusion welding processes, cracks may also occur as a result of poor welds. A good example is an incomplete consolidation flaw in friction stir welding (FSW). This is a tunnel defect that forms at the intersection of the weld nugget, thermomechanically affected zone, and band of material running from the weld nugget toward the joint edge on the advancing side of the tool. These defects are attributable to a combination of welding parameters: insufficient or excessive rotational speed combined with a weak downward force. In such cases, the welded parts cannot be correctly stirred and mixed together, and hence, a tunnel, or so-called “wormhole,” is created, running along the entire weld (Ref 4). An x-ray image of a wormhole defect is shown in Fig. 4. In this case, the material was a 13 mm (0.5 in.) thick, 30 cm (12 in.) long high-strength low-alloy steel plate. A wormhole defect, shown as a dark line on the advancing side of the weld, was detected from the entering site to the exit site.

Because the size of flaws in diffusion bonding is determined by the scale of roughness and contaminations of the surfaces being bonded, both flatness and cleanliness influence the bond quality. Real-time radiography, coupled with a microfocus x-ray source and digital image enhancement, has been used to detect flaws in a diffusion-bonded titanium sample (Ref 5). Intentional voids 1 mm (0.04 in.) in size created by a high-melting oxide powder were successfully detected.

Ultrasound

A majority of solid-state welds are comprised of smooth, flat surfaces, where the most likely flaw would be located at the interface of the materials being joined. Because ultrasound is

sensitive to planar-type flaws, they provide a good reflecting surface for an incoming ultrasonic wave. This, in turn, makes them relatively easy to detect, provided the sound energy is reflected at an angle that allows reception by the receiving ultrasonic transducer(s).

If a pulse-echo technique, one of the conventional ultrasonic testing techniques, is used, the primary plane of the flaw must be oriented approximately perpendicular to the beam propagation direction, as shown in Fig. 5. When there is a discontinuity in the weld, the incoming wave reflects back at the discontinuity due to a strong impedance mismatch, and hence, the reflected signal appears early in time, as shown in the A-scan mode display on the left of the top illustration. Normally, multiple ultrasound reflections occur between the top surface of the specimen and the discontinuity, and hence, multiple peak signals would be displayed in the A-scan mode. Alternately, if there is no flaw in the weld, the incoming ultrasound continues its travel through the weld and reflects back at the opposite side of the material. The back surface reflection signal appears at a later time compared to the aforementioned defect signal, because of a longer propagation distance.

In situations where the sound beam cannot be aligned perpendicular to the flaws, an angle beam through-transmission (Fig. 6) or tandem pitch-catch (Fig. 7) technique may provide good detection. These techniques use two probes, with one probe transmitting and the other receiving. Precise placement of the probes is critical to assure proper coverage of the weld area. To obtain full inspection coverage, it is important to acquire data at different probe locations to inspect the full weld thickness. As an alternative to multiple probes and multiple probe positions, phased array probes could

be used to provide electronic beam steering and scanning (Fig. 8). For some applications, it may be necessary to inspect for cracking, porosity, or other flaws resulting from a joining process (Ref 6). In these cases, additional scans using pulse-echo angle beam shear waves or surface waves may be needed to detect certain types of flaws.

A related defect in FSW is incomplete penetration or lack of penetration (LOP), which can be a natural stress raiser from which a crack may propagate. An LOP defect can occur when the weld metal fails to penetrate the joint. As an example, a linear phased array NDE technique was used to detect an LOP defect in a friction stir weld of two aluminum plates. By using an angle beam wedge and a 5 MHz 60-element phased array probe, as shown in Fig. 9, shear wave conversion was achieved in the part. To increase the inspection zone, a sectorial scan was performed between angles 40 and 70°.

A corresponding snapshot image of the test result is shown in Fig. 10. It should be noted that the two images in Fig. 10, both D-scan and S-scan, are upside down when compared with the setup shown in Fig. 9. Because the sectorial scan data were collected with the reflected beam from the bottom surface of the part, the images appear to be upside down when reconstructed. As indicated in the D-scan image, the bottom of the part (root side) shows up on the top portion of the image, while the top surface of the part shows up on the bottom portion of the image. The situation is the same with the S-scan image; the top of the weld is on the bottom portion of the image, while the root area is on the top. A-scan data in Fig. 10 show a strong ultrasonic signal reflection at the bottom of the weld root. Macro sections depicted in Fig. 11 show the corresponding LOP defect near the bottom of the weld.

Different ultrasonic NDE techniques have been discussed extensively by Nagy and Adler in connection with the evaluation of similar and dissimilar inertia and friction welds (Ref 7). The main conclusion they drew from the results of the study was that the great variety of solid-state bonding technologies,

material combinations, defect types, bond-quality considerations, and quantitative parameters made it necessary to evaluate the feasibility of any particular ultrasonic technique on a case-by-case basis. They also concluded that similar joints were much easier to interrogate for gross defects, but such defects were more common in

dissimilar joints. A symmetric reflection technique was introduced to detect weak flaws in the strongly reflecting interface region of dissimilar solid-state bonds. Depending on the accuracy of the reflection measurement, the detection threshold for interface imperfections was improved by approximately a factor of 10. In this way, even apparently flawless interfaces were also able to be characterized in a quantitative way by using an effective softening (or hardening) parameter.

Another specific problem associated with inertia and friction welds studied by Nagy and Adler was the so-called cold weld effect. Frequency analysis was introduced to assess interface conditions in this particular case, where conventional ultrasonic interrogation would often be less sensitive. The slope of the reflected spectrum was shown to be closely correlated to welding pressure and interface temperature. They suggested that the technique may be useful to monitor these welding process parameters. Finally, frequency analysis was used to study the sandwich-like layered structure of similar inertia welds. The ultrasonic technique proved to accurately predict the characteristic thickness of the interface layer, a principal macrostructure parameter closely related to bond quality. No frequency analysis study was reported for dissimilar bonds.

Flaws resulting from diffusion and inertia bonds are influenced by several manufacturing

Fig. 5 Ultrasonic pulse-echo technique for a solid-state weld examination. UT, ultrasonic testing

Fig. 6 Through-transmission pitch-catch technique

Fig. 7 Tandem pitch-catch technique

Fig. 8 Tandem pitch-catch technique using a linear phased array probe

variables, such as part geometry, part fit-up, surface finish, surface contamination, as well as bonding conditions such as time, temperature, and force. An ultrasonic C-scan inspection technique interrogating the bonding plane has been developed by combining a data-reduction technique with pattern-recognition algorithms (Ref 8, 9). A set of inertia-bonded copper-to-

stainless steel samples showed a good correlation with the bond strengths and the C-scan procedure, while diffusion-bonded copper-to-stainless steel and stainless steel-to-stainless steel samples did not show a reliable test result.

A planar distribution of flaws in diffusion-bonded IN100 aircraft engine rotor material has been investigated by using an ultrasonic

wave-scattering theory based on a quasi-static model (Ref 10, 11). Comparison to exact elasto-dynamic solutions and experimental results confirmed that the wave-scattering approach can provide a useful nondestructive inspection technique as well as a tool for fracture mechanics studies.

Various ultrasonic techniques, such as the time-of-flight diffraction (TOFD) technique, scanning acoustic microscopy (SAM), ultrasonic spectroscopy, and the compound scanning technique, have been used to detect diffusion bond defects (Ref 5). The TOFD method showed a promising result for sizing defects, but the location of defects in the material influences the test results, particularly shallow defects for which weak defect signals are often obscured by the later interface signals. For the SAM method, a high-frequency ultrasonic signal above 50 MHz is often scattered by grain boundaries and causes an image-dappling effect, resulting in loss of information about the bond interface. The ultrasonic spectroscopy method uses a Fourier transformation of pulse signals in the frequency domain to identify the scattering feature of microscopic voids and clusters of such voids related to diffusion bonds. In the compound scanning method, focused transducers were used in water tanks to improve the signal-to-noise ratio over the grain-boundary scattering noise. This method proved to be a better approach compared to conventional immersion

techniques, but technical difficulties were found with the probe positioning and alignment when a short pulse is used.

An acoustic emission technique has been used to measure resistance projecting weld strength in Zircaloy-2, a nuclear reactor alloy, followed by various surface treatments (Ref 12). Based on the acoustic emission

counts during the weld process, it was found that tensile-shear weld strength for a range of welder settings and surface-quality variations could be correlated. The weld nugget or process zone was thought to be the primary source of acoustic emission. The magnitude of the acoustic emission count and weld strength level was considered to be related

to the amount of material in the process zone that is plastically deformed during the weld process.

Another ultrasonic method, based on the electromagnetic acoustic transduction technology, has been used to monitor weld quality of flash butt welding of steel coil (Ref 13). The on-line real-time monitoring system detects voids, laps, misalignment, and over/under trim conditions in the weld. Results of the inspection are immediately presented to the weld machine operator for disposition. The information is used to correct suspect weld joints when they occur and to avoid weld breakage in subsequent processing operations.

Eddy Current

A majority of the eddy-current-based NDE work on solid-state welds has been performed for flaws in friction stir welds (Ref 14–20). Instead of using a conventional single probe consisting of transmitting and receiving coils in the same housing, various specialized eddy current techniques have been adapted. One such example is an array eddy current probe having several coils configured in a two-dimensional planar format. An array probe can provide the advantage of covering a wide surface area with one pass, which helps minimize the lift-off variations. Considering the noise source in the eddy current method, having a small variation in the lift-off is a big advantage over many single-probe-based scan techniques. In many cases, advanced signal processing algorithms can be used to produce more intuitive and easy-to-interpret test results when compared to conventional scanning techniques. Model-based algorithms can be developed to use eddy current signal amplitude and phase information to plot the array data in terms of the material electrical conductivity. The conductivity data collected with an array technique have been used to correlate the eddy current measurement results with an LOP defect in a friction stir weld (Ref 15).

Other eddy current techniques, such as pulsed eddy current and specialized eddy current sensors, have been used to demonstrate flaw detection and electrical conductivity mapping, which can be correlated with hardness change on a friction stir weld surface (Ref 16–19). Carr et al. have used the high-temperature superconducting SQUID system to characterize the inertia welds of stainless steel (Ref 20).

Recent advances in computer hardware and software have made possible computer modeling and simulation to be employed for optimization and prediction of eddy current technique performance (Ref 21). The computer models allow fast and comprehensive eddy current procedure development with significantly reduced costs for specimens and representative flaws fabrication.

An example of array eddy-current-based NDE performed on a friction stir weld in an

Fig. 9 Setup for the shear wave weld inspection technique with an angle beam wedge and a 5 MHz 60-element linear phased array probe

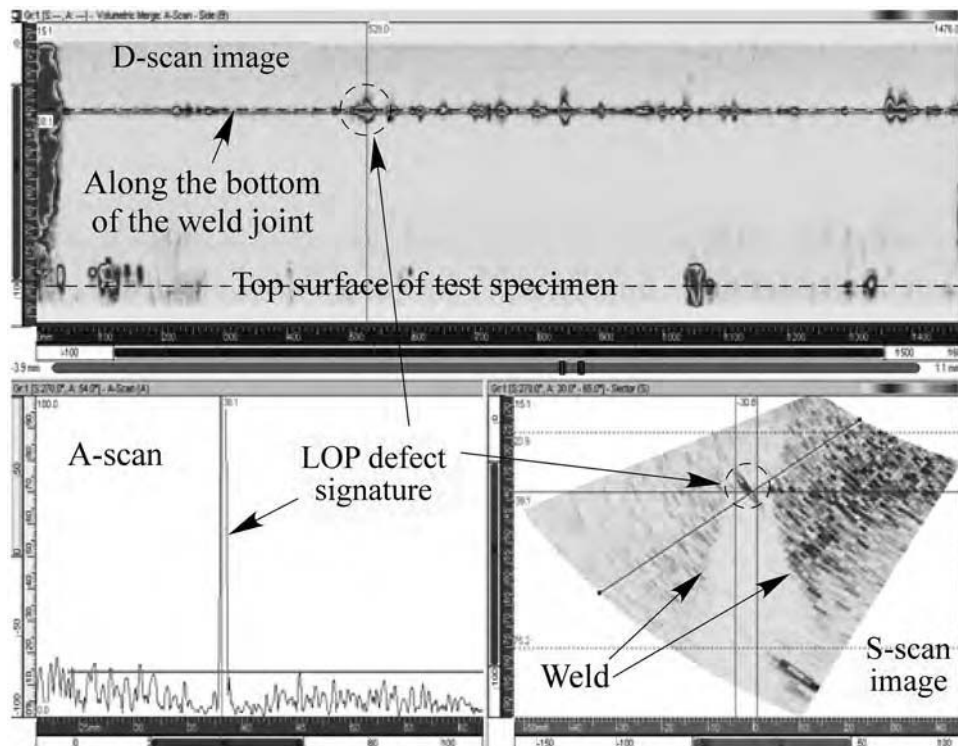

Fig. 10 Linear phased array results for a lack-of-penetration (LOP) defect in a friction stir weld part

Fig. 11 Macro sections showing (a) lack-of-penetration (LOP) defect in a friction stir weld (FSW) aluminum part and (b) magnification (25×) of the LOP defect

aluminum part is shown in Fig. 12(a). For this test, a 32-element array probe was operated at 20 and 480 kHz, and the corresponding test results are shown in Fig. 12(b) and (c), respectively. It should be noted that the array sensor used for this particular specimen had a conformable front face made of a semiflexible polymer material to minimize lift-off noise on a slightly curved surface, as in this case.

The surface of the specimen was prepared to remove any irregularity as well as metal “lips” on the side section of the weld. Both C-scan images and isometric plots in Fig. 12(b) and (c) clearly show two groups of flaws. The biggest flaw, which was invisible on the surface, was detected along the central line of the weld near the tool exit site, location “B” in the images in Fig. 12(b) and (c). The other two lateral flaws, located at positions “A” and “C,” were detected along the advancing side of the weld. Another characteristic feature is the tool exit marks, as shown in the scan images. It may be caused by an increase in the electrical conductivity (possibly correlated to the hardness change), and it is clearly visible in an arc shape in the 20 kHz image. The same tool exit mark shown in the 480 kHz image is not as clear as in the 20 kHz case.

Mechanical Properties of Soft-Interlayer Solid-State Welds*

THE UTILIZATION OF METAL INTERLAYERS for solid-state welding can be an appropriate joining method when brittle intermetallic compound formation, differential thermal contraction during cooling, or oxide dissociation and dissolution temperature preclude the use of conventional methods, such as fusion welding, brazing, and direct solid-state welding of the base metals. An interlayer can have the form of a foil (Ref 1–8), or it can be applied to one or both of the base metal surfaces by various coating methods, such as electrodeposition (Ref 1, 2, 4, 9), plasma spraying (Ref 2), or vapor-deposition methods.

Methods that utilize coated interlayers require a two-step joining procedure (coating and welding), as opposed to joints fabricated with foil interlayers, which may only require a single solid-state welding step. However, methods that utilize coated interlayers have the advantage of not requiring solid-state welding at the interface of the interlayer and base metal, as necessitated by the use of foil interlayers. The solid-state welding of some foil interlayer and base-metal combinations may require high temperatures and/or pressures, because of the high dissociation temperatures of the surface oxides, which may preclude or restrict their use (Ref 10–12).

Various base-metal combinations have been solid-state welded using coated silver as the interlayer metal. The principal advantage of silver as an interlayer for solid-state welding is that high-strength joints can be fabricated at relatively low temperatures (473 to 673 K) and pressures (100 to 200 MPa, or 15 to 30 ksi), because of the low dissociation temperature (<460 K) for silver oxide. Depending on the strength of the base metals and the method (hydrostatic or uniaxial stress) by which pressure is applied to the silver/silver interface, the joining process may result in variable deformation in the base metals. Because some plasticity in the base metal may be important to assist with intimate atomic contact across the interface, “soft” interlayers are often preferred.

Silver interlayers for solid-state welding are usually applied to one or both of the base metals by deposition using either electrodeposition (Ref 1, 13–17) or vacuum-coating methods. The vacuum-coating methods have included electron beam evaporation (Ref 18), hot-hollow cathode (HHC) evaporation (Ref 15, 19–26), ion plating using sputtering (Ref 27–29), and planar-magnetron (PM) sputtering (Ref 30–33).

Prior to deposition, the surface oxide layer may require removal from the base metal in order to achieve adequate adhesion of the silver. The surface oxide layer is usually removed by chemical- or sputter-etching methods. One advantage of vacuum coating over electrodeposition is the ability to sputter-etch the base metal in situ. This permits silver deposition with minimal recontamination of the oxygen on the base-metal surface (Ref 34).

Soft-interlayer solid-state welds that join stronger base metals have unique mechanical properties that are of fundamental interest and may be of critical importance to designers. These assemblies can be subjected to various applied stress states, such as tensile, where the load is applied perpendicular to the interlayer/base-metal interfaces, or shear, where the applied shear stress lies within the plane of the interlayer. Of course, in application, the interlayer may be subjected to a combination of applied tensile and shear loads. This is important because these types of welds are, mechanically, quite anisotropic. This includes the case where interlayers may be subjected to residual stresses from fabrication. The loading may be continually increasing, as with a conventional tensile test, or static, as with creep tests. Again, these behaviors are quite different.

Additionally, some interlayer/base-metal interfaces have been shown to be susceptible to stress-corrosion cracking when exposed to critical environments (Ref 35). The mechanical properties of soft-interlayer solid-state welds and the implications of these behaviors to service stress states and environments are

discussed in this article. It should be noted that although silver interlayers are emphasized, primarily because of their selection by previous researchers and industrial fabricators, the described trends appear to be completely consistent with joints that use other soft-interlayer metals.

Microstructure of Interlayer Welds

As-Deposited Coatings. A fine-grained (typically <1 μm , or 40 $\mu\text{in.}$, in diameter) columnar structure commonly forms in coatings that are vacuum deposited onto low-temperature substrates ($\sim 0.3 T_m$) using a low working-gas pressure (~ 1 Pa, or 1.5×10^{-4} psi). This type of structure has been reported previously in silver coatings fabricated for interlayer welding by HHC evaporation (Ref 20) and PM sputter deposition (Ref 30). The columns are perpendicular to the base-metal surface, and the axes of the columns are oriented perpendicular to a close-packed crystallographic direction. The columnar grains resulting from the PM sputter-deposition of silver often contain a high density of growth twins that are approximately 15 nm (0.6 $\mu\text{in.}$) thick (Ref 30).

Solid-State-Welded Interlayers. Figure 1 shows a solid-state-welded silver interlayer that is 150 μm (6 mils) thick between steel base metals after solid-state welding at 673 K (Ref 17). The silver interlayer typically consists of two types of structures: nonrecrystallized silver that has retained the columnar grains and fine microtwins of the as-deposited coating and silver that has recrystallized into large grains (>1 μm , or 0.04 in., in diameter) containing a high density of annealing twins. The solid-state-welded interfaces are generally free of any large voids, or nonbonded regions. In the case of rough base-metal surfaces, large voids can remain along the silver/silver interface.

Tensile Loading of Soft-Interlayer Welds

Despite the relatively low strength of the interlayer material, it has long been known that thin (1 μm to 1 mm, or 40 μin. to 0.04 in.) interlayer welds or brazes between stronger base materials can have ultimate tensile strengths (UTS) that are much higher than that of the bulk interlayer material (Ref 36, 37). For example, the UTS of silver-interlayer solid-state welds between maraging steel base metals has been reported to be nearly 800 MPa (120 ksi) (Ref 32, 33), whereas the UTS of the bulk silver is only about 250 MPa (35 ksi) (Ref 38). The high tensile strength of the joint is due to the mechanical constraint provided by the stronger base metal, which restricts transverse contraction of the interlayer (Ref 36, 37, 39–45). The constraint establishes radial (triaxial) stresses that inhibit the development of shear stresses within the joint, thereby decreasing the effective, or von Mises, stress in the interlayer. This inhibits the plastic flow that leads to ductile fracture.

Effect of Interlayer Thickness on Stress.

The degree of mechanical constraint in the soft interlayer and the joint strength tend to increase with a decreasing thickness-to-diameter ratio, t/d , of the interlayer (Ref 36, 37, 39–42, 44, 46–53). Figure 2 summarizes the effect of t/d on the UTS of solid-state-welded silver interlayers fabricated using PM sputter deposition (Ref 30) and electrodeposition (Ref 15), compared with Ag-4Pd brazed interlayers (no hardening, because of the addition of palladium) (Ref 41). The UTS is shown to increase with a decreasing t/d ratio to about 0.002, below which only small strength increases can be expected. The higher UTS of sputter-deposited silver interlayers, compared with those utilizing

Fig. 2 Effect of interlayer thickness on ultimate tensile strength of solid-state-welded silver interlayers fabricated using planar-magnetron sputter deposition and electrodeposition, compared with Ag-4Pd brazed interlayers

electrodeposition or brazed-silver alloy, are discussed in the section “Effect of Interlayer Fabrication Method” in this article.

Although the tensile behavior of interlayer joints has been reasonably well understood qualitatively, particularly for thick interlayers, quantitative prediction has only recently been accomplished with finite-element method (FEM) codes. Orowan (Ref 36, 37) was perhaps the first to derive an analytical expression for

the radial (constraining) stress within the interlayer. It was proposed that:

$$\sigma_r = \frac{\sigma_y}{t} \left(\frac{d}{2} - r \right) \tag{Eq 1}$$

where σ_r is the radial stress, t is the thickness, d is the diameter, r is the radius, and σ_y is the yield stress of the interlayer. This equation

was originally derived by assuming ideal plastic behavior (that is, no strain hardening) of the interlayer and uniform plastic strain in the interlayer. Analytical attempts to account for strain hardening within the interlayer have led to modifications of Eq 1 that have, experimentally at least, provided reasonable correlation with upper bounds for UTS of soft-interlayer joints (Ref 41, 43, 48, 49).

More recently, FEM analyses (Ref 53, 54) reveal significant deviation from Eq 1. Figure 3(a) illustrates the effect of t/d on the radial stress distribution at the center plane for silver interlayer welds between nonplastically deforming base metals at a fixed applied tensile stress. These were determined from an FEM analysis that included the observed strain hardening of the interlayer metal and are plotted along with results predicted by Eq 1. This comparison shows that for large t/d ratios ("thick" interlayers), Eq 1 predicts qualitatively correct behavior for the radial stress distribution. However, for small t/d ratios ("thin" interlayers), the

FEM results indicate a relatively uniform and substantially lower stress distribution over most of the central portion of the interlayer than predicted by Eq 1. This is partly due to the simplifying assumptions in Eq 1, particularly that of a radially uniform strain state.

This effect is further illustrated in Fig. 3 (b), which shows the stress state in a strain-hardening silver interlayer at a small fixed t/d ratio. Although it is not shown, the effective (von Mises) stress, which measures the tendency to plastically deform, decreases with decreasing t/d , down to approximately 0.025. Hence, a decreasing t/d ratio increases the mechanical constraint in the interlayer such that a larger applied stress is needed to produce a given amount of plastic strain in the interlayer. Interestingly, and in contrast with Eq 1, the effective stress does not appear to substantially change with decreases in t/d that are less than approximately 0.025 (Ref 54). This is qualitatively consistent with the extrapolations of the solid-state-welded silver data in Fig. 2 (but not the braze data).

Early investigators (Ref 15, 40, 44, 45, 55) believed that this phenomenon was due only to discontinuities (solidification shrinkage cavities, surface flatness, and such) in very thin brazes and solid-state welds. Recent results (Ref 17, 30) of solid-state-welded interlayers fabricated using sputter-deposited silver onto lapped base metals (surface roughness of 0.03 μm , or 1.2 $\mu\text{in.}$) indicate that the modest increase (or plateau) in strength occurs even in the absence of preexisting voids that are common in thin brazes.

Interlayer Strain. Associated with the increased UTS of the constrained interlayers, compared to the UTS of the bulk or unconstrained interlayer metal, is a decreased plastic strain-to-failure, ϵ_f , of the interlayer. Early results (Ref 42) found that for brazed-silver interlayers joining elastically deforming base metals with a t/d ratio of 0.016, the ϵ_f is about 0.01. The results from specimens fabricated using solid-state welding of PM sputter-deposited silver interlayers, in which the base metals did not plastically deform, indicated plastic strains of only about 0.001 for a comparable t/d ratio of 0.024 (Ref 17, 33). The reason for the disparity is not clear. Perhaps the relatively large number of interfaces in the PM sputter-deposited interlayers (Ref 30, 33) led to higher cavity-nucleation rates. Other works do not appear to have made reliable attempts at determining the plastic strain-to-failure value. It should be emphasized that despite the relatively low plastic strain-to-failure, the fracture surface is that of a classic, ductile, microvoid-coalescence type of failure (Ref 33).

Time-Dependent Failure. It has been observed that at stresses substantially less than the UTS, delayed or time-dependent ductile fracture may occur. For at least the case of silver interlayers, decreases in the applied stress are associated with increased times-to-rupture, as indicated in Fig. 4. This figure shows that decreasing the t/d ratio (to about 0.02) and/or improving the base-metal surface finish (lapping) results in longer tensile creep-rupture times. Time-dependent failure is believed to be a consequence of cavity nucleation and/or growth (Ref 33), as is observed in short-term tensile tests that

Fig. 3 Finite-element method analysis of the effect of t/d on the radial stress distribution at the center plane for silver interlayer welds between non-plastically deforming base metals at a fixed applied tensile stress. (a) Predictions of Eq 1 are given by dashed lines. (b) The stress state in a strain-hardening silver interlayer at a small fixed t/d ratio

Fig. 4 Effect of interlayer thickness and base-metal surface finish on creep rupture of solid-state-welded silver joints between nonplastically deforming base metals

determine the UTS. For solid-state welds in which two coatings are joined, nucleation occurs principally at the silver/silver welded interface or the base-metal/silver-coated interface. The cavities appear to nucleate as a consequence of time-dependent plasticity within the interlayer. The cavities expand in diameter and final interlinkage, and failure appears to occur at relatively low “macroscopic” strains within the interlayer (for example, $\epsilon_f < 10^{-3}$).

Figure 5 shows scanning electron micrographs of a solid-state-welded silver interlayer joining steel base metals, loaded at the relatively low stress level of 207 MPa (30 ksi) (albeit, for a substantial fraction of the expected creep-rupture time). Some of the larger cavities consist of clusters of smaller ($< 0.5 \mu\text{m}$, or $200 \mu\text{in.}$, in diameter) microvoids. A typical fracture surface of a creep-rupture specimen is illustrated in Fig. 6. Naturally, the fracture surfaces appear identical to those of the short-term tests in which UTS values

were measured. It should be emphasized that, consistent with Fig. 2, as the interlayer metal strength increases, the strength of the weld joint increases. Similarly, as the interlayer metal creep resistance increases, the rupture times of the weld joint should increase. Hence, as reported for gold-nickel high-strength/creep-resistant interlayer brazes (Ref 56), time-dependent failure has not been observed over periods of about 1 year. Also, it appears that for silver brazes (Ref 33), time-dependent failure is observed but at increasingly longer times at decreasing stresses, perhaps because of differences in substructures, compared with solid-state-welded silver interlayers.

A nucleation-based theory has been proposed to explain the low plastic strain, time-dependent failures of soft-interlayer solid-state welds in which preexisting voids do not exist, and the base metal does not plastically deform. (Ref 17, 33, 57). Plastic deformation of the

interlayer, acting under the effective stress, causes cavity nucleation by dislocation pile-ups at interfaces. Nucleation continues with further creep of the interlayer, until the concentration of nuclei is sufficiently high to lead to instability in the material between the cavities. Coalescence by interlinkage or by uniform wall expansion (“growth”) then occurs. The point of instability between two small nanometer-sized cavities or nuclei separated by a few diameters or so may lead to subsequent rapid nucleation between the cavities, resulting in the formation of a single, larger cavity (as shown in Fig. 5). This process is repeated and eventually leads to the onset of final rupture, and gives the appearance of a classic, ductile, microvoid-coalescence type of fracture.

In contrast with this nucleation-based theory, other investigators (Ref 42) suggest that the macroscopic strain-to-failure is determined by the details of the uniform cavity expansion (growth). Here, once the cavities expand and come in proximity to other cavities, coalescence and ductile fracture occurs. In a creep experiment, according to the usual cavity-growth models, the rupture time is determined by the cavity growth rate or the speed of the expanding cavity wall. In the absence of vacancy-controlled growth, this speed is controlled by the macroscopic plastic strain rate. Therefore, the static (or creep) and dynamic (or quasi-static) failures of the thin interlayer welds should be, according to cavity-growth-based theories, related to the macroscopic strain in the interlayer. If steady-state plasticity is achieved throughout the silver interlayer material surrounding the cavities, then unstable cavity wall expansion may occur. However, since the macroscopic strains-to-failure are small ($\epsilon_f < 10^{-3}$), the time or strain up to the onset of final catastrophic failure (where a large ductile-dimple fracture surface begins to form) is not easily explained by a cavity-growth model in a strain-hardening material.

The silver-plasticity concept for rationalizing creep rupture is consistent with the temperature dependence of the time-to-rupture. The activation energy for the creep of silver at ambient and near-ambient temperatures for various substructures falls within the range of 50 to 71 kJ/mol (Ref 38, 58). The activation energy for the creep rupture of the solid-state-welded silver joints of Fig. 2, equal to 65 kJ/mol (Ref 33), falls within the range of activation energies for silver plasticity.

Effect of Base-Metal Properties. Time-dependent tensile fracture can be dramatically accelerated if there is creep, or time-dependent plasticity, of the base materials. Figure 7 shows the creep-rupture behavior of solid-state-welded silver interlayers ($t/d = 0.024$) joining one of two different strengths of type 304 stainless steel base metals: annealed or cold worked (Ref 17, 33). Interestingly, these base metals undergo time-dependent plasticity, or creep, at ambient temperatures at stresses that are less than the conventional yield stress of the metal.

Fig. 5 Scanning electron micrographs showing solid-state-welded silver interlayer joining nonplastically deforming base metals, loaded at 207 MPa (30 ksi) ($\sim 1/3$ ultimate tensile strength) for a substantial fraction of the expected creep-rupture time

Fig. 6 Solid-state-welded silver interlayer fracture surface between lapped maraging steel base metals

Although the accumulated plastic strain in the creeping stainless steel is only about 0.001 to 0.01 at low stress levels, this nonetheless induces concomitant plastic strain within the interlayer that exceeds that which would occur within the interlayer in the absence of base-metal plasticity, resulting in shorter creep-rupture times. This behavior is consistent with previous reported data for creep ruptures of interlayers that join plastically deforming base metals (Ref 25, 26, 59, 60).

Finite-element analyses have confirmed that plasticity in the base metal allows the interlayer to plastically deform to a much greater extent than if the base metal deforms only elastically (Ref 54). This observation is important, because these small levels of time-dependent plasticity (0.001 to 0.01) are often observed, over time, in other structural metals and alloys at ambient temperature at stresses significantly below the conventionally defined yield stress. With an increase in test temperature, the stainless steel base-metal creep rate significantly increases and rupture times decrease. The activation energies for the creep rupture of silver interlayers between stainless steel base metals and for plastic flow in stainless steel are comparable, further suggesting that the temperature dependence of creep rupture is determined by creep plasticity in the stainless steel base metal. The transition from base-metal to interlayer-controlled creep rupture occurs at the "knee" of the cold-worked stainless steel data plot, at stress levels below which base-metal creep is negligible.

Figure 7 also shows the effect of base-metal surface finish, which is eventually coated, on the creep-rupture behavior of joints utilizing cold-worked type 304 stainless steel. Lapped cold-worked stainless steel base-metal specimens have longer rupture times than those of machined cold-worked stainless steel, as was the case with the maraging steel specimens. However, the increase in creep-rupture times of specimens utilizing lapped versus machined plastic base metals is only a factor of 5, which is considerably less than the increase of approximately 50 for specimens utilizing lapped versus machined elastic base metals. The difference between the increases in creep-rupture times for lapped plastic versus lapped elastic base-metal specimens may be due to the difference in failure processes. For the case of a plastic base metal, the strain in the silver is externally and uniformly imposed by the deformation of the base metal. For elastic base metals, plasticity is caused by the effective stress within the interlayer. It is believed that the heterogeneities along the solid-state-welded silver interface caused during the joining of the comparatively rough machined surfaces could result in regions that may be more resistant to plasticity than other regions. The heterogeneities at the solid-state-welded silver interface may be less significant in increasing the nucleation and coalescence rate of cavities in specimens utilizing plastic base metals than those utilizing elastic base metals, where the strain is indigenous to the interlayer, rather than being imposed by base-metal deformation.

Effect of Interlayer Fabrication Method. In general, the tensile strengths of PM sputter-deposited silver joints between various base metals have been reported to be equal to or greater than those utilizing other silver-coating methods and similar solid-state-welding parameters. For elastic base metals with lapped surfaces, PM sputter-deposited silver joint tensile strengths (Ref 30) of 758 and 793 MPa (110 and 115 ksi) using interlayers that are 150 and 50 μm (6 and 2 mils) thick, respectively, are comparable with HHC-deposited silver joints (758 MPa, or 110 ksi, using 10 μm , or 0.4 mil, thick interlayers) and greater than those of electrodeposited silver joints (669 MPa, or 97 ksi, using 25 μm , or 1 mil, thick interlayers) (Ref 15). However, the tensile strength values for silver-interlayer welds fabricated using these other two coating methods are achieved with considerably thinner interlayers, which have the advantage of greater plastic constraint produced by the base metals. For type 304 stainless steel (plastically deforming) base metals with machined surfaces and 150 μm (6 mils) thick joints, PM sputter-deposited silver joint tensile strengths (Ref 30) of 304 MPa (44 ksi) ($\sigma_{y,SS} = 221$ MPa, or 32 ksi) and 400 MPa (60 ksi) ($\sigma_{y,SS} = 359$ MPa, or 52 ksi) are comparable with electrodeposited silver joint strengths of 321 to 367 MPa (47 to 53 ksi) ($\sigma_{y,SS} = 296$ MPa, or 43 ksi) (Ref 16). For uranium (plastic) base metals with machined surfaces, the PM sputter-deposited silver joint tensile strength of 442 MPa (64 ksi) ($\sigma_{y,U} = 242$ MPa, or 35 ksi) (Ref 30) exceeds electrodeposited silver joint strengths of approximately 255 MPa (37 ksi) (despite the higher base-metal yield stress; $\sigma_{y,U} = 345$ MPa, or 50 ksi) and HHC-deposited silver joint strengths of 345 to 373 MPa (50 to 54 ksi) (Ref 16, 61). However, the lower joint strength using HHC-deposited silver (Ref 61) may have resulted from a lower solid-state welding pressure (138 MPa, or 20 ksi) and temperature (589 K) than those using PM sputter-deposited silver. The tensile strength of solid-state-welded silver joints between dissimilar metals, such as uranium ($\sigma_y = 345$ MPa, or 50 ksi) and type 304 stainless steel ($\sigma_y = 296$ MPa, or 45 ksi) fabricated using HHC deposition has been reported to average 442 MPa (64 ksi) (Ref 25). The tensile strength of electrodeposited silver joints between the same uranium and stainless steel base metals that were solid-state welded at the same pressure (207 MPa, or 30 ksi), temperature (873 K), and time (2 h) averaged only 345 MPa (50 ksi) (Ref 17, 30). Therefore, solid-state-welded silver joints fabricated using electrodeposition appear to be weaker than those fabricated using HHC deposition or PM sputter deposition.

Although there is only a limited amount of published test results of interlayer joint strengths fabricated by low-temperature solid-state welding of foils, it appears that interlayer/base-metal adhesion is difficult to achieve at temperatures below approximately $0.7 T_m$ of

Fig. 7 Creep-rupture behavior of solid-state-welded silver interlayers ($t/d = 0.024$) joining one of two different strengths of type 304 stainless steel base metals (annealed or cold worked), both of which undergo time-dependent plasticity or creep at ambient temperatures at stresses less than the conventional yield stress of the metal

the interlayer. Tensile strengths of silver joints between alumina and type 321 stainless steel were reported to be only 40 MPa (5.8 ksi) when solid-state-welding parameters were 1073 K and 50 MPa (7.3 ksi) for 0.5 h (Ref 11). The investigators reported threshold solid-state-welding temperatures below which no measurable bonding was produced for each of the foils utilized (silver, aluminum, copper, and nickel). The threshold temperature to achieve solid-state welding of silver foils to alumina and type 321 stainless steel was reported to be 873 K (0.7 T_m of the silver), considerably higher than the temperature required to achieve solid-state welding of silver to itself (0.35 T_m) (Ref 18). Joint strengths of the previous interlayer fabrication processes were reported to be comparable (40 to 50 MPa, or 5.8 to 7.3 ksi) to those of silver foils (Ref 11). Tensile tests reported for silver-foil interlayers between type 304L stainless steel and Ti-6Al-4V alloy suggest that higher strengths may be achieved with coated interlayers than with foil interlayers (Ref 62). These joints were fabricated by solid-state welding a 125 μm (5 mils) thick silver foil between the base metals at 1153 K (0.94 T_m). The investigators (Ref 62) reported average joint strengths of 280 MPa (40 ksi). For annealed type 304 stainless steel and 150 μm (6 mils) thick joints fabricated using PM sputter deposition, the reported (Ref 30) tensile strength of 304 MPa (44 ksi) is higher, despite the higher base-metal yield stress of Ti-6Al-4V alloy used in the silver-foil study.

Shear Loading

Effect of Microstructure. The base metals provide relatively little mechanical constraint of the interlayer during shear loading (shear stress is parallel to the plane of the interlayer) and therefore reveal the mechanical behavior of the interlayer material itself. The behavior of the interlayer in shear can be converted to equivalent uniaxial tensile behavior using the von Mises stress and strain criteria:

$$\bar{\sigma} = \tau\sqrt{3}$$

$$\bar{\epsilon} = \gamma\sqrt{3}$$

where τ and γ are shear stress and strain, respectively. Effective (von Mises) stress-strain ($\bar{\sigma} - \bar{\epsilon}$) behavior for a 150 μm (6 mils) thick ($t/d = 0.024$) silver joint, fabricated using PM sputter-deposition (between maraging steel) and tested in torsion is shown in Fig. 8 (Ref 33), along with the reported results for bulk polycrystalline (annealed) silver (Ref 38). The yield stress ($\bar{\epsilon}_p = 0.2\%$) of the solid-state-welded joint is six times greater than the bulk-silver value, presumably because of the much more refined, twinned substructure. The strain-hardening rate, $d\bar{\sigma}_{\text{eff}}/d\bar{\epsilon}_{\text{eff}}$, at an effective stress of 100 MPa (15 ksi) is over nine times greater than bulk polycrystalline silver (Ref 38). The maximum interlayer stress is attained after a

strain of only 0.3 (99% of the maximum value is attained after a strain of only 0.1). Therefore, although the interlayer silver has a higher yield stress and strain hardens at a higher rate, it reaches essentially the same maximum stress as bulk silver at a substantially lower strain.

Differences in the maximum (steady-state) stress may result from two factors. First, the interlayer microstructure may not be identical to that of the bulk material. The second explanation is that slip (plasticity) is not isotropic. The plasticity is not isotropic. The plasticity is the result of dislocation activity on limited slip planes with specific Burgers vectors. The shear displacements of individual grains in the interlayer must generally be accommodated by neighboring grains. However, near the base metal, the accommodation is not possible, and additional slip systems may operate in the interlayer grains near the base metal, leading to greater local hardening and higher flow stresses. Torsion tests of solid-state-welded silver interlayers coated by HHC evaporation, using uranium-to-stainless steel base metals (Ref 26), showed similar increases in the yield stress and strain-hardening rates, compared with those of bulk-silver values. However, the steady-state stress of silver joints was approximately 25% higher than that of bulk silver, compared with 10% higher values for interlayers using PM sputter-deposited silver. One explanation for this difference may be the presence of HHC deposits, which may further raise the maximum, or steady-state, stress.

Time-Dependent Failure. Although not shown in Fig. 8, the plastic strain-to-failure in pure shear is very high ($\bar{\epsilon}_f = 5$ to 10) for thin, silver-interlayer specimens, just as for macroscopic, or bulk, silver specimens (Ref 33). This is nearly 4 orders of magnitude higher than for the case of tension. As previously discussed, cavity nucleation is promoted by the triaxial stress state established with simple uniaxial loading of constrained interlayers. The fact that torque saturates is consistent with the observation that some face-centered cubic metals, such as aluminum, copper, and silver (Ref 38), show a saturation in the flow stress. This fact is important because such saturations imply constant torque, or time-dependent, shear-stress failures. Figure 9 shows a comparison between the rupture time versus effective (von Mises) stress behavior in shear (Ref 26) (at torsional stresses less than the maximum of HHC-deposited-silver interlayers), compared with that of tension (Ref 17) (calculated using FEM analyses of PM sputter-deposited silver interlayers). The shear rupture times are longer than tensile rupture times at equivalent uniaxial stresses (calculated using the von Mises relation), consistent with the higher plastic strains-to-failure that are much higher for the torsion specimens ($\bar{\epsilon}_f > 5$) than for the tensile specimens ($\epsilon_f \sim 0.001$). The shorter rupture times for tensile joints are a direct result of the hydrostatic tensile stresses superimposed on the

Fig. 8 Effective (von Mises) stress-strain behavior for a 150 μm (6 mils) thick silver interlayer ($t/d = 0.024$), fabricated using planar-magnetron (PM) sputter deposition, tested in torsion, along with results reported for bulk polycrystalline (annealed) silver

effective stresses caused by the mechanical constraint imposed by the base metal.

The change in steady-state strain-rate (or time-to-rupture, according to the Monkman-Grant relationship) with applied stress is predictable according to the steady-state stress exponent, n :

$$n = \left(\frac{\partial \ln \dot{\epsilon}}{\partial \ln \bar{\sigma}} \right)_i \quad (\text{Eq 2})$$

where n is about 30 for silver at ambient temperature (Ref 38). Naturally, the steady-state strain rate of the torsional specimens shown in Fig. 9 is less than the constant applied strain rate of the torsional specimens shown in Fig. 8. If the steady-state rate is not achievable in the interlayer metal, then time-dependent failure in shear is not expected to occur.

It is important to realize the consequence of the difference in plastic strains-to-failure between the constant shear-stress case and the constant tensile-stress case. For example, residual shear or tensile stresses may develop during fabrication of interlayer brazes or solid-state welds. This is particularly true in cases where dissimilar base materials are joined but have substantially different coefficients of thermal expansion. For thin interlayers subjected to residual shear stresses, the dimensions of the base metal and interlayer may be such that the stress is relaxed at strains less than the shear strain-to-failure. However, because the observed tensile strains-to-failure are small, creep rupture by residual tensile stresses is possible, provided a significant stress level exists. If the interlayer metal is resistant to time-dependent failure, then only the indirect implications of residual stress are important (for example, environmentally induced failure).

Fig. 9 Comparison between the rupture time versus effective (von Mises) stress behavior in shear, at torsional stresses less than the maximum of hot-hollow-cathode-deposited silver interlayers, compared with that of tension, calculated using finite-element method analyses of planar-magnetron sputter-deposited silver interlayers

Multiaxial Loading

As discussed earlier, in tension there is significant mechanical constraint by the base material, which tends to reduce the effective stress. In torsion, where the shear stress is parallel to the plane of the interlayer, there is no constraint, other than, perhaps, the relatively minor constraint associated with plastic strain incompatibilities between the interlayer and the base metal. It was also mentioned earlier that the equivalent uniaxial strain-to-failure for torsional deformation of soft-interlayer joints is roughly 4 orders of magnitude higher than the values for uniaxial tension, and the (effective) shear stress-to-failure is only about one-half the UTS. This suggests that the interlayers will behave anisotropically to imposed stresses. The mechanical properties of the intermediate cases of biaxial deformation are not readily interpolated between these limits. The authors have preliminary experimental evidence, for example, that low-strain ductile failures in thin interlayers may occur at particularly low stress levels and strains for cases where tensile loads are accompanied by in-plane shear stresses (Ref 63). This implies that some multiaxial residual stress states may render solid-state-welded interlayer joints substantially more vulnerable to failure than simple tensile-stress states, even though the “macroscopic” effective stress may be comparable, when calculated on the basis of the applied stress state in the base material away from the interlayer.

Environmentally Induced Failure of Interlayers

The interlayer/base-metal interfaces of some soft-interlayer welds appear particularly vulnerable to failure when exposed to external (corrosive) environments. For example, it is known that brazed silver interlayers between stainless steel are subject to galvanic corrosion in aqueous NaCl media (Ref 64, 65). When dissimilar base materials are joined, the potential for stress-corrosion cracking (SCC) exists if the joints are exposed simultaneously to some external (corrosive) environments and either shear or tensile stresses. If an interlayer is subjected to stress, then a determination of the vulnerability to SCC is appropriate. It was mentioned earlier that elevated-temperature joining using either solid-state or brazing processes may leave the joint under substantial residual stress, particularly in the case of dissimilar metals for which the coefficients of thermal expansion are significantly different. The authors have reported (Ref 35) that the uranium to type 304 stainless steel solid-state welds, fabricated using HHC-deposited silver interlayers (Ref 25, 26), are very susceptible to SCC. These silver solid-state welds were joined at 873 K, and the difference in thermal expansion coefficients leaves the joints of cylindrical specimens under significant residual shear stresses after cooling to ambient temperature. It was found that these residual stresses led to SCC at the uranium/silver interface in

air saturated with water vapor (100% relative humidity) (Ref 35). This cracking resulted in reduced tensile strengths and rupture times, when compared with those specimens tested in laboratory air (~40% relative humidity). Specimens subjected to the same 100% relative humidity in air in an unstressed state exhibited no loss in strength, even after lengthy exposure. This, of course, emphasizes the importance of considering the residual stresses as not only rendering the interlayer joints vulnerable to “pure mechanical” rupture but also to environmentally induced failures such as SCC, hydrogen embrittlement, and metal-induced embrittlement, if exposed to critical environments.

Introduction to Arc Welding*

ARC WELDING is one of several fusion processes for joining metals. By the application of intense heat, metal at the joint between two parts is melted and caused to intermix directly or, more commonly, with an intermediate molten filler metal. Upon cooling and solidification, a metallurgical bond results. Since the joining is by intermixture of the substance of one part with the substance of the other part, with or without an intermediate of like substance, the final weldment has the potential for exhibiting at the joint the same strength properties as the metal of the parts. This is in sharp contrast to nonfusion processes of joining, such as soldering, brazing, or adhesive bonding, in which the mechanical and physical properties of the base materials cannot be duplicated at the joint.

In arc welding, the intense heat needed to melt metal is produced by an electric arc. The arc is formed between the work to be welded and an electrode that is manually or mechanically moved along the joint (or the work may be moved under a stationary electrode). The electrode may be a carbon or tungsten rod, of which the sole purpose is to carry the current and sustain the electric arc between its tip and the workpiece. Or, it may be a specially prepared rod or wire that not only conducts the current and sustains the arc but also melts and supplies filler metal to the joint. If the electrode is a carbon or tungsten rod and the joint requires filler-metal addition, that metal is supplied by a separately applied filler-metal rod or wire. However, most welding in the manufacture of steel products where filler metal is required is accomplished with the second type

of electrodes: those that supply filler metal as well as provide the conductor for carrying electric current.

This article introduces the fundamentals of arc welding, which is described in more detail in other articles on specific topics. This article also provides a brief summary of the history and early discoveries of arc welding. For many centuries, the only method man had for metallurgically joining metals was forge welding, a crude and cumbersome blacksmith-type operation in which heated metals were pounded or rammed together until they bonded. Then, within the span of a few years prior to 1900, three new processes came into existence. Arc welding and resistance welding were developed in the late 1880s and put to work in industry a few years later. Oxyacetylene welding was developed during the same period and was first used industrially in the early 1900s.

Today (2011), a wide variety of arc welding processes are used, as described further in separate articles. A general comparison of the most commonly used processes relative to some general application factors is summarized in Table 1. Although some of the ratings are subjective, they provide a general overview of the different processes. The general ratings encompass broad variation depending on application. For example, the rating of fair to excellent for FCAW in the field covers the broad range of alloys that might be used, and the difference between gas-shielded and self-shielded. Productivity (weld metal deposited per hour) is often a key factor, but the other factors in Table 1 also must be considered, as a minimum, when

selecting a welding process. Selection may involve a balance of productivity and weld quality, and each process has a number of conflicting advantages and limitations in specific situations.

Arc Welding Fundamentals

The basic arc welding circuit is illustrated in Fig. 1. An alternating current (ac) or direct current (dc) power source, fitted with whatever controls may be needed, is connected by a ground cable to the workpiece and by a "hot" cable to an electrode holder of some type, which makes electrical contact with the welding electrode.

When the circuit is energized and the electrode tip touched to the grounded workpiece

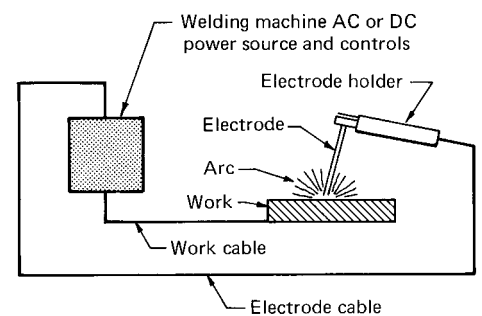

Fig. 1 Basic arc welding circuit. ac, alternating current; dc, direct current

Table 1 General application characteristics of selected arc welding processes

Parameter or characteristic	Process(a)					
	SMAW	GTAW	GMAW	FCAW	SAW	
Weld quality	Good	Excellent	Excellent	Good	Excellent	
Weld deposition rate	Fair	Poor	Good	Good	Excellent	
Field work	Excellent	Poor	Fair/good	Fair/good	Poor	
Equipment maintenance	Low	Low	Medium/high	Medium/high	Medium	
Smoke/fume emission	Medium/high	Low	Medium	Medium/high	Very low	
Heat input control	Good	Poor	Good	Good	Excellent	
Arc visibility and filler-metal placement	Good	Excellent	Satisfactory	Satisfactory	Not applicable(b)	
Variety of metals weldable	Excellent	Excellent	Good	Good	Fair	

(a) SMAW, shielded metal arc welding; GTAW, gas tungsten arc welding; GMAW, gas metal arc welding; FCAW, flux cored arc welding; SAW, submerged arc welding (b) Arc visibility is not applicable for SAW, as electrode placement is established prior to welding

and then withdrawn and held close to the spot of contact, an arc is created across the gap. The arc produces a temperature of approximately 3590 °C (6500 °F) at the tip of the electrode, a temperature more than adequate for melting most metals. The heat produced melts the base metal in the vicinity of the arc and any filler metal supplied by the electrode or by a separately introduced rod or wire. A common pool of molten metal is produced, called a crater. This crater solidifies behind the electrode as it is moved along the joint being welded. The result is a fusion bond and the metallurgical unification of the workpieces.

What takes place immediately under the welding arc is similar to what happens in an electric furnace for metal production. Electrical furnace steels are premium grades; weld metal from steel electrodes is newly prepared electric-furnace steel and also premium grade. Properly executed welds are almost always superior in mechanical properties to the metals they join. In no other metals-joining process is the joint customarily stronger than the metals joined. However, the heat during arc welding also can cause various metallurgical effects in the weld metal and the adjacent base metal.

Arc Shielding

Joining metals with the heat of an electric arc, however, requires more than the moving of the electrode with respect to the weld joint. Metals at high temperatures are chemically reactive with the main constituents of air: oxygen and nitrogen. Should the metal in the molten pool come in contact with air, oxides and nitrides would be formed, which upon solidification of the molten pool would destroy the strength and toughness properties of the weld joint. For this reason, the various arc welding processes provide some means for covering the arc and the molten pool with a protective shield of gas, vapor, or slag. This is referred to as arc shielding. Arc shielding may be accomplished by various techniques, such as the use of vapor-generating and/or slag-forming coverings on filler-metal-type electrodes, the covering of the arc and molten pool with a separately applied inert gas, or a granular flux. The use of materials within the core of tubular electrodes also generates shielding vapors and slag.

Whatever the shielding method, the intent is to provide a blanket of gas, vapor, or slag that prevents or minimizes contact of the molten metal with air. The shielding method also affects the stability and other characteristics of the arc. When the shielding is produced by an electrode covering, by electrode core substances, or by separately applied granular flux, a fluxing or metal-improving function is usually also provided. Thus, the core materials in a flux cored electrode may supply a deoxidizing function as well as a shielding function. In submerged arc welding, the granular flux applied to the joint ahead of the arc may add

alloying elements to the molten pool as well as shielding it and the arc.

Figure 2 illustrates the shielding of the welding arc and molten pool with a covered "stick" electrode, the type of electrode used in most manual arc welding. The extruded covering on the filler-metal rod, under the heat of the arc, generates a gaseous shield that prevents air from contacting the molten metal. It also supplies ingredients that react with deleterious substances on the metals, such as oxides and salts, and chemically ties up these substances in a slag that, being lighter than the weld metal, rises to the top of the pool and crusts over the newly solidified metal. This slag, even after solidification, has a protective function; it minimizes contact of the very hot solidified metal with air until the temperature falls to a point where reaction of the metal with air is reduced.

While the main function of the arc is to supply heat, it has other functions that are important to the success of arc welding processes. It can be adjusted or controlled to transfer molten metal from the electrode to the work, to remove surface films, and to bring about complex gas-slag-metal reactions and various metallurgical changes. The arc itself is a very complex phenomenon that has been intensively studied. In-depth understanding of the physics of the welding arc is of little value to the welder, but some knowledge of its general characteristics is introduced in the following section, with more details given in the article "Arc Physics of Gas Tungsten and Gas Metal Arc Welding" in this Volume.

Nature of the Arc

An arc is an electric current flowing between two electrodes through an ionized column of gas, called a plasma. The space between the two electrodes or, in arc welding, the space between the electrode and the work can be divided into three areas of heat generation: the cathode, the anode, and the arc plasma (Fig. 3).

The welding arc is characterized by a high-current, low-voltage arc that requires a high concentration of electrons to carry the current. Negative electrons are emitted from the cathode and flow, along with the negative ions of the plasma, to the positive anode. Positive ions flow in the reverse direction. A negative ion is an atom that has picked up one or more electrons beyond the number needed to balance the positive charge on its nucleus, thus the negative charge. A positive ion is an atom that has lost one or more electrons, thus the positive charge. However, just as in a solid conductor, the principal flow of current in the arc is by electron travel.

Heat is generated in the cathode area mostly by the positive ions striking the surface of the cathode. Heat at the anode is generated mostly by the electrons. These have been accelerated as they pass through the plasma by the arc voltage, and they give up their energy as heat when striking the anode.

The plasma, or arc column, is a mixture of neutral and excited gas atoms. In the central column of the plasma, electrons, atoms, and ions are in accelerated motion and constantly colliding. The hottest part of the plasma is the central column, where the motion is most intense. The outer portion or the arc flame is somewhat cooler and consists of recombining gas molecules that were disassociated in the central column.

The distribution of heat or voltage drop in the three heat zones can be changed. Changing the arc length has the greatest effect on the arc plasma. Changing the shielding gas can change the heat balance between the anode and cathode. The addition of potassium salts to the plasma reduces the arc voltage because of increased ionization.

The difference in the heat generated between the anode and cathode can determine how certain types of arcs are used. For example, when gas tungsten arc welding of aluminum using argon gas, the electrode as a cathode (negative) can use approximately 10 times more current without melting than when used as an anode (positive). This indicates that more heat is generated at the anode than at the cathode. The submerged arc welding process generates more heat at the cathode rather than the anode, as

Fig. 2 The coating on a coated (stick) electrode provides a gaseous shield around the arc and a slag covering on the hot weld deposit.

Fig. 3 Areas of heat generation in the arc

evidenced by the higher melt-off rate when the electrode is negative. The same is also true for EXX10 stick-electrode welding.

In welding, the arc not only provides the heat needed to melt the electrode and the base metal but, under certain conditions, must also supply the means to transport the molten metal from the tip of the electrode to the work. Several mechanisms for metal transfer exist. In one, the molten drop of metal touches the molten metal in the crater, and transfer is by surface tension. In another, the drop is ejected from the molten metal at the electrode tip by an electric pinch. It is ejected at high speed and maintains this speed unless slowed by gravitational forces. It may be accelerated by the plasma, as in the case of a pinched plasma arc. These forces are the ones that transfer the molten metal in overhead welding. In flat welding, gravity also is a significant force in metal transfer.

If the electrode is consumable, the tip melts under the heat of the arc, and molten droplets are detached and transported to the work through the arc column. Any arc welding system in which the electrode is melted off to become part of the weld is described as metal arc. If the electrode is refractory—carbon or tungsten—there are no molten droplets to be forced across the gap and onto the work. Filler metal is melted into the joint from a separate rod or wire.

More of the heat developed by the arc is transferred to the weld pool with consumable electrodes than with nonconsumable electrodes. This produces higher thermal efficiencies and narrower heat-affected zones. Typical thermal efficiencies for metal arc welding are in the range of 75 to 80% and for welding with nonconsumable electrodes, 50 to 60%.

Because there must be an ionized path to conduct electricity across a gap, the mere switching on of the welding current with a cold electrode posed over the work will not start the arc. The arc must first be ignited. This is accomplished either by supplying an initial voltage high enough to cause a discharge or by touching the electrode to the work and then withdrawing it as the contact area becomes heated. High-frequency spark discharges are frequently used for igniting gas-shielded arcs, but the most common method of striking an arc is the touch-and-withdraw method.

Arc welding may be done with dc, with the electrode either positive or negative, or with ac. The choice of current and polarity depends on the process, the type of electrode, the arc atmosphere, and the metal being welded. Whatever the current, it must be controlled to satisfy the variables—amperage and voltage—that are specified by the welding procedures.

Overcoming Current Limitations

The objective in commercial welding is to get the job done as fast as possible without sacrificing quality, so as to lessen the labor-time

costs of skilled workers. One way to speed the welding process would be to raise the current (use a higher amperage), because the faster the electrical energy can be induced in the weld joint, the faster will be the welding rate.

With manual stick-electrode welding, however, there is a practical limit to the current. The covered electrodes are from 23 to 46 cm (9 to 18 in.) long, and, if the current is raised too high, electrical resistance heating within the unused length of the electrode will become so great that the covering overheats and breaks down; that is, the covering ingredients react with each other or oxidize and do not function properly at the arc, or the coating simply falls off of the electrode. Also, the hot core wire increases the melt-off rate, and the arc characteristics change. The mechanics of stick-electrode welding are such that electrical contact with the electrode cannot be made immediately above the arc, a technique that would circumvent much of the resistance heating.

Not until the development of semiautomatic guns and automatic welding heads, which are fed by continuous-electrode wires, was there a way of solving the resistance-heating problem and thus making feasible the use of high currents to speed the welding process. In such guns and heads, electrical contact with the electrode is made close to the arc. The length between the tip of the electrode and the point of electrical contact is then inadequate for enough resistance heating to take place to overheat the electrode in advance of the arc, even with currents two or three times those usable with stick-electrode welding.

This solving of the point-of-contact problem and circumventing the effects of resistance heating in the electrode was a breakthrough that substantially lowered welding costs and increased the use of arc welding in industrial metals joining. In fact, through the ingenuity of welding equipment manufacturers, the resistance-heating effect has been put to work constructively in a technique known as long-stickout welding. Here, the length of electrode between the point of electrical contact in the welding gun or head and the arc is adjusted so that resistance heating almost, but not quite, overheats the protruding electrode. Thus, when a point on the electrode reaches the arc, the metal at that point is almost ready to melt. Thus, less arc heat is required to melt it, and, because of this, still higher welding deposition rates and speeds are possible.

Historical Development of Arc Welding

As noted, forge welding was the only method man had for metallurgically joining metals for many centuries. No one knows when man first learned to use forge welding. The working and hardening of steel—advanced arts that doubtless took centuries to evolve—were commonly

practiced 30 centuries ago in Greece. However, primitive tribes on different continents, and with no apparent means of communication, developed the same basic methods for smelting, shaping, and treating iron. Thus, the principles of welding probably were discovered, lost, and rediscovered repeatedly by ancient peoples.

By the time of the Renaissance, craftsmen were highly skilled in forge welding. Parts to be joined were shaped and then heated in a forge or furnace before being hammered, rolled, or pressed together. Vannoccio Biringuccio's *Pyrotechnia*, published in Venice in 1540, contains several references to such operations. Biringuccio was obviously intrigued by the process, because he wrote, "This seems to me an ingenious thing, little used, but of great usefulness."

For a few centuries thereafter, ordinary fire remained the principal source of heat for welding. The traveling tinker, a familiar figure on the dusty roads of the countryside, carried with him a small charcoal furnace for heating his irons. During this era, tinsmiths and other workers in metal often used the heat of burning gases to braze and solder.

Forge welding of iron developed into a recognized industry. However, the joining of large, heavy pieces required great skill and much labor, because they could be brought to the required temperature only if a fire were maintained around them. When the two parts were hot enough, they were forced together by various means and were often hung from cranes for this operation. The ends were struck repeatedly with a sledge hammer while the heat was maintained. Then, the work was withdrawn from the fire and finished on an anvil. Forge welding is still practiced today (2011) but to a very limited extent.

Just prior to 1900, three new processes changed the manner in which metals were joined together:

- Arc welding
- Resistance welding
- Oxyacetylene welding

Of these three new processes, arc welding has emerged as the most widely used and commercially important method. There is evidence that a Professor G. Lichtenberg may have joined metals by electric fusion as early as 1782 in Germany, but most accounts trace the history of electric welding to the discovery of the electric arc by Sir Humphrey Davy. In 1801, while experimenting with the infant science of electricity, Davy discovered that an arc could be created with a high-voltage electric circuit by bringing the two terminals near each other. This arc, which cast a bright light and gave off considerable heat, could be struck and maintained at will, and its length and intensity could be varied within limits determined by the circuit voltage and by the type of terminals used. Davy demonstrated the arc at the Royal Institute of England in 1808, where his discovery aroused a great deal of interest. For many years, however, it remained a scientific plaything; there appeared to be no practical use

for the phenomenon. In fact, Davy did not apply the term *arc* to his discovery until 20 years later.

After the discovery of the arc, the first person known to intentionally join metals by electric welding was an Englishman named Wilde. In the early 1860s, he melted together small pieces of iron, and, in 1865, he was granted a patent on his process—the first patent relating to electric welding.

The electric arc, however, remained of scientific interest only until 1881, when the carbon arc street lamp was introduced. Shortly thereafter, the electric furnace made its appearance in England. One of the earliest was installed in 1886 for the production of aluminum alloys. This particular application of the electric arc was an important step in the early development of the aluminum industry.

New Welding Methods Are Put to Work

Probably the first attempt to use the intense heat of the carbon arc for welding was made in 1881 when Auguste de Meritens used a carbon electrode to arc weld lead storage-battery plates. In this experiment, de Meritens connected the work to the positive pole of a current source and attached a carbon rod to the negative pole in such a manner that the distance between the rod and plate could be controlled. Some of the heat developed was lost to the surrounding air, but enough reached the plate to fuse the lead and join the parts. Other early efforts with arc welding employed carbon electrodes arranged similarly to the positions of electrodes in an arc lamp. The heat of the arc was deflected against the work by magnetic fields or by a jet of compressed air.

Two other scientists, Nikolas de Benardos and Stanislaw Olszewski, were interested in the de Meritens process and experimented with it. In 1885, they were issued a British patent for a welding process employing carbon electrodes (Fig. 4). A voltaic arc is formed by the approach of carbon to the part of the metal operated upon, the carbon usually forming the positive pole and the metal the other pole. The carbon, which may be solid or hollow, is fixed in an apparatus, one form of which is shown in Fig. 4. The frame “A,” having a jointed lever

Fig. 4 Apparatus for applying a fused metallic coating for ornamental or other purposes in the British welding patent 12,984 issued to N. de Benardos and S. Olszewski on October 28, 1885. Layers of metal are formed by holding an insulated stick of metal in the electric arc. See text for description.

“B” to lower the carbon “C,” is insulated and supported on the plate or held in the hand. The frame may have wheels running on rails. The work may be supported on an insulated electrically connected plate.

Benardos, a Russian, also filed for a patent in his homeland. His application described a process in which the work was connected to a negative pole, and the carbon rod was fastened to the positive pole of a dc circuit. The rod was not fixed, as in de Meritens’ method, but was fitted with an insulated handle so that it could be manipulated by hand. This process was patented in 1887. Thus, Benardos is generally credited as the holder of the first patent on arc welding.

Benardos’ carbon arc process was put to work on a limited scale in England soon after it was developed. In 1887, a shop was using it to make tanks, casks, and iron garden furniture. In the 1890s, another English shop was welding wrought iron pipe up to a foot in diameter. In the United States, the Baldwin Locomotive Works established a shop in 1892, where carbon arc welding was used extensively for locomotive maintenance. In general, acceptance of the carbon arc process was slow, because the procedures used at that time introduced particles of carbon into the weld metal. These particles made the welded joint hard and brittle.

In the early days of arc welding, a bank of storage batteries was used as the power source (Fig. 5). Voltage could be controlled by the number of cells placed in series. Current could be controlled by the number of cells in parallel and by series resistors. The batteries were kept charged by dynamos or generators, powered by the shop steam engine or water wheel.

Two years after Benardos’ patent was granted, another Russian, N.G. Slavianoff, announced a process in which the carbon electrode was replaced by a metal rod. After an arc was struck, the rod gradually melted and added fused metal to the weld. In the same year, 1889, unaware of Slavianoff’s work, Charles Coffin was granted a U.S. patent on a similar metal arc welding process. (Coffin later became president of General Electric Company.)

Fig. 5 Carbon arc welding shop of the late 1800s. The power source is a bank of batteries. Note the dynamo on the right.

The metal arc process simultaneously developed by Coffin and Slavianoff represented a giant step forward, because the metal electrode supplied not only fusing heat but also added additional filler metal necessary for the joint. In the carbon arc process, filler metal was supplied by excess metal along the weld line or by a metal rod held in the welder’s hand. Despite this advance in the technology, commercial application of the metal arc process in the following years was slow because satisfactory metal electrodes were not available.

Commercial Arc Welding Comes to America

Two Germans who had been working on the metal arc process in Europe came to the United States in 1907. They formed the Siemund-Wienzell Electric Welding Company and patented a metal arc welding method. A short time later, another German concern, Enderlein Electric Welding Company, also started operations in the United States. Then, a bit of intrigue was attempted. It is reported that Enderlein offered to ensure the validity of the Siemund-Wienzell patent by violating it, then putting up a weak defense when Siemund-Wienzell sued. The condition was that the two companies would then share the patent rights. Siemund-Wienzell refused the proposal. When Enderlein began using the process, the firm was promptly and sincerely sued.

In the suit, the patent holders were completely confounded when Enderlein introduced a copy of *Mechanics Handbook*, published in England in 1888. This handbook contained a woodcut unmistakably showing a shop using the metal arc process, and its publication date was before any patents had been issued. This revelation cast doubt on the validity of any patents on the process and, by so doing, opened the field of metal arc welding in the United States.

By 1917, there were four well-established manufacturers of arc welding equipment in the United States. One of these was The Lincoln Electric Company, which today (2011) is the world’s largest producer of arc welding equipment. Lincoln began experimenting with welding in 1902 and introduced its first machines in 1912 (Fig. 6).

Fig. 6 Portable arc welder of the early 1920s

Electrodes—The Key to Progress

In the early work with metal arc welding, it was apparent that the limiting factor was the electrode. The earliest electrodes were bare wire of Norway or Swedish iron, which produced brittle, weak welds. The arcs often overheated the weld metal, and the metal deposited by the electrode was embrittled by the reaction with the air. In an attempt to overcome these difficulties, researchers developed a number of electrodes that were lightly coated with various organic or mineral materials. Oscar Kjellborg of Sweden, who received a patent in 1907, is credited with being one of the pioneer developers of covered electrodes.

The coverings developed during this time did more to stabilize the arc than to shield or purify the weld metal. It was not until 1912, when Strohmenger obtained a U.S. patent for a heavily covered electrode, that industry had an electrode capable of producing weld metal with good mechanical properties. The early covered electrodes, however, were slow in gaining acceptance because of their cost. The covering process required expensive production operations, involving the application of fine aluminum wire and other materials.

The Impetus Onward—World War I

The first major increase in the use of welding occurred during World War I. The sudden need for large numbers of transport ships was a contributing factor. At the onset of the war, ships were built by the relatively slow process of riveting. Government officials realized that faster manufacturing methods were needed, and an Emergency Fleet Corporation was set up to find improved shipbuilding methods. Professor Comfort Adams of Harvard was asked to appoint a committee to investigate the problem, and in July 1917, the first committee meeting was held.

Many members of this committee were of the opinion that the key to increased production would be found in resistance welding, a process that had been invented in 1886 by Professor Elihu Thomson, a member of the committee. To gather background information, the committee visited England, where shipbuilders were using welding to some extent. There the committee discovered that it was arc, not resistance, welding that the British were using. Forced by gas shortages to curtail gas welding, England was using arc welding with both bare and covered metallic electrodes to produce bombs, mines, and torpedoes. The British had gone so far as to start construction of a ship with an all-welded hull.

The American committee returned as proponents of the arc welding method. The various supporters of gas and resistance welding, however, would not accept their findings at face value, and the subsequent debate included the relative merits of carbon and metal electrodes,

covered and bare-metal electrodes, and direct and alternating current.

During this discussion, a dramatic incident publicized the capabilities of arc welding. German ships interned in New York Harbor at the outbreak of the war had been scuttled by their crews so that the vessels could not be used in the Allied war effort. Damage was so extensive that revolutionary repair processes were clearly needed if the ships were to be put back into service without long delay. The Navy called in welding experts from two railroad companies, and these men recommended that repairs be made by arc welding. Most of the damaged components were subsequently repaired by this process, and the ships were rapidly returned to service. The potential of the process was clearly established.

In Europe, at approximately the same time, an all-welded cross-channel barge had been put in service. Also, the British launched their all-welded ship, the *Fulagar*, in 1920. Arc welding thus became an accepted process for shipbuilding.

The first application of arc welding to aircraft also occurred during World War I. Anthony Fokker, the Dutch airplane manufacturer, used the process to produce fuselages for some German fighter planes.

The Era of Slow Growth

In the years immediately following the war, applications for arc welding did not increase appreciably. In 1919, a patent was granted for a paper-covered electrode that did not leave a slag coating on the joint yet produced a tough, ductile weld. This welding electrode was used in 1925 to fabricate heavy pressure vessels for oil refineries. A three-span, 150 m (500 ft), all-welded bridge was erected in 1923 in Toronto, Canada. At approximately this time, manufacturers began to use arc welding increasingly for building storage tanks for fuel oil, gasoline, and petroleum distillates. An early application of large proportions was the construction of a million-gallon standpipe that stood 39 m (127 ft) high.

In 1928, the steel framework for the upper Carnegie Building in Cleveland, Ohio, was erected, using arc welding in a joint effort by The Austin Company and The Lincoln Electric Company (Fig. 7). Construction of this building brought out several important advances in construction techniques. No connection angles or plates were used at intersections, as commonly required with riveted assembly. Because welded lattice joists were used, piping could be concealed between floors. The building was 18 by 36 m (60 by 119 ft) and four stories high. The 115 tons of steel required was estimated to be 15% less than required for a riveted design. A factor contributing to this savings was the use of continuous beams, which permitted lighter beams and columns with no sacrifice in strength or rigidity.

In the 1920s, manufacturers were also using arc welding in the production of sheet steel fabrications, such as hot water tanks (Fig. 8), blower fans, air conduits, housings for machinery, and bases for machine tools. Foreseeing the potential, the arc welding industry began advocating the conversion of cast iron parts to welded assemblies.

In 1927, the development of an extrusion process for applying a covering to the metal core substantially lowered the cost of covered electrodes. These lower-cost electrodes proved to be one of the most significant developments in the evolution of arc welding. The extrusion process permitted varying the composition of the electrode covering to give desirable operating characteristics and meet specific application requirements. The shielded arc electrode, with its deoxidizers and protective gases and slag, became feasible.

Fig. 7 This building was erected in 1928 using arc welding and bare-wire electrodes.

Fig. 8 Early machine for welding the longitudinal seam in a hot water tank with an automatic carbon arc welding head.

Years of Rapid Advance

The applications for arc welding grew rapidly after 1929, and, by the onset of World War II, the process was becoming the dominant welding method. Prior to 1929, the largest undertaking involving welding was the construction of a 1.5 m (5 ft) diameter, 145 km (90 mile) pipeline for carrying water to cities east of San Francisco Bay. It was estimated that this pipeline would have leaked enough water to supply a city of 10,000 if riveted construction had been used. Leakage was minimal with welding.

In the 1930s, welding became increasingly important in shipbuilding (Fig. 9). The U.S. Navy, which had contributed much to welding research, turned to the process for practical reasons after the London Naval Treaty of 1930. This treaty imposed limits on the gross tonnages of the major navies of the world, and thereafter, the Navy often found welding advantageous to minimize weight and thereby maximize the firepower permitted by the tonnage restriction. For the same reason, the Germans used arc welding in their pocket battleships, three of which were launched from 1931 to 1934. Armor plate was difficult to weld, and the Germans developed a method for satisfactorily welding it.

In 1930, the first all-welded merchant ship was built in Charleston, South Carolina. This ship was the forerunner of the thousands of all-welded ships that were to be produced during World War II. Also in the 1930s, the U.S. Army became interested in welding, and a considerable amount of ordnance equipment was redesigned at the Watertown Arsenal for production by welding.

In approximately 1935, improved ac machines (or welders) were becoming available. These welders offered certain advantages, but ac arcs often proved difficult to maintain. To overcome this difficulty, producers of electrodes developed coverings that ionized more easily and thus stabilized the arc. Also during this decade, more stainless steels came into use in metalworking. These materials were relatively difficult to weld because hydrogen in the electrode coverings often caused porosity in the weld. Low-hydrogen electrode coverings were developed to overcome this difficulty.

Fig. 9 All-welded naval vessel that won a major award in a design competition in 1932.

Then, in the early 1940s, it was discovered that these low-hydrogen electrodes also provided good welds in armor plate. Stainless steel coverings were applied to low-alloy steel electrodes to further improve the quality of welded joints in armor plate.

During the 1930s, numerous attempts were made to bring some degree of mechanization with good shielding to the arc welding processes (Fig. 10). The early attempts at automatic welding were made with continuously-fed bare wire, with no shielding other than a thin slag flux that was sometimes painted on the workpiece. Shielding for automatic carbon arc welding was provided by passing a flux-impregnated paper string near the arc as it traveled along the seam. In 1932, an innovation was introduced. A heavy layer of flux was placed on the seam ahead of the carbon electrode. The heat of the arc melted the flux into a slag, which provided shielding. The development proved successful, and penstocks for the Tennessee Valley Authority project and water conduit for the Los Angeles Water Authority were welded by this precursor to the submerged-arc welding process.

Advances in welding fabrication also led to design innovations, such as the Hortonspheroids (Fig. 11). Chicago Bridge and Iron Company, after having invented the design, built

Fig. 10 Welding a steel beer barrel (1933)

many of these vessels between approximately 1930 and 1960 for storage of volatile liquids. The unique geometry makes the most efficient use of the steel shell plates by balancing the latitudinal and longitudinal membrane stresses. (Today, however, most of these vessels have been retired or derated from pressure service, because the unique geometry presents a challenge in the inspection and evaluation of vessel integrity.)

Use of a granular flux with a continuously-fed bare-steel electrode led to development in 1935 of the submerged arc process, which found its first major use in pipe fabrication and shipbuilding. A 159 m (521 ft) tanker was fabricated by this process in 1936. By 1940, the submerged arc process was well accepted but had proved practical primarily on steel plate over 6.3 mm ($\frac{1}{4}$ in.) thick. In approximately 1942, the process was improved to accommodate stock down to 2.4 mm ($\frac{3}{32}$ in.) thick and thus become feasible for automotive use and for general metal fabrication.

Hand-held, semiautomatic guns (Fig. 12) were developed for the submerged arc process in 1946. Voltage and current were controlled automatically, so that weld quality was uniform and results varied less with operator skill. Multiple arcs were introduced in 1948, primarily for manufacturing pipe with 6.3 to 12.7 mm ($\frac{1}{4}$ to $\frac{1}{2}$ in.) walls in diameters from 46 to 91 cm (18 to 36 in.). Subsequent improvements in submerged arc welding have been mainly in the areas of improved fluxes and more sophisticated welding equipment and controls.

One problem that continued to defy solution was the joining of the reactive metals aluminum and magnesium. Neither the submerged arc process nor covered electrodes provided enough shielding to adequately protect these metals from atmospheric contamination. To overcome this difficulty, welding engineers began to use bottled inert gases as shielding agents in the early 1930s. Later in that decade, successful gas-shielded processes powered by direct current (dc) began to emerge from the aircraft industry in response to a specific need to weld magnesium.

The first gas-shielded process employed a tungsten electrode and helium shielding gas

Fig. 11 Chicago Bridge and Iron Company Hortonspheroid of 80,000 barrel capacity in southern Texas (May 1940)

and became known as the the HeliArc process, as well as the gas tungsten-arc (GTA) or tungsten inert-gas (TIG) process. Initially, direct current and a positive electrode were used. It was found, however, that the tungsten electrode tended to overheat and transfer particles of tungsten to the weld unless a low current was used. Researchers then discovered that overheating could be avoided by making the electrode negative. This change proved satisfactory for welding stainless steel but still was not suitable for magnesium or aluminum. The next development was the use of ac with a high-frequency, high-voltage current superimposed over the basic welding current to stabilize the arc. This proved to be the solution to the problem of making good welded joints in aluminum and magnesium. In 1953, the tungsten arc process was modified by directing the arc through a nozzle, and the resulting method became known as the plasma arc process.

Postwar Developments Continue

The tungsten arc process proved unsatisfactory for welding thick sections of highly conductive materials because the workpieces tended to act as heat sinks. To overcome this difficulty, a consumable metal electrode was substituted for the nonconsumable tungsten electrode. The resulting process, announced in 1948, became known as gas metal arc (GMA) or metal inert-gas (MIG) welding. It proved successful for welding aluminum and was subsequently adapted for other nonferrous materials and for stainless and mild steels. About this time, studies showed that a more stable arc could be obtained by using gas mixtures instead of pure helium or argon.

An important development in manual covered-electrode welding also occurred in this era, namely, the use of iron powder in electrode coverings. One benefit of iron powder in the covering was a higher deposition rate and thus greater welding speed. Another was that the welder could simply drag the electrode along the seam without trying to hold it a fixed distance from the work. Thus, less skill was required, and proper welding technique could more easily be taught to beginners. The disadvantage of the iron powder in the covering was the high manufacturing cost. However, by 1953, advances in manufacturing technology and electrode design resulted in cost reductions that made possible the marketing of iron-powder electrodes at acceptable prices. The use of iron-powder electrodes became widespread.

As the gas metal arc and gas tungsten arc processes gained acceptance in the early 1950s, users found that shielding gases based on argon or helium were often too costly. To lower the material cost of the processes, researchers turned to one of the early developments in arc welding, using carbon dioxide gas as a shielding agent. John C. Lincoln, founder of The Lincoln Electric Company,

had applied for a patent on this idea in 1918. Refinements in both the process and equipment for welding steel using carbon dioxide as a shielding gas resulted in a low-cost process. This was immediately adopted by automotive shops and other metalworking plants for applications where the quality of the weld was not exceedingly critical.

One of the most significant developments of the period was the Innershield process, introduced by Lincoln Electric in 1958 for the welding of steel. Prior to its development, self-shielded processes derived protective gases from the decomposition of chemical coverings on the electrode. One could envision possibilities in mechanization with the covered electrode if it could be fed to the arc from a continuous coil. The coverings of such electrodes, however, tended to crack if wound into a coil, and also there was no practical way to feed electric current to a covered continuous electrode. Therefore, self-shielded electrodes as constituted could not be used with automatic or semiautomatic processes.

The Innershield process, also referred to as the self-shielded, flux cored arc welding process, solved the problem by incorporating the fluxing and shielding materials inside tubular filler-metal wire. The result was a self-shielded electrode that could be coiled and used with high-speed automatic and semiautomatic equipment. Some of the carbon-dioxide-shielded processes also began to employ a flux cored electrode at this time. The concept of a tubular electrode sheath to contain a powdered processing ingredients had been employed prior to 1958 but was limited to electrodes for surfacing applications.

In 1961, the Innershield electrode was introduced, providing exceptionally high deposition rates. This electrode, referred to as a fast-fill electrode, is widely used in semiautomatic welding (Fig. 13). Because heat input with the fast-fill electrode was considerably less than required by older types, the automatically-fed electrode holders, or welding guns, developed for its use did not require water cooling and thus were lightweight and easy to manipulate. The electrode produced welds that had good resistance to cracking and operational characteristics that lessened the amount of care required to fit up workpieces prior to welding.

When first introduced, the fast-fill electrode was limited to single-pass welds in the flat or horizontal positions. By 1962, fast-fill electrodes were available for multiple-pass welds. Thick plates could thus be welded at high deposition rates. In 1967, an all-position electrode was introduced that considerably broadened the application of the process. The American Welding Society has written specifications for flux cored electrodes. These specifications include both self-shielded electrodes and electrodes requiring gas shielding. These developments provided the means for enhancing the design of structures that exhibit cleaner lines,

lighter weight, lower cost, and an architectural appearance (Fig. 14–16).

As the arc welding processes reached a high level of development in the 1960s, research emphasis shifted somewhat. Producing reliable welds was unquestionable, but there was some difficulty in being able to determine whether a given weld made in the plant or field met the metallurgical standards for its particular application. Considerable attention was therefore focused on nondestructive testing,

Fig. 12 Four submerged arc passes are made inside the tower of this flame-gouged seam joining the head to the shell. A current of 400 A and a speed of 36 cm/min (14 in./min) were used.

particularly ultrasonic, radiographic, magnetic particle, and dye penetrant techniques.

Researchers also exerted considerable effort on the development of new and emerging joining methods, such as laser welding and electron beam welding processes that use electricity but

do not employ an arc, as well as new forms of arc welding such as plasma arc welding. Although the newer processes do produce welds that were not previously possible, their limitations somewhat restrict their use to specialized applications.

Arc welding continues to serve as the primary means of metal joining. The flash, smoke, and sputter that emanated from the early European laboratories produced one of the most important processes of modern industry.

Arc Physics of Gas Tungsten and Gas Metal Arc Welding

Y.M. Zhang, University of Kentucky

THIS ARTICLE provides basic physics needed to understand two most widely used arc welding processes: gas tungsten arc welding (GTAW) and gas metal arc welding (GMAW). The GTAW part is an update from the article "Arc Physics of Gas-Tungsten Arc Welding" authored by J.F. Key (of EG&G Idaho, Inc.) and published in *Welding, Brazing, and Soldering*, Volume 6 of *ASM Handbook*, 1993. Treatments for general arcs, arcs in other specific arc welding processes, and arc physics in greater depths may be found in the Selected References listed at the end of this article and from other literature. A general description of arc welding processes is also given in the article "Overview of Welding Processes" in this Volume.

Gas Tungsten Arc Physics

The GTAW process is performed using a welding arc between a nonconsumable tungsten-base electrode and the workpieces to be joined. C.E. Jackson defined a welding arc as "a sustained electrical discharge through a high-temperature conducting plasma producing sufficient thermal energy so as to be useful for the joining of metals by fusion." This definition is a good foundation for the discussion that follows.

The physics of GTAW are fundamental to all arc processes and are more straightforward, because the complications of materials (for example, filler and flux) transferred through and interacting with the arc can be avoided. Geometrically, the arc discharge in GTAW is between a rod-shaped tungsten electrode and a planar-shaped electrode, that is, the workpiece.

Pure tungsten electrodes are less expensive and, possibly, more environmentally compatible than those with rare earth or other oxide additions. They are used for less critical welds, where tungsten contamination that could be caused by the molten electrode surface can be tolerated. They are also used for alternating current (ac) welding of aluminum, copper,

magnesium, and thin sections of low-alloy and stainless steels.

Analysis of the arc discharge is separated into electrode regions and the arc column. The electrode regions are confined to very small distances from the electrode surfaces, have very high electrical and thermal fields, and have much higher current density, because of the contraction of the arc to a small spot. As a result, electrode regions for both the cathode and the anode are difficult to analyze by diagnostic measurements and theoretical computation. This situation must be remedied for a thorough understanding of the process, because the process parameters control the arc discharge at the cathode, with the anode serving as the connection to ground. The arc column, on the other hand, is relatively easy to analyze but is important primarily as a means to deduce arc characteristics at the electrodes.

Polarity. The GTAW process generally uses a direct current (dc) arc, where the tungsten electrode has a negative polarity. The tungsten electrode thus becomes the cathode and the workpiece becomes the anode. The polarity is called straight polarity, or direct current electrode negative (DCEN).

Reverse polarity, or direct current electrode positive (DCEP), is literally the reverse of DCEN. The workpiece is the cathode and the tungsten electrode serves as the anode. Because most heat is generated at the anode in the GTAW process, DCEP is used for welding certain thin-section, low-melting-point materials when DCEN would be likely to cause excessive penetration or burn-through.

Either ac or DCEP is used for removing an oxide film from the surface of the weld pool or workpiece. This is particularly important in obtaining a sound joint in metals with a tenacious oxide, such as aluminum. The oxide film promotes emission during the half-cycle (ac) when the workpiece is negative polarity. As the oxide is depleted, the emission moves to a new location that has a high enough oxide content to sustain the discharge of electrons. The arc root or cathode spot where the emission

occurs is highly mobile in ac or DCEP and, as a result, the arc is much less stable than in DCEN.

Gas Shielding. In all cases, the arc and both electrodes are shielding by gas, usually an inert gas or a gas mixture. Argon and argon-helium mixtures are used most often, although argon-hydrogen mixtures are used for some applications. The GTAW process may simply use the arc to fuse the workpieces together without the addition of filler materials (autogenous), or filler may be added to the molten pool to fill grooves in thicker weldments. A reasonable understanding of welding arc fundamentals and the GTAW process requires a more thorough discussion of the electrode regions of the arc and the arc column.

Electrode Regions and Arc Column. The cathode and anode are similar in several respects. Both exhibit a voltage drop caused by a space charge that covers a very thin region over their surfaces, and the arc is significantly contracted on the surfaces. Figure 1 shows that the total arc voltage is partitioned between the electrode drops and arc column. The relative magnitude of these drops depends on welding parameters and electrode material.

The arc discharge requires a flow of electrons from the cathode through the arc column to the anode, regardless of polarity or whether ac or

Fig. 1 Plot of relative arc voltage distribution versus relative arc length between electrodes

dc is used. Two cases of electron discharge at the cathode are discussed: thermionic emission and nonthermionic emission, also called cold cathode or field emission.

Thermionic emission results from joule heating (resistance) of the cathode by the imposed welding current until the electron energy at the cathode tip exceeds the work function (energy required to strip off an electron). This case applies to the general case of DCEN, where the tungsten electrode is the emitter, or cathode. Pure tungsten electrodes must be heated to their melting point to achieve thermionic emission. Once molten, the equilibrium tip shape becomes a hemisphere, and a stable arc results from uniform emission over this surface. Thoria (ThO₂), zirconia (ZrO₂), or ceria (CeO₂) are added to pure tungsten in amounts up to 2.2 wt% ThO₂, 0.4 wt% ZrO₂, or 3.0 wt% CeO₂ to lower the work function, which results in thermionic emission at lower temperatures and avoids melting the cathode tip. These electrodes typically have a ground conical tip, and thermionic emission is localized to a cathode spot. Thermionic emission creates a cloud of electrons, called a space charge, around the cathode. If a second electrode at a higher potential is nearby (the workpiece, in this case), then the electrons will flow to it, thus establishing the arc.

Nonthermionic, or field, emission creates an electron discharge with a very high electric field, typically exceeding 10⁹ V/m. This intense electric field literally pulls electrons out of a relatively cold or unheated cathode. This would not appear to be applicable to welding until one considers that for reverse polarity or DCEP, a condensation of positive ions from the arc column can build up in a very thin (1 nm, or 0.04 μin.) layer over the cathode surface, creating a very high localized electric field even though the cathode voltage drop may only amount to several volts.

An oxide layer, which is always present on the cathode surface in an actual weld, facilitates the discharge with a source of lower work-function electrons. When the oxide layer is very thin (on the order of one atom layer), emission occurs via a tunneling mechanism through the film to an emitting site. Thicker oxide films exhibit locally conducting spots at the end of filamentary channels through the oxide. Large currents flow in these channels, which are on the order of 100 nm (4 μin.) in diameter and have lifetimes of 0.001 to 1 μs.

The cathode cleaning action, which is one of the principal reasons to use DCEP or ac, results from stripping away the oxide film at the emitting sites by very small and intense jets of metal vapor and debris. It becomes obvious that a practical implication of the short lifetime of these cathode spots is a generally unstable arc that is due to the necessity of continual movement of the cathode spot to undepleted regions of oxide film. Arc instability is undesirable and DCEP or ac is only used when cathodic cleaning or the minimizing of heat input to the

workpiece is a higher priority than optimizing weld bead shape and location.

Anode. Welding process parameters (for example, current and voltage) control the arc discharge at the cathode. The electron flow enters the anode through the anode spot and constitutes 85% of the energy going into the weld pool, thus making current density the single most important welding parameter that determines pool shape. However, events at the anode can only be controlled indirectly by controlling the cathode. Anode spot stability does depend somewhat on shielding gas composition and the shape of the anode (that is, weld groove).

Current density and heat input measurements at the anode help to explain how process

parameters that are largely controlling events at the cathode will, in turn, influence the shape and melting rate of the weld pool. The relative contributions of heat transfer to the workpiece, in terms of the GTAW process, are shown in Fig. 2.

The Thomson effect represents the energy lost by electrons as they move from higher to lower temperatures. The sum of work function, Thomson effect, and anode fall gives an electron contribution to heat transfer of approximately 84%. The remaining 16% is due to thermal effects (that is, conduction, convection, and radiation). There are small heat losses from the pool that are due to evaporation of metal ions and radiation. Figure 3 shows that the

Fig. 2 Relative heat-transfer contributions to workpiece with gas tungsten arc welding. (a) Contribution of individual parameters to anode heat input. (b) Heat output at cathode (workpiece) relative to weld pool heat loss

Fig. 3 Plot of electron and thermal contributions to heat transfer. A, total arc power (standard deviation, σ , of 0.8 mm, or 0.031 in.); B, electron contribution ($\sigma = 0.7$ mm, or 0.028 in.); C, thermal contribution. Weld parameters: current, 10 A; voltage, 10 V; time, 10 s; shielding gas, argon; electrode angle, 30°

energy distribution for this particular case approaches a Gaussian distribution (that is, normal distribution curve). High helium contents in the shielding gas have produced data that are typically better fit by a Lorentzian curve, indicating a narrower current density distribution (that is, a more-contracted arc at the anode spot).

Arc efficiency, in addition to those variables that have an effect on it, is an extremely important term in the heat-transfer analysis of welding. It gives the percentage of heat dissipated in the arc that actually is captured by the workpieces and is available for melting. Arc efficiency, as a function of all GTAW welding parameters and many materials, has been determined experimentally and found to be nominally 75%. The variables having the greatest effect on arc efficiency are arc voltage and anode material. For those variables, the effect is usually no more than $\pm 5\%$. Other parameters have a negligible effect.

Arc Column. The electron discharge between the electrodes partially ionizes the shielding gas in its path, thus making the arc column a conductor, or plasma. Overall, the arc column is neutral and is composed of electrons, positive gas and possibly metal ions, and neutral gas atoms.

Ironically, fundamental measurements of arc properties are most easily made in the arc column, although the actual effect of these properties on the electrode region of an actual weld must still be inferred. Nevertheless, it is useful to understand fundamentals of the arc that relate essential welding variables (for example, current, voltage, electrode gap, choice of shielding gas, and electrode shape) to arc temperature, current density distribution, and gas flow structure at the anode surface.

Effect of Cathode Tip Shape. For the general case of straight polarity, DCEN, the tip of the tungsten alloy cathode is ground to a point and then truncated somewhat to prevent the sharp tip from burning off and contaminating the weld. The included angle of the cone and the diameter of the truncation under some welding conditions have a significant effect on weld pool shape. Figure 4 shows examples of the effect of these two parameters on weld pool shape.

For a stationary spot-on-plate weld shielded by pure argon, the weld depth-to-width ratio increased with an increasing vertex angle up to 90° and with an increasing truncation diameter. The arc became less "bell shaped" and more "ball shaped" as the vertex angle or truncation diameter increased. These results should be a valid indication of the effect of cathode tip shape for pulsed current welding, which produces a series of overlapping spot welds.

A study of bead-on-plate welds (Fig. 5) made with constant current and velocity indicated a similar but less pronounced trend. These conditions produce a tear-drop molten pool shape when viewed from above, compared to a circular shape for spot or pulsed current welding.

Fluid and heat flow within the pool is less uniform front-to-rear in a tear-drop-shaped pool and probably has a greater influence on pool shape than electrode tip shape.

When the arc is used in a weld groove, the relative shapes of the cathode tip and the anode groove become more important. The arc discharge from the cathode will seek a path to ground with the lowest electrical resistance. For a stable arc properly centered in the groove (for example, a root pass), the shortest path to ground should be between the cathode tip and the bottom of the groove (Fig. 6). This will require the cathode vertex angle to be somewhat less than the included angle of the groove and/or a sufficiently wide groove to ensure that the shortest path to ground is from the cathode tip to the groove bottom and not, for example, from the electrode shoulder to the groove wall, as the case would be with a 90° electrode in a 10° narrow groove. Welding in a groove places a higher priority on arc stability and location than on maximum penetration.

To understand the effects of tip shape, temperature distributions in the plasma were measured. Figure 7 shows that as the cathode vertex angle increases, the plasma radius of the arc column increases at midgap and becomes more constricted near the anode. The quantitative interpretation of these results requires theoretical modeling, which has yet to be completed.

Effect of Shielding Gas Composition. The GTAW process typically uses either an inert gas, such as argon, or an inert gas mixture, such as argon and helium, to shield the arc and the weld from atmospheric contamination. Occasionally, a slightly reactive gas mixture, such as argon with up to 15 vol% H_2 , is used. (The 15 vol% limit is based on safety considerations.) Shielding gas composition has a rather strong effect on arc temperature distribution and, under certain conditions, a significant effect on weld pool shape.

Figure 8 shows how shielding gas affects arc voltage. The curves would all be displaced downward for shorter arc lengths, but the relative positions would be maintained. Figure 9 shows the effects of both cathode vertex angle and shielding gas composition on weld pool shape for spot-on-plate welds. Increasing additions of helium to argon show a remarkable increase in penetration when using a 30° vertex angle. However, the effect is much less evident when using a 90° vertex angle.

To understand these phenomena, arc temperature distributions for a variety of shielding gases and mixtures, electrode shapes, current, arc voltages (electrode gaps), and anode materials have been measured in order to clarify welding arc fundamentals. Welding arcs are composed of electrons, positive gas ions, and neutral gas atoms. Some measurement techniques give the temperature of one species (electrons), whereas other techniques give the

Fig. 5 Fusion zone profile for bead-on-plate welds as a function of electrode tip geometry using 100% Ar as a shielding gas. Weld parameters: current, 150 A; welding speed, 3 mm/s (0.12 in./s)

temperature of another species (neutral atoms). If the arc is in local thermodynamic equilibrium (LTE), all techniques should give the same temperature.

Although the assumption of LTE used to be considered completely valid, contemporary investigations have suggested that this is not always the case and that some of the older measurements may be somewhat in error. Absolute values of arc temperature are only needed to establish boundary conditions for detailed arc modeling of temperature-dependent properties. What is of more importance to the welding engineer or technologist is the relative effect of essential variables on heat input to the workpiece. Arc temperature measurement is one useful indication of how these variables affect the arc.

When compared to Fig. 7(a), Fig. 10 shows that large additions of helium to argon decrease peak temperatures slightly and increase the plasma diameter in the plasma column. The arc appears to become a broader and more isothermal heat source. The lower peak temperature is reasonable, because a combination of the high ionization potential of helium and relatively low currents of welding arcs gives

an arc column that is only slightly ionized. Figure 7 showed that a large vertex angle had a similar, but less pronounced, effect on arc temperature when adding helium to the shielding gas (that is, the axial peak temperature decreased and the plasma diameter increased).

Figure 11 shows that doubling the current from 150 to 300 A produces an increase in plasma diameter (that is, that portion of the arc above approximately 8000 K, or 13,900 °F). This effect occurs regardless of the shielding gas composition.

The arc length or gap between the electrodes is yet another process parameter that must be considered, especially for mechanized welding, where it can be kept reasonably constant. Because arc voltage increases roughly in proportion with arc length, longer arcs have higher arc voltages and consume more energy for the same current. However, this increased energy is generally lost through radiation to the environment surrounding the weld and does not effectively supply additional heat to the workpieces. Mechanized welding generally uses rather short arc lengths (2 to 3 mm, or 0.08 to 0.12 in.), whereas manual welding uses a longer arc length. Unfortunately, relationships that

establish a direct correlation between the temperature distribution in the arc column and the weld pool shape still have not been established, primarily because weld pool shape depends on other factors, such as compositionally dependent molten metal properties.

Flow Structure. Shielding gas is used to displace reactive gases in the atmosphere from the vicinity of the weld. Inert gases are preferred for the GTAW process, because they minimize unwanted gas-metal reactions with the workpieces. A uniform laminar flow of gas from the gas cup would be ideal and, in fact, is usually achieved as long as there is no welding arc. However, the arc discharge rapidly heats the gas in the arc column, and thermal expansion causes plasma jets. The lower temperature near the cathode tip in Fig. 11 is an indication of a jet pumping in cooler gas. This becomes an important factor at high currents, because these jets can depress the surface of the weld pool and alter heat transfer to it. The rapid gas expansion can cause the flow to deviate from laminar and, in extreme cases, the flow can become turbulent. Turbulence tends to mix atmospheric contaminants into the arc, often where they can do the most harm: at the surface

of the molten weld pool. Holographic interferometry and Schlieren photography have been used to characterize gas flow.

Figures 12 to 14 show examples of laminar and turbulent flow. The flow from a commercial-design gas cup for three current levels is shown in Fig. 12. Laminar flow occurs where the fringes are generally straight and parallel. Turbulent flow is indicated by very wavy or circular fringes. Increasing current tends to make the laminar region somewhat broader and thicker, effectively increasing the area shielded from atmospheric contamination.

Figures 13 and 14 result from experiments with gas cup shapes that were designed to improve shielding. Figure 13 shows that a converging cone would be a very poor choice for the GTAW process, as indicated by the very small area of laminar flow and the extreme turbulence in the surrounding region.

Figure 14 is a venturi shape, which provides a large laminar flow region for all current levels and excellent shielding. This design may be somewhat better than commercial designs, but weld contamination studies should be conducted to verify this possibility.

Arc Length Control. As mentioned earlier, the arc length or gap between the electrodes is an important process parameter that must be considered. In particular, the distribution of the arc (thus arc force and heat distributions) is also determined by the arc length together with the arc current. Unlike the tungsten shape and flow gas that can be easily controlled, the arc length fluctuates and needs to be controlled for precision joining, where GTAW has its advantages.

The most convenient way to control the arc length is to use the arc voltage as a feedback of the arc length. This is because a change in the arc length would result in the same change in the arc column.

In a first-order approximation, the voltage of the arc column is considered to be proportional to the arc length (length of the arc column), and the voltage drops at the anode and cathode are considered to be constant for the given shielding gas and workpiece material. Hence, the change in the arc voltage is considered to be proportional to the change in the arc length, and controlling the arc length at a constant would be the same as controlling the arc voltage at a constant.

For precision sensing and control of arc length, especially when the arc length is small or the current may change, the aforementioned first-order approximation may not always be sufficient. The complexity has been demonstrated through the following:

- For the same arc length, the voltage of a tungsten-copper arc in argon decreases rapidly before the current increases to 50 A and decreases significantly before the current increases to 100 A (Ref 1).
- When the current is the same, the arc voltage decreases before the arc length increases to approximately 1 mm (0.04 in.) and then increases gradually when the arc length further increases (Ref 2, 3).

To use the arc voltage, V , as a precision feedback/measurement of the arc length, l , studies are needed for the particular anode (workpiece) to measure the arc voltage at different currents and arc lengths in order to establish an accurate model for the specific material being welded:

Fig. 15 Argon atomic line intensity versus arc length

$$I = f(V, I) \tag{Eq 1}$$

where I is the current. However, despite the possibility that such a model may be established and the model is deterministic, it is likely that this model will be nonlinear, as has been demonstrated in the previously referenced studies.

In the previous studies, because of the lack of capabilities to measure the weld pool surface, the arc length was difficult to accurately measure, and the gap between the tungsten and the unmelted workpiece was typically used as the measurement of the arc length. When the arc length is small and the welding current is large (such that the difference between the weld pool surface and the

workpiece surface is large), the arc length should be measured more accurately. To this end, technology recently developed to measure the three-dimensional weld pool surface may be used (Ref 4).

The nonlinearity issue seen in Eq 1 may be overcome by replacing the arc voltage using an argon atomic line intensity (Ref 5). Figure 15 shows the linear relationship between argon atomic line intensity and arc length. Ideal linear relationships are found in the entire arc length range that is typically used. Of course, the measurement of the line intensity requires the use of an optical-electric sensor with a band-pass filter, and it is more complex than the measurement of the arc voltage.

Gas Metal Arc Physics

The gas metal arc welding (GMAW) process is performed using a welding arc established in a shielding gas between a continuously-fed consumable wire electrode and the workpieces or base metal to be joined. Part of the shielding gas that is continuously supplied around the wire is ionized to form the arc column and to establish the arc; the rest surrounds the arc and molten metal to shield them from the atmosphere. The most widely used variant of GMAW is flux cored arc welding, where the wire electrode is solid metal and cored with flux of specific chemical powders.

The most fundamental difference between GMAW and GTAW is the presence of the metal-transfer process; that is, the consumable electrode must be melted and the liquid metal of the melted consumable wire must transfer from the electrode into the pool being formed by molten metal from the workpieces and

electrode. Both the melting of the electrode and how the melted electrode metal detaches from the electrode into the weld pool play fundamental roles in determining the behavior of the arc, the quality of the resultant welds, and the productivity of the process.

The detachment of the melted electrode is controlled by forces acting on the liquid droplet formed by the melted electrode. Of these forces, the electromagnetic force often plays a dominant role in determining the mode of the metal-transfer process and how the detachment is completed. The primary variable that controls the electromagnetic force is the welding current, while other factors such as electrode diameter, shielding gas, polarity, and so on also affect the electromagnetic force, but they are not conveniently adjusted during welding.

Another fundamental difference between GMAW and GTAW is that the material of the electrode varies with the application, because it will be melted and transferred into the base metal to become part of the weld metal. Also, the electrons are emitted from the material being welded in typical direct current electrode positive GMAW applications. Because the material that emits the electrons varies with application, the cathode voltage varies from application to application. Further, the electrons tend to emit from areas of lower electron voltage in the weld pool, the location of the cathode in relation to the anode (wire tip) may change, and the arc column may not always be straight if the reduction in the voltage for electron emission is greater than the increase in the arc column voltage. Because the location of the area of lower electron voltage in relation to the wire tip may change during welding, the arc (path, column, distribution) may be subject to change. In particular, because of cyclic changes in the arc length due to metal-transfer variations, the arc length in GMAW typically must be long enough to tolerate these periodic changes. This increased length of the arc also promotes the change of the arc. As a result, the arc voltage fluctuates in addition to the periodic change. For constant voltage (CV) power supplies, the current also fluctuates accordingly. Such fluctuations make it more difficult to sense by use of the arc signals than in GTAW.

The GMAW process generally uses a dc arc, where the electrode wire has a positive polarity. The wire thus becomes the anode and the workpiece becomes the cathode. The polarity is called reverse polarity, or DCEP. The purpose of DCEP is to detach the droplets formed by the melted wire. This is because the component of the electromagnetic force generated by the current along the wire axis direction typically has the same direction as the current in argon-rich gases. Hence, when the current flows away from the droplet, the electromagnetic force is a detaching force. Further, DCEP can remove oxide films from the surface of the weld pool or workpiece. The oxide film promotes emission. As the oxide is depleted, the emission moves to a new location that has sufficient

oxide content to sustain the discharge of electrons. The arc root or cathode spot where the emission occurs is highly mobile. Together with the oscillation of the weld pool surface caused by impact from the detached droplets, the arc is typically not completely stable. The arc voltage fluctuates, and for CV power supply the fluctuation in the arc voltage will cause the current to fluctuate.

In DCEP, the wire is primarily melted by the anode heat whose power is IV_{anode} , where I is the welding current, and V_{anode} is the anode voltage. The heat directly imposed on the workpiece by the arc is IV_{cathode} . For GMAW applications, the workpiece and wire are similar materials, and the $V_{\text{cathode}}/V_{\text{anode}}$ ratio is approximately 2 (Ref 6). Hence, if GMAW is performed using straight polarity, the wire is expected to be melted at double speed, so the deposition speed is doubled. That is, straight polarity helps GMAW to increase the deposition rate or reduce the heat input. However, in DCEN, the electromagnetic forces prevent the droplet from being detached. Hence, variable polarity or ac GMAW has been proposed that uses DCEN to speed the wire melting and DCEP to detach the droplet.

In all cases, the arc and both electrodes are shielded by gas, usually an inert gas, a gas mixture, or pure CO_2 . The inert gas is typically argon, and the gas mixture is Ar- O_2 or Ar- CO_2 . A gas mixture is used to improve the penetration capability and weld bead, and pure CO_2 is used for reduced costs and increased deposition and arc temperature.

A reasonable understanding of welding arc fundamentals and the GMAW process requires a more thorough discussion of electrode melting and droplet detachment/metal transfer, including the physics and physics-based controls.

Wire Melting. In GMAW (Fig. 16), a consumable wire is fed to the contact tube, which is typically connected to the positive terminal of the power supply. A shielding gas is supplied to surround the wire and is restricted by the nozzle to deliver to the local area that surrounds the wire. When the wire touches the negatively charged workpiece (connected to the negative terminal of the power supply), the tip of the wire is rapidly melted, forming a gap between the wire and the workpiece, and an arc is ignited across this gap. The anode of the arc directly melts the wire, and melted metal forms a droplet at the tip of the wire. The formation and detachment of the droplet is typically referred to as the metal-transfer process.

Before droplet detachment and metal transfer are analyzed, the melting of the wire in GMAW must be understood. Basically, the wire is melted by the anode and resistive heat, which are proportional to the current and its square, respectively. However, the resistive heat also depends on the length of the wire extension (E). The heat that melts the wire is often simplified as:

$$Q_{\text{wire}} = IV_{\text{anode}} + \left(\frac{\rho}{A}\right)EI^2 \quad (\text{Eq 2})$$

where ρ is the resistivity of the wire material, and A is the cross-sectional area of the wire. In a first-order approximation, ρ is treated as a constant. If greater accuracy is needed, the dependence of resistivity on temperature, that is, $\rho(T)$ and $\partial\rho(T)/\partial T \neq 0$, can be considered, and an equivalent resistivity can be calculated as the average resistivity over the wire extension to replace the constant resistivity in Eq 2:

$$\bar{\rho} = \left(\int_0^E \rho(T(\tau))d\tau\right)/E \quad (\text{Eq 3})$$

However, a more accurate calculation of this equivalent resistivity requires the following:

- $\rho(T)$, the dependence of resistivity on temperature for the given wire material
- $T(\tau)$, the dependence of temperature on position τ ($0 \leq \tau \leq E$) in the wire extension for the given wire material, diameter, current, and wire extension

One may find that extremely high precision for the heat that melts the wire is often not required because the temperature in the liquid droplet is not uniform, and the average temperature of the droplets changes with the current and droplet volume in addition to other metal parameters. Hence, the wire metal melt cannot be accurately determined from the heat.

Arc Length/Voltage Control. The length of the arc column from the droplet to the cathode on the weld pool surface is the arc length. The welding voltage is the sum of the voltage drop on the wire extension, the anode voltage drop, the arc column voltage, and the cathode voltage. The arc length is an approximate indicator for the distance from the wire tip to the weld pool surface and must be controlled at an appropriate level to prevent unintentional

Fig. 16 Illustration of gas metal arc welding processes

short-circuiting (too short an arc length) or burning of the contact tube (too long an arc length). To this end, the arc length must be feedback controlled. Because the voltage drop on the wire extension is typically much smaller than the arc column voltage, and the cathode and anode voltage drops are both approximately constant, the arc column voltage can be approximately controlled by controlling the welding voltage.

The major parameter that determines the arc column voltage is the arc length, although the welding current also affects the arc column voltage. A first-order approximation is:

$$V = V_0 + kl \tag{Eq 4}$$

where $V_0 = V_{\text{anode}} + V_{\text{cathode}} + V_{\text{wire}}$ and k are both considered constant, although V_{wire} and k are both current-dependent and V_{wire} is also wire-extension-dependent. Hence, the welding voltage can be used to indicate the arc length, and the control of the arc length can be converted into the control of the welding voltage, which can be easily measured.

The arc length control is based on the following melting-feeding balance equation:

$$\frac{dl}{dt} \approx c_1 Q_{\text{wire}} - v_f \tag{Eq 5a}$$

or

$$\frac{dV}{dt} \approx k(c_1 Q_{\text{wire}} - v_f) \tag{Eq 5b}$$

where v_f is the nominal wire feed speed, and c_1 is a constant that depends on wire material, diameter, and droplet temperature.

When the contact-tube-to-work distance suddenly increases, the arc length immediately increases, such that the welding voltage also increases immediately. In this case, the feedback control system will reduce the voltage, and the needed dV/dt is negative. Based on Eq 5(b), Q_{wire} must decrease. From Eq 2, the current must be reduced. Once the current decreases, $dV/dt < 0$ will be realized, and the voltage will decrease.

Metal Transfer. The wire is continuously melted, but the metal melted from the wire may not transfer continuously/immediately into the base metal/weld pool. Instead, it accumulates at the tip of the wire to form a droplet, primarily because of the surface tension at the droplet (liquid)/wire (solid) interface that functions as a retaining force for the droplet. The metal-transfer process is often loosely used to refer to the entire process associated with wire melting, droplet formation and detachment, and merging with the base metal. Droplet detachment is specifically referred to in this section.

The droplet is transferred into the base metal through three major modes/types described subsequently: short-circuiting, globular, and spray transfer. There are two major established theories for when and how the droplet is detached: pinch instability and static force balance.

Detailed discussion and application of either theory to determine when and how the droplet is detached is beyond the scope of this article. This article only introduces the principle of static force balance.

When applying the static force balance theory, all forces imposed on the droplet are projected to the axis of the wire and are categorized into detaching forces (pointing away from the liquid-solid interface) and retaining forces (pointing toward the liquid-solid interface). In typical cases (an argon-rich shielding gas and DCEP), the major detaching forces are the electromagnetic force, which can be considered to approximately increase quadratically with the current, and the gravitational force, which increases proportionally with the mass of the accumulated mass in the droplet; the major retaining force is the surface tension at the liquid-solid interface, along with some supportive force from the momentum of electrons and ions. For a given wire material and diameter, the surface tension is approximately fixed, and the major parameters that determine when and how the droplet is detached are the welding current and arc length:

- Short-circuiting transfer is characterized by the occurrence of short-circuiting between the droplet and weld pool. When the wire feed speed is low, such that the current needed to melt the wire is small, the electromagnetic force will be small. Unless a condition exists for the droplet to grow to a level such that its gravitational force, together with the electromagnetic force,

exceeds the surface tension, the droplet will touch/short-circuit with the weld pool before transferring into the weld pool. Figure 17 shows a typical short-circuiting metal-transfer process. It is found that much spatter may be generated in this process.

- Globular transfer is characterized by relatively large droplets whose diameters are significantly greater than that of the wire. Two conditions are needed for this to occur: the arc length, l (Fig. 16), is sufficient to allow the droplet to grow to a diameter that is significantly larger than that of the wire, and the current is relatively small, such that the corresponding electromagnetic force is not sufficient to form a competent detaching force that exceeds the surface tension without a droplet of relatively large diameter to provide a sufficient gravitational force. Two typical globular transfers are shown in Fig. 18.
- In spray transfer, if the current is sufficient that the detaching electromagnetic force is close to or exceeds the retaining surface tension, the droplet will detach without a need for additional gravitational force. The diameters of the droplets will thus be similar to (drop spray) or much smaller than that of the wire. Figure 19 shows a typical drop spray metal transfer.

The occurrence of spray transfer is primarily determined by the current level for the given wire diameter and material, and the arc length, l , is irrelevant as long as it is not extremely short. The current level that determines if a

Fig. 17 Typical short-circuiting metal-transfer process

Fig. 18 Schematic of typical globular metal transfer. (a) Axial globular transfer. (b) Nonaxial globular transfer

Fig. 19 Typical drop spray metal transfer

spray transfer could occur is referred to as the transition current, I_t , and it is approximately 230 A for steel wire of 1.2 mm (0.05 in.) diameter. At $I < I_t$, the gravitational force will play a role in providing sufficient detaching force. If I is sufficient, globular transfer theoretically could occur at any $I < I_t$, and the diameter (volume) of the droplets detached decreases as I increases; otherwise, short-circuiting would occur. For a given I , the transfer tends to change from short-circuiting to globular as I increases.

Static Force Balance and Arc Climb. The wire is continuously melted, but the resultant droplet typically detaches from the wire and transfers into the base metal discontinuously. The static force balance can be a good start to understanding the metal-transfer process.

The major forces acting on the droplet include gravitational force, electromagnetic force (Lorentz force), aerodynamic drag force, surface tension, and momentum force. The force due to gravity can be expressed as:

$$F_g = m_d g = \frac{4}{3} \pi r_d^3 \rho g \quad (\text{Eq 6})$$

where m_d is the mass of the droplet, r_d is the droplet radius, ρ is the droplet density, and g is the acceleration of the gravity. The surface tension is given as:

$$F_\sigma = 2\pi R\sigma \quad (\text{Eq 7})$$

where R is the electrode radius, while σ is the surface tension coefficient. The aerodynamic drag force can be expressed as:

$$F_d = \frac{1}{2} C_d A_d \rho_p v_p^2 \quad (\text{Eq 8})$$

where C_d is the aerodynamic drag coefficient, A_d is the area of the drop seen from above, and ρ_p and v_p are the density and fluid velocity of the plasma, respectively. The momentum force can be expressed as:

$$F_m = v_s \dot{m}_d \quad (\text{Eq 9})$$

where v_s is the wire feed speed, and \dot{m}_d is the change of the droplet mass. The electromagnetic force, F_{em} , is given by:

$$F_{em} = \frac{\mu_0 I^2}{4\pi} \left(\frac{1}{2} + \ln \frac{r_i}{r_u} \right) \quad (\text{Eq 10})$$

where μ_0 is the magnetic permeability, I is the welding current, r_i is the exit radius of the current path, and r_u is the entry radius of the current path; r_i and r_u are related with the process of the droplet status. Before the droplet starts to be detached, r_u is the same as the radius of the wire and is thus a constant. However, once the droplet is being detached, r_u decreases. The increase of F_{em} thus accelerates the detachment of the droplet. In the conventional GMAW process, the droplet is not detached when the retaining force, F_σ , is still sufficient to balance the detaching force, F_τ :

$$F_\tau = F_g + F_d + F_m + F_{em} \quad (\text{Eq 11})$$

During the metal-transfer process, the major variables that affect the detaching force are the droplet mass and the current, as can be seen from Eq 6 to 10. Because the surface tension is the major retaining force and it is fixed for the given wire, the droplet can only be detached either by waiting for the droplet to grow into a larger size, such that the gravitational force is sufficient to break the balance; waiting for the droplet to touch the weld pool, such that an additional detaching force—surface tension between the droplet and weld pool—is added; or by increasing the current to increase the electromagnetic force.

The phenomenon of the transition current implies that the effect of the electromagnetic force as the detaching force changes rapidly around the transition current. The rapid increase of the electromagnetic force reduces the dependence on the gravitational force to overcome the surface tension at the liquid-solid interface on the wire tip. Such a rapid increase in the electromagnetic force at detaching is due to the rapid climb of the arc (anode) from the bottom of the droplet toward the neck of the droplet (the solid-liquid interface). The climb of the arc increases the exit radius of the current in Eq 10. When the arc climbs rapidly as the current increases, the exit radius of the current in Eq 10 increases rapidly, such that the required gravitational force component is much smaller. (Figure 20 demonstrates the arc climb phenomenon.) As a result, the diameter of the droplet decreases rapidly in the narrow range around the transition current, from being much larger than that of the wire to being much smaller than that of the wire.

Metal-Transfer Control. Metal transfer plays a critical role in determining the quality of the welds produced. In conventional GMAW with a continuous waveform CV power supply, the continuous waveform current is dictated by the wire feed speed. If the wire feed speed is large, such that the resultant current is higher than the transition current, that is, $I \geq I_t$, the droplets are automatically detached smoothly at relatively small diameters as spray transfer, and the metal transfer is typically not an issue of concern unless the current is extremely high, producing a rotating transfer. However, if $I < I_t$ is required, the metal transfer could cause problems. If the arc length is long, the large droplets pending at the tip of the wire would wander about the wire axis and cause not only an arc instability but also uncertainties in the travel direction of the detached droplet. Droplets thus merge into the weld pool at different locations, forming irregular weld beads. If the arc length is short, resulting in short-circuiting transfers, spatters would be produced. Hence, a continuous waveform current is typically not used in the large current range $I < I_t$. A number of methods have been developed to control the metal-transfer process if the needed current is smaller than the transition current.

Pulsed Arc Control. This is a method to achieve the desired spray transfer over a wide range of average current by using a square waveform with a background current, $I_b < I_t$, to maintain the arc and a peak current, $I_p \geq I_t$, to detach the droplet, as shown in Fig. 21. The applications of GMAW that require different levels of heat input are thus greatly extended.

Surface Tension Transfer (STT, Lincoln Electric). This technology was developed from an understanding of phenomena associated with short-circuiting transfer. By detecting the progress of the short-circuiting process, the current waveform is controlled/optimized differently in different metal-transfer stages to minimize the production of spatters. Figure 22 shows its typical current waveform.

Cold Metal Transfer (CMT). Gas metal arc welding typically feeds the wire forward continuously by using a motor (wire feeder) at a distance from the welding torch to minimize the weight being carried and to maximize the torch accessibility. The CMT uses a second motor installed close to the torch to draw the wire back after the droplet touches the weld pool. As a result, the droplet can be successfully separated from the solid wire and transferred into the weld pool, and the arc is re-established during the separation process, as shown in Fig. 23. During the separation and arc re-establishment, the current is controlled at a minimal level to minimize the production of spatter.

Double-Electrode GMAW. In conventional GMAW, the current melts the wire. By adding a bypass electrode and bypass loop (Fig. 24), such that part of the current passes through the bypass loop, there will be two cathodes, one on the base metal and another on the bypass electrode. The current flowing to the workpiece becomes lower than the melting current. As a result, the arc root on the wire becomes more distributed, and the spray transfer is achieved with a base-metal current much smaller than the transition current (Ref 7).

Heat Input Control. Many GMAW applications require that a certain amount of metal be deposited into the workpiece with a minimal heat input. This problem can be posed as

Fig. 20 Arc climb phenomenon. (a) Below transition current. (b) Above transition current

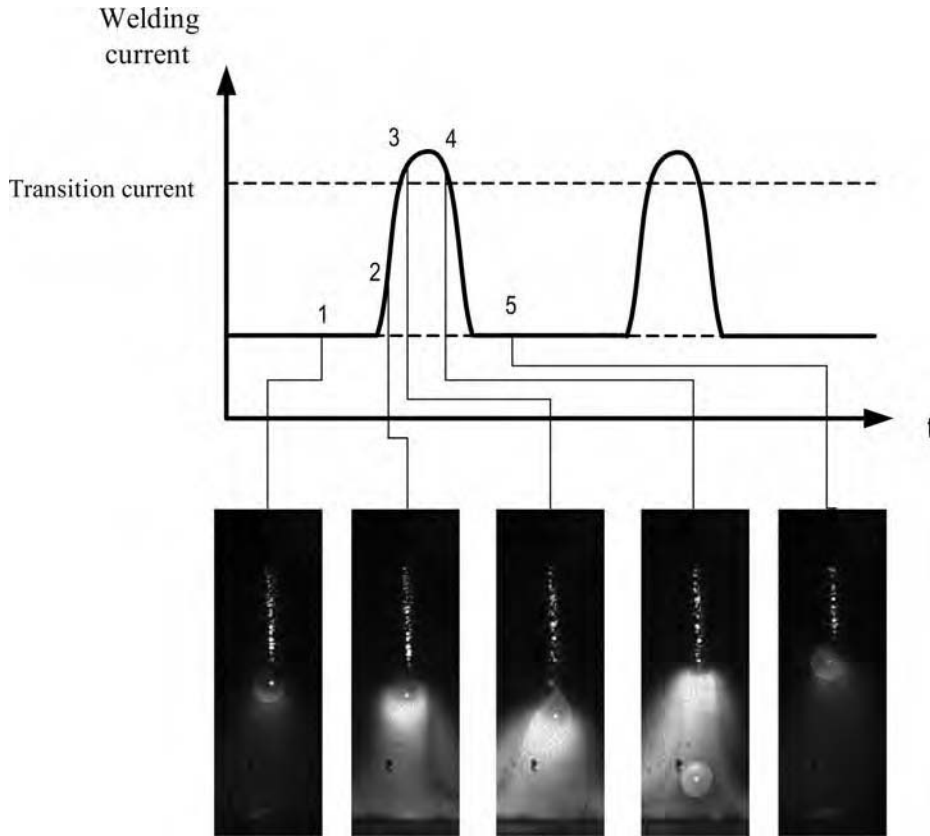

Fig. 21 Typical pulsed gas metal arc welding process

Fig. 22 Schematic of surface tension transfer process and current waveform

achieving a maximum efficiency ratio, defined as the effective heat over heat input ratio:

$$\lambda = H_e/H \tag{Eq 12}$$

where H is the heat input into the workpiece, and the effective heat, H_e , is the heat that melts the wire.

This can be simplified by omitting the arc column heat and resistive heat. In conventional direct current electrode positive GMAW:

$$H_e = V_a I/v \tag{Eq 13}$$

$$H = (V_a + V_c)I/v \tag{Eq 14}$$

where V_a is the anode voltage drop, V_c is the cathode voltage drop, and v is the travel speed. Their ratio is:

$$\lambda = V_a/(V_a + V_c) \tag{Eq 15}$$

In GMAW, the materials of the wire and base metal are similar, and $V_c \approx 2V_a$ (Ref 6). Hence, for conventional direct current electrode positive GMAW, the efficiency ratio is approximately 33%.

In direct current electrode negative GMAW:

$$H_e = V_c I/v \tag{Eq 16}$$

$$H = (V_a + V_c)I/v \tag{Eq 17}$$

The efficiency ratio is approximately 66%. However, in electrode negative (EN) mode, the electromagnetic force prevents the droplet from being detached. To resolve this issue, the polarity can be switched between EN and electrode positive (EP), such that the efficiency ratio is increased using EN but the droplet is detached using EP. The resultant processes are variable-polarity GMAW and ac GMAW.

In double-electrode GMAW, if the bypass electrode is nonconsumable, such as a tungsten:

$$H_e = V_a I/v \tag{Eq 18}$$

$$H = (V_a I + V_c I_{bm})/v \tag{Eq 19}$$

where I_{bm} is the base-metal current, and the melting current $I = I_{bp} + I_{bm}$, that is, the sum of the base-metal current and bypass current. The efficiency ratio is:

$$\lambda \approx I/(I + 2I_{bm}) \tag{Eq 20}$$

If $I_{bp} = I_{bm}$, then $\lambda = 50\%$. If $I_{bp} = 4I_{bm}$, then $\lambda = 5/7 = 71\%$.

For consumable double-electrode GMAW where the bypass electrode is a wire:

$$H_e = (V_a I + V_c I_{bp})/v \tag{Eq 21}$$

$$H = (V_a + V_c)I/v \tag{Eq 22}$$

Fig. 23 Cold metal-transfer process (metal inert gas/metal active gas dip-transfer arc process). Courtesy of Fronius USA LLC, 2007

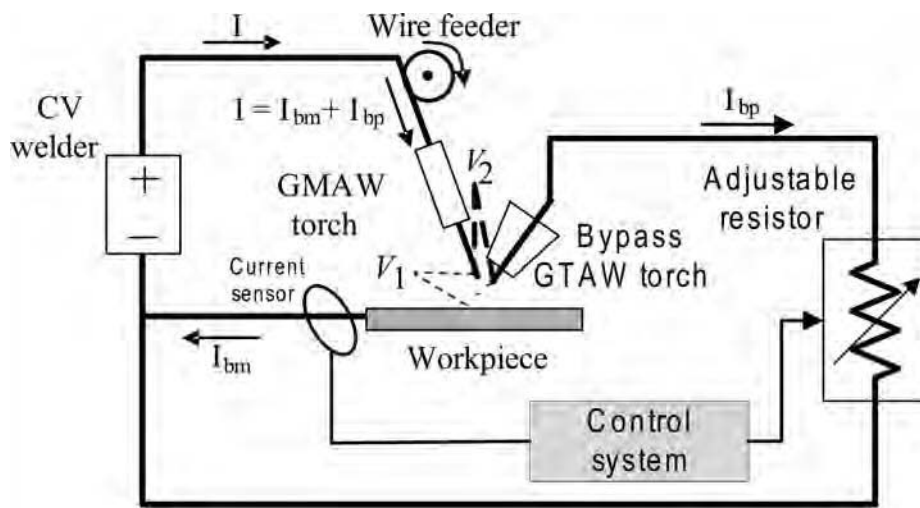

Fig. 24 Nonconsumable double-electrode gas metal arc welding (GMAW). GTAW, gas tungsten arc welding

The efficiency ratio is:

$$\lambda \approx 33\% + \left(\frac{2}{3}\right) \left(\frac{I_{bp}}{I}\right) \quad (\text{Eq 23})$$

If $I_{bp} = I_{bm}$, then $\lambda = 66\%$. If $I_{bp} = 4I_{bm}$, then $\lambda = 86\%$.

Qualification of Welding Procedures and Personnel

Harvey R. Castner, Edison Welding Institute

QUALIFICATION of welding procedures and personnel is an important step to assure the quality and performance of any welded component or structure. These qualifications confirm that the welding procedure will meet design requirements and that personnel are competent to produce welds that meet the expected quality levels. These are the reasons that welding codes, standards, and fabrication documents require the qualification of welding procedures and personnel. This article summarizes common welding procedure and personnel qualification variables and test methods. The reader is referred to the specific code, standard, or specification for the detailed qualification requirements that govern their particular application.

Several widely recognized codes and standards address qualification of welding procedures and personnel, including:

- Section IX of the American Society of Mechanical Engineers (ASME) “Boiler and Pressure Vessel Code”
- AWS B2.1, “Standard for Welding Procedure and Performance Qualification”
- NAVSEA Technical Publication S9074-AQ-GIB-010/248, “Requirements for Welding and Brazing Procedure and Performance Qualification”

Many other codes and standards include welding procedure and performance qualification requirements, for example:

- AWS D1.1, “Structural Welding Code—Steel”
- AWS D1.5, “Bridge Welding Code”
- API 1104, “Standard for Welding Pipelines and Related Facilities”

Purpose of Qualification and Responsibility for the Task

Fabricators, manufacturers, and contractors are responsible for the selection, definition, and control of the welding procedures they

use and the personnel who use them. This control normally includes the preparation of detailed written instructions known as welding procedure specifications (WPS)—or just welding procedure—and the qualification of both welding procedures and personnel. The purpose of qualifying a welding procedure is to demonstrate that the resulting welds will meet prescribed quality standards and have the requisite mechanical properties for the intended application. The qualification of personnel demonstrates their ability to produce welds that meet the quality requirements using the prescribed welding procedure.

Some fabrication codes and standards (for example, AWS D1.1) permit the use of a prequalified WPS that is within specified guidelines for materials, joint designs, processes, and methods. Other codes and standards (ASME “Boiler and Pressure Vessel Code Section IX”) permit the use of American Welding Society (AWS) Standard Welding Procedure Specifications. However, the majority of WPSs must be qualified by the user. The use of standard or prequalified procedures does not lessen the responsibility of the fabricator or contractor to ensure that the welding procedures are satisfactory for the application.

In all cases, all the important process variables must be documented in a welding procedure specification. A sample WPS form is shown in Fig. 1. If these variables change, then a new WPS may have to be prepared to reflect these changes. Whether the WPS must be requalified when revised depends on which variables are being revised. The qualification standard will identify which changes require requalification.

Qualification of Welding Procedures

Procedure qualification involves demonstrating that welds made using the procedure meet minimum soundness and mechanical property requirements. This is accomplished by

preparing, examining, and testing a qualification test weldment as well as documenting the results on a procedure qualification record (PQR). The most common method of procedure qualification involves welding a test weldment that is specifically designed for this purpose and testing it as described by the applicable code or standard. Some codes and standards permit qualification of procedures by testing special or prototype welds. The fabricator, manufacturer, or contractor must supervise and control the preparation of the qualification test welds.

The PQR documents the details of the welding variables used to prepare the qualification test weldment as well as the results of its inspection and testing. The sample form shown in Fig. 1 can be used for the PQR document along with the test results. The application of a WPS that is prepared based on the PQR is limited by the details of the test specimen and ranges of variables used in the test. For example, the range of base-metal thicknesses over which the procedure can be used is determined by the thickness of the qualification test specimen. Other variables in the WPS, such as preheat and interpass temperature or welding heat input, also may be limited by the ranges of the variables used for qualification.

While another organization may assist in the removal and assessment of test specimens, the contractor or fabricator is ultimately responsible for the procedure qualification tests, the results of these tests, and the control and application of the procedures in production. A single welding procedure qualification test may support a number of WPSs, or a single WPS may be supported by several procedure qualifications.

Types of Qualification Tests

Welding procedure qualification tests can be categorized as either standard or special tests. Standard procedure qualification test weldments represent the type of weld and weld joint that are to be used in production. Special welding

Fig. 1 Welding procedure specification form. Source: Ref 1

procedure qualification tests use the specified welding procedure to fabricate prototype structures or mock-up components that are then subjected to loads that simulate the actual conditions encountered in service.

Groove-welded butt joints in plate and pipe are shown in Fig. 2 and 3, respectively, as examples of standard test weldments. Two examples of fillet welds in T-joints are shown in Fig. 4. Fillet welds can also be deposited on lap, corner, or edge joints. A partial penetration weld in a T-joint is shown in Fig. 5, whereas a plug weld test specimen is shown in Fig. 6. The latter could be a slot weld as well, and a similar weldment could be used for spot welds.

Resistance spot and seam welds are typically made on lap joints. Other test weldments are appropriate for friction, laser beam, electron beam, and stud welding or for cladding and surfacing weld deposits. The thickness of test weldments should be selected after considering the thickness of materials used in actual fabrications and the thickness limitations of the fabrication code or standard. The length and width of the test weldment should be sufficient to permit removal of the necessary test specimens.

Fig. 2 Typical location of test specimens from groove welds in butt-joint test plate

After the test weldment is prepared and welded using the methods that are detailed in the PQR, it is examined and tested to the requirements of the applicable qualification code or standard. Standard tests include visual,

metallurgical, and nondestructive examinations, chemical analysis, and tests to determine mechanical properties. The mechanical property tests can include tension, bend, torque, nick-break, shear, peel, and hardness tests, as

Fig. 3 Typical location of test specimens from groove welds in butt-joint pipe test

Fig. 4 Two examples of T-joint weldments for fillet weld qualification. (a) Fillet weld on one side of T-joint. (b) Fillet weld on both sides of T-joint

well as tests to determine impact (Charpy test) toughness or perhaps plane-strain (K_{Ic}) or plane-stress (K_{Ic}) fracture toughness.

Although the use of standard tests to qualify a WPS demonstrates the ability of the procedure to produce sound welds that meet the minimum required properties, these tests may not ensure that the welding procedure is suitable for all applications. Standard test plates are relatively small and are normally welded under laboratory, rather than production, conditions.

Special Qualification Tests. Codes and standards may permit the qualification of welding procedures by testing special or prototype welds. In other cases, the code, standard, designer, owner, or operator of the welded structure or component may require additional special qualification tests to establish the acceptability of a welding procedure. Special tests may involve welding mock-up or prototype structures and then subjecting these structures to loads that simulate the actual conditions encountered in service. Tests can

include static or dynamic loads, corrosive environments, high temperatures, shock, impact loading, or other tests. After load testing, the structure can also be tested destructively; welds can be sectioned and the cross sections examined for proper penetration, bead placement, and profile. Testing of roll-over protection structures is an example of a special test.

Standard Qualification Tests

Tests for Full-Penetration Groove Welds. Typical tests for full-penetration groove welds include tension, bend, and impact (Charpy) toughness tests. It is also common to subject weldments to chemical analysis, hardness tests, and macroexaminations of weld cross sections. Figures 2 and 3 indicate the location of tension and bend specimens in plate and pipe test weldments, respectively. Figure 7 shows the configuration of tension and bend specimens. The details of specimen size, orientation, removal,

Fig. 5 Partial-penetration weld specimen

Fig. 6 Plug weld specimen

testing, and acceptance are provided in the welding code or standard or by references to ASTM International test standards or AWS B4.0, "Standard Methods for Mechanical Testing of Welds."

Tension Tests. Transverse tension tests are performed on full-penetration groove welds to determine the tensile strength of the weld region. The specimens can be full-section or reduced-section rectangular or round specimens (Fig. 7). Multiple tension specimens may be needed to test the entire thickness of plates that are more than 25 mm (1 in.) thick, as shown in Fig. 8. The acceptance of tension test results is normally based on a tensile strength that is either equal to or greater than the minimum specified tensile strength of the base metal being welded. If the weld metal has a lower specified strength than the base metal, then the tension test must exceed the specified minimum tensile strength of the weld metal. Some codes permit the strength of the tension specimen to be 5% below the specified minimum tensile strength of the base metal if the specimen breaks outside of the weld or fusion line. If all-weld-metal tension tests are required, then round specimens are typically removed from the center of the weld and oriented parallel to the weld axis.

Guided-Bend Tests. Bend tests are performed to verify the soundness and ductility of the weld and the heat-affected zone (HAZ). Figures 2, 3, and 8 show bend specimens that are typically oriented transverse to the weld axis, with the center of the weld in the center of the specimen. Face-bend and root-bend specimens are typically specified for base-metal thicknesses of less than 9.5 mm (0.375 in.). These specimens place either the face of the weld (face-bend) or the root of the weld (root-bend) on the convex side of the bend specimen. Side-bend specimens, taken through the thickness of the test weldment, are required for thicker test plates in order to test the entire weld cross section. Test weldments that are more than 38 mm (1.5 in.) thick may require multiple side-bend specimens to ensure that the entire weld thickness is tested (Fig. 8).

Under some circumstances, longitudinal bends are removed with their length parallel to the axis of the weld. Longitudinal-bend specimens are used for welds between dissimilar metals where there is a large difference in bend properties between the two base metals or between the weld metal and the base metal.

Guided-bend specimens are forced into a specified curvature (Fig. 7) by either applying a load to a plunger or forming the specimen around a fixed mandrel. The width and thickness of the specimen and the radius of the plunger or mandrel are designed to produce a minimum specified elongation in the outer surface of the specimen. It is important to follow the recommendations for specimen dimensions, because width and thickness influence test performance. The most common bend specimen for steel welds is 9.5 mm (0.375 in.) thick and

is formed around a 20 mm (0.75 in.) radius to yield 20% elongation in the outer surface of the specimen. Larger bend radii are permitted to match the lower ductility of some base metals or weld metals. Acceptable bend specimens must not fracture or have cracks or other open defects that exceed a specified maximum size (usually 3.2 mm, or 0.125 in.) on their convex surface.

Impact Toughness Tests. Charpy V-notch impact tests are often used to measure the fracture toughness of weld metals and HAZs. Charpy V-notch specimens are usually removed from the weld metal and HAZ, with the notch oriented normal to the surface. One face of the V-notch specimen is located within 1.6 mm (0.06 in.) of the surface of the material. Thick materials require additional specimens at subsurface locations. When permitted, subsized impact specimens can be used for thin materials that do not permit the removal of standard specimens. The number of specimens, their location and orientation, and the test temperature are determined by the design requirements or material specifications. Acceptance criteria may be a minimum specified absorbed energy in joules (ft-lbf), a minimum percentage of shear fracture appearance, or a minimum specified lateral expansion opposite the notch. The applicable code or standard should be consulted for test conditions and acceptance criteria for subsized specimens.

The assessment of toughness, in terms of dynamic tear or plane-strain fracture properties, using compact-tension or crack tip opening displacement specimens may be required for some welding procedures. Drop-weight tests are sometimes used to determine the minimum nil-ductility transition temperature for ferritic steel weld metal and HAZs. Codes and specifications describe how specimens should be

removed from the weld metal and HAZs to permit the measurement of each of these fracture toughness properties.

Tests for Fillet Welds, Partial-Penetration Groove Welds, and Spot and Plug Welds.

The procedure qualification of fillet welds typically involves T-joint test weldments, similar to those shown in Fig. 4. Some codes and specifications permit lap joints, corner joints, or other joint configurations that represent the actual joint used in production.

Procedures for partial-penetration groove welds can be qualified by making test weldments that represent the joint used for the application. Figure 5 shows a T-joint test weldment for a partial-penetration groove weld. Figure 6 shows the configuration of the test weldment for the qualification of plug or slot welds.

Completed fillet, partial-penetration, and plug or slot weldments are usually examined visually and tested to ensure that they meet the acceptance requirements of the weld-quality specification. These welds do not normally lend themselves to mechanical property testing, although tension-shear tests and weld-break tests can be conducted on them. The required mechanical properties must be determined from a standard groove-weld test. Macrosections are removed to verify root penetration.

Figures 4 and 5 show how macroexamination specimens are removed from fillet or partial-penetration welds. Figure 6 illustrates how plug or slot welds are cut through their center to produce macroetch specimens. The faces of macroetch specimens are ground smooth, etched, and then examined. Acceptable welds must have:

- The designated weld size and profile
- Fusion to the root of the joint
- No cracks

Fig. 8 Removal of multiple bends and tension specimens from thick test plates

- Complete fusion between adjacent layers of weld metal, as well as between weld metal and base metal

Shear tests can also be used to measure the strength of fillet, partial-penetration, plug, or slot welds. Usually, acceptable shear strength is at least 60% of the minimum specified tensile strength of the base metal.

Weld-break tests also may be required for fillet and partial-penetration welds. These specimens are removed from the weld, as shown in Fig. 4, and loaded so that the root of the weld is in tension until the specimen fractures or bends flat upon itself. Acceptance is determined by examining the fractured surface for complete fusion, the required depth of penetration, and porosity and inclusion levels that do not exceed a specified maximum size. The specimen is also acceptable if it bends flat upon itself without fracturing.

Procedure qualification tests for arc and resistance spot welds include tension-shear, torsion, peel, and hardness tests, as well as macroexaminations. Tension, torsion, and peel test specimens are examined to determine the location of failure and the size and soundness of the weld nugget.

Tests for Stud Welds. The qualification of stud welding procedures can involve welding and testing multiple specimens for each diameter, welding position, and geometry to be qualified. Sectioning and macroexamination can determine whether or not the welds and HAZs have the proper fusion and are free of cracks. Bend tests for stud welds involve bending the stud through a minimum angle (for example, 30°) and then bending it back to the original position. An alternative test is to bend the studs by hammering them flat onto the test plate. The bent studs must be free of visible separation or fracture. Stud welds also are tested by applying torque or tension loads.

Tests for Weld Cladding and Surfacing. The qualification of weld cladding procedures can involve liquid penetrant testing, chemical analysis of the deposit, macroexamination of cross sections, and bend tests. The qualification for hard-surfacing welding procedures can include hardness tests in addition to chemical analysis of the deposit and macroexamination of cross sections.

Limitations on Procedure Qualification. A new welding procedure must be qualified if it differs significantly from another qualified procedure. The application range of a welding procedure qualification is determined by placing limits on the welding variables specified in the procedure. Codes and standards define these limiting variables as essential variables, essential elements, or qualification variables. A welding procedure must be requalified if changes in these variables exceed specified limits.

Supplementary essential variables are the variables that affect notch toughness. Supplementary

variables become essential variables when notch toughness tests are required.

Nonessential variables are the remaining variables contained in the WPS that can be changed without requiring requalification. An essential variable for one process may be nonessential for another process.

Although there are differences in how codes and standards define essential variables, the variables described as follows are considered to be essential by most codes and standards.

Welding Process. A change of welding process will require requalification, because the process has a significant effect on the mechanical properties and metallurgical structure of the weld.

Base Metal. Changing from one base-metal type or thickness to another can affect weldability as well as the metallurgical and mechanical properties of the weld. Changes in base metals also can cause differences in weld penetration and weld fusion characteristics for certain welding processes. Therefore, significant changes in base-metal type, composition, heat treatment, or processing will require requalification.

Codes and standards group together base metals that have similar weldability characteristics, metallurgical properties, chemical compositions, or mechanical properties. The grouping of base metals reduces the number of required qualifications by allowing the qualification of a procedure on one of the materials in the group to qualify the procedure for use on the other base metals in that group. Changing to a base metal of another group requires requalification.

Separate welding procedure qualifications are typically required for pipe and plate. While a procedure qualification on pipe may also cover plate, a procedure qualification on plate may be restricted to welding plates and large-diameter pipes. Limitations also are placed on metal thickness for procedure qualification. Base-metal thickness influences cooling rate and therefore metallurgical and mechanical properties. The composition of a metal may also change with thickness. Most codes permit qualification on one thickness of test specimen to cover a range of base-metal thicknesses. Some codes require qualification on the exact thickness of metal that is to be used for production welds. Other codes require qualification on the thinnest and thickest metals that are used in production.

Filler Metal. Filler metals and welding electrodes with similar chemical compositions and operating characteristics also are grouped together for the purposes of procedure qualification. Grouping reduces the number of qualifications that must be done by allowing the qualification of one of the filler metals in the group to also qualify the others in that group. Ferrous filler metals can be grouped by both chemical composition and usability. The addition or deletion of a filler metal, supplementary filler metal, or consumable insert is an essential variable for arc welding processes.

Position is not an essential variable for some codes and standards, while other specifications allow qualification in one position to cover qualification in another position. Welding position usually is an essential variable for procedures requiring notch toughness testing.

Joint design is an essential variable for some processes and applications but not for others. Weld joint design should be an essential variable for processes where changes to the joint affect metallurgical structures and weld properties. Examples of these processes include stud, laser beam, electron beam, and friction welding.

Electrical Characteristics. Variations in the type of welding current (alternating or direct, for arc welds) or in polarity normally require requalification. A small change in welding current or voltage within limits permitted by the document does not typically require requalification. The results of more than one PQR can be used to support the acceptable performance of the range of variables for a given WPS. Procedures meeting notch toughness requirements may limit changes in electrical characteristics and travel speed through limits on weld heat input. The use of current pulsation and the pulse parameters may be essential variables. For example, beam current or beam power are essential variables for both laser beam and electron beam welding. Use of pulsed welding current is an essential variable for gas tungsten arc welding and gas metal arc welding in some codes or standards.

Shielding. The use and the composition of a shielding gas are essential variables for gas shielded arc welding, friction welding, and laser beam welding processes.

Preheat and Interpass Temperatures. Significant changes in preheat or interpass temperatures will affect properties and therefore will require requalification. Codes and standards differ on the size of the change in temperature that is permitted. Some codes limit changes to a maximum of 14 °C (25 °F), whereas others permit an increase or decrease of up to 56 °C (100 °F) before requalification is required.

Postweld Heat Treatment. The use of postweld heat treatment requires qualification that includes the heat treatment. The applicable code or standard should be consulted regarding changes in the postweld heat treatment temperature or time at temperature that requires requalification.

Other variables that affect the soundness, metallurgical structure, or mechanical properties of the weld are essential or qualification variables. These variables depend on the welding process being used. Examples of these variables include:

- Changing from a stringer to a weave bead, or changing the direction of welding for vertical arc welding procedures
- Changes in electrode composition or configuration for resistance welding

- Changes in filament type, size, or shape and in gun-to-work distance for electron beam welding
- Changes in focal length, focus position, or spot size for laser beam welding
- Changes in energy, applied loads, or the amount of upset for friction welding

Qualification of Welding Personnel

The employer is responsible for assuring that their personnel are trained and qualified to the specific requirements of the codes, specifications, or fabrication documents under which work is to be performed. Welding personnel, including welders, tack welders, and welding operators, are qualified by demonstrating their ability to produce welds that meet minimum requirements for soundness and quality. Qualification of personnel is also referred to as performance qualification.

Welding personnel are qualified by welding a test plate while following a welding procedure specification and having the test plate examined to determine its acceptability. Some standards permit qualification of personnel by examination of workmanship samples or production welds. Critical applications may require the welder to produce special welds that simulate the actual conditions encountered during fabrication. Training, knowledge tests, and visual acuity are part of the requirements of some specifications.

Performance Qualification Tests. The test specimens, types of tests, and variables that govern personnel qualification are based on the level of knowledge or skill required for the task and those variables that have an effect on the ability of the individual to produce sound welds. Therefore, personnel that are qualified only to produce tack welds or fillet welds do not have to demonstrate the same skill levels as those qualified for out-of-position pipe welding. Welding operators are qualified to produce welds using the mechanized, automated, or robotic equipment and the welding procedure specification that they intend to use.

Qualification using standard tests involves the individual preparing the test weld using the WPS and having the weld tested according to the requirements of the code or standard being used. These requirements typically include visual and nondestructive examination and/or the removal of specimens for mechanical property or other tests. Guided-bend tests, fillet weld-break tests, and macroexamination of weld cross sections are typical types of tests performed on performance qualification welds. These tests are similar or identical to those described previously for qualification of welding procedures. Many codes and standards permit radiographic tests to be substituted for guided-bend testing for performance qualification, since

the issue being examined is the welder's ability to produce a sound weld.

Limitations on Performance Qualification.

Variables that determine the limits of performance qualification include the welding process; base-metal type, composition, and thickness; type of weld; use of weld backing; a change in welding position to a more difficult position; changes in uphill or downhill progression for vertical-position welding; and a change in the filler-metal operating characteristics grouping.

Process. Use of each welding process requires specific knowledge and skills that make it essential that a welder is tested on the welding process to be used in fabrication. There are also certain changes within a process that affect usability and require requalification, such as the use of short-circuit metal transfer or pulsed welding current.

Base Metal. Similar to welding procedure qualification, changing from one base-metal grouping to another often requires requalification since the base metal can affect the filler metal used, weld penetration, and fusion characteristics. Codes and standards permit qualification on one base-metal group to allow personnel to weld metals in similar groups. The type and thickness of the base metal also are essential variables for performance qualification. Pipe, sheet, and plate may require different welding abilities or techniques that need to be verified by testing. Specific limits must be considered during performance qualification for welding of small-diameter pipes and heavy-thickness materials.

Weld Type. Producing fillet welds or groove welds can require different levels of skill, and therefore, qualification for groove welds is tested differently than qualification of an individual that will only produce fillet welds. The deletion of backing from a groove weld joint also requires requalification of individuals that have previously been qualified only on joints with backing.

Position. Welding in the vertical or overhead positions or welding pipe in the horizontal-fixed position requires greater skill than flat-position welding. Normally, a performance test in the more difficult position also qualifies for less demanding positions. A change in the direction of weld progression from uphill to downhill or vice versa requires requalification.

Filler Metal. A change to a filler metal from another operating characteristics group (F-number) usually requires requalification of the individual. There are some instances where qualification on one filler-metal group also qualifies the individual on other similar groups. The addition or deletion of a filler metal, supplementary filler metal, or consumable insert is an essential variable for arc welding processes.

Maintenance of Qualification. Failure to maintain their qualification or to demonstrate

competence can result in an individual having to requalify their ability to perform a welding operation. Once the welder or welding operator has passed a performance qualification test, they must continue to use the qualified skills in order to maintain their qualified status. Maintenance of personnel qualification requires verification that the individual has used the welding process during a period of time that is specified as every six months by some codes and standards or three months by others. Qualification of an individual can be revoked if their ability to produce satisfactory welds comes into question.

Qualification Documentation

Record keeping of procedure and performance qualification is an essential part of the responsibility of the activity (fabricator, manufacturer, and contractor) that uses welding procedures and employs welding personnel. Documentation includes preparation and maintenance of the WPS that defines the variables and methods to be used for welding. A PQR is used to document the actual welding variables that are used for the procedure qualification test weldment as well as the results of the tests of this weldment. Performance qualification test records are used to document the preparation, inspection, and testing of the performance qualification test. The activity also needs to record the use of a process by their qualified personnel in order to maintain their qualified status. The manufacturer or contractor should have these records available for review by customers or authorized inspectors.

General Design Considerations for Arc Welding Processes

W.C. Mohr, Edison Welding Institute,
 O.W. Blodgett, The Lincoln Electric Company

A WELD JOINT serves to transfer the stresses between the joined members and throughout the welded assembly. The type of loading and service of the weldment influences the selection of a joint design and how forces and loads at different points are transmitted to different areas throughout the weldment.

Joint types describe how the members meet, and the names of different joint types are butt, T, corner, lap, and edge. The selected weld also may or may not require preparation in the form of a groove to permit proper access to the root of the joint. Several methods of joint preparation include machining, chipping, shearing, grinding, gas cutting, gas gouging, or air carbon arc gouging, which may be used to create single- or double-bevel, V-, J-, or U-grooves.

No preparation is needed for a square groove weld. The members can be abutted in the same plane. If there is zero root opening, the weld arc essentially fuses the members together. Usually, very little or no weld metal bridges the weld members, although some weld metal or reinforcement may be left on the top and bottom surfaces. Similarly, fillet welds, which join pieces perpendicular to each other, can be used on T-joints without preparation. The welds and the fusion into both members join the two pieces.

Groove preparations are often necessary, however, for successful welding of various corner, T-, and butt-joint applications. Frequently required with larger metal thicknesses, these weld preparations ensure that the welding heat and weld metal reach and fuse the root of the joint.

Nomenclature

Terminology describing various joints and welds is often confused. Types of welds and joints recognized by the American Welding Society (AWS) are illustrated in Fig. 1. Note that joints are the junctions where the members join, and welds are the mechanisms (groove or preparation) that complete joints. Figure 2 shows applications of some single-bevel and single-V welds on T- and corner joints.

Although precise nomenclature to differentiate between welds and joints is desirable, engineers will probably continue to use the terms interchangeably. For example, although Fig. 16 (discussed later) is technically a joint made with two partial-penetration double-bevel groove welds, the joint is referred to as a partial-penetration double-bevel groove joint. Thus, in this article as well as other practical applications, the terms *joint* and *weld* are used interchangeably to describe how a joint is constructed.

Types of Joints

Butt joints are joints between two abutting members lying approximately in the same plane. Although they may be welded with no preparation, butt joints are often grooved, especially with thicker and heavier plate.

Butt joints are preferable in uses where continuity of section is desired, such as fusion-welded joints in sheet or plate for pressure vessels, pipelines, decking, tanks, and similar construction applications. Generally, when the

Fig. 1 Types of joints and welds

metal thickness exceeds approximately 6 mm (1/4 in.), the butt joint requires grooving to prevent a lack of fusion from weakening the weld.

T-joints are joints in which the members are positioned in the form of a "T." They are well suited for no-preparation fillet welds, but in thick material the preparation welds, such as the single-bevel in Fig. 2, may be necessary.

T-joints are frequently used in production of fabricated weldments, welded machinery components, attachment of flanges and plate stiffeners to webs of girders, and assembly of rolled section and tubular building structures. Fillet-welded T-joints should not be used for fusion welding with ordinary gas or arc welding of containers because corrosive solids may be trapped in the unwelded area between the members.

Corner joints are joints between members located at approximately right angles to each other that meet in the form of an "L." Typical applications are the same as those for T-joints.

Figure 3 shows various corner joints with fillet and preparation welds. The corner-to-corner joint (Fig. 3a) is difficult to assemble because neither plate can be supported by the other. A small electrode with low welding current must be used to prevent the first welding pass from melting through. This joint requires a large amount of weld metal. In contrast, the corner joint in Fig. 3(b) is simple to assemble, does not melt through easily, and requires half the amount of weld metal. Half the weld size is also used when welding the identical joint with two welds, one outside and the other inside (Fig. 3c), a design that has the same total throat as Fig. 3(a).

With thick plates, a partial-penetration groove weld (Fig. 3d) is often used in a corner joint. This weld requires beveling. For a deeper weld, a J-groove preparation may be chosen instead of a bevel (Fig. 3e). Another possibility, the fillet weld in Fig. 3(f), is inconspicuous and makes a neat and economical corner.

Fig. 2 Welds in T- and corner joints. (a) and (b) Single-bevel welds. (c) Single-V-groove weld

Fig. 3 Corner joints. (a), (b), (c), and (f) Fillet welds. (d) V-groove weld. (e) J-groove weld

Lap joints are joints made with two overlapping members. They do not require edge preparation. Lap joints are necessary for use in seam and spot welding of sheet metals.

Edge joints are joints between the edges of two or more parallel or nearly parallel members. They may not require the addition of filler metal for welding and are frequently used to join thin turned-out edges, such as those formed where the sides of a container meet.

Types of Welds

Fillet welds are welds approximately triangular in cross section, joining two surfaces essentially at right angles to each other in a lap, T-, or corner joint. Fillet welds require no preparation and are the most common type of weld used in structural work.

Square groove welds are welds in which the abutting surfaces are square (0° included angle). Because welding from one side makes penetration difficult, the double-square weld is used frequently to ensure the strength of the weld. Sometimes the root of the weld is opened and a backing bar is used. The purpose of a backing material, which is placed at the root of the weld joint, is to support the molten weld metal.

Bevel groove welds are welds in which only one member is beveled. The bevel angle (material removed by cutting) is measured between the prepared edge of a member and a plane perpendicular to the surface of the other member. Single-bevel groove preparations are widely used because they are easily prepared by oxyfuel gas cutting. They are well suited for corner and T-joints (Fig. 2), as well as butt joints 6 mm (1/4 in.) in thickness and greater. Double-bevel grooves are recommended, if welding from both sides is possible, when metal is 19 mm (3/4 in.) or thicker, because these grooves produce less distortion of the welded parts and reduce weld-metal requirements by approximately half.

V-groove welds are welds in which the total included angle of the groove between the members to be joined is the sum of the two bevel angles. Similar to single-bevel groove welds, single-V-groove welds are widely used because they are easily prepared by oxyfuel gas cutting. Figure 2 shows a single-V weld in a corner joint. These groove preparations are also used extensively in edge preparations for butt joints 6 mm (1/4 in.) in thickness and greater. The advantages of double-V bevel grooves are the same as those for double-bevel grooves.

J-groove welds are welds made in J-shaped grooves between the two members to be welded. Single-J-grooves are well suited for butt, corner (Fig. 3e), and T-joints. The advantages of double-J-groove preparations are the same as for double-bevel grooves.

U-groove welds are welds made in U-shaped grooves between two members to be

welded. Because of the rounded base, larger electrodes can be used with narrower groove angles than for V-groove welds. The U-groove preparations can be prepared by air carbon arc gouging or by machining, which yields more uniform grooves. Because J-grooves and U-grooves require at least 3 mm (1/8 in.) root face and 6 mm (1/4 in.) radius at the root of the joint, the material must be more than 9 mm (3/8 in.) thick for this joint to be used. The advantages of double-U-groove welds are the same as those for double-bevel welds.

Weld Joint Design

The first consideration in the design of a weld joint is its ability to transfer load; the second is cost. The ideal weld joint is one that can handle the loads imposed, usually with a substantial safety margin, and still be produced at minimal cost.

Therefore, once the type of joint has been selected primarily on the basis of load requirements, the choice of weld to complete the joint should be determined by the effects of the structural design and layout on weld metal, accessibility, and preparation requirements—variables that directly influence the cost of the weld joint. There may be other factors, such as distortion and fatigue resistance, that enter into the decision. Design factors can also be important in the prevention of defects such as incomplete fusion, solidification cracking, or lamellar tearing.

Weld Metal. In general, joint and weld types specified should require the least amount of filler metal to avoid unnecessary expense. The size of the weld should always be designed with reference to the size of the thinner member. The joint cannot be made any stronger by matching the weld size to the thicker member, which would require a greater amount of weld metal.

In the design stage, joints that create extremely deep grooves should be avoided, because these require more filler metal. Deep-penetration welding processes, such as submerged arc welding, especially automatic welding, reduce the volume of weld metal needed. Because greater thickness of plate can be welded, use of these methods may reduce the cost of groove preparations.

If groove welds are required, minimum root openings and included angle should be used to reduce the filler metal required. The use of double- instead of single-groove welds on thick plate where welding from both sides is feasible decreases the total filler metal.

To prevent waste of weld metal, welding specifications should avoid the unnecessary use of continuous welds. Welding everything that touches may have no engineering advantages yet increases the amount of weld metal used. Where sealing is required, other methods of postweld sealing can be preferred.

When joining high-strength materials, cost can be minimized by specifying the use of

high-strength weld metal only where required for primary load-carrying welds, in cases where alternate and lower-cost materials are compatible.

Accessibility. An important factor in the design of a weld joint is the accessibility of the members to be welded. The welder needs space to manipulate the electrode when making the weld. Frequently, what appears straightforward on the drawing board may be impractical in the shop or very costly to produce. As a rough estimate, there should be 200 mm (8 in.) above the weld cap to manipulate the electrode or torch and freedom to angle the arc toward either side of the joint by approximately 10°.

Distortion. There are several modes of welding distortion that can change the shape of the finished weldment. These are more severe with larger amounts of weld metal, larger amounts of heat input, and welds further from the center of the thickness of the parts being joined. These same parameters also increase the variability of distortion. Groove welds can be advantageous over fillet welds because they can reduce all of these parameters related to distortion. However, as earlier distortion builds up during progressive construction, it may become more difficult to control the gaps in groove welding, and fillet welding may need to be used.

Fatigue. Detail geometry and joint configuration are the most important variables affecting the fatigue life of a structural detail. Discontinuities associated with a weld detail can behave as preexisting cracks and serve as the initiation site (s) for further fatigue crack propagation. Fatigue cracks tend to grow from local stress concentrations, such as the weld edge on the surface or the weld root of a fillet weld.

The joint designs with poorest fatigue resistance are the nonsymmetrical types, such as strap, tee, and lap joints in which large secondary stresses are also developed. Poor fatigue resistance is also observed in non-load-carrying attachments or reinforcements to a plate strictly due to the stress-concentration effect of those attachments. Bevel welds are usually superior; lack of fusion and incomplete penetration problems often occur in fillet welds or square joints. Size effects must also be considered, because fatigue results obtained from small-scale specimens demonstrate distinctly higher fatigue limits than those obtained in full-scale sections.

The precise location and the magnitude of stress concentration in welded joints depend on the design of the joint and on the direction of the load. Some examples of stress concentrations in butt welds and fillet welds are given in Fig. 4. Concentration of stress at the toes of the weld may initiate cracking, even if the weld does not carry any load. Indeed, the weld toe is often the primary location for fatigue cracking in joints that have good root penetration. In situations where the root penetration is poor or the root gap is excessive, or in load-carrying

fillet welds where the weld throat is insufficient, the root area can become the region of highest stress concentration. Fatigue cracks in these situations start from the root of the weld and generally propagate through the weld (Fig. 5).

Standard methods are available for assessment of the acceptable fatigue stresses in welded structures. The preference for one type of weld joint over another may be affected by the need to prevent fatigue cracking. Groove welds can usually be made with lower stress concentrations than fillet welds. Moving weld ends to low-stress areas can also improve fatigue resistance.

Design Aspects in Prevention of Defects Associated with Arc Welds. Welded joints may include various types of discontinuities, some of which may be considered as defects if the discontinuity is an unacceptable condition for joint performance. The types of discontinuities may be divided into three broad classifications: design related, welding process related, and metallurgical. Design-related discontinuities include problems with design or structural details, choice of the wrong type of weld joint for a given application, or undesirable changes in cross section. Process-related discontinuities include lack of fusion, lack of penetration, porosity, shrinkage voids, inclusion, or other process effects. Metallurgical discontinuities include various types of cracking phenomena (e.g., lamellar tearing, solidification cracking) and the nonuniform distribution (segregation) or concentration of impurities or alloying elements during weld solidification.

The observed occurrence of discontinuities and their relative amounts depend on several factors, including the welding process used, process parameters, the type of weld made, the joint design and fit-up obtained, the material used, and the working and environmental conditions. Typical types of process-related discontinuities are discussed in other articles on specific arc welding processes. However, joint design can be a factor in preventing or reducing the likelihood of some types of metallurgical defects, such as solidification cracks and lamellar tearing.

Fig. 4 Examples of stress concentrations in welded joints

Solidification cracks occur in the fusion zone near the end of solidification. Simplistically, they result from the inability of the semisolid material to accommodate the thermal shrinkage strains associated with weld solidification and cooling. Cracks then form at susceptible sites to relieve the accumulating strain. Susceptible sites are interfaces, such as solidification grain boundaries and interdendritic regions that are at least partially wetted.

Solidification cracking requires both a sufficient amount of mechanical restraint (strain) and a susceptible microstructure. Alloys with a wide solidification temperature range are more susceptible to solidification cracking than alloys that solidify over a narrow temperature range. Simply described, this is because accumulated thermal strain is proportional to the temperature range over which a material solidifies. This temperature range is determined primarily by chemical composition.

The development of shrinkage strains, and the rate at which the strain is applied, also influences the ability of an alloy to solidify without cracking. Because of the limited quantitative understanding of strain development in a solidifying weld, the practical approach taken to minimize the mechanical factor is to reduce the overall weld restraint through judicious joint design and appropriate choice of welding parameters. A simple way to minimize the restraint on a solidifying weld joint is to keep the joint gap to a minimum by designing hardware with good fit-up. Another approach, particularly attractive for small parts, is to design the weld joint as a standing edge.

Lamellar tearing is cracking that occurs beneath welds. It is found in rolled steel plate weldments. It is associated with nonmetallic inclusions such as oxides, sulfides, and silicates that are elongated in the direction of rolling. The net result of these inclusions is a decrease in the through-thickness ductility. The crack originates internally because of tensile strains produced by the contraction of the weld metal and the surrounding heat-affected zone (HAZ) during cooling.

The tearing always lies within the base metal, generally outside the HAZ and parallel to the weld fusion boundary. The problem is caused by welds that subject the base metal to tensile loads in the z-, or through-thickness, direction of the rolled steel. Occasionally, the tearing comes to the surface of the metal but

Fig. 5 Fatigue cracking from the weld root

more commonly remains under the weld (Fig. 6) and is detectable only by ultrasonic testing.

Thicker, higher-strength materials appear to be more susceptible. However, the phenomenon affects only a very small percentage of steel plates. The problem can be avoided by proper attention to joint details. In T-joints (Fig. 6), double-fillet welds appear to be less susceptible than full-penetration welds. Also, balanced welds on both sides of the joint appear to present less risk than large, single-sided welds. In corner joints, common in box columns, lamellar tearing can be readily detected on the exposed edge of the plate (Fig. 7a). The problem can be overcome by placing the bevel for the joint on the edge of the plate that would exhibit the tearing rather than on the other plate (Fig. 7b). Butt joints rarely exhibit lamellar tearing, because weld shrinkage does not set up a tensile stress in the through-thickness direction of the plates.

Fillet Welds

A fillet weld is measured by the leg size (ω) of the largest right triangle that may be inscribed within the cross-sectional area (Fig. 8). Although the actual leg of the fillet weld is defined by the distance from the root of the joint (the point where the members are closest before welding)

Fig. 6 Typical location for lamellar tearing in a T-joint. Stress across the plate thickness (the z-direction) occurs from strains that develop from weld-metal shrinkage in the joint. Lamellar separation is roughly parallel to the fusion line. Lamellar tearing can be prevented when the rolling direction of the plate is oriented perpendicular to the fusion line.

Fig. 8 Leg size (ω) of a fillet weld. t , throat

to the toe, which is the junction of the weld face and base metal, the leg size of the weld may be shorter than the leg in a concave fillet, as shown in Fig. 8. The leg size (ω) is equal to the side of a right triangle but does not extend from root to toe of the weld. Unequal leg size should be avoided, because the longer leg adds nothing to strength but does add to cost.

For efficient weld filler-metal use, the convexity of the fillet weld should be minimized. The 45° flat fillet, very slightly convex, achieves maximum strength and economy.

Throat Size. The shortest distance between the root of the joint and the face of the diagrammatical weld, or the throat (Fig. 8), is a better index of strength of a weld than leg size. It is along this throat (t) that the allowable stress over the minimum thickness is actually applied. The leg size (ω) of a fillet weld simply provides this throat.

Weld Size. Table 1 provides two basic methods of sizing fillet welds, with the first based on achieving the full strength of the adjacent members and the second based on the peak loadings. While the examples here are for steel, the same ideas apply to other arc-welded materials. The limit considered is the shear strength of the fillet weld material considered to be 30% of the minimum ultimate strength required for the weld metal.

When sizing fillet welds, the direction of loading should be considered. Extensive test

data have shown a 50% increase in weld strength under transverse versus parallel loading. However, a weld under transverse loading has less deformation capacity than a weld under parallel loading. So, when accounting for loading direction in a group of welds, both the angle of load on the weld element of interest and the angle of load on the element with the lowest capacity should be considered. AWS D1.1 has three methods for doing this calculation, using equations, tabular data, and graphs.

At one time, two 45° fillet welds that had legs equal to three-fourths of the plate thickness were considered to develop the full strength of the plate for either transverse or parallel loading, assuming that the weld metal was equivalent to the base metal and average penetration was obtained. Originally, calculations for full-strength welds were based on thinner plate welded on both sides, with the welds extending full length. Although this ratio of 0.75 is true for the old values of E60 weld metal and A 7 low-carbon steel prior to 1969, these values are not necessarily applicable when working with the wide range of steels and weld-metal strength levels available today (2011). Table 2 shows how the full-strength factor varies with weld-metal and plate strength levels for a number of steel grades. Suggested factors for the weld size in relation to plate thickness in rigidity or non-full-strength designs are also given.

25	2560	3840			

Weld Placement. In addition to sizing, the placement of welds in the most effective load-carrying positions can conserve weld metal. Welds that carry uniform loads along their length can carry much greater loads for the same weld size as welds that have part of their length loaded very lightly. A common example of this is a weld of a connection in bending where welds across the neutral axis must be much larger or longer to carry the same loading as welds remote from the bending neutral axis. Therefore, selection of the most effective weld position facilitates the use of smaller welds.

Comparison of Fillet and Groove Welds. Cost is the major consideration in the choice between fillet or groove welds. Although simple fillet-welded joints are the easiest to make, they may require excessive weld filler metal for larger sizes. The fillet welds in Fig. 9(a) are easy to apply and require no special plate preparation. Because these welds can be made with large-diameter electrodes using high welding currents, the deposition rate is high. However, the amount of weld metal increases in relation to the square of the leg size.

The double-bevel groove welds in Fig. 9(b) have approximately one-half the weld area of the fillet welds (Fig. 9a) but require extra preparation and the use of smaller-diameter electrodes with lower welding currents to place the

initial pass without melt-through. As plate thickness increases, this initial low-deposition region becomes a less important factor, and the higher cost factor (preparation and operation expenses) decreases in significance.

One means of deciding at what point in plate thickness double-bevel groove welds become less costly than fillet welds is from analysis of the cost of welding, cutting, and assembling. By reading upward from the plate thickness in Fig. 10, the relative costs of fillet welds or double-bevel welds of 45° or 60° can be determined. Thus, for smaller plate sizes, the 45° double-bevel groove weld is more expensive, but as plate thickness increases, the cost of fillet welds is higher. The accuracy of this technique depends on the accuracy of the cost data used in constructing the curves.

The single-bevel groove weld in Fig. 9(c) requires approximately the same amount of weld metal as the fillet welds in Fig. 9(a). Thus, there is no apparent economic advantage. There are some disadvantages, however. The single-bevel joint requires bevel preparation and, initially, a lower deposition rate at the root of the joint. From a design standpoint, the single-bevel groove weld offers a more direct transfer of force through the joint, which provides better service under fatigue loading.

Although the full-strength fillet welds (Fig. 9a) would be sufficient, some codes have

lower allowable limits for fillet welds and may require a leg size equal to the plate thickness. In those cases, the cost of the fillet-welded joint may exceed the cost of the single-bevel groove in thicker plates. Also, if the joint is positioned so that the weld can be made in the flat position, a single-bevel groove weld would be less expensive than fillet welds, because one of the fillets would have to be made in the overhead position, a costly operation (Fig. 11).

Groove Preparation Welds

The important design considerations for groove-weld selection are the depth of groove included angle, root opening, root face, and radius at root. Both complete joint penetration and partial joint penetration groove welds can be designed. The included angle, which is the angle of the groove weld, and the root opening, which is the portion of the joint before welding where the weld members are closest, are directly related. The root opening should be increased as the included angle decreases (Fig. 12) to allow for electrode access. The root face of a groove preparation, which helps to prevent melt-through at the root opening, is the portion of a weld groove face that is adjacent to the root of the joint. The radius at the root (groove radius) is the radius used to form the shape of a J- or V-groove joint.

Included angles vary from 20 to 60° (Fig. 12). Generally, the smaller the included angle, the less weld metal is required. The included angle and root opening must be sufficient to

Table 2 Weld size factors for full-strength and rigidity fillet welds

Steel ASTM grade	Yield strength of base metal		Strength level of weld metal			
	MPa	ksi	E70	E80	E90	E100
Full strength			Ratio of weld leg length to plate thickness for double-longitudinal fillet welds at full plate strength			
A36	248	36	0.56
A572-50	345	50	0.76
A572-65	448	65	1.00	0.86	0.77	...

permit the electrode access to the root of the joint and to ensure good fusion to the side walls with multiple passes. All four preparations in Fig. 12 are acceptable; all are conducive to good welding procedure and good weld quality. Therefore, selection usually depends on root opening and joint preparation, which directly affect weld cost (pounds of metal required).

Although the smaller included angle apparently requires less weld metal, it also requires a wider root opening. The wider root opening may defeat any savings achieved by the need for less metal in a narrower included angle, particularly in thinner plates. Thus, with 16 mm (5/8 in.) plate, a 60° included angle in a double-bevel joint, with its 3 mm (1/8 in.) root opening, is more economical than a 20° included angle with a 13 mm (1/2 in.) root opening. However, with 53 mm (2 in.) plate, the same combinations of root opening and bevel angle make the 20° included angle the choice, with less weld metal than the 60° angle.

Root openings are the separations between the members to be joined and provide electrode access to the root of the joint. The smaller the angle of bevel, the larger the root opening must be to obtain good fusion at the root.

If the root opening is too small, root fusion is more difficult to obtain, and smaller electrodes must be used, thus slowing the welding process. If the root opening is too large, weld quality does not suffer with use of a backing bar, but more weld metal is required, thus increasing welding cost and tending to increase distortion.

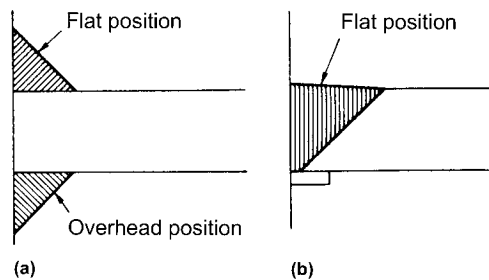

Fig. 11 Comparison of welds in the flat position in a T-joint. Fillet welds (a) are more expensive than a single-bevel groove joint (b) because of the overhead weld required.

Fig. 12 Relationship of included angle size to the root opening

Bevel angles, because they affect the size of the root opening, also affect accessibility to all parts of the joint and the quality of fusion throughout the entire weld cross section. Accessibility can be improved by compromising between maximum bevel and minimum root opening. As in Fig. 13, the importance of maintaining proper electrode angle in confined quarters may affect the angle of bevel. The minimum recommended bevel for the conditions in Fig. 13 is 45°.

Double-groove weld joints reduce the amount of weld filler metal required for single-groove preparations by approximately half (Fig. 14). The decreased welding reduces distortion and facilitates alternating weld passes on each side of the joint, which further reduce distortion, at the cost of moving the welder or the part to switch sides.

Joint preparation after assembly has not always been considered acceptable. This practice—assembly and tackup before gouge preparation of V-grooves for welding—is practical and less costly in certain applications. V-groove joints for complete- and partial-penetration welds may be made prior to or after fitting.

Groove- and Fillet-Weld Combinations

Combinations of partial-penetration groove welds and fillet welds, such as those shown in Fig. 15, are used for many joints. The AWS prequalified, single-bevel groove T-joint, for example, is shown reinforced with a fillet weld.

Combination Double-Bevel Groove and Fillet Welds. The combination weld joint in Fig. 16 is welded using a partial-penetration double-bevel groove weld and two fillet welds. The plates are beveled to 60° on both sides to give a bevel whose depth is at least 29% of the thickness of the plate (0.29t). After the

Fig. 13 Relationship of electrode angle on bevel angle

Fig. 14 Comparison of weld metal required for single- and double-V-groove weld joints

grooves are filled, they are reinforced with fillet welds of equal cross-sectional area and shape. This joint has a strength equal to that of the plate. These partial-penetration double-bevel groove joints have 57.8% of the weld metal of full-strength fillet welds. Although they require joint preparation, the 60° angles allow the use of large electrodes and high welding current.

Comparison of Single-Bevel Groove, Fillet, and Combination Welds. When full-strength fillet welds are not required in the design, savings can often be achieved by using partial-penetration groove welds. A 45° partial-penetration single-bevel groove weld with a 25 mm (1 in.) throat requires only one-half the weld area needed for a fillet weld. For smaller welds, however, this weld may not be as economical as the same-strength fillet weld, because of the cost of edge preparation and the need to use a smaller electrode and lower current on the initial pass.

Throat Size. Similar to the use of the minimum throat for fillet or partial-penetration groove welds, the minimum throat is used for designing a partial-penetration combination groove weld. As Fig. 17 shows, the allowable unit force for a combination weld is not the sum of the allowable unit forces for each portion of the combination weld, which would result in a total throat larger than the actual.

Edge Preparation

When considering whether to construct the weld joint using any of the groove welds—bevel, V-, J-, or U-groove—the cost of preparing the plate and weldment handling must be weighed

Fig. 15 Combination groove- and fillet-welded joints

Fig. 16 Partial-penetration double-bevel groove joint. t, plate thickness. Depth of bevel is 29% of plate thickness.

against the savings in weld metal or other advantages of the groove-preparation welds.

Methods of cutting the groove-weld preparations include machining, chipping, shearing, grinding, flame (gas) cutting, gas gouging, and air carbon arc gouging. The choice of the most economical means depends on factors such as the type of material, section characteristics, quality required, and available equipment.

Edge preparations are cut into the weld member using flame cutting, shearing, sawing, punch-press blanking, nibbling, or cutoff machining (for bar and tube stock). In addition to cost, selection of the appropriate cutting operation depends on the quality of the edge for fit-up and whether a bevel is needed.

Because they are easily prepared by gas cutting, bevel and V-groove welds are more widely used. Although they offer the advantages of less weld filler metal and a more accessible work area, J- and U-groove preparations are not as applicable because they usually require machining or air carbon arc gouging, more costly methods of edge preparation. Thus, the bevel-groove preparation with a backing bar may be more economical than a J- or V-groove. If a plate planer is available, however, J- or V-groove preparations are often specified because of reduced weld-metal requirements.

For single-bevel and single-V-groove preparations, single-tip flame-cutting torches are used because only one cut is necessary. Double-bevel or double-V-groove preparations are usually made with multiple-tip flame-cutting

torches, which facilitate completion of the cut in one pass of the cutting machine.

Root faces on edge preparations provide additional thicknesses of metal to minimize melt-through, the tendency of the weld metal to pass through the root opening during welding. Feather-edge preparations, which provide only minimal thickness at the root opening, are more prone to melt-through than weld joints with root faces, especially if the gap becomes too large, and they require more weld filler metal to fill the joint.

A root face is more difficult to obtain than a feather edge. A feather edge can be achieved by one cut with a torch, while a root face usually requires two cuts or possibly a torch cut plus machining. If a 100% weld is required, a root face usually requires back gouging. When welding into a backing bar, root faces are not used because they decrease fusion at the root of the joint into the bar.

Spacer bars may be required to prevent melt-through when very large root openings are used on double-grooved joints (Fig. 18d). A wide gap may be unavoidable for practical reasons, such as difficulty in pulling the parts together for desired fit-up.

The metal spacer bar serves as a backing and maintains root opening throughout the course of the welding operation. When using a spacer bar, the joint must be back gouged to sound metal before the second side is welded.

Backing bars, another edge preparation frequently required when the root opening is

excessively large, are also used when welding must be done from one side (Fig. 18). Composed of metal, weld metal, or nonmetal, a backing bar is placed under or behind a joint to enhance the quality of the weld at the root. The bar usually remains in place after welding, becoming an integral part of the joint.

Steel backing bar material should conform to the base metal, maintaining a close contact with both edges to avoid trapped slag at the root of the weld joint. Feather edges are recommended on the weld members for best performance of backing bars in ensuring weld quality. To hold the backing bar in place, short intermittent tack welds should be used, preferably staggered to reduce any initial restraint of the joint (Fig. 19).

Back gouging, or removal of metal at the weld root, is often necessary to eliminate fusion defects at the root face when a butt weld is made without a backing bar. Without back gouging, penetration (the distance weld metal and fusion extend into a joint) may be incomplete (Fig. 20). Proper back gouging extends deep enough to expose sound weld metal and creates a contour that provides complete accessibility to the electrode (Fig. 21). Means of back gouging include grinding, chipping, and gouging. The most economical method, gouging, also leaves an ideal contour for subsequent beads.

Power Sources for Arc Welding

Lee Allgood, The Lincoln Electric Company

POWER SOURCES for the major arc welding methods are discussed in this article. The characteristics and technology of power sources are discussed along with suggested criteria for assuring that a power source selection can safely deliver the desired output and yield long service life when properly used. Arc welding consists of a number of distinct processes that require specific types of electrical power (amps \times volts) for the welding of many different materials in various thicknesses, joint configurations, and welding position. Therefore, there are a number of different types of power sources (welders) available.

Power Source Characteristics

Electric arc welding encompasses various methods, which are introduced in the article "Overview of Welding Processes" in this Volume and are covered in more detail in separate articles for each method. The methods of arc welding include:

- Shielded metal arc welding (SMAW)
- Gas tungsten arc welding (GTAW)
- Flux cored arc welding (FCAW) with some type of gas shielding or without requiring gas shielding
- Gas metal arc welding (GMAW) with short arc, spray arc, or pulsed arc modes of operation, as described subsequently
- Submerged arc welding (SAW) using direct current (dc), the most common, or alternating current (ac), with some operations using a number of independent arcs working in a tandem configuration (each arc requiring its

own power source) or two electrodes arranged together, with power from a common welder (power source)

- Plasma arc welding (PAW)

The type of current and voltage suitable for each of these processes is shown in Table 1. The power source output characteristics for all of these welding methods may be loosely described as constant current, constant voltage, and waveform control. As noted, GMAW also includes three different modes of operation. Short arc GMAW is loosely defined as using an arc voltage less than 24 V. (See the section "Short Arc GMAW Power Sources" in this article.) Spray arc GMAW usually involves arc voltages above 24 V and uses an argon-base shielding gas mixture. Pulsed arc, or waveform-controlled arc, operation may involve both short arc and spray arc in some form of controlled manner.

Typical volt-amp output curves are shown in Fig. 1 to 5. Figure 1 is typical of constant current welders primarily designed for manual stick electrode welding (SMAW). Setting the power source for maximum open-circuit voltage results in a very steep output curve, as shown by "A." This allows minimum current change but a relatively large voltage change, which is desirable for out-of-position welding with smaller-sized electrodes. Curve "B" allows a relatively large change in welding current as the arc length is manipulated during welding. This can be beneficial when welding in the flat and horizontal positions using larger electrodes. Most dc SAW uses constant current, especially for larger-sized single-pass welds.

Although the term *constant voltage* is used to describe the amps-volts relationship of the

power sources used for a number of arc welding methods, the output does vary somewhat as current increases (Fig. 2). Curve "A" in Fig. 2 is a common output used for the FCAW methods and is nearly a flat curve. Curve "B" is typical of the output used for GMAW. This curve usually droops 3 to 4 V per 100 A. This is sometimes referred to as slope control. Curve "C" is seldom used any longer but is designed to rise slightly as current increases, thus offsetting the effects of internal power source and cable heating at higher currents when welding with FCAW processes.

Waveform-controlled welding (Fig. 3) is also known as pulse welding (PW) but with some significant differences that enhance the process. Earlier welders for PW usually had a fixed number of pulses per second and permitted adjusting only the peak and background currents. Present-day PW machines permit changing the shape and frequency of the pulse. By doing this, optimum arc characteristics can be established for welding any type of material, using any appropriate type of gas and providing optimum control when welding thin or thick material while using small- or large-diameter electrodes. Some

Table 1 Type of current and voltage suitable for each arc welding process

Type of current and voltage(a)	Type of welding(b)						
	SMAW	GTAW	FCAW/gas	FCAW/no gas	GMAW	SAW	PAW
Constant current dc	X	X	X	X
Constant current ac	X	X	X	...
Constant voltage dc	X	X	X	X	...

ac custom sine wave	...	X
Waveform dc	X	...	X

(a) dc, direct current; ac, alternating current. (b) SMAW, shielded metal arc welding; GTAW, gas tungsten arc welding; FCAW, flux cored arc welding; GMAW, gas metal arc welding; SAW, submerged arc welding; PAW, plasma arc welding

Fig. 1 This is typical of constant current welders primarily designed for manual stick electrode welding (shielded metal arc welding). OCV, open-circuit voltage

machines allow altering the waveform by using a number of external controls. Other machines can incorporate a library of predetermined, optimized waveforms. These are then accessed by a relatively simple external control. Today (2011), most of these machines incorporate advanced inverter technology.

Conventional sinusoidal ac welding (Fig. 4) has been and still is a very important type of current used for arc welding. It is the dominate type used for small, limited-input SMAW machines. In larger, industrial-sized machines, it is usually included as an option along with dc output. With larger-sized electrodes, ac virtually eliminates magnetic interference with the arc (arc blow) and is the preferred choice. Alternating current was, and largely still is, the preferred method by which aluminum and its alloys are GTA welded. Alternating current has traditionally been used for SAW applications where arc blow is a problem with dc or where larger-sized electrodes are used at high current. Multiple electrode configurations necessitate the use of ac. The use of ac with single-electrode SAW has sometimes been limited, especially on short-length welds, because of difficulty with arc starting.

Some square-wave-type power supplies (Fig. 5) have been built as specialized machines

specifically for GTAW for some time. The use of newer inverter technology has permitted the building of powerful machines designed primarily for SAW. These machines do not exhibit the arc striking problem mentioned in the Fig. 4 discussion. Arc stability is further enhanced because significantly less time is spent transitioning from positive voltage to negative voltage. Frequency from 0 (dc) to 80 Hz is easily accomplished by using external controls. This has been shown to have beneficial effects when welding different material thicknesses. These machines are usually software controlled and also provide rapid responses to changes in the weld puddle. The wave may be unbalanced to favor the positive side for increased penetration or to favor the negative side to increase deposition rate (Fig. 5b, c).

While there is some commonality in the power source output requirements between these processes, each process has many unique requirements. The type and thickness of material to be welded, size and type of electrode, shielding type, position of welding, and the weld joint influence how a particular power source will perform. More detailed information on each of these processes is available in other articles of this Handbook as well as from several other sources (Ref 1–3).

One common requirement is that the power source be designed to deliver the required power—current and voltage—at a sufficiently sustained rate to satisfy the job requirements. Sustained rate is expressed by percent duty cycle. Duty cycle (Ref 4) is the time a power source must operate at rated load within a 10 min period, expressed as a percentage, and not to exceed a stated temperature rise from a specified ambient temperature.

Power sources with single-phase ac input voltage are common and are available with outputs of ac only as well as ac/dc output. Welders with ac output are available in a wide range of output sizes from 80 to 1500 A. The ac/dc voltage output welders are usually available from 250 to 500 A output ratings. Typical schematic diagrams are illustrated in Fig. 6 to 8.

The dc current output is usually achieved by placing a rectifier in the secondary circuit of the power transformer, as shown in Fig. 7. These machines are primarily used for SMAW with ac or dc welding. Machines of this general size are readily available.

Power sources in the range of 175 to 350 A ac and ac/dc outputs and configured with additional controls suitable for GTAW welding are available. The smaller-sized machines, 80 to 250 A ac output type, are commonly used in

Fig. 2 Output variation of constant voltage supply as current increases

Fig. 4 Conventional sinusoidal alternating current (ac) for arc welding

Fig. 5 Some square-wave-type power supplies

Fig. 6 Typical small, single-phase, alternating current output transformer welder

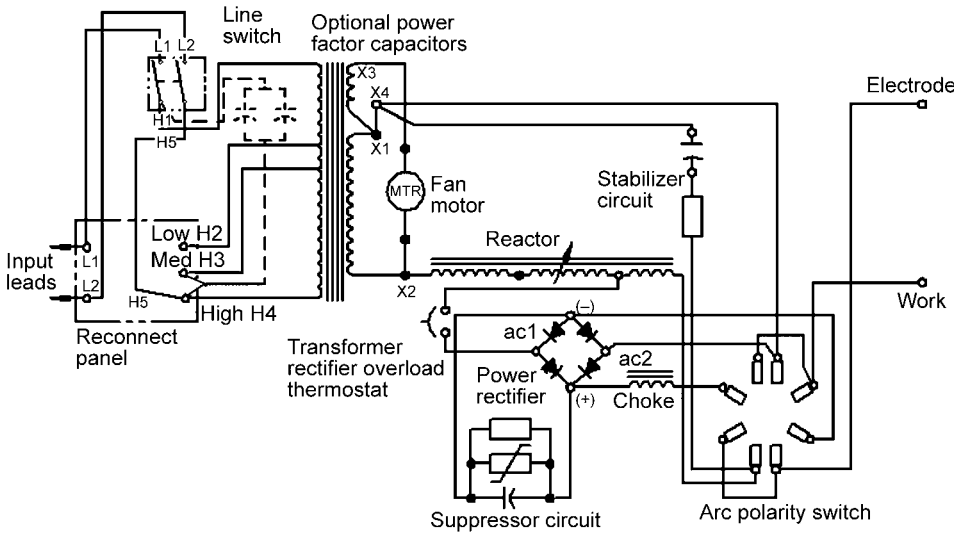

Fig. 7 Single-phase, alternating current/direct current, constant current welder

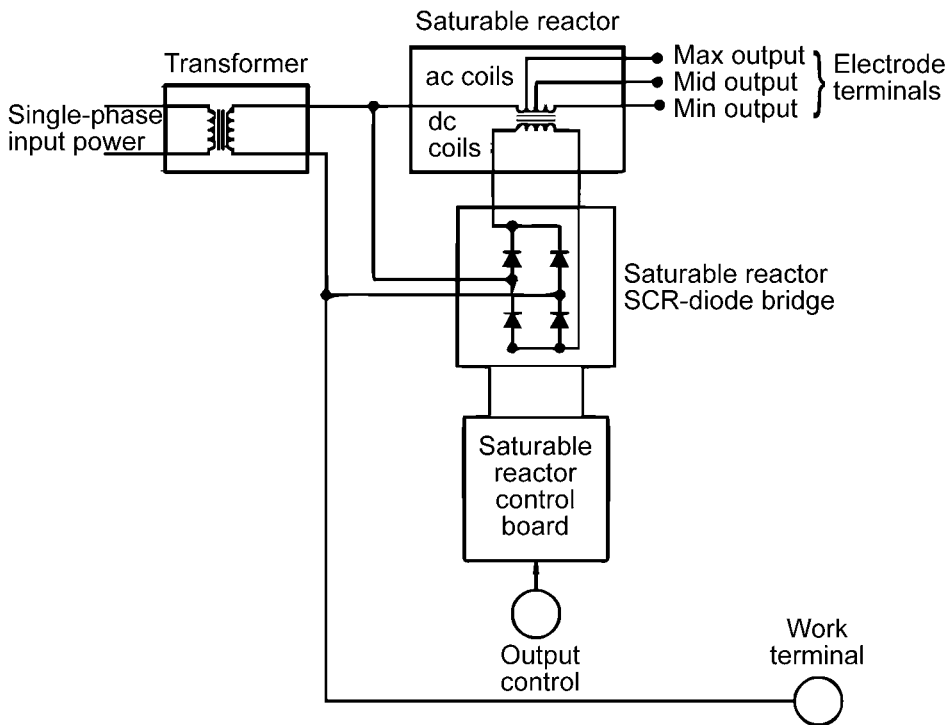

Fig. 8 Large-output, alternating current (ac), single-phase welder. dc, direct current; SCR, silicon-controlled rectifier

small machine shops, schools, maintenance departments, and by consumers. The smallest of these machines (80 to 225 A output rated) are usually designed to operate on 230 V, single-phase input and are rated at a 20% duty cycle. There are some machines rated at 80 A output that will operate on 120 V single-phase input. These machines have very limited output and duty cycle.

When a number of single-phase welders are connected to a single-phase power system or

to the same phase lines of a three-phase system, the supply line current draw will be the sum of the input current for each connected machine. If a number of machines are connected to the same phase of a three-phase system, significant line imbalance can occur. This can result in requiring larger supply lines and, perhaps, increased utility power costs. (See the section "Other Operational Costs" in this article.) The solution to this, whenever possible, is to establish groups of three machines and then connect

each machine in a group to a different pair of phase lines, as shown in Fig. 9. In group "A," the sum of the input current for each of the welders is drawn from lines L2-L3. In group "B," the current draw is balanced across all three input lines. The current draw for each line is 1.73 times the line draw for each welder.

There are also single-phase input, silicon-controlled rectifier, constant voltage dc output machines that are integrated with built-in wire feeders for FCAW and GMAW. These usually have a limited duty cycle at rated amperage and voltage but are adequate for many production welding applications involving smaller-diameter electrodes.

Three-phase input machines are the most commonly used machines for industrial applications today (2011). They are available as:

- Constant current machines for SMAW, GTAW, SAW, and PAW
- Constant voltage machines for FCAW and GMAW
- Combination constant current/constant voltage machines based on rated output that are well suited for SMAW, GMAW, and SAW

These machines are usually available in rated output sizes ranging from 250 to 1500 A. Typical electrical schematic drawings for this group are shown in Fig. 10 to 12.

Inverter-based power sources began to appear in about 1980 as a solution to requests for increased portability and to allow the operator ready access to controlling welding current at the point of use, especially on large construction sites. Inverter-based welders have become increasingly important and can be made to produce excellent output characteristics for SMAW, FCAW, GMAW, GTAW, and SAW. Most are configured for a specific process or combination of processes:

- SMAW
- SMAW, GMAW, FCAW
- GMAW and FCAW
- GTAW
- SAW

Inverter-based welders are available in output sizes ranging from 100 to 1000 A. The conversion from input voltage frequency (60 or 50 Hz) to high frequency (20 KHz or more) facilitates transforming the line voltage to welding voltage with transformers that are more efficient, smaller, and much lighter in weight than conventional step-down transformers. The lower voltage is then rectified and filtered to provide a smooth dc output. Figure 13 is a basic diagram of a three-phase input inverter. Figure 14 visually compares a typical 275 A rated inverter unit to a conventional 250 A ac/dc welder. Figure 15 illustrates a visual size comparison between a 400 A constant current/constant voltage (CC/CV) transformer welder and a 450 A inverter-based CC/CV welder.

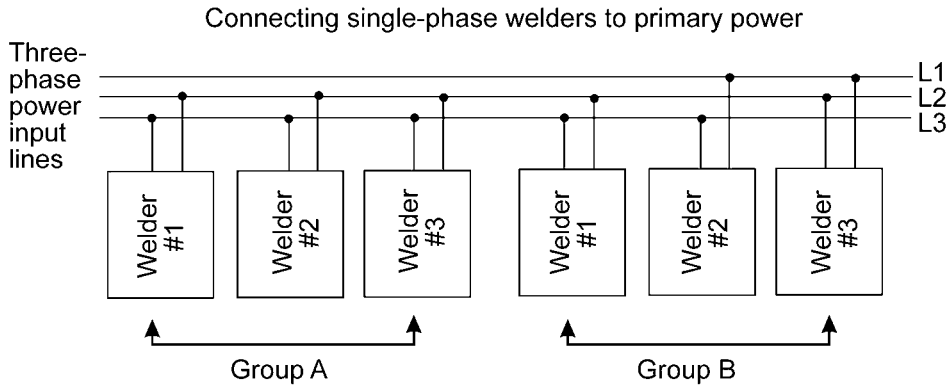

Fig. 9 Groups of three machines with connections to different pairs of phase lines. Each group consists of three single-phase welders with the same input current rating.

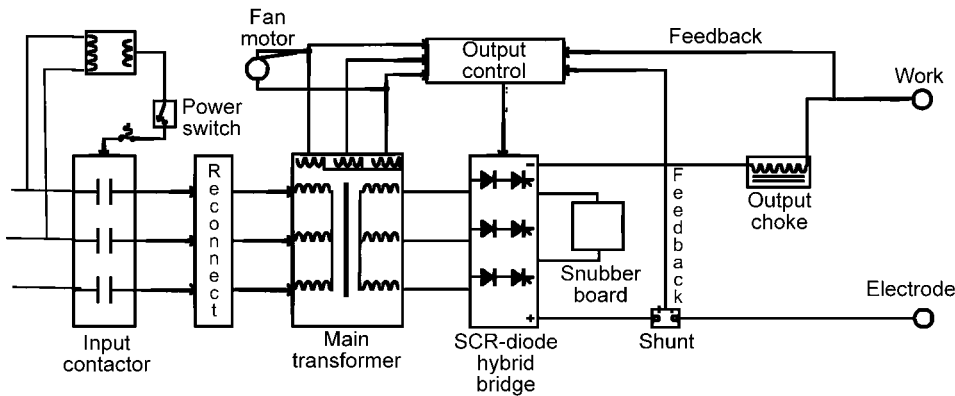

Fig. 10 Three-phase, constant current, direct current welder. SCR, silicon-controlled rectifier

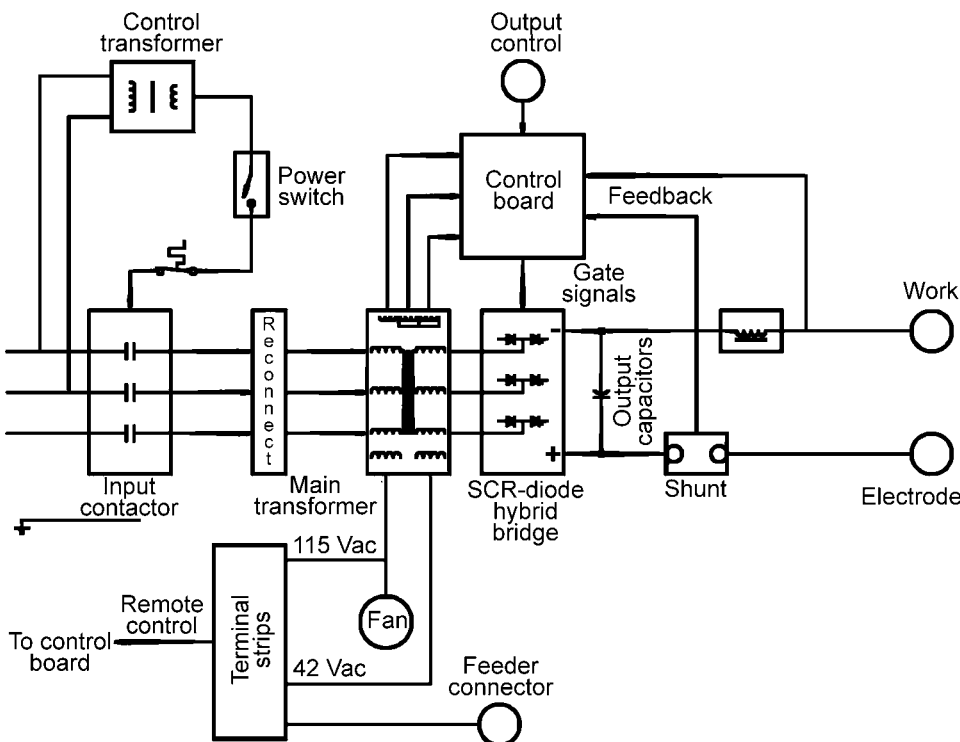

Fig. 11 Three-phase, constant voltage welder. SCR, silicon-controlled rectifier

Some of the smaller-rated units are designed so that they will operate on either three-phase or single-phase input voltage.

The versatility of inverter technology with solid-state electronics makes it possible for the designer to include many features with appropriate output characteristics within a single machine. Specific arc dynamics can be studied and replicated for all processes. For this reason, it is highly recommended that manufacturer's specifications be carefully reviewed.

Power Source Efficiency. The efficiency of a power source is a major factor in determining the cost to operate the welder. Figure 16 is a graphical comparison of the major power source groups. There are no specific industrial standard values for a power source, so each manufacturer's specifications should be checked. Typically, a power source will be more efficient as the output load approaches its rated value. The actual energy cost will be a combination of time at load and time at idle.

Other Operational Costs. There is another consideration in determining the cost of operation of a particular machine and that is the power factor of the unit. Power factor is related to the amount of current drawn from the power line in excess of what is needed to supply the operational energy. Power factor is usually expressed as a percentage number. The lower the number, the greater the current demand on the input line. It is not uncommon for power companies to impose an extra charge for systems operating below some fixed value. Poor power factor may also require heavier-gauge input wiring. One source for further information about power factor and operating costs is available from Cos Phi Inc. (Ref 5).

Short Arc GMAW Power Sources

Short arc welding is a method within the GMAW process, and it requires power sources with specific output characteristics. Traditionally, GMAW short arc (GMAW-S) power supplies used a CV transformer with varying means to control the magnitude of short-circuit current, usually using fixed or variable slope (Fig. 2 and 17) and fixed or variable inductance to control the rate of current response (Fig. 18). As inductance is increased, the rate of current change from short-circuit current to operating current is slowed. Properly adjusted, this provides increased fluidity in the weld puddle and results in improved weld appearance and reduced spatter.

Hybrid inverter power sources have been developed that cannot be classified as either true CC or CV power sources. Instead, they deliver current of a suitable waveform that uses continuous feedback information to control the short-circuiting dynamics. As with pulsed GMAW welding, the frequency of shorting may be set to optimize the arc. These power sources are ideally suited for the GMAW-S process.

Fig. 12 Three-phase, constant current/variable voltage, direct current power source. SCR, silicon-controlled rectifier

inbred from years of welding experience. Typically, these machines offer a source of auxiliary dc power. This is suitable for temporary lighting or for universal voltage-powered hand tools. These machines are usually available in output rating sizes from 200 through 600 A with various duty cycles.

Alternator generators with rectified power output have largely replaced dc generator machines. In combination with solid-state component technology configured to operate in switch mode, these machines can be suitable for most of the welding processes. They are available with dc output and CC/CV welding modes. While engine power is still the limiting factor in establishing maximum welding current output at rated voltage, many of these machines have engines that permit nameplate rating at 100% output duty cycle.

Some machines are manufactured to offer other significant capabilities that allow them to function as portable generators, including:

- 120 V single-phase ac output
- 240 V single-phase ac output
- 240 V three-phase ac output

Machines offering any or all of these capabilities usually include appropriate connection plugs, circuit breakers, fuses, or ground fault circuit interrupter devices. Output frequency is regulated so that they may be used for true emergency power.

There are a few machines that also include a built-in air compressor. The pressure and cubic feet per minute output is suitable for most air-driven portable tools and carbon arc scarfing. Because of the versatility and wide choices within this family, manufacturer's specifications should be carefully considered.

Figure 19 is a schematic of a typical machine in this group, providing both three-phase and single-phase ac auxiliary output.

Multiple Arc (Multiple Operator) Power Sources

These actually represent a welding system rather than a single power source. Typically, one central power supply provides the output to a number of independent welding locations. These units are of special interest for welding projects that require a number of welding arcs within close proximity to each other, such as large construction projects, power plant and chemical plant turnaround, large offshore drilling platforms, and so on. There are two systems in common use:

- Resistance grid
- Multiple dc positive welders using dc switch-mode converters

Resistance grid systems generally are suitable only for SMAW and carbon arc air

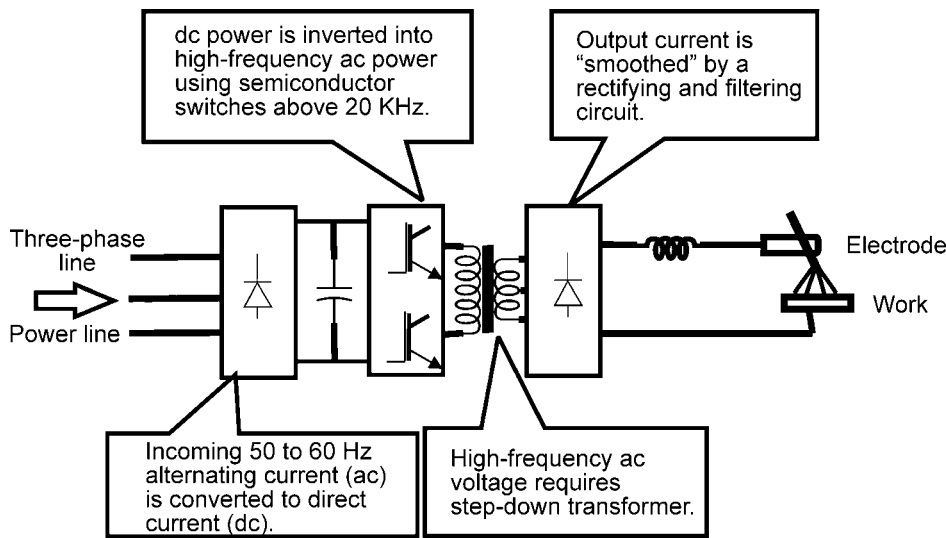

Fig. 13 Basic inverter diagram

Engine-powered welders have long been the power source of choice and still are today (2011) when portable welding power is needed. These machines are available from 125 to 600 A ratings. They may be powered by:

- Air-cooled engines
- Water-cooled gasoline engines
- Water- and/or air-cooled diesel engines

There are three fundamental types of engine-powered welders: generator, alternator, and alternator rectified.

The pure alternator output machines are usually small, air-cooled, engine-powered, limited-output machines of low duty cycle

that provide only for SMAW. These machines usually deliver only ac or dc. They usually provide a source of 120 or 240 V single-phase auxiliary power. The waveform of the auxiliary power may not be well regulated; therefore, it is not a substitute for a comparably sized power generator for use with sensitive electronic equipment and appliances but is amply suited for emergency power lighting and electric tools. Maximum output is usually limited by available engine horsepower.

The dc generator machines have been in use for years and are still preferred by some welding operators for demanding SMAW applications. This is largely a preferential legacy

Fig. 16 Typical efficiency range of different types of power sources

scarfing. The power source is usually a three-phase, 100% duty cycle, dc constant voltage, 80 V output welder. Welding is accomplished by connecting individual resistance grid boxes across the power source welder output. The arc polarity dc+ must be the same for all attached units. A typical block diagram is shown in Fig. 20.

This system is inherently inefficient because the welding arc is usually in the range of 18 to 30 V. A 25 V, 150 A welding arc requires 3.75 kW of energy, but the power source must deliver 80 V at 150 A or 12 kW of energy. This amounts to an output power efficiency of only 26.6%. The efficiency of the power source itself would bring this efficiency down a bit more.

Multiple dc+ Welders. This system incorporates solid-state technology to permit SMAW, FCAW, GMAW, and carbon arc air scarfing. Unlike the resistance grid system, any constant current welder with an ample current output rating may be used. The connected units use advanced solid-state technology known as buck converters or choppers operating in switch mode (Fig. 21).

Each individual unit incorporates a power-off, CV output, CC output switch. All of the units connected to the main power source do not need to be welding with the same process. The individual units are usually rated for continuous output at 350 A, 34 V dc+. The number of units that can be connected and used is dependent on the rated kilowatt output capacity of the power supply. This can be approximately calculated using the formula:

$$\begin{aligned} \text{Power source capacity (Volts} \times \text{Amps)} \\ = 1.1 \times \text{Number of units} \times (\text{Volts} \times \text{Amps}) \end{aligned}$$

It is unlikely that all units will be operating at any one time or that all will be using the same output settings. Some units may be operating

in the SMAW mode and others in FCAW. For this reason, the aforementioned formula should be considered a conservative estimate. Figure 22 illustrates a typical unit setup. All connected units operate with the electrode positive. The advantage with this is that the operator has almost any process readily available with fully presettable current and voltage output. Operator units may be paralleled for high current output to permit carbon arc air scarfing or resistance heating.

Power Source Selection Considerations

A welding machine should deliver the desired output, provide adequate service life durability, and be safe to use when properly installed and operated. The following items are some considerations when selecting a power source for desired output and adequate service life durability are:

- Duty cycle (Ref 4) that the power source must operate
- Electrical installation and wiring requirements
- Output capability of the power source
- Servicing and identification information
- Safety in use of properly installed and operated machines

Reference 6 identifies basic equipment characteristics to be included on the nameplate of the machine:

- Manufacturer's type designation and/or identification number
- Maximum open-circuit voltage
- Rated load volts
- Rated load amperes
- Duty cycle at rated load
- Maximum rated speed of generator in revolutions per minute at no load (for engine-powered machines)
- Rated frequency(s) of power supply
- Number of phases of power supply
- Rated input voltage(s) of power supply

In the United States, electric-powered machines should be installed in accordance with the National Electrical Code. National Fire Protection Association (NFPA) 70, Article 630 (Ref 7) describes installation requirements. It is possible that local electrical codes may impose more rigorous requirements than the National Electrical Code. Installations outside the United States should be in compliance with local codes or regulations.

The operating environment of a power source requires careful consideration, such as whether it will be subjected to weather elements, whether workers and operators will be in close proximity to the power source (creating possible welding spatter or grinding particles), and whether the welder may be subjected to falling

or blowing foreign material. Standards for various levels of protection have been developed by the International Electrotechnical Commission (IEC) (Ref 8). Standards IEC 60529 (Ref 10) and IEC 60934-1 classify the various degrees of protection provided by electrical enclosures from intrusion of solid objects (including body parts such as hands and fingers), accidental contact, and water as follows.

A welder designed for indoor use should have a protection rating of at least IP21S. Welders that are to be used outdoors should at least meet the requirements of IP23S. In these designations:

- The first digit indicates the level of protection that the enclosure provides against

access to hazardous parts (e.g., electrical conductors, moving parts) and the ingress of solid foreign objects.

- The second digit indicates protection of the equipment inside the enclosure against harmful ingress of water.
- The ending designator letter “S” indicates moving devices are standing still or stationary during water testing.

For example, in the aforementioned rating of IP21S, the “2” designates protection from the ingress of fingers or similar objects greater than 12.5 mm (0.5 in.), and the “1” designates protection from vertical dripping of water. A “3” designates protection from spraying water. The rating IP23S is for storing welders out of doors but not intended to be used outdoors during precipitation unless otherwise sheltered. An abbreviated presentation of these ratings may be found at http://wikipedia.org/wiki/IP_code.

For guidance on safe installation and use of arc-welding equipment, welders should be used and welding should be done at least following the safe practice recommendations of AWS/ANSI Z49.1, “Safety in Welding, Cutting, and Allied Processes” (Ref 9), and the article “Safe Welding Practices” in this Volume.

R. Bruce Madigan, Montana Tech of the University of Montana
David R. DeLapp, Vanderbilt University

WELDING is a complex, multidisciplinary process in which both intelligent and conventional control techniques have been successfully applied to mechanized welding systems in an attempt to control one or two system parameters, such as penetration, bead width, heat-affected zone, or cooling rate. However, to develop significantly higher degrees of autonomy, a weld controller must be able to regulate a number of functions of the welding process over an extended period of time and under varying process conditions and disturbances. Advances in the fields of artificial intelligence, operations research, sensor networks, and distributed control, improvements in network bandwidth and computational performance, and the availability of low-cost sensors and single-board computers offer the opportunity for collaboratively monitoring and controlling as many relevant process parameters as possible to achieve more robust, highly autonomous, general weld process controllers.

Although great strides continue to be made in the research community, the flexibility and judgment of a human welder has yet to be transferred successfully to a mechanical system. This article provides an overview of the research associated with the development of closed-loop feedback control of the arc welding process.

Overview on Welding Process Control

In a typical manual arc welding situation, a human welder can observe the sights, hear the sounds, and sense the reactive forces from the welding process. Using this feedback information, a welder can assess the welding process with respect to its desired state, make minor changes in the weld parameters under his/her immediate control (e.g., weld current, voltage, travel speed and electrode orientation with respect to the joint path), and maintain proper torch orientation and distance in an effort to control the desired state of the weld. Adapting these sensory inputs to machine control and making the appropriate decisions is a challenging task.

The human operator makes decisions based primarily on past learned experience. For instance, when a weld is performed in the vertical position, a seasoned welder knows that when the weld pool gets too large the liquid will run out of the pool, leaving a crater. Acquiring the skill and knowledge to perform complicated tasks, such as full-penetration vertical-up or overhead welds, is the result of countless hours of practice through acquired rule-of-thumb techniques. Explaining this knowledge involving precise visual cues to another person or to a knowledge engineer is difficult.

Most welding automation techniques did not evolve from traditional manual methods. Instead, control engineers have applied conventional quantitative techniques of system analysis through the use of difference, differential, and integral equations to model and control the mechanized aspects of welding. Applications involving through-the-arc sensing, such as arc voltage control and seam tracking, have met with a great amount of success, and they have found their way into commercial use and have been successfully used in industry (Ref 1–3). The sensing technique is low cost, reliable, and nonintrusive. Both of these automated solutions are mechanistic, governed by electromagnetic laws, and employ a single-input, single-output controller. These laws are well understood and are therefore strategically and efficiently applied to both the sensor feedback information and to the control laws within the closed-loop feedback path. In short, their success is directly correlated to their relative simplicity, inherent robustness, and adequate performance in a production environment.

More complex systems, such as bead geometry or penetration control, are well-understood phenomena that can be accurately modeled from a theoretical standpoint, but the computational complexity of the numerical models and the multiple-input, multiple-output nature of the required control laws have precluded their integration into mainstream commercial weld process controllers. Yet, the ability of a skilled human welder to assess and control bead geometry, for example, is not due

to a fundamental understanding of the laws of physics. Instead of applying a mechanistic approach to the control of the weld pool, a seasoned welder applies a more humanistic approach in which the feedback information is not based on precision and formal truths but rather on imprecision and partial truths. Fully automated welding robots will require a marriage between mechanistic approaches for phenomena that are physically well understood and mathematically feasible for both sensors and control algorithms and heuristic approaches for phenomena that are otherwise difficult or impractical to implement using conventional control techniques due to the required complexity resulting in a diminished accuracy.

Control System Requirements

Careful consideration of the power density of the heat source, the interaction time of the heat source on the weldment, and the effective spot size of the heat source must be thoroughly understood in order to design a weld process controller. In general, a heat intensity of approximately 10^3 W/cm² is required to melt most metals (Ref 4). Below this heat intensity, the solid metal can be expected to conduct heat away as fast as it is being introduced. On the other hand, a heat intensity of 10^6 or 10^7 W/cm² will cause vaporization of most metals within a few microseconds, thus preventing any fusion welding from occurring. Most fusion welding processes therefore lie between approximately 10^3 and 10^6 W/cm².

Examples of welding processes that are characteristic of the low end of this range include oxyacetylene welding, electroslag welding, and thermit welding. The high end of the power density range of welding is occupied by laser beam welding and electron beam welding. The various arc welding processes encompass the midrange of the heat source power densities.

The interaction time required to produce melting determines the appropriate bandwidth of the controller. For continuous welding, the interaction time is proportional to the spot

diameter divided by the travel speed. The minimum interaction time required to produce melting can be estimated from the relation for a planar heat source given by (Ref 4):

$$t_m = \left[\frac{K}{Pd} \right]^2 \tag{Eq 1}$$

where p_d is the heat intensity (W/cm^2), and K is a function of the thermal conductivity and thermal diffusivity of the material.

Figure 1 illustrates the relationship between the weld pool-heat source interaction time and the heat intensity. Eagar (Ref 4) states that materials such as copper or aluminum in which the thermal diffusivity is relatively high will lie on

the high end of the band, whereas materials such as steel, nickel alloys, or titanium will lie in the middle of the band. Uranium and ceramics in which the thermal diffusivity is relatively low will lie on the bottom of the band.

System Parameters

The arc welding process is a tightly coupled system which is composed of the arc; the power source, sometimes a wire feeder, and accessories; any tooling, fixtures, and positioning system; any consumables; and the part itself. Decoupling such a complicated system is extremely difficult. However, mapping the arc welding process as a parameter space can help identify aspects of the process that need to be explored in terms of process variability that can adversely impact product quality. Figure 2 illustrates how the arc welding process can be separated into process and product attributes and follows the guidance provided in Ref 5. Process attributes are those aspects of the process that the welding engineer has control over. They include the indirect weld parameters (IWP), preselected parameters, workpiece parameters, and other influential aspects of the process. The product attributes, or direct weld parameters (DWP), represent the characteristics of the postwelded product.

The weld quality is characterized by the direct weld parameters and is affected to varying degrees by the coupled effects of the process attributes. Indirect weld parameters are parameters that can be modified in-process as part of an open- or closed-loop control procedure, while the preselected parameters remain fixed during the process, for example, the electrode type, size, and tip geometry, the torch nozzle size, and the shielding gas type. Finally, other factors that can affect weld quality include clamping, heat sinks such as tack welds, heat buildup, backing, and impurities that may be found within the material, electrode, or shielding gas.

Once the preselected parameters are properly chosen, the quality of the weld can be controlled through proper selection and modification of the IWP. In general, the welding process presents the control engineer with two principal problems:

- In most cases, the relationship between the IWP and the DWP are nonlinear.
- The variables are highly coupled.

The job of the welding engineer is to determine a set of IWP (usually in a laboratory environment) that will produce the desired DWP. If the production floor conditions do not differ too much from the laboratory conditions and the process and environmental variability is kept to a minimum, then the welding operation can be expected to satisfy the postprocess quality inspection procedures. Otherwise, human or computer intervention must provide the necessary feedback to make corrective actions in the welding equipment settings.

Fig. 1 Typical weld pool-heat source interaction time. Source: Ref 4

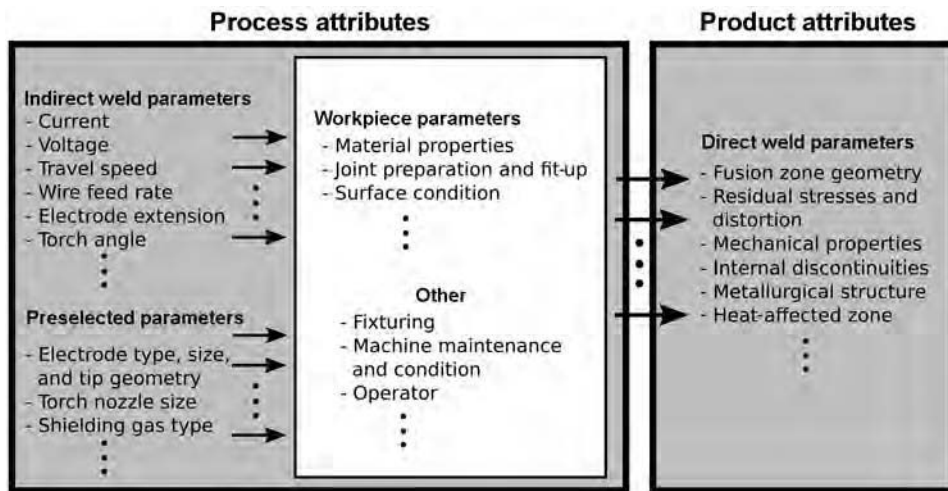

Fig. 2 The arc welding process can be separated into process and product attributes. The process attributes include those aspects of the process that the engineer has control over. The product attributes represent characteristics of the postwelded product.

A feasible solution is to sense the DWP of interest, compare the sensed variables with the desired variables, and adjust the IWP in real-time to reduce the error between the desired and sensed DWP. For a multiple-input, multiple-output and highly-coupled manufacturing process such as arc welding, the previously described approach usually involves a multivariable controller. The controller requires both dynamic and steady-state process models. The models must be computable in real-time, although they do not need to be as globally accurate as a computationally-intensive numeric model.

Successful implementation of a closed-loop feedback control system for arc welding requires sensing, modeling, and control. Each of these is discussed in the following sections.

Sensing

Directly sensing the DWP of interest provides the most robust feedback to a closed-loop control system. However, in certain cases, directly sensing many of the DWP associated with arc welding is impractical and/or infeasible in a production environment. Therefore, indirect sensing techniques are employed where a sensor is coupled with a model to “indirectly” sense, or infer, the DWP of interest. The following sections provide an overview of the more commonly applied sensing techniques for arc welding control.

Arc Sensing

Arc sensing (also commonly referred to as through-the-arc sensing) monitors the change in current (constant voltage power sources) or voltage (constant current and pulsed current power sources) in the arc. Systems employing arc sensors rely on the principle that the resistance between the welding torch electrode and the workpiece is a function of the distance separating the two. The obvious advantage of arc sensing is the use of the arc itself as a sensor. This reduces costs and avoids the technical challenges associated with instrumenting external sensors in or around the harsh environment of the welding arc. Active research and successful applications involving through-the-arc sensing date back over 40 years (Ref 6).

Arc sensing has been instrumental in achieving robust mechanized and robotic automation by providing joint tracking, bead width control, torch height control, and torch orientation. The sensing technique has been applied successfully to both consumable and nonconsumable arc welding processes. The feedback mechanism relies primarily on the voltage drop in the arc column as a rough order prediction of arc length (Ref 7). The voltage-arc length characteristic has been successfully employed in arc voltage control systems where the welding engineer specifies a desired arc voltage and a servomotor is used to vertically adjust the welding torch height with respect to the workpiece

surface (Ref 8). The arc-voltage length relationship has also been applied to joint tracking and width control in which the torch oscillates back and forth across the joint (Ref 8–11).

Rotating arc sensors, using either mechanical or electromagnetic oscillation, have been investigated to improve the sensitivity and responsiveness over conventional torch weaving methods (Ref 12). Recently, an electromagnetic arc oscillation system was developed for narrow-groove gas metal arc welding (GMAW) to achieve uniform sidewall penetration and provide feedback for an automatic joint tracking system (Ref 13). A mechanized arc rotation sensor was employed in Ref 14 to detect the end points of joints during GMAW of fillet welds. Robotic torch orientation detection and control is demonstrated in Ref 15 where a high-speed rotational arc sensor provides feedback of the deviation and inclination of the welding gun with respect to the workpiece surface.

Detection of surface contaminants on the workpiece and/or the electrode was accomplished in Ref 16 where the authors demonstrated that the electrical arc signals vary as a function of contaminants on the workpiece and/or electrode. Through-the-arc sensing of gas metal arc weld quality was also demonstrated in Ref 17 to 19. The characteristic changes in the current and voltage records were correlated to weld process instabilities such as loss of shielding gas, contact tip wear, change in contact-tube-to-work distance, and variations in the welding procedure that may induce changes in the droplet-transfer mode. A real-time monitoring system was developed that measures process stability and infers weld quality. In Ref 20, a process signature using arc voltage and wire feed rate is established to monitor arc start instability and estimate the amount of spatter generated during the unstable arcing period during GMAW.

The voltage-arc length characteristic has also been used to monitor the metal-transfer mode and droplet detachment during GMAW. Johnson et al. have demonstrated a correlation between the perturbations in the electrical arc signal with droplet transfer (Ref 21). Using high-speed video that is correlated with the arc voltage and current traces, they were able to detect the droplet detachment and to distinguish between the three transfer modes: globular, spray, and streaming. Using features of the arc signal, an artificial neural network was developed to estimate the spatter rate during GMAW short-circuit transfer mode (Ref 22).

Recently, the decreasing cost of titanium and its high strength-to-weight ratio, combined with its excellent corrosion-resistant properties, make it an ideal candidate for many chemical, marine, and military applications. Research into pulsed-current GMAW of titanium offers the potential for lower heat-input fabrication without the typical occurrence of spatter found in globular transfer. Active control of the waveform during pulsed-current GMAW of titanium has been demonstrated by Zhang et al. (Ref 23, 24). Spatter-free, one-drop-per-pulse metal transfer is

achieved by ensuring that the electromagnetic force that is generated by the detachment pulse is in phase with the downward oscillatory motion of the undetached droplet.

A method for detecting contact tube wear in GMAW is presented in Ref 25. The approach calculates a “wear parameter” that is based on the integral from 0.3 to 4 Hz of the power spectral density of the voltage or current. Real-time monitoring of the wear parameter during welding can predict the onset of tube wear when the parameter begins to grow nonlinearly or exceeds a predetermined threshold.

Weld pool oscillation sensing as a means of indirectly assessing the depth of penetration in an autogenous gas tungsten arc weld was first proposed by Hardt et al. (Ref 26). Originally recognized by Cheever and Howden (Ref 27) and later investigated further by Kotecki et al. (Ref 28), the authors were able to empirically verify that the pool’s natural resonant frequency increased as the pool’s radius decreased. The coupled sensing and modeling technique is founded upon the premise that the weld puddle oscillations are a function of the external force, the properties of the molten region, the surface tension, and the shape of the container. Determining the depth of penetration using the natural resonant frequency of the pool vibrations involves exciting the pool into motion, sensing the weld pool oscillations, and modeling the relationship between the frequency and the pool geometry. Through-the-arc voltage sensing can detect small fluctuations in the arc voltage as an indicator of weld pool surface displacement. Renwick and Richardson (Ref 29) and later Madigan et al. (Ref 30) used the alternating current component of the arc voltage as an indicator of pool oscillations. Other research attempts followed that improved upon the excitation and sensing techniques and extended the modeling fidelity (Ref 31–36).

Optical—Nonimaging and Imaging Optics

The arc light radiation and the resulting diffuse and specular reflections from the molten weld pool, the mass transfer, and the workpiece can provide valuable insight into the behavior and state of the welding process. Researchers have attempted to capture the dynamics of the welding process optically through both imaging and nonimaging techniques. Illumination comes from either the arc itself or an auxiliary high-intensity light source, for example, laser. Nonimaging and imaging optics are discussed in the following two sections.

Nonimaging optics are concerned with the capture of light radiation but without the intent to form an image of the source. Examples of nonimaging optical devices for monitoring an arc welding process include fiber optics and/or nonimaging lenses that are coupled with a photosensor, for example, photodiodes or photomultipliers. Although the arc light spectrum encompasses the

visible, ultraviolet, and infrared, the photosensor can be chosen to be more sensitive to one area of the spectrum, depending upon the need. A typical arc light sensor consists of a glass fiber bundle shrouded in some sort of light-limiting tube (such as a copper tube) that is pointed at the welding arc or the weld pool surface.

Several research efforts have investigated a more robust method of detecting changes in the arc length using the amount of light emitted by the arc as an improvement over arc voltage control (Ref 37) and as a method of sensing weld pool vibrations (Ref 38–43). Better sensitivity to fluctuations in the arc length using arc light rather than arc voltage can be attributed to the fact that most of the arc light is produced in the arc column, whereas only a minor amount of the arc voltage drop is from the arc column (Ref 41). A novel control system was demonstrated by Madigan (Ref 44) that relied on the arc light to monitor and control both the droplet frequency and the arc length during GMAW.

Although the sensitivity of monitoring pool oscillations using arc light is improved over arc voltage, the averaging effect of the pool motion over its entire surface remains as an obstacle. An alternative optical method for assessing pool oscillations relies on the specular reflections of arc light from the pool's mirrorlike surface (Ref 45–47). Unlike the previous optical methods that sense diffuse arc light emitted from the arc column, the optical probe is positioned approximately 45° to the workpiece in an effort to collect specular reflections from the arc and the electrode, as illustrated in Fig. 3. A novel excitation method (Ref 46) and modeling approach (Ref 45) are integrated in an effort to provide real-time closed-loop control of partial- and full-penetration welding conditions (Ref 47).

Imaging optics are concerned with the optical reconstruction of a light source. In welding control systems, imaging optics are typically

applied to the capture and reconstruction of the fusion zone geometry, the workpiece and joint geometry, or the mass transfer. Although vision-based systems have a long history of being employed as diagnostic tools in laboratory environments (Ref 27, 28, 48, 49), the continued advances in computational capabilities and reduction in cost have recently led to an increase in the research and application of vision-based systems for closed-loop control.

One of the first optical tracking systems was a coaxial viewing system developed by Richardson (Ref 50). The vision system is integrated inside the welding torch to detect the edges of the weld pool for process monitoring, joint tracking, and weld pool control. Pietrzak (Ref 51) also applied a coaxial vision-based system in which the weld pool width was monitored and controlled as a first-order approximation to the depth of penetration.

Due to the difficult optical environment that is caused by arc glare, welding spatter, and fume, most commercially successful joint tracking systems employ an auxiliary light source. Therefore, a number of optical tracking systems make use of a projected laser stripe to provide structured lighting that permits three-dimensional profiling of the joint (Ref 52, 53). However, improvements in the performance of vision-based platforms and the application of sophisticated image processing routines have enabled joint tracking without the external light source (Ref 54, 55). Xue has demonstrated a vision-based system for joint tracking GMAW that relies on the arc itself as an illumination source (Ref 56). A high-speed, vision-based spatter classification and contamination detection system is presented in Ref 57.

Using a digital camera imaging system, a penetration control technique has been developed during root pass welding of an open butt joint (Ref 58). The digital camera is positioned

in front of the torch at an angle of approximately 10 to 20° from a line tangent to the workpiece. A frontal view of the weld is obtained such that penetration can be viewed directly from the weld contour line. Penetration can therefore be directly monitored and controlled. This method is only applicable to the root pass with an open joint and provides no information during subsequent fill passes.

A novel, dual-camera backside and topside sensing system was developed to monitor the root opening during pulsed gas tungsten arc welding (GTAW) with filler metal (Ref 59). The system uses a neural network to predict the backside width and topside height and control the wire feed rate and the pulse duty cycle to compensate for root-opening variability.

Through the use of an elaborate laser-enhanced stroboscopic video system (Ref 60), the geometrical appearance of the weld pool has been extensively studied (Ref 61–63) as a means of monitoring and controlling weld joint penetration. Previous research contends that important information such as weld defects and penetration are contained in the surface deformation of the weld pool during GTAW and GMAW processes (Ref 64, 65). Therefore, the authors set out to investigate the possible application of monitoring and controlling weld penetration through pool surface shape. In particular, the weld pool area (two-dimensional shape) and three-dimensional surface can provide varying degrees of accuracy for controlling the weld process. However, when they are used in combination, the authors found that an improvement in maintaining both desired penetration and mechanical properties is achieved. The researchers employed artificial neural networks to emulate the human operator ability to extract weld quality information, in particular, penetration, from the shape of the weld pool. Additional efforts followed that have extended upon the previously described principles (Ref 66–68).

A novel imaging system to monitor the solidification and surface flow of autogenous gas tungsten arc weld pools is presented in Ref 69 and 70. The system was designed to investigate the formation of weld surface ripples. The authors present a theory of ripple formation that is based on solidification mode instability during columnar dendritic solidification (Ref 71).

Other Measurements

Temperature measurements involve either a direct contact method using thermocouples or a noncontact method employing either an infrared (IR) point source or a vision-based digital IR camera. Temperature distribution sensing methods involve certain disadvantages. Thermocouples, in particular, require intimate contact with the weldment at all times, while IR systems require calibration for differences in the thermal emissivity of the workpiece. In GTAW, accurate IR temperature measurements can be further hampered by interfering radiation from the arc

Fig. 3 A nonimaging optical probe can be used to collect arc light from an arc welding process. The probe can be elevated and rotated depending on the light source of interest

and the tungsten electrode (Ref 72). Finally, unlike IR sensors, which typically have a fast response time, contact temperature transducers such as thermocouples tend to have a slow response time (Ref 73), thus preventing them from being incorporated into a real-time feedback control system.

Monitoring the temperature distribution around the weld can infer many attributes of the welding process that can be applied to automated control. Thermally-based weld penetration estimation has been investigated using both contact (Ref 74–76) and noncontact-based sensing methods (Ref 72, 77–79). Independent of the sensor employed, thermally-based depth estimation requires a heat-transfer model in the closed-loop feedback path in order to address time-varying welding conditions. Consequently, controller accuracy depends on the accuracy of the sensor and the thermal model. Various research efforts have investigated the effects on the weld bead shape, penetration in particular, from the magnitude of heat input from the arc, the distribution of heat input over the surface of the weldment, and the duration of heat input (Ref 80–84). The effect of plate thickness, thermal properties, and operating variables (of the welding process) on the thermal phenomena, such as the cooling rate and the peak temperature distribution, must be thoroughly understood in order for a thermal model to accurately assess, and control, the weld bead geometry. Consequently, the process parameters, such as material thickness, thermal conductivity, and material composition, must be known a priori. The accuracy of the model predictions depends on the type of model employed and the accuracy of selecting various parameters. Furthermore, model parameters such as arc efficiency and distribution are only first-order approximations and therefore result in potential ambiguities or uncertainties in the ability of the model to accurately predict penetration.

In addition to penetration assessment methods, other potential applications to automated control involve sensing discontinuities (Ref 85), seam tracking (Ref 86), and cooling-rate measurements (Ref 87, 88).

Acoustical Signals. The airborne acoustical signals generated by the welding arc are a principal source of feedback for manual welders (Ref 89). Research into airborne acoustics as a means of inferring weld quality date back to the late 1960s (Ref 90) and are founded upon the principle that sound pressure variations occur due to changes in the electrical power of the arc column (Ref 91). Changes in the electrical power of the arc can be manifested by the effects of variation in gas flow, welding speed, welding current or voltage, and arc length or by the behavior of the molten weld pool, mass transfer, or heat source to material interaction. Therefore, the audio signal is a natural feedback mechanism for evaluating process stability, detecting defects in situ, and automated control.

The use of acoustical signals generated by GMAW for detection of metal-transfer mode

is presented in Ref 21. In Ref 92, Grad et al. identified that the main source of acoustic waves in GMAW short-circuit metal-transfer mode is arc reignition. Using airborne acoustics, the authors were able to assess process stability and detect welding conditions that lead to welding defects. Similar efforts are presented in Ref 93 to 97. The arc sound was also used in GTAW for monitoring welding quality (Ref 98), while acoustic arc length control was demonstrated in Ref 99.

Ultrasonic Techniques. Postweld inspection using ultrasonic techniques has been an effective and proven method for locating internal flaws such as discontinuities, cracks, slag inclusions, and porosity of a welded joint. Capable of working on all materials, ultrasonic testing is extremely sensitive, allowing it to detect exceptionally small flaws. Based upon an established technology, several researchers have applied ultrasonic techniques to weld penetration measurement for feedback control (Ref 100–103). The use of ultrasonics for weld process sensing has the potential to detect weld pool geometry and discontinuities in real-time. However, to be useful in a production system, a means must be developed for injecting and receiving the ultrasound with noncontact sensors. A noncontact system was developed that combined a laser array generation source and an electromagnetic acoustic transducer receiver (Ref 104, 105). Similar to other external sensing methods, movement of the sensor must be synchronized with the torch motion. Finally,

large temperature gradients within the heat-affected zone can reflect ultrasonic waves, thus limiting the quality and accuracy of measuring the weld pool dimensions.

Arc Tracer Spectroscopy. The use of arc tracer spectroscopy to determine root penetration during pulsed autogenous GTAW from the top-side of the workpiece is demonstrated in Ref 106. Although access to the back of the plate is necessary in order to attach tracer elements for spectroscopy detection, topside penetration sensing is accomplished and demonstrated in both the 2G position as well as in orbital welding. Penetration defects were determined by comparing predetermined root penetration spectroscopy to the current workpiece spectroscopy.

Modeling

There are at least two roles for models in a generic nonadaptive weld process controller. First, a model can be used in defining the initial equipment parameters of the process. The welder specifies the desired DWP, such as weld bead width and/or penetration, and the model is then used to arrive at suitable IWP, such as welding current and/or travel speed. Secondly, a model can be operated in parallel with the actual process and provide predictions of the DWP that cannot be measured directly in real-time. For example, a weld model can provide the controller with an estimate of the weld bead penetration. Figure 4 illustrates the application

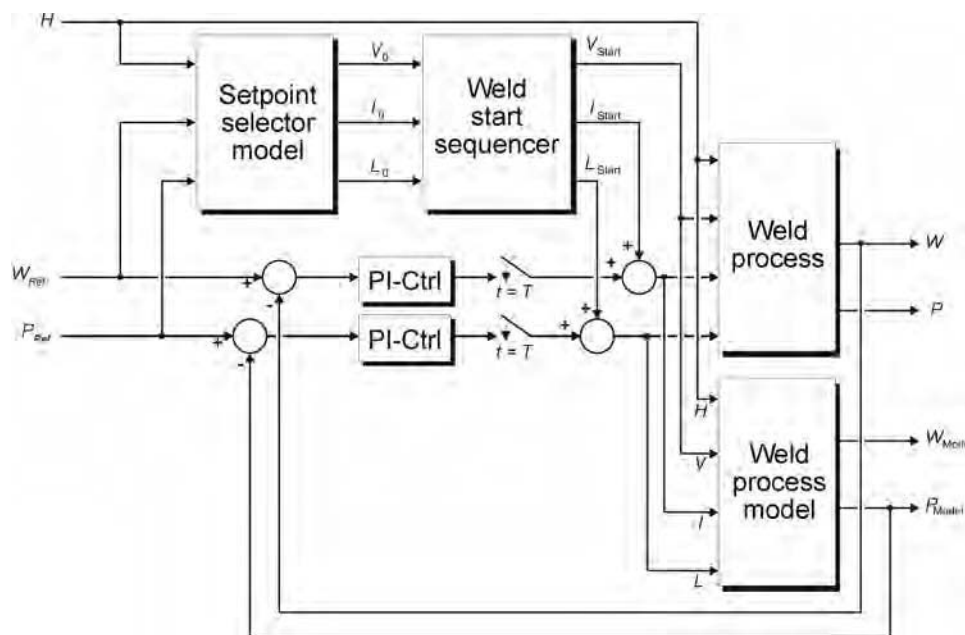

Fig. 4 An example closed-loop control system employs both a setpoint selector model and a steady-state weld process model. The desired bead width, W_{Ref} , and penetration, P_{Ref} , are specified by the user. These parameters, as well as the workpiece thickness, H , are fed to a setpoint selector model, which yields the nominal travel speed, current, and arc length (v_0 , i_0 , and L_0 , respectively). Upon reaching steady state, the closed-loop control is enacted. The bead width from the process is monitored in real-time, while penetration is estimated. The measured bead width and the estimated penetration are subtracted from the respective reference values, processed through proportional-plus-integral controllers, and added to the final values obtained from the setpoint sequencer. Source: Ref 107

of both models within the context of a closed-loop control system for GTAW bead width and depth of penetration (Ref 107).

A distinguishing characteristic of process models used for control purposes is they must be computed in real-time. This rules out many of the more exact numerical models that have been developed using finite-element and finite-difference methods. While simpler models may lack the precision and the fidelity of a numerical solution, they provide the necessary real-time responsiveness for automation of mechanized and robotic systems.

Weld process models are either derived from the fundamental physics of heat transfer, or they are constructed from empirical data. The models derived from heat-transfer physics frequently assume that the arc can be modeled as a heat source of a given form (a point source, a disk-shaped source of heat, etc.), and then the laws of heat conduction are applied to calculate the temperatures at various points in the workpiece (Ref 80, 81, 84, 108). The analytical derivations usually require significant simplifications, such as assuming that the workpiece is either infinitely thick or of a specific shape and that the thermal properties of the molten pool are homogeneous and the same as those of the solid base metal. As a result, physics-based models can be fairly inaccurate for open-loop control (Ref 109).

An alternative to a physics-based model is an empirically-derived model (Ref 110–112). These models may simply consist of one or more equations relating the DWP to the IWP and are derived by obtaining a best fit of experimental data to the given equations. In such cases, the models are derived without any consideration of the underlying physics of the process.

A number of weld process models can be placed between the two extremes of a purely physics-based model and an empirically-derived model. Frequently, physics-based models are derived using the necessary approximations, and then various “empirical constants” and other unspecified variables are tuned until the model adequately agrees with experimental welding data. By the same token, empirical models frequently use pieces of general knowledge of the process, derived from the underlying physics. Therefore, the physics-based and the empirical models bookend the opposite extremes in weld modeling.

Neural networks are an alternative to formal analytical techniques. Empirical in nature, neural network models are not governed by the physics of the process. Instead, they rely on the input and output relationships of the training data to define the weight matrix within a sophisticated pattern-mapping architecture. The advantages of neural models include relative accuracy and broad generality across many different problem domains. In particular, if the training data are general enough and span the entire range of process parameters, then the resulting model can capture the complexity

of the process, including nonlinearities and parameter cross couplings (Ref 107, 113–115).

Neural network model development is usually much simpler than other analytical alternatives. A neural model tailors itself to the training data. Speed is also a benefit. In a real-time control loop, a feed-forward neural model is relatively fast, because the input data are only propagated once through the network. Finally, neural networks can learn when new training instances become available. When compared to other control modeling methodologies, neural networks also have certain drawbacks. The most notable one is a lack of a comprehensive model that reflects the physics of the process. Finally, relating the qualitative effects of the networks structure or parameters to the process parameters is usually impossible.

Control of Arc Welding

Although an extensive amount of research has investigated multivariable feedback control of the fusion process, most commercial applications of control for arc welding have thus far been largely focused on the control of one, or at most two, parameters of the process. The control techniques for these parameters have usually been limited to classical feedback control, based on the assumptions of linear and time-invariant behavior of the controlled systems. Examples of such control schemes include voltage and current control of the welding power source, control of the arc voltage through adjustment of the arc length, and other isolated single-variable control applications.

The following sections discuss some of the research and development activities that attempt to extend the commercial, state-of-the-art welding process controllers.

Adaptive Control. The highly nonlinear relationships that generally exist between the direct and indirect weld parameters require a feedback control system with self-tuning capabilities. A feedback control system that has this added ability to modify its control law, for example, through modifications of gains and/or time constants, in response to changes in the process being controlled is formally known as an adaptive controller. (The term *adaptive control* that is widely used in industry refers to a system that automatically determines changes in process conditions and directs the equipment to take appropriate action. From an open-loop perspective, this approach does appear “adaptive” in nature; this is simply known as feedback control, whereas adaptive control is feedback control with the added capability of self-adjustment.) Assuming localized linearity, an adaptive controller can be used to change the controller characteristics in response to changes in the operating domain. An adaptive controller provides the robustness to maintain stable control over the entire operating range of the process.

Adaptive control algorithms have been developed for the nonlinear operating regions

of the arc-voltage length relationship to ensure a more robust and stable control system throughout the entire operating region (Ref 116, 117). In fusion welding, the time constant and gain of a linear controller for weld geometry regulation are highly dependent upon the welding conditions, for example, torch speed, arc length, material thickness, and material properties. Suzuki et al. demonstrate the advantages and benefits of an adaptive controller over a traditional linear controller for bead width control during GTAW (Ref 118).

Intelligent Control. Researchers working in the field of intelligent control typically derive an approach to solving a control problem that is inspired by the decision-making process in humans and other biological systems. Certain approaches are heuristic in format, and most turn out to be nonlinear and possibly adaptive. Unlike conventional methods in which stability is proven, verification that the approach is successful is commonly determined by simulation or by experimental evaluation. The relative advantages and disadvantages of using an intelligent method over a conventional method or over another intelligent method are difficult to assess due to the lack of a clear and objective set of evaluation criteria.

The tools used for artificial intelligence depend upon the application. Four of the most commonly applied intelligent tools are neural networks, expert systems, fuzzy logic, and genetic algorithms. Neural networks and genetic algorithms operate on unstructured data in the form of numbers, usually normalized between 0 and 1. Expert systems excel through the use of rules that operate on structured data in the form of words or symbols. Fuzzy logic can work well with both structured and unstructured data in the form of both symbols and numbers.

Methods of evaluating the performance of a controller using various techniques are complicated. When considering different techniques, Passino (Ref 119) suggests evaluating the following attributes of the system:

- Time-domain performance analysis, including stability and performance measures such as rise-time, overshoot, and steady-state error
- Simplicity of the design method
- Ease of understanding the approach
- Lead-time to design and implementation
- Ease of implementation

The development of a self-organizing, fuzzy logic weld penetration controller was presented in (Ref 120). The adaptive controller was modeled after expert human welding knowledge and tuned online to automatically adjust the sensitivities to its membership functions according to the current welding conditions. The single-input, single-output fuzzy logic controller relies on simple heuristics to capture the nonlinear, time-varying, asymmetric thermal relationship of the arc welding process. The translation from

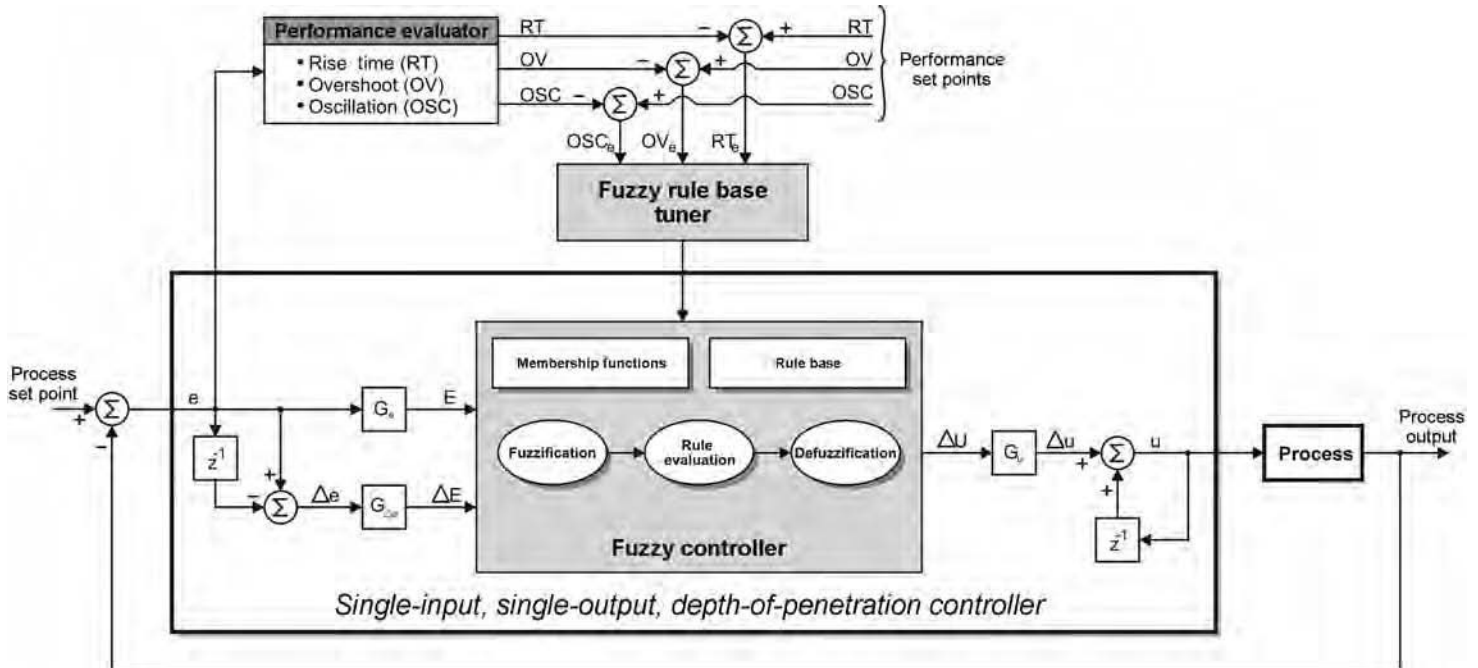

Fig. 5 A self-organizing fuzzy logic controller for depth-of-penetration control.

an expert's knowledge to a set of fuzzy variables and rules inevitably results in a generalized, yet nonoptimal, control rule base and therefore requires tuning to optimize the transient and steady-state performance under process-specific conditions. Figure 5 illustrates the controller and performance supervisor. The approach avoids the time-consuming, unsystematic, and error-prone manual tuning that is considered by some to be the greatest drawback to using fuzzy logic for control purposes. The performance tuner exploits the fundamental advantage of fuzzy systems by incorporating a vague, yet intuitive, human-based model of the system.

Multivariable Control. The welding control applications mentioned in the previous sections are usually adequate for their specific purposes, that is, to maintain one or two system parameters at predefined values. These traditional schemes, however, are not easily applicable to the more complex task of directly controlling multiple outputs of the process through the available equipment parameters, that is, controlling the DWP in terms of the IWP (Ref 5).

Cook et al. (Ref 107) have described a multivariable weld process control system that makes use of a model to estimate one of two DWP(s) controlled. The system, shown in Fig. 4, was configured to accept weld bead width and weld penetration as its two inputs. The system used width sensing, while penetration was estimated using a forward process model acting in parallel to the actual process. Conventional time-based up-sloping/down-sloping was used for weld initiation and termination, and an inverse process model was used

to provide initial weld IWPs (following up-slope) to the weld start sequencer. Using the layout in Fig. 4, the desired bead width and penetration are specified by the user as W_0 and P_0 , respectively. These parameters, as well as the workpiece thickness, H , are routed to a neural network setpoint selector (inverse process model), which produces the nominal travel speed, current, and arc length (v_0 , I_0 , and L_0 , respectively). Arc initiation and stabilization are controlled in an open-loop fashion by the weld start sequencer. Given the desired equipment parameters, the arc is typically initiated and established at a relatively low current, with the other equipment parameters set at some nominal value. Once the arc has been established, the equipment parameters are ramped to the setpoint values specified by the neural network. When the setpoint values have been reached, at time $\tau = T$, the closed-loop process control is enacted. The bead width was measured in real-time, while a real-time, neural network penetration predictor (forward process model) was run in parallel with the process to yield estimates of the penetration. The measured bead width and the estimated penetration are subtracted from the respective reference values, processed through proportional-plus-integral controllers, and added to the final values obtained from the setpoint sequencer.

Controlling a single or multivariable system is not a trivial task without an adequate quantitative model. In the case of arc welding, relationships between the various process inputs and outputs are not well defined. Furthermore, the process variables are coupled (that is, any given input parameter affects more than one

output parameter), and, in general, the welding processes are nonlinear (that is, the output parameters are not adequately described in terms of a linear combination of the input parameters and their time derivatives). All of these facts add to the difficulty of designing a general weld controller using conventional multivariable control.

Distributed, Hierarchical Control. An alternative to conventional multivariable control is a distributed, hierarchical control architecture. Decoupling of the process is accomplished through a loosely-coupled and hierarchical network of supervisors that oversee the application of successful one- and two-parameter conventional, adaptive, and intelligent controllers. The supervisors work together toward a common goal and achieve modularity, while increasing reliability and decreasing complexity.

Autonomy and multivariable control is achieved through the use of high-level, intelligent, decision-making techniques that supervise low-level, real-time control methodologies. Relevant information about the process that is typically overlooked or generalized upon in a conventional mathematical approach to control design can be incorporated more formally and logically using a collection of intelligent supervisory components. Communication, synchronization, and supervision are therefore critical in order to guarantee that the system will satisfy an overall or global goal.

A network architecture that facilitates communication permits integration of distributed components through a communication layer and maintains system integrity by preventing

deadlock. Equally important is an architecture that can help manage a diversity of decision-making processes. Cooperation, collaboration, and supervision between various agents is necessary in order to address resource management, conflict resolution, controller tuning, scheduling, and crisis and contingency management. Furthermore, the control system must be capable of interacting with a human expert or other system in order to generate goals, assess capabilities of the system, monitor overall performance, and alert the operator when human intervention is necessary.

A proposed architecture for an intelligent, multivariable, autonomous weld controller for arc welding is proposed in Fig. 6 and evolves from established conventional welding control systems by adding intelligent components (Ref 121). In addition to interfacing with sensors and other hardware, the execution layer is responsible for executing low-level numeric signal processing and control routines, process parameters identification routines, and failure identification routines. Essentially, the execution layer is responsible for individual control algorithms and monitoring techniques of the

physical process. The coordination level tunes, schedules, supervises, and redesigns the execution-level functions; performs crisis and contingency management; plans and coordinates execution-level tasks; and executes heuristic-type functions. Finally, the management level supervises all lower-level functions, allows humans or other systems access to relevant process monitoring and control information, and performs high-level learning about the user and the lower-level functions.

The intelligent supervisory agents in the coordination level would be responsible for managing multiple, concurrent, and often conflicting goals that are associated with the process of joining two components. The execution-level control elements would still execute low-level control algorithms (such as proportional, integral, or derivative functions, adaptive control, and intelligent methods) that provide accurate and fast response times, while an automated supervisory module can mimic a human welder's expert supervision of the welding process by incorporating this intuitive knowledge into a set of fuzzy rules.

Shielding Gases for Arc Welding*

THE SHIELDING GAS used in a welding process has a significant influence on the overall performance of the welding system. Its primary function is to protect the molten metal from atmospheric nitrogen and oxygen as the weld pool is being formed. The shielding gas also promotes a stable arc and uniform metal transfer. In gas metal arc welding (GMAW) and flux cored arc welding (FCAW), the gas used has a substantial influence on the form of metal transfer during welding. This, in turn, affects the efficiency, quality, and overall operator acceptance of the welding operation.

The shielding gas interacts with the base material and with the filler material, if any, to produce the basic strength, toughness, and corrosion resistance of the weld. It can also affect the weld-bead shape and the penetration pattern.

Understanding the basic properties of a shielding gas will aid in the selection of the right shielding gas or gases for a welding application. Use of the best gas blend will improve the quality and may reduce the overall cost of the welding operation as well.

Basic Properties of a Shielding Gas

The controlled electrical discharge known as the welding arc is formed and sustained by the establishment of a conductive medium called the arc plasma. This plasma consists of ionized gas, molten metals, slags, vapors, and gaseous atoms and molecules. The formation and structure of the arc plasma is dependent on the properties of the shielding gases used for welding. Table 1 lists the basic properties of gases used for welding (Ref 1).

The ionization potential is the energy, expressed in electron volts, necessary to remove an electron from a gas atom—making it an ion, or an electrically charged gas atom. All other factors held constant, the value of the ionization potential decreases as the molecular weight of the gas increases. Arc starting and arc stability are greatly influenced by the ionization potentials of the component shielding gases used in the welding process. A gas with a low ionization potential, such as argon,

Table 1 Properties of shielding gases used for welding

Gas	Chemical symbol	Molecular weight	Specific gravity(a)	Density		Ionization potential	
				g/L	g/ft ³	aJ(b)	eV
Argon	Ar	39.95	1.38	1.784	0.1114	2.52	15.7
Carbon dioxide	CO ₂	44.01	1.53	1.978	0.1235	2.26	14.4
Helium	He	4.00	0.1368	0.178	0.0111	3.92	24.5
Hydrogen	H ₂	2.016	0.0695	0.090	0.0056	2.16	13.5
Nitrogen	N ₂	28.01	0.967	12.5	0.782	2.32	14.5
Oxygen	O ₂	32.00	1.105	1.43	0.0892	2.11	13.2

(a) At 100 kPa (1 atm) and 0 °C (32 °F); air = 1. (b) 10⁻¹⁸ J. Source: Ref 1

can easily turn atoms into ions. Helium, with its significantly higher ionization potential, produces a harder-to-start, less stable arc.

Although other factors are involved in sustaining the plasma, the respective energy levels required to ionize these gases must be maintained; as a consequence, the arc voltage is directly influenced. For equivalent arc lengths and welding currents, the voltage obtained with helium is appreciably higher than it is with argon. This translates into more available heat input to the base material with helium than with argon.

The thermal conductivity of a gas is a measure of how well it is able to conduct heat. It influences the radial heat loss from the center to the periphery of the arc column as well as heat transfer between the plasma and the liquid metal. Argon, which has a low thermal conductivity, produces an arc that has two zones: a narrow hot core and a considerably cooler outer zone. The penetration profile of the weld fusion area then exhibits a narrow “finger” at the root and a wider top. A gas with a high thermal conductivity conducts heat outward from the core; this results in a wider, hotter arc core. This type of heat distribution occurs with helium, argon-hydrogen, and argon/carbon dioxide blends; it gives a more even distribution of heat to the work surface and produces a wider fusion area.

Dissociation and Recombination. Shielding gases such as carbon dioxide, hydrogen, and oxygen are multiatom molecules. When heated to high temperatures within the arc plasma, these gases break down, or dissociate, into their component atoms. They are then at least partially ionized, producing free electrons and current flow. As the dissociated gas comes into contact with the relatively cool work

surface, the atoms recombine and release heat at that point. This heat of recombination causes multiatomic gases to behave as if they have a higher thermal conductivity, similar to that of helium. Dissociation and recombination do not occur with gases, such as argon, that consist of a single atom. Thus, at the same arc temperature, the heat generated at the work surface can be considerably greater with gases such as carbon dioxide and hydrogen.

Reactivity/Oxidation Potential. The oxidizing nature of the shielding gas affects both welding performance and the properties of the resultant weld deposit. Argon and helium are completely nonreactive, or inert, and thus have no direct chemical effect on the weld metal. Oxidizing or active gases, such as CO₂ and oxygen, will react with elements in the filler metal or baseplate and will form a slag on the surface of the weld deposit. The loss of elements, such as manganese and silicon, from steel can affect the quality and cost of the weldment produced. Both weld strength and toughness generally decline as the oxidizing nature of the shielding gas increases.

Additions of reactive gases such as oxygen or carbon dioxide enhance the stability of the arc and affect the type of metal transfer obtained. Metal droplet size is decreased, and the number of droplets transferred per unit time increases as the level of oxygen in the shielding gas increases. Oxygen reduces the molten weld-bead surface tension, promoting better bead wetting and higher welding travel speeds. Small additions of CO₂ work in a similar manner.

The surface tension between the molten metal and its surrounding atmosphere has a pronounced influence on bead shape. If the surface

energy is high, a convex, irregular bead will result. Low values promote flatter beads with minimal susceptibility for undercutting.

Pure argon is generally associated with high interfacial energy, producing a sluggish weld puddle and high, crowned bead. The addition of a small amount of a reactive gas, such as oxygen, lowers this surface tension and promotes fluidity and better wetting of the base material; it does this without creating excessive oxidation of the weld metal.

Gas Purity. Some metals, such as carbon steel and copper, have a relatively high tolerance for contaminants in the shielding gas; others, such as aluminum and magnesium, are fairly sensitive to particular contaminants. Still others, such as titanium and zirconium, have an extremely low tolerance for any foreign constituent in the shielding gas.

Depending on the metal being welded and the welding process used, very small quantities of gas impurities can significantly affect welding speed, weld surface appearance, weld bead solidification, and porosity levels. The effects of any given impurity are wide ranging, but weld quality and eventual fitness for purpose are major areas of concern.

There is always a possibility that the gas, as delivered, is contaminated; however, it is far more likely that impurities will enter somewhere between the supply and the end-use points. For this reason, properly designed piping systems and high-quality hose are recommended for use with welding shielding gases. Typical industry minimum purity levels for welding gases are listed in Table 2 (Ref 1).

Gas density is the weight of the gas per unit volume. Density is one of the chief factors that influence shielding gas effectiveness. Basically, gases heavier than air, such as argon and carbon dioxide, require lower flow rates in use than do the lighter gases, such as helium, to ensure adequate protection of the weld puddle.

Shielding Gas Blends

To obtain a shielding gas that is suited to a specific application, a mix of gases is generally

needed. Each basic gas contributes certain characteristics to the performance of the overall mix. Some gas blends have relatively specific areas of application and limited operating ranges; others can be used on many materials under a variety of welding conditions. Each component of the blend brings with it properties that are supplemented by the others to produce an enhanced level of performance.

Argon is inert or unreactive with respect to the materials present in the welding electrode. With its low ionization potential, argon promotes easy arc starting and stable arc operation. Its lower thermal conductivity promotes the development of axial "spray" transfer in certain forms of GMAW. It is also used in applications where base material distortion must be controlled or where good gap-bridging ability is required.

Helium. Unlike argon, helium is lighter than air and has a low density. Like argon, it is chemically inert and does not react with other elements or compounds. Because of its high thermal conductivity and high ionization potential, more heat is transferred to the base material, thus enhancing the penetration characteristics of the arc. In many applications, it also allows higher weld travel speeds to be obtained. Because of its higher cost, helium is frequently combined with argon or argon mixtures to enhance the overall performance of the blend while minimizing its cost.

Oxygen combines with almost all known elements except rare and inert gases; it vigorously supports combustion. Small amounts of oxygen are added to some inert mixtures to improve the stability of the welding arc developed as well as to increase the fluidity of the weld puddle.

In the spray-transfer mode of GMAW, small additions of oxygen enhance the range over which this spatterless form of welding can be performed. The droplet size decreases and the number of drops transferred per unit time increases as oxygen is added to the blend.

Carbon dioxide is a reactive gas that is commonly used alone in certain types of GMAW. Oxidation of the base material and any filler electrode occurs readily. Carbon dioxide is

added to argon blends to improve arc stability, enhance penetration, and improve weld puddle flow characteristics. The higher thermal conductivity of carbon dioxide (because of the dissociation and recombination of its component parts) transfers more heat to the base material than does argon alone. A broader penetration pattern versus argon is obtained; however, base material distortion and lack of gap-bridging ability are possible problems.

Hydrogen is the lightest known element and is a flammable gas. Explosive mixtures can be formed when certain concentrations of hydrogen are mixed with oxygen or air. It is added to inert gases to increase the heat input to the base material or for operations involving cutting and gouging. Because some materials are especially sensitive to hydrogen-related contamination, its use is generally limited to special applications, such as the joining of stainless steels, and to plasma arc cutting and gouging.

Nitrogen is generally considered to be inert except at high temperatures. At arc welding temperatures, it will react with some metals (e.g., aluminum, magnesium, steel, and titanium), so it is not used as a primary shielding gas. It can be used with other gases for some welding applications (e.g., copper) and is also widely used in plasma cutting.

Shielding Gas Selection

In most welding applications, more than one shielding gas or gas blend can be used successfully. For example, there is no one optimal gas blend for joining carbon steels, but a considerable array of mixes are available depending on the specific requirements of the application. For some processes, such as gas tungsten arc welding and plasma arc welding, the choices may be somewhat limited by the nature of the electrodes used and the materials being welded. However, for applications involving GMAW, a multitude of blends can be selected from when carbon steels are being joined. Determination of the best blend depends on a number of specific job-related needs.

Accuracy of Gas Blends

The accuracy with which gases are blended is a function of the way in which they are supplied. If the source of the gas is a high-pressure cylinder, the following generally applies:

1. $\pm 10\%$ relative, minor component (Ref 2)
2. $\pm 0.5\%$ absolute for concentrations up to 5%; $\pm 10\%$ relative for concentrations between 5 and 50% (Ref 3)

For example, the mix accuracy of an Ar-2O₂ blend would be Ar/1.8–2.2O₂ (method 1) or Ar/1.5–2.5O₂ (method 2). A blend of Ar-25CO₂ would yield Ar/22.5–27.5CO₂ by either method of calculation.

Table 2 Typical gases purity and moisture content of shielding

Gas	Product state	Minimum purity, %	Maximum moisture(a), ppm	Approximate dewpoint at maximum moisture content	
				°C	°F
Argon	Gas	99.995	10	-60	-77
	Liquid	99.997	6	-64	-83
Carbon dioxide	Gas	99.5	19	-51	-60
	Liquid	99.8	50	-58	-73
Helium	Gas	99.95	32	-51	-61
	Liquid	99.995	3	-69	-92
Hydrogen	Gas	99.95	8	-63	-80
	Liquid	99.995	5	-65	-86
Nitrogen	Gas	99.7	32	-51	-61
	Liquid	99.997	5	-65	-86
Oxygen	Industrial	99.5	50	-48	-54
	Liquid	99.5	6	-64	-83

(a) Moisture specifications are measured at full cylinder pressure, the pressure at which the cylinder is analyzed. Source: Ref 1

When gas cylinders are properly filled with the appropriate blend, the components of that mixture will not separate unless the temperature of the environment is reduced far below normal working temperatures. If the gases are supplied from a liquid source, such as a bulk tank, the accuracy of the blend is a function of the mixing equipment used, but most likely falls within the $\pm 10\%$ minor component range.

Shielding Gases for GMAW

By far, the largest number of gas blends have been developed for GMAW, especially for joining carbon steel. These can be roughly divided into four categories: pure gases, argon-oxygen mixes, argon/carbon dioxide mixes, and three-part gas blends composed of either argon, helium, oxygen, carbon dioxide, or hydrogen. Table 3 contains suggestions for shielding gas selection based on material type, thickness, and mode of metal transfer.

Argon. Pure argon is generally used on nonferrous base metal, such as aluminum, nickel, copper, and magnesium alloys, and on reactive metals, such as titanium. Argon provides excellent arc stability, penetration, and bead profile when joining these materials. Its low ionization potential results in easy arc starting. Argon produces a constricted arc column with high current density, which concentrates the arc energy over a small area; deep, fingerlike penetration results.

Carbon Dioxide. A reactive gas, carbon dioxide is generally used only for joining carbon steel. It is readily available and relatively inexpensive. Because CO_2 will not support spray transfer, deposition efficiency is lower and spatter and fume levels are higher than with argon blends. Weld bead surfaces are more oxidized and irregular in shape. The higher ionization potential of CO_2 and its characteristic dissociation upon heating provide greater weld fusion and penetration while still achieving acceptable mechanical properties.

Helium. Because of its higher thermal conductivity, helium can provide additional heat input to the base material while still maintaining an inert atmosphere. Wetting action, depth of fusion, and travel speed can be improved over comparable argon levels. This advantage is most frequently used in the welding of heavier sections of aluminum, magnesium, and copper alloys.

Argon-Oxygen. The addition of a small amount of oxygen to argon greatly stabilizes the welding arc, increases the filler-metal droplet rate, lowers the spray transition current, and influences bead shape. The weld pool is more fluid and stays molten longer, allowing the metal to flow out toward the edges of the weld (Fig. 1a).

The most common blends contain 1, 2, 5, or 8% O_2 in argon. Increasing oxygen improves arc stability and makes higher travel speeds possible by enhanced puddle fluidity. Some

increased alloy loss and a greater chance of undercut occur as the oxygen level is increased, especially beyond 5%.

Argon/carbon dioxide blends are primarily used for carbon and low-alloy steels and have limited use for stainless steels. The addition of CO_2 to argon produces results similar to the addition of oxygen, but it also broadens the penetration pattern as the CO_2 content is increased (Fig. 1b). Above a range of 18 to 20% CO_2 , spraylike transfer can no longer be obtained; short-circuiting/globular transfer with somewhat increased spatter levels is found from this point up to approximately 50% CO_2 in argon.

The most common blends for spray transfer are argon plus 5, 8, 10, or 13 to 18% CO_2 . With increased CO_2 content, the more fluid weld puddle permits higher weld travel speeds.

Mixes with higher carbon dioxide levels can also be used for short-circuiting transfer—commonly, argon plus 20 or 25% CO_2 . Mixtures in this range provide an optimal droplet frequency for minimum spatter when small-diameter (0.9 and 1.2 mm, or 0.035 and 0.045 in.) wire is used.

Argon-Helium. Helium is often mixed with argon to obtain the advantages of both gases. These blends are primarily used for nonferrous base materials, such as aluminum, copper, and nickel alloys. Helium increases the heat input to the base material and thus is used for joining thick, thermally conductive plates. As the helium percentage increases, the arc voltage, spatter, and weld width-to-depth ratio increase (Fig. 1c).

The most common blends contain 25, 50, or 75% He in argon. The highest percentage of helium is used for joining thick (>50 mm, or 2 in.) plate material, especially aluminum and copper. Higher travel speeds can be obtained using helium-enhanced blends.

Three-Gas Blends. Mixtures containing three gas components are versatile because of their ability to operate in short-circuiting, globular, and spray-transfer modes. These blends are generally proprietary, and manufacturers' recommendations should be followed for their proper use.

Argon/Oxygen/Carbon Dioxide. Blends of argon, carbon dioxide, and oxygen are generally used to join carbon and alloy steels.

Argon/Helium/Carbon Dioxide. Helium and carbon dioxide additions to argon increase the heat input to the base metal, which improves wetting, puddle fluidity, and weld bead profile. With helium plus CO_2 additions less than 40%, good spray transfer is obtained for carbon and low-alloy steel welding. Some increase in tolerance of base material surface contamination is also noted.

When the helium content exceeds 50 to 60%, transfer is restricted to short-circuiting and globular. Blends in which the CO_2 content is relatively low ($\leq 5\%$) are generally used for the joining of stainless steels without any loss in corrosion resistance.

Argon/Carbon Dioxide/Hydrogen. Three-part blends of this design are intended for the joining of austenitic stainless steel in the spray or short-circuiting transfer modes. Because of the addition of hydrogen, these blends should not be used for carbon steel. The carbon dioxide and hydrogen increase the heat input to the base material and improve bead shape characteristics, as well as promote higher welding travel speeds.

Shielding Gas Selection for FCAW

Carbon Dioxide. The majority of large-diameter (>1.6 mm, or $> \frac{1}{8}$ in.) wires that use a shielding gas use carbon dioxide. Some smaller-diameter wires are formulated to operate in 100% CO_2 . The arcs are generally stable and provide a globular transfer over the usable operating range. Good performance over rust and mill scale on the plate surface is obtained with these large-diameter wires and CO_2 shielding.

Argon/Carbon Dioxide. A significant number of small-diameter (≤ 1.6 mm, or $\frac{1}{8}$ in.) cored wires are shielded with blends of argon with 15 to 50% CO_2 . These blends provide better out-of-position weld puddle control versus that of CO_2 . To obtain the best performance from a particular cored wire, check the manufacturer's product literature for the recommended gas blend.

Shielding Gas Selection for GTAW

Argon. The most commonly used gas for GTAW, argon exhibits low thermal conductivity, which produces a narrow, constricted arc column; this allows greater variations in arc length with minimal influence on arc power or weld bead shape. Its low ionization potential provides good arc-starting characteristics and good arc stability using the direct current electrode negative (DCEN) power connection plus superior arc cleaning action and bead appearance when alternating current (ac) power is used. Argon is the most commonly selected gas for DCEN welding of most materials and ac manual welding of aluminum.

Helium. The high thermal conductivity and ionization potential of helium make it suitable for the high-current joining of heavy sections of heat-conductive materials such as aluminum. Helium increases the penetration of the weld as well as its width. It also allows the use of higher weld travel speeds.

Argon-Helium. Blends of argon and helium are selected to increase the heat input to the base material while maintaining favorable arc stability and superior arc-starting characteristics. Blends of 25, 50, and 75% He in argon are commonly used.

Argon-Hydrogen. Hydrogen is added to argon to enhance its thermal properties. The slightly reducing atmosphere improves weld

Table 3 Recommended shielding gas selection for gas metal arc welding

Material	Thickness		Transfer mode	Recommended shielding gas	Advantages and limitations		
	mm	in.					
Carbon steel	<2.0	<0.080	Short circuiting	Ar-25CO ₂	Good penetration and distortion control to reduce potential burnthrough		
				Ar-15CO ₂			
	2.0–3.2	0.080–0.125	Short circuiting	Ar-8CO ₂	Higher deposition rates without burnthrough; minimum distortion and spatter; good puddle control for out-of-position welding		
				Ar-15CO ₂			
				Ar-25CO ₂			
	>3.2	>0.125	Short circuiting	Ar-15CO ₂	High welding speeds; good penetration and puddle control; applicable for out-of-position welds		
				Ar-25CO ₂			
				Globular	Ar-25CO ₂	Suitable for high-current and high-speed welding; deep penetration and fast travel speeds but with greater burnthrough potential	
					CO ₂		
				Conventional spray arc	Ar-1O ₂	Good arc stability; produces a more fluid puddle as O ₂ increases; good coalescence and bead contour; good weld appearance and puddle control	
Ar-2O ₂							
Ar-5CO ₂							
Ar-8CO ₂							
Ar-10CO ₂							
Ar-15CO ₂							
Pulsed spray				Ar-CO ₂ -O ₂ blends	Used for both gage and out-of-position weldments; achieves good pulsed spray stability over a wide range of arc characteristics and deposition ranges		
				Argon-5CO ₂			
	Ar-He-CO ₂ blends						
Alloy steel	All sizes	Short circuiting	Ar-8CO ₂	High welding speeds; good penetration and puddle control; applicable for out-of-position welds; suitable for high-current and high-speed welding			
			Ar-15CO ₂				
			Ar-CO ₂ -O ₂ blend				
		Spray arc (high-current density and rotational)	Ar-2O ₂	Reduces undercutting; higher deposition rates and improved bead wetting; deep penetration and good mechanical properties			
			Ar-5O ₂				
			Ar-CO ₂ -O ₂ blends				
		Pulsed spray	Ar-He-CO ₂ blends	Used for both light-gage and heavy out-of-position weldments; achieves good pulsed spray stability over a wide range of arc characteristics and deposition ranges			
			Ar-5CO ₂				
		Stainless steel, copper, nickel, and Cu-Ni alloys	All sizes	Short-circuiting transfer	Ar-He-CO ₂ blends	Low CO ₂ contents in helium mix minimize carbon pickup, which can cause intergranular corrosion with some alloys; helium improves wetting action; CO ₂ contents >5% should be used with caution on some alloys; applicable for all-position welding	
					He-Ar-CO ₂ blends		
Ar-1O ₂							
Spray arc	Ar-2O ₂			Good arc stability; produces a fluid but controllable weld puddle; good coalescence and bead contour; minimizes undercutting on heavier thicknesses			
	Ar-He-CO ₂ blends						
Pulsed spray	Ar-1O ₂			Used for both light-gage and heavy out-of-position weldments; achieves good pulsed spray stability over a wide range of arc characteristics and deposition ranges			
	Ar-2O ₂						
	Ar-He-CO ₂ blends						
Aluminum, titanium, and other reactive metals	≤13			≤½ in.	Spray arc	Argon	Best metal transfer, arc stability, and plate cleaning; little or no spatter; removes oxides when used with direct current electrode positive (reverse polarity)
					Spray arc	75He-25Ar	
	>13	>½ in.	Spray arc	50He-50Ar	High heat input; produces fluid puddle, flat bead contour, and deep penetration; minimizes porosity		
			Pulsed spray	Helium	High heat input; good for mechanized welding and overhead; applicable to heavy-section welding		
			Pulsed spray	50He-25Ar	Good wetting; good puddle control

puddle wetting and reduces some surface oxides to produce a cleaner weld surface. To minimize problems associated with arc starting, additions of hydrogen are generally limited to 5 to 15%. These blends are primarily used to join some stainless steels, nickel, and nickel alloys. These mixtures should not be used to join alloy steels; delayed weld cracking may result.

Argon/2–5H₂ is used in manual welding applications on materials thicker than 1.6 mm (⅝ in.). Additions of 10 to 15% H₂ are used in

mechanized applications, such as those found in the manufacture of stainless steel tubing.

Warning: Special safety precautions are required when mixing argon and hydrogen. Do not attempt to mix argon and hydrogen from separate cylinders. Always purchase ready-mixed hydrogen blends from a qualified supplier.

Shielding Gas Selection for Plasma Arc Welding

The physical configuration of the plasma arc welding (PAW) system requires the use of two gases: a “plasma” or orifice gas and a shielding gas. The primary role of the plasma gas, which exits the torch through the center orifice, is to control arc characteristics and shield the electrode. The shielding gas, introduced around the periphery of the arc, shields or protects the weld area. In many applications, the shielding gas is also partially ionized to enhance the performance of the plasma gas.

Low-Current (<100 A) PAW. Argon is the preferred plasma gas for low-current PAW because of its low ionization potential, which ensures easy and reliable arc starting. Argon-helium mixtures are used for some applications

requiring higher heat inputs. The choice of the shielding gas depends on the type and thickness of the base material. Recommendations can be found in Table 4.

High-Current (≥100 A) PAW. The choice of gas used for high-current PAW also depends on the material to be welded. In almost all cases, the shielding gas is the same as the orifice gas. Again, argon is suitable for welding all metals, but it does not necessarily produce optimal results. Depending on the welding mode used (keyhole or melt-in), the optimal gas blend will vary. Table 4 lists gases recommended on the basis of materials joined.

Influence of Shielding Gas on Weld Mechanical Properties

The mechanical properties of a weld are dependent on specific characteristics of the shielding gas. When the gas blend is totally inert, the effects are less pronounced and are derived more indirectly. In this case, the shielding gas affects penetration and solidification, which can influence the microstructure of the resulting weld.

When the shielding gas contains active components, such as oxygen or carbon dioxide, the influence is direct and more substantial. The

oxygen potential of the shielding gas influences the amount of surface slag, the fume emission rate, the fluidity of the weld puddle, and the mechanical properties (both strength and toughness) of the weld metal. A number of empirical formulas have been developed to estimate the oxygen potential of a gas blend (Ref 5); the differences lie in their treatment of the CO₂ component of the gas mix. Because parameters other than gas composition can affect the oxygen level of the weld metal (e.g., welding speed), most of the recently developed formulas are also welding parameter and material specific. Their importance centers on how the oxidation potential is linked to elemental loss of silicon and manganese in the weld metal, to weld-metal oxygen content, and to weld mechanical properties.

Because a relatively complex relationship exists between the loss of alloying elements, the composition of the shielding gas, and the mechanical properties of the resulting weld metal, it is difficult to select an optimal gas blend that will work well with all types of wires. This influence is most noticeable in the GMAW of carbon steel. Figure 2 (Ref 5) and Table 5 (Ref 6) illustrate the effect of the shielding gas on impact strength and tensile strength. In general, as the oxidation potential of the shielding gas increases, the toughness and the tensile strength of the weld deposit decrease. Because of their lower oxidizing gas content, argon blends will generally produce weld properties superior to those obtained by shielding with CO₂ only. There appears to be an “optimal” oxygen content, because too low an oxygen level can also be detrimental to toughness.

Shielding Gas and Fume Generation

The shielding gas used in solid and flux cored wire welding affects the rate at which fumes are produced during welding, as well as

Table 4 Recommended guidelines for selecting plasma arc welding (PAW) shielding gases

Material	Thickness		Mode of penetration	
	mm	in.	Keyhole technique(a)	Melt-in technique(b)
Low-current PAW(c)				
Aluminum copper	<1.6	<1/16	Not recommended	Argon Helium
	≥1.6	≤1/16	Helium	Helium
Carbon steel	<1.6	<1/16	Not recommended	Argon Helium 75Ar-25He
	≥1.6	≥1/16	Argon 75He-25Ar	Argon 75He-25Ar
Low-alloy steel	<1.6	<1/16	Not recommended	Argon Helium Ar-1.5H ₂
	≥1.6	≥1/16	Argon 75He-25Ar Ar-1.5H ₂	Argon Helium Ar-1.5H ₂
Stainless steel, nickel alloys	<1.6	<1/16	Argon 75He-25Ar Ar-1.5H ₂	Argon Helium Ar-1.5H ₂
	≥1.6	≥1/16	Argon 75He-25Ar Ar-1.5H ₂	Argon Helium Ar-1.5H ₂
High-current PAW(d)				
Aluminum	<6.4	<1/4	Argon	Argon 75He-25Ar
	≥6.4	≥1/4	Helium	Helium 75He-25Ar
Copper	<2.4	<3/32	Not recommended	Helium
Carbon steel; low-alloy steel	<3.2	<1/8	Argon	Argon 75He-25Ar
	≥3.2	≥1/8	Argon	Argon
Stainless steel; nickel alloys	<3.2	<1/8	Argon Ar-5H ₂	Argon
	≤3.2	≥1/8	Argon Ar-5H ₂	75He-25Ar

(a) Properly balanced gas flow rates produce complete joint penetration by forming a small weld pool with a hole penetrating completely through the base metal. As the plasma torch is moved, metal melted by the arc is forced to flow around the plasma steam, producing the “keyhole” to the rear where the weld pool is formed and solidified. (b) Conventional fusion welding similar to that done with gas tungsten arc welding. (c) Gas selections shown are for shielding gas only. Orifice gas in all cases is argon. (d) Gas selections shown are for both the orifice and shielding gas. Source: Ref 1

the composition of the fumes. The type of shielding gas also affects the composition of the pollutant gases in the welding area. The fumes and gases generated in some welding applications impact health and safety; therefore, it is important for the user to review the Material Safety Data Sheets and precautionary labeling provided by the manufacturers and suppliers of welding consumables. Welding safety and health information can also be found in this Handbook and in ANSI Z49.1, "Safety in Welding and Cutting."

Fume generation rates are generally highest when CO₂ shielding is used. Inert gas blends containing CO₂ produce higher fume levels than those containing only oxygen additions. For solid wire welding at the same weld-metal deposition rate, argon blends typically generate significantly less fumes than when CO₂ only is used (Ref 7–9). Figure 3 (Ref 10) illustrates the dependence of the fume generation rate on shielding gas composition as a function of current level in GMAW. Similar trends can be seen when using gas-shielded flux cored wires.

Pollutant gases must be considered when arc welding. The gases of greatest interest are carbon monoxide, ozone, and nitrogen oxides. When CO₂ is used for shielding in confined spaces, CO can be a potential problem. Ozone can be a concern when high-energy gas-shielded welding is conducted, particularly on aluminum and stainless steel plate. It is produced in the immediate arc area as well as in the surrounding environment. Oxides of nitrogen can be present in some plasma welding and cutting applications (Ref 11).

Self-Shielded Flux Cored Arc Welding

The self-shielded flux cored wire welding process employs a continuous wire electrode that requires no external shielding. These cored wires generate protective shielding gases from components in the core material similar to those found in coated electrodes. The unique feature of this class of consumables is that they rely only partly on the exclusion of air from the molten electrode and weld pool to produce a quality deposit. In addition to deoxidizers, they contain denitrifiers to react with nitrogen that may be entrained in the molten metal. The less a given consumable relies on shielding and the more it relies on "killing" to control nitrogen and produce sound weld metal, the less that consumable will be affected by cross air currents and side winds.

Through careful control of welding parameters and the proper balance of core constituents, good-quality weld metal can be obtained under poor welding conditions. Self-shielded flux cored wires are especially suited to welding outdoors, where it is difficult to provide acceptable external gas shielding. Both light- and heavy-gage materials have been successfully joined with these electrodes.

Shielded Metal Arc Welding*

Revised by Steve Knostman, Hobart Brothers Company

SHIELDED METAL ARC WELDING (SMAW), commonly called stick or covered electrode welding, is a manual welding process whereby an arc is generated between a flux-covered consumable electrode and the workpiece. The filler metal is deposited from the electrode and uses the decomposition of the flux covering to generate a shielding gas and to provide fluxing elements to protect the molten weld-metal droplets and the weld pool. This welding process has its origins in the 1800s, but it was not until the early 1900s that coverings for these electrodes began to be developed. In the 1930s, this method of welding began to grow in popularity and retains an important role in the welding industry. Shielded metal arc welding is one of the most used of various electric arc welding processes.

The SMAW Process

The important features of the SMAW process are shown in Fig. 1. The arc is initiated by momentarily touching or “scratching” the electrode on the base metal. The resulting arc melts both the base metal and the tip of the welding electrode. The molten electrode metal/flux is transferred across the arc (by arc forces) to the base-metal pool, where it becomes the weld deposit covered by the protective, less-dense slag from the electrode covering.

Fig. 1 Shielded metal arc welding process

Advantages and Limitations. The SMAW process is the simplest, in terms of equipment requirements, but it is, perhaps, the most difficult in terms of welder training and skill-level requirements. Although welder skill level is a concern, most new welders start as “stick welders” and develop the necessary skills through training and experience. The equipment investment is relatively small, and welding electrodes (except for the very reactive metals, such as titanium, magnesium, and others) are available for virtually all manufacturing, construction, or maintenance applications. Specific electrodes can be selected depending upon base-metal requirements and can be formulated to match specific base-metal requirements if necessary. Shielded metal arc welding has the greatest flexibility of all the welding processes. It can be used to weld both ferrous and nonferrous metals, it can be used in all positions (flat, vertical, horizontal, and overhead), with virtually all base-metal thicknesses (1.6 mm, or 1/16 in., and greater), in areas sensitive to wind and drafts, and in areas of limited accessibility, which is a very important capability.

Because the SMAW process is basically a manual process, the skill level of the welder is of paramount importance in obtaining an acceptable weld. The welder duty cycle is generally low, because of the built-in work break, which occurs after each electrode is consumed and requires replacement. In addition to replacing the electrode when the arc is stopped (broken), the welder may “chip” or remove slag and clean it away from the starting and welding area with a wire brush to allow the proper deposition of the subsequent weld. This electrode replacement and cleaning operation occurs many times during the work day (about every 2 min, or the time it generally takes to consume an electrode). This stopping, chipping, wire brushing, and electrode replacement prevents the welder from attaining an operator factor, or duty cycle, that is much greater than 25%.

Weld Quality. The quality of the weld depends on the design and accessibility of the joint, as well as on the electrode, the technique, and the skill of the welder. If joint details vary greatly from established design details, then a lower-quality weld can result. Other factors that also reduce quality are improper interbead cleaning, poor location of individual weld beads within the joint, and various problems with individual electrodes, including partially missing flux (chipped ends), core wires that are not centered within the flux covering, and covered ends (coating covering the strike end of the electrode). Overall, welds of excellent quality can be obtained with the SMAW process, as demonstrated by its use in naval ship repairs and off-shore oil jack-up rigs, nuclear power plants, and high-pressure oil/gas pipeline construction.

Base-Metal Thickness. The SMAW process can be used on thicknesses above 1.6 mm (1/16 in.) to an unlimited thickness. The thinner materials require a skilled welder, tight fit-up, and the proper small-diameter welding electrode. Welding position also is important when determining the minimum plate thicknesses that can be welded. Flat-position butt welds and horizontal fillet welds are generally considered the easiest to weld. Out-of-position welding (vertical, overhead) requires greater skill.

Welding Circuit. The circuit diagram for the SMAW process is shown in Fig. 2. The equipment consists of a power source, electrode holder, and welding cables that connect the power source to the electrode holder and the workpiece. Alternating current (ac), or direct current, electrode negative (DCEN), or direct current, electrode positive (DCEP) can be used, depending on the electrode coating characteristics. The DCEN source is also called dc straight polarity, whereas the DCEP source is also called dc reverse polarity.

Equipment. The welding machine, or power source, is the crux of the SMAW process. Its primary purpose is to provide electrical power

* Revised from R.H. Juers, Shielded Metal Arc Welding, *Welding, Brazing, and Soldering*, Vol 6, *ASM Handbook*, ASM International, 1993, p175–179.

of the proper current and voltage to maintain a controllable and stable welding arc. Its output characteristics must be of the constant current type. SMAW electrodes operate within the range from 25 to 500 A. The electrode producer should suggest a narrow optimum range for each size and type of electrode. Operating arc voltage varies between 15 and 35 V.

The electrode holder, which is held by the welder, firmly grips the electrode and transmits the welding current to it. Electrode holders are available in several designs, such as the pincher type and the collet, or twist, type, shown in Fig. 3. Each style has its proponents, and the selection is usually a personal preference. Electrode holders are designated by their current capacity. Selection factors, such as the current rating, duty cycle, maximum electrode size, and cable size, are shown in Table 1. The most lightweight holder that will accommodate the required electrode size is usually desired.

All electrode holders should be fully insulated. Because they are used in proximity to the arc and are exposed to high heat, they will deteriorate rapidly. It is extremely important to inspect and maintain electrode holders to ensure that they retain their current-carrying efficiency, their insulating qualities, and their electrode gripping action. Manufacturers supply spare parts so that the holders can be rebuilt and maintained for safe and efficient operation.

Certain pieces of auxiliary equipment can be used with the SMAW process, such as low-voltage control circuits, which enable the relatively high open-circuit voltage to be cut off until the electrode touches the workpiece. Other items include remote-control switches for the contactors, remote-control current-adjusting devices, and engine idling controllers for engine-driven power sources.

Applications

Most manufacturing operations that require welding will strive to use the mechanized processes that offer greater productivity, higher quality, and therefore more cost-effective production. For these reasons, the SMAW process has been replaced where possible. However, the simplicity and ability of the SMAW process to achieve welds in areas of restricted accessibility means that it still finds considerable use in certain situations and applications. Heavy construction, such as shipbuilding, and welding “in the field,” away from many support services that would provide shielding gas, cooling water, and other necessities, rely on the SMAW process to a great extent.

Although the SMAW process finds wide application for welding virtually all steels and many of the nonferrous alloys, it is primarily used to join steels. This family of materials includes low-carbon or mild steels, low-alloy steels, high-strength steels, quenched and tempered steels, high-alloy steels, stainless steels, and many of the cast irons. The SMAW process is also used to join nickel and its alloys and, to a lesser degree, copper and its alloys. It can be, but rarely is, used for welding aluminum.

In addition to joining metals, the SMAW process is frequently used for the protective surfacing of base metals. The surfacing deposit can be applied for the purpose of corrosion control or wear resistance (hard surfacing).

Electrodes

The electrodes used in the SMAW process have many different compositions of core wire and a wide variety of flux-covering types and weights. Standard electrode diameters of the core wire range from 1.6 to 8 mm (1/16 to 5/16 in.). Electrode length usually ranges from 230 to 455 mm (9 to 18 in.); the shorter lengths are associated with the smaller-diameter electrodes. A bare, uncoated end of the electrode (the grip end) is provided for making electrical contact in the electrode holder.

The coating on the electrode has numerous functions. It provides:

- Gas (normally, carbon dioxide), from the decomposition of certain coating ingredients to shield the arc and weld zone from the atmosphere
- Deoxidizers, for scavenging and purifying the deposited weld metal
- Slag formers, to protect the deposited weld metal from atmospheric oxidation and to help shape the weld bead
- Ionizing elements, to make the arc more stable and to operate with alternating current
- Alloying elements, to provide special characteristics to the weld deposit
- Iron powder, in certain electrodes, to increase productivity for welding ferrous metals

The American Welding Society (AWS) has established a system for identifying and classifying the different types of welding electrodes. All SMAW electrodes have the prefix letter “E” to indicate welding electrode. The symbols that follow the prefix are based on criteria that best describe the welding capabilities of the electrode metal. These criteria include chemical composition of the deposited weld metal, weld-metal mechanical properties, certain process parameters, or combinations of all factors.

The condition of the electrode coating is important to the quality of shielded metal arc welds. There are two general types of coatings: one is a cellulose type, which breaks down in the arc to produce hydrogen; the other is a cellulose-free coating that produces very low hydrogen levels. The first type of electrode coating is used when hydrogen in moderate amounts is acceptable for welds on noncritical structures. Electrodes with cellulose-type coatings have also been used when fast-freeze and good penetration characteristics are desirable and when hydrogen is controlled by preheat requirements (see the section “Preheating” in this article).

The second type of electrode coating is used for welds on structures for which even small amounts of hydrogen are not tolerable. The low-hydrogen electrode coatings are hygroscopic and pick up moisture from the atmosphere, particularly if the relative humidity is high. This occurs especially if the electrodes

Fig. 2 Shielded metal arc circuit diagram

Fig. 3 Shielded metal arc welding electrode holders

Table 1 Size and capacity of electrode holders

Electrode holder	Rating		Maximum electrode size		Maximum cable size
	Maximum current, A	Duty cycle, %	mm	in.	
Small	100	50	3.2	1/8	1
	200	50	4.0	5/32	1/0
Medium	300	60	5.5	7/32	2/0
Large	400	60	6.4	1/4	3/0
Extra large	500	75	7.9	5/16	4/0
	600	75	9.5	3/8	4/0

are exposed to the air for more than 2 to 4 h. Moisture or other hydrogen-containing compounds in the coating are dissociated by the arc temperature, and the resulting atomic hydrogen is readily dissolved in the weld puddle.

Mild and Low-Alloy Steel-Covered Electrodes. The prefix used to identify these electrodes is followed by a number series that indicates minimum strength level, position capability, and type of covering and welding current. Table 2 explains how the number series is used in AWS A5.1, the specification for carbon steel electrodes for SMAW, and AWS A5.5, the specification for low-alloy steel electrodes. The first two digits after the “E” in the E6010 electrode designate a tensile strength of at least 430 MPa (60 ksi) for the deposited metal in the as-welded condition. The third digit indicates the position in which satisfactory welds can be made with the electrode. Thus, the “1” in E6010, for example, means that the electrode is satisfactory for use in all positions (flat, vertical, horizontal, and overhead). The “2” in E6020 indicates that the electrode is suitable for the flat position and horizontal fillets. The last digit or last two digits, taken together, indicate the applicable current type to be used and the type of covering on the electrode.

If electrodes have been exposed to moisture, low-hydrogen-covered electrodes, such as E7015, E7016, and E7018 for SMAW, must be baked at 230 to 260 °C (450 to 500 °F) for at least 2 h prior to welding. Higher-strength

electrodes (such as E8018, E9018, and E10018) must be dried at 370 to 430 °C (700 to 800 °F).

Stainless Steel-Covered Electrodes. The three-digit number that follows the prefix “E” indicates the chemical composition. In addition, letters or numbers can be used to indicate composition modifications or position usability. The specification AWS A5.4 identifies and classifies covered corrosion-resisting chromium and chromium-nickel steel welding electrodes.

Nickel and Copper Alloys. The designations for nonferrous product classifications, such as nickel and nickel alloys in AWS A5.11 and copper and copper alloys in AWS A5.6, follow the prefix with a list of chemical element abbreviations that are significant in identifying product composition, such as ENiCu, ENiCrFe, ECuSi, and ECuNi.

Surfacing Welding Electrodes. The designations for these products are contained in specifications AWS A5.13 and A5.21. They are very similar to the system used to identify nonferrous electrodes.

Aluminum and Aluminum Alloys. The specification for aluminum and aluminum alloy arc welding electrodes, AWS A5.3, uses the “E” prefix to indicate a covered electrode, followed by a series of numbers that identify the chemical composition that is equivalent to Aluminum Association alloy designations (for example, E1100, E3003, and E4043).

Suffix symbols are used in various classifications. The AWS A5.5 specification for low-

alloy filler metals uses suffixes such as -A1, -B2, -B2L, and -C1 to indicate chemical compositions. Table 3 identifies the weld deposit chemical composition associated with a number of suffixes found on low-alloy electrodes. The classifications for nonferrous products in the AWS A5.6 specification for copper alloys and in the AWS A5.11 specification for nickel alloys list a letter or number suffix that indicates position in a series of similar alloy groupings. A similar suffix pattern is also used in the AWS A5.13 and AWS A5.21 specifications for surfacing welding electrodes. Covered stainless steel electrodes employ a number, -15, -16, -17, or -26 as a suffix to identify usability. The -15 suffix indicates that the electrode is designed for all-position operation using DCEP electrical current. The -16 or -17 suffix indicates all-position operation with either ac or DCEP. The -26 suffix is designed for flat and horizontal fillet welding, and manufacturers should be contacted for operating currents.

Deposition Rates. The melting rate of the electrode is directly related to the welding current. The current density in the electrode increases with higher current, which increases the melting rate, which, in turn, increases the deposition rate.

The electrode coating also affects deposition rate. The iron powder types are designed to have higher deposition rates and therefore greater productivity. Figure 4 shows the expected deposition rate versus amperage for various electrodes at a 100% duty cycle. (The actual deposition rate will be considerably less. Deposition rate is a function of the duty cycle, which is affected by the time spent changing the electrodes, cleaning slag off of the weld, etc.) Electrode size and therefore usable current range are determined by the base-metal thickness, welding position, welder skill level, and joint details.

Weld Schedules and Procedures

Welding schedules are tables of operating parameters that will provide high-quality welds under normal conditions. Strict welding schedules are not as important for the manual SMAW process as they are for semiautomatic and automatic welding for several reasons. First, in a manual welding process, the welder controls conditions by arc manipulation, which achieves better control than any of the other arc welding processes. The welder also directly controls the arc voltage and travel speed and, indirectly, the welding current.

Second, meter readings are rarely used in the SMAW process for the duplication of jobs. It is generally considered that the recommended welding current ranges given in Table 4 for the different types of electrodes are sufficient for most operations. The settings provide a good starting point when first welding on a new application, although they are not necessarily the only welding settings that can be used

Table 2 Carbon and low-alloy steel-covered electrode identification system

AWS classification(a)	Minimum tensile strength		Minimum yield strength		Minimum elongation, %
	MPa	ksi	MPa	ksi	
E60XX	414	60	331	48	17–22(b)

(a) The suffix indicates the chemical composition of the weld-metal deposit. (b) Amount depends on electrode classification. Single values indicate maximum; check AWS A5.5 for the various electrode classes. (c) There are several different M classes; M classifications are intended to conform to military specifications.

Fig. 4 Deposition rate versus amperes for various electrodes

under every condition. For example, for high-production work, the current settings could be increased considerably over those shown. Factors such as weld appearance, welding position, and welder skill also allow variations from the settings.

Welder Training. The SMAW process generally requires a high degree of welder skill to consistently produce quality welds. As a result, many training programs emphasize the SMAW process because of the arc manipulation skills developed by the welder. This acquired skill level makes the training on other processes much easier.

The exact content of a training program will vary, depending on the specific application of

the process. The complexity of the parts to be welded and the governing codes or specifications involved also dictate the length of the training program. For example, because a pipe welder would need more skill than a tack welder, the length of his training program would be greater.

The job title of arc welder (DOT 810.384-014) describes a person whose responsibility is to weld together many components. This job includes setting up the machine and part to be welded, striking the arc and guiding it along the joint, and performing such duties as chipping, grinding, and slag removal. The welder should be able to:

- Weld in all positions
- Pass employer performance tests
- Meet certification standards of governmental agencies or professional and technical associations

A tack welder (DOT 810.684-010) makes short beads at specific points to hold the parts in place for final welding. The tack welder also performs the duties of fitter helper.

A combination welder (DOT 819-384-010) welds metal parts together to either fabricate or repair assemblies. The combination welder is able to produce gas welds and electric arc welds and to perform flame-cutting operations.

The welder portion of the pipefitter description (DOT 862.381-018) must weld the pipe joint after it has been assembled and tacked in place.

Procedures. There is a definite relationship between the welding current, the size of the welding electrodes, and the welding position. These parameters must be selected to ensure that the welder has the molten weld-metal pool under complete control at all times. If the pool becomes too large, then it becomes unmanageable, perhaps allowing molten metal to run out, particularly during out-of-position welding. The welder should maintain the steady frying and crackling sound that comes with the use of correct procedures. Both the shape of the molten pool and the movement of the metal at the rear of the pool serve as guides in checking weld quality. The ripples produced on the bead should be uniform and have good side tie-in with no undercut or excessive reinforcement. The following factors are essential for maintaining high-quality welding.

Correct Electrode Type. It is important to select the proper electrode for each job. The selection should be based on the type of base metal, expected service, and mechanical properties required.

Correct Electrode Size. The choice of electrode size should depend on the type of electrode, welding position, joint preparation, base-metal thickness, and welder skill.

Table 4 Typical amperage ranges for selected shielded metal arc welding electrodes

(a) These diameters are not manufactured in the E7028 classification.

Correct Current. If the current is too high, then the electrode melts too fast and the molten pool becomes large, irregular, and difficult to control. Current that is too low will not provide enough heat to melt the base metal, causing the molten pool to be sluggish, with a high, irregular, ropey weld bead. It should also be noted that the electrode has inherent current limits. If the current is too high, then the core wire overheats and the coating cracks. If the current is too low, then there is insufficient heat to maintain the arc and form the protective gas shield.

Correct Arc Length. If an arc is too long, then the metal melts off the electrode in large globules that wobble from side to side, resulting in a wide and irregular weld bead with considerable spatter and, possibly, porosity and mechanical property degradation. If the arc is too short, then it has insufficient heat to melt the base metal and electrode, which often results in the electrode sticking to the work.

Correct Travel Speed. A speed that is too fast allows the weld pool to freeze before impurities and gases can escape, and the bead will be narrow and inadequate in size. When the speed is too slow, the metal piles up and the bead is larger than required.

Correct Electrode Angle. In fillet welding and deep-groove welding, the electrode angle is particularly important. When making a fillet weld, the electrode should be held so that it bisects the angle between the plates and is perpendicular to the line of the weld. When undercut occurs in the vertical member, the angle should be lowered and the arc directed toward the vertical member.

Correct Arc Manipulation. When weaving is used, the width of the weave and the pause at the ends of the weave become important. The welder must pause at each end of the weave to allow adequate fill buildup and fusion to occur. The welder should also quickly move across the center of the weld, because heating is more concentrated in the center than at the edges.

Breaking the Arc. Before an arc is broken, it is important to know whether it will be reestablished with the next electrode and the weld continued or whether it is the end of a weld

pass. If welding is to continue, then the crater should remain and the arc quickly broken. If it is the end of a weld pass, then the arc should not be broken until the crater has filled.

Correct Interbead Cleaning. Proper interbead cleaning to remove slag and any spatter is essential to the production of high-quality welds. Proper cleaning prevents slag inclusions, lack-of-fusion defects, and porosity.

Preheating. Hydrogen levels in the weld can be reduced by preheating, such that rapidly diffusing hydrogen atoms escape from the weld surface. At approximately 250 °C (480 °F), no hydrogen-induced cracking of steels is possible, because hydrogen diffuses so rapidly that it will not segregate at the tips of the discontinuities or stress concentrations. The level of preheat or other precaution necessary to avoid cracking will depend on which region (weld metal or heat-affected zone) is more sensitive.

Variations of the SMAW Process

Gravity Welding. Gravity feed is considered to be an automatic method of applying the SMAW process. It uses a relatively low-cost mechanism that includes an electrode holder attached to a bracket, which slides down an inclined bar arranged along the line of weld. Special electrodes with a heavy coating are maintained in contact with the workpiece by the weight of the electrode holder and electrode. Once the process is started, it continues automatically until the electrode has burned to a short stub, whereupon the bracket and electrode holder are automatically kicked up to break the arc. One welder can operate several gravity feeders at the same time (Fig. 5). This increases productivity, reduces welder fatigue, and requires less-skilled welders, all of which result in substantial savings in welder labor costs. Table 5 compares the deposition rate, based on pounds per hour, when using one electrode manually versus two, three, four, or five gravity feeders.

Although gravity-fed SMAW was investigated in the United States, England, and the Scandinavian countries in the late 1940s and early 1950s, credit must be given to the

**Fig. 5** Gravity feeders being used on ship subassemblies**Table 5** Comparison of deposition rates for conventional shielded metal arc welding and multi-arc gravity-fed welding

Data are for making 7.9 mm (5/16 in.) fillet welds using E6027 electrodes.

Method	Deposition rate, lb/h
Manual, one arc	9

Gravity, three arcs	26
Gravity, four arcs	34
Gravity, five arcs	43

Japanese shipbuilders for perfecting and using the process on a large scale in the early 1960s. The gravity welding process is being used in shipyards, railroad car shops, and barge yards throughout the world. It has reasonable acceptance in applications where large amounts of horizontal fillet welds must be made in a relatively small area.

Firecracker welding is an automatic method by which shielded metal arc welds are made using a long electrode with an electrically non-conductive coating. Human involvement is not required after the arc is initiated. A firecracker weld is generally positioned in the flat position. The welding electrode is placed in the joint, and a retaining bar is placed over it. The arc is started by shorting the end of the electrode to the workpiece. The arc length is controlled by the coating thickness. As the arc

travels along the stationary electrode, the electrode melts and makes a deposit on the metal immediately underneath. Once the arc is started, the process proceeds to completion automatically. Electrodes that are up to 1 m (39 in.) long and have a core diameter of 5, 6, or 8 mm (0.20, 0.24, or 0.32 in.) have been used. Both alternating and direct current have been applied, and the former may be preferred, because of arc blow problems associated with direct current.

Underwater Welding

Underwater welding began during World War I when the British naval force used it to make temporary repairs to leaking rivets on ship hulls. The introduction of covered electrodes enabled successful underwater welding and the production of welds having approximately 80% of the strength and 40% of the ductility of similar welds made in air.

Underwater welding can be subdivided into two major categories: welding in a wet environment and welding in a dry protective environment (Ref 1). When underwater arc welding is conducted directly in the water, the SMAW process is usually used, although more recently flux cored arc welding has been used as well. Wet underwater welding has been demonstrated to be an acceptable repair technique at depths of 100 m (330 ft). However, wet welds have been made on carbon steel structures at depths as low as 200 m (660 ft).

Welding that is performed in a dry but high-pressure (hyperbaric) environment requires the construction of a chamber around the weld zone to create the dry habitat. The cost of hyperbaric welding is therefore much higher than that of wet welding. The setting up and tearing down of equipment can be very expensive in a deep-sea environment. Additionally, hyperbaric welding exhibits low mobility. Each fabrication situation often requires a customized setup. Both the gas metal arc welding (GMAW) and gas tungsten arc welding (GTAW) processes can be used in hyperbaric welding, unlike wet welding.

For both wet and dry underwater arc welding, the process is done with increased pressure of 0.1 MPa (1 bar) for each 10 m (33 ft) increase in depth. The influences of water depth (pressure) on arc behavior are similar for both wet welding and hyperbaric welding (Ref 2–4). The major difference is the cooling rate during wet welding, which affects the nature of the weld-metal phase transformation. The cooling time ($\Delta t_{8/5}$) is in the range of 8 to 16 s for cooling from 800 to 500 °C (1470 to 930 °F) during surface welding by SMAW. In contrast, a typical wet-welding procedure by SMAW has cooling-time ($\Delta t_{8/5}$) values between 1 and 6 s, depending on heat input (0.8 to 3.6 kJ/mm) and plate thickness (Ref 5–7). The greater cooling rate produces significant amounts of heat-affected zone (HAZ) martensite in nearly all low-carbon steels. As the carbon

equivalent (CE) of these steels approaches a value of 0.40 wt%, the fusion-line hardness usually exceeds 400 on the Vickers scale (98 N, or 10 kgf), where:

$$CE = \%C + \frac{\%Mn}{6} + \frac{\%(Cr + Mo + V)}{5} + \frac{\%(Ni + Cu)}{15} \quad (\text{Eq 1})$$

As the martensite content increases in the coarse-grained HAZ, the susceptibility to hydrogen cracking becomes a measurable concern. Because of the somewhat diminished weld properties, this SMAW application is generally restricted to salvage operations or underwater repair work.

Wet Welding. The relatively poor quality of welds made in a wet environment is due primarily to the problem of heat transfer, welder visibility, and the presence of hydrogen in the arc atmosphere during the welding operation. When the base metal and the arc area are surrounded entirely by water, there is little temperature or heat buildup of the base metal at the weld, nor is preheating possible. This creates a weld-metal quench effect, which traps higher amounts of hydrogen and also produces a weld solidification structure with reduced toughness and ductility. Both conditions contribute to the weld-metal cracking tendency experienced when welding steels underwater. Another disadvantage is the restricted visibility, which is due to the equipment and the existing local contaminants in the water, as well as those generated by the welding arc. Under the most ideal conditions, welds produced in wet environments using covered electrodes have rougher beads and poorer mechanical properties than those produced in air. They are used when no other option exists.

The covered electrodes used for wet welding must be waterproofed prior to underwater use. This can be done by wrapping them with waterproof tape or by dipping them in special sodium silicate mixes and allowing them to dry.

Dry Welding. The dry environment enables the production of high-quality welds that meet all code quality requirements. The SMAW process is not very popular for welding in the dry environment, because large amounts of smoke and fumes are produced. An extensive air-moving, filtering, and refrigeration system must be employed when the SMAW process is used, because a dry-environment area will quickly fill with the welding fumes, making it impossible for the welder to see that weld area and to function. For this reason, the GTAW and GMAW processes have broader use in dry welding applications.

Repair Welding

Depending on the specific application, all of the common welding processes can be used for repair welding:

- Shielded metal arc welding (SMAW)
- Gas metal arc welding (GMAW)
- Gas tungsten arc welding (GTAW)
- Submerged arc welding (SAW)
- Plasma arc welding (PAW)

For general repairs, the SMAW process still enjoys the widest range of applications for out-of-position welding and for short runs, especially when time is critical and when readily portable equipment is used. For the highest-quality welds, the GTAW and PAW processes find the widest application. For long runs or when a large amount of weld metal must be deposited and mechanization is feasible, the SAW process or, to a lesser extent, the GMAW process, is used.

When selecting a welding process, a number of factors must be considered in balancing productivity and weld quality. Productivity of each process can be ranked in terms of its deposition rate, but productivity is usually not an important consideration on most repair jobs. Some general comparisons are given in Table 6, but sometimes selection can be difficult because each process has a number of conflicting advantages and limitations in specific situations in terms of:

- Base-metal type
- Joint design and thickness
- Welding position
- Environmental conditions
- Equipment availability

Safety Considerations

The SMAW process, like all open arc welding processes, has a number of potential hazards. To alert welders about these safety concerns, all SMAW electrode containers carry a warning label that identifies the three most common safety hazards in these terms:

- Electric shock can kill.
 - Do not permit electrically live parts or electrodes to contact skin...or your clothing or gloves if they are wet.
 - Insulate yourself from work and ground.
- Fumes and gases can be dangerous to your health.
 - Keep fumes and gases from your breathing zone and general area.
 - Keep your head out of fumes.
 - Use enough ventilation or exhaust, or both, at the arc.
- Arc rays can injure eyes and burn skin.
 - Wear correct eye, ear, and body protection.

In addition to the general warnings on the container, further detailed information relating to safety is contained in ANSI/AWS Z49.1, "Safety in Welding and Cutting." The information described as follows is intended to expand

Table 6 Rating of selected welding processes as a function of weld parameters and characteristics

Parameter or characteristic	Process				
	SMAW	GTAW	GMAW	FCAW	SAW
Weld quality	Good	Excellent	Excellent	Good	Excellent
Weld deposition rate	Fair	Poor	Good	Good	Excellent
Field work	Excellent	Poor	Fair	Excellent	Poor
Equipment maintenance	Low	Low	Medium	Medium	Medium
Smoke/fume emission	High	Low	Medium	High	Very low
Heat input control	Excellent	Poor	Good	Good	Satisfactory
Arc visibility and filler-metal placement	Good	Excellent	Satisfactory	Satisfactory	Poor
Variety of metals weldable	Excellent	Excellent	Good	Good	Fair

9.5	3/8	

Source: Ref 8

on the general warnings and should be particularly useful for SMAW welders.

First, the filter plates installed within welding shields must be capable of stopping the harmful levels of infrared, ultraviolet, and visible light rays originating in the arc. Filter plates are now able to absorb 99% or more of the infrared and ultraviolet rays from the arc. The shade of the filter plate suggested for use with SMAW electrodes is given in Table 7.

Second, in addition to protecting himself, the welder must also be aware of others in the area who need protection, which can usually be provided by portable screens. The failure of those working around the arc to use adequate protection can result in eye burn, which is similar to sunburn and is extremely painful for a period of up to 48 h. Usually, eye burn does not permanently injure the eyes, but it can cause intense pain. A physician should be

consulted in the case of severe arc burn, regardless of whether it involves the skin or the eyes.

Third, the welding area must be adequately ventilated because of the heavy concentrations of smoke and fumes generated in the SMAW process. If welding is being performed in confined spaces with poor ventilation, such as in a tank, an external air supply in the form of a mask or special helmet may be required. In addition, a second person should be stationed at the tank manhole to provide any necessary assistance. Special ventilation is required when welding stainless steels or metals coated with copper, zinc, lead, or cadmium, because of the toxic nature of these fumes.

Fourth, cables with frayed or cracked insulation and faulty or badly worn connections can cause electrical short circuits and electrical shocks to personnel. When it is necessary to weld in a damp or wet area, the welder should wear rubber boots and stand on a dry, insulated platform.

Gas Metal Arc Welding

Chris Conrardy, Edison Welding Institute

GAS METAL ARC WELDING (GMAW) employs an electric arc established between a consumable wire electrode and the workpiece to be joined. Heat from the electric arc melts the continuously fed metal wire and the metal workpiece surface to deposit a weld bead. An externally supplied gas or gas mixture acts to shield the arc and molten weld pool from the atmosphere.

While *gas metal arc welding* is the standard terminology recognized by the American Welding Society (in accordance with ANSI/AWS A3.0-2010), the process is also commonly referred to as metal inert gas welding, because early applications employed a chemically inert shielding gas. Flux cored arc welding (FCAW) is a similar process but is differentiated from GMAW by the use of a tubular wire containing flux and may or may not require an externally supplied shielding gas.

Since its commercial introduction in 1948, GMAW consumables and equipment have continued to evolve and expand the range of applications. Today (2011), there are many equipment and consumable options suitable for a broad range of materials and applications. Materials include a variety of steel, stainless steel, aluminum, nickel, copper, magnesium, and titanium alloys. Applications range from welding of thin sheet to thick-section plate, pipe, forgings, and castings as well as cladding, hardfacing, and additive manufacturing. To achieve the desired results for a particular application, it is important to employ a suitable welding procedure, including wire and gas consumable types, equipment type, weld joint preparation, and welding process parameters.

Advantages. The flexibility and productivity of GMAW make the process a popular choice for many applications, and it is particularly well suited to high-production welding applications. Other advantages include:

- Continuous wire feeding allows long weld beads to be deposited without stopping. Welding speed and deposition rates are typically several times higher than gas tungsten arc welding (GTAW) or shielded metal arc welding (SMAW).
- GMAW can be implemented as a semiautomatic (i.e., handheld), mechanized, or

automatic operation and is the most widely used robotic arc welding process. When used as a semiautomatic process, less skill is typically required as compared with manual GTAW or SMAW.

- Unlike submerged arc welding (SAW), GMAW can be used in all positions with proper welding procedures.
- Unlike SAW and FCAW, GMAW does not produce a heavy slag or require postweld slag-removal operations.
- GMAW generally produces less smoke and fumes than SMAW or FCAW processes.
- There are many GMAW process variations that provide additional advantages for specific applications.

Limitations. As with any welding process, GMAW has limitations that restrict its use:

- Continuous wire feeding and externally supplied shielding gas makes the process equipment more complex, less portable, and requires more routine maintenance as compared with SMAW.
- Disruption of the shielding gas coverage, wire feeding problems, or improper gun maintenance can affect weld quality. Outdoor usage may require protection from air drafts that can disrupt proper shielding gas coverage.
- Accessibility is limited by the close proximity of the gun nozzle to the workpiece (generally less than 20 mm, or 0.8 in.) in order to maintain proper shielding gas coverage and wire stickout.
- Depending on the welding procedure and consumables used, GMAW can produce spatter that may adhere to the workpiece, welding gun, or part tooling.
- GMAW is generally less precise than GTAW and generally has lower deposition rates than SAW, although recent GMAW equipment advancements are reducing these limitations.
- Operator acceptance can be reduced by the higher GMAW gun weight relative to SMAW and greater radiated arc light intensity compared with SMAW, FCAW, or SAW.

Principles of Operation

A common GMAW process configuration is shown in Fig. 1. A basic GMAW system includes a welding power source, wire spool, wire feed unit, gas supply and delivery equipment, welding gun, workpiece, and electrical leads to connect the power source to the workpiece and gun. A wire electrode is continuously fed from a wire spool through a contact tube in the welding gun. Conventional GMAW employs direct current electrode positive (DCEP) polarity. The contact tip (also called a contact tube) creates an electrical contact to apply a voltage to the wire from the welding power source. The welding power source is also connected to the workpiece such that an electrical circuit is completed and current flows when the wire contacts the workpiece. Current flow causes a high-temperature electric arc to be established between the wire and the workpiece which melts the wire as it is continuously fed into the arc. The arc also melts the workpiece surface, forming a weld pool comprised of molten material from both the wire and the workpiece. An externally supplied shielding gas is directed through the gas nozzle to protect the molten weld pool and arc from atmospheric contamination and to influence the arc and weld pool characteristics.

Arc Length Regulation. Arc length has important effects on the process stability, weld shape, and weld integrity. An advantage of GMAW is self-regulation of the arc length in response to reasonable variations in the distance between the gas nozzle and the workpiece (called the standoff distance). In its most common configuration, the GMAW power source is designed to maintain a balance between wire feed and wire melting, such that a constant arc length is automatically maintained as the standoff distance is varied. This automatic arc length regulation is one reason semiautomatic GMAW generally requires lower skill as compared with SMAW or GTAW. Automatic arc length regulation is most commonly achieved through control of the welding current (amperage) to maintain a constant voltage. Arc voltage is directly related to arc length, so maintaining constant voltage results in a consistent arc length.

Fig. 1 Typical gas metal arc welding equipment configuration

The welding current determines the rate at which the wire melts and thereby affects the arc length. When the standoff distance is increased and the arc voltage begins to rise, the power source lowers the average welding current to reduce the wire melting rate and thereby return the voltage and arc length to the desired level. Conversely, reducing the standoff distance increases the current and wire melting rate to keep voltage and arc length constant.

Modes of Metal Transfer. The GMAW electrode continuously melts off at the same rate at which it is fed into the arc to maintain a consistent arc length. The mechanism by which the molten metal is transferred from the end of the electrode to the workpiece (called the mode of metal transfer) has significant effects on the weld characteristics. The three most commonly used modes of metal transfer are short-circuiting transfer, globular transfer,

and spray transfer. The mode that is obtained depends on a number of factors, including:

- Electrode and shielding gas compositions
- Electrode diameter
- Welding current and voltage levels
- Electrical polarity
- Power source output waveform and control methods
- Electrical extension of the wire beyond the contact tip

Short-circuiting transfer occurs at the lowest range of GMAW current and voltage levels and is typically employed with the smallest range of wire diameters. The low heat input produces a small, fast-freezing weld pool that is generally suited for joining thin sections, for out-of-position welding, and for bridging large root openings. The low heat input also results in

relatively little base-metal melting, which can contribute to incomplete fusion defects when welding thick sections. For this reason, short-circuit gas metal arc welding is restricted for some applications.

Figure 2 illustrates conventional short-circuiting transfer. When the arc initiates, the tip of the wire melts. As the wire advances, the molten tip contacts the weld pool, and the metal is transferred from the electrode to the workpiece. Metal transfer occurs only during the period when the electrode is in contact with the weld pool and not across the arc gap. When short circuiting begins, the welding current rises rapidly, which acts to pinch off the molten metal from the wire, thereby reestablishing the arc. The stability of the metal transfer depends on the rate and level of current rise. The current increase must be high enough to promote metal transfer yet not so high that violent separation and excessive spattering occurs.

The welding power source design and settings largely determine the current output and the stability of the transfer. In conventional constant voltage power sources, the open-circuit voltage and inductance of the power source affect the current level and rate of current rise. The optimum inductance setting depends on the electrical impedance of the welding circuit and the wire melting characteristics. More recent power source innovations employ sophisticated control methods to optimize the current output, metal-transfer stability, and fusion characteristics. Rather than rely on the natural electrical response of the power source transformer, these systems sense the arc and short-circuiting characteristics and actively control the current and voltage waveform output. In some cases, welding current and voltage control is synchronized with wire feed pulsation. The result is improved process stability and an expansion of the process capabilities beyond what is achievable with conventional short-circuiting transfer, as is discussed in the section “Process Variations” later in this article.

The choice of shielding gas influences the operating characteristics of the arc, weld metal wetting, and weld penetration. For example, when welding steels with conventional power sources, carbon dioxide shielding gas allows for deeper penetration and improved fusion characteristics but generally produces more spatter than inert shielding gases such as argon. Mixtures of carbon dioxide and argon can be used to achieve a compromise between weld penetration and spatter generation. Advanced controls employed by some modern power sources minimize spatter even when using carbon dioxide shielding gases.

Globular transfer occurs at current and voltage levels that are higher than used for short-circuiting transfer. This mode is characterized by large, irregular drops of molten metal that form on the end of the wire before transferring across the arc. Figure 3 illustrates globular transfer. The cycle starts with a drop forming on the end of the wire. As the wire continues

to melt, the drop grows until it is large enough to detach. If the arc length is too short, the drop may occasionally bridge the gap between the wire and pool, creating a short-circuit condition. The short circuit superheats the drop, causing it to explode and produce spatter. Because gravity is a significant contributor to the drop detachment and transfer, use of the globular mode of metal transfer is generally limited to the flat position.

The welding current and voltage ranges that produce globular transfer depend on the consumables used. For steel electrodes and substantially inert shielding gases, axial globular transfer occurs at current and voltage levels that are slightly higher than that used for short-circuiting transfer. With carbon dioxide shielding, however, this mode occurs up to very high current levels. Carbon dioxide shielding produces a randomly directed globular transfer when the welding current and voltage values are significantly higher than that used for short-circuiting transfer. Although severe spatter conditions may result with conventional arc lengths, carbon dioxide is still the most widely used

shielding gas for welding steel with the globular transfer mode. The spatter can be controlled to some extent by “burying” the arc below the base-metal surface, using high currents and relatively low voltages, as illustrated in Fig. 4. In this case, the high arc force depresses the weld pool surface to create a cavity that contains the spatter. This condition results in deep weld penetration but can produce poor weld metal wetting and excessive weld reinforcement. Recent advances in welding power source control technology have improved the arc stability and expanded the usable range with carbon dioxide shielding gas.

Spray transfer occurs at the highest current and voltage levels of the three modes. In spray transfer, small drops of metal stream from the end of the electrode and are axially accelerated across the arc gap with little or no spatter. The drops are typically smaller than the wire diameter and form at frequencies of over 100 times per second. Spray transfer is most easily recognized by the pointed appearance of the end of the wire electrode and the bright metal vapor arc core, as illustrated in

Fig. 5. If the arc length is sufficiently long, short circuits are avoided, resulting in very little spatter.

Spray transfer requires use of DCEP polarity and a welding current level that is above a critical value called the transition current. At current levels below the transition current, transfer occurs in globular mode. The transition current level depends on the wire chemistry, wire diameter, shielding gas composition, and, to a lesser extent, the electrode stickout beyond the contact tip. Transition currents for various diameters and shielding gas compositions are provided in Table 1. The table shows that transition current increases with wire diameter and with shielding gas CO₂ content for mild steels. For high CO₂ concentrations, a stable spray transfer cannot be achieved under normal usage conditions.

The spray transfer mode results in a highly directed stream of discrete drops that are dominated by arc forces that overcome the effects of gravity. This allows spray transfer to be used in any position with proper procedures. Another characteristic of spray transfer is the “finger” weld penetration produced directly under the electrode tip. The depth of this penetration is related to the current density and travel angle, with higher current levels and drag angles producing the greatest penetration. While increased penetration is often desirable, excessively deep and narrow finger penetration may be difficult to align with the weld joint and can lead to root defects such as cracking or porosity in some materials.

Spray transfer is often preferred for welding thick sections in the flat position due to the low spatter, high productivity, and good fusion characteristics. However, the high current levels can be problematic for welding thin materials or for welding out of position. For thin materials, the deep penetration can result in excessive root reinforcement or burn-through. Also, the large, fluid weld pool produced with high wire feed speeds and high average power levels can be difficult or impossible to control when welding in the vertical or overhead positions.

Fig. 2 Short-circuiting transfer

Fig. 3 Globular transfer

Fig. 4 Buried-arc technique

Pulsed spray is a variation of spray transfer in which the welding power is cycled from a low level to a high level, at which point spray transfer is attained. The lower average power allows pulsed gas metal arc welding to be used on thinner materials and provides better out-of-position operability than conventional spray transfer. A specially designed power source is employed to produce the pulsed output power. Figure 6 is a simple example of a pulse waveform. In this example, the current is raised to a high peak level exceeding the spray transition current for a short period of time (typically a few

milliseconds), then dropped to a low background level for the rest of the cycle. The peak pulse causes a drop of metal to be detached and propelled across the arc. The background period maintains the arc and melts the end of the wire. The cycle repeats up to several hundred times per second. The result is a stable, low-spatter spray transfer at average welding power levels significantly below that which is required for conventional spray transfer. Pulse spray waveforms may be designed to produce one drop per pulse, with the drop size similar to the wire diameter, as shown in Fig. 7.

Power source manufacturers tailor their pulse waveforms to provide preferred operation characteristics for given electrode material, diameter, and shielding gas combinations. In some cases, complex multilevel waveforms are developed for specific applications. The power source output waveforms also adapt for changes in wire feed speed setting, voltage trim setting, or stickout distance. This synergic adaptation may involve changing pulse frequency or levels to maintain the proper arc length and stable spray transfer over a wide range of operating conditions.

Process Parameters

The important variables of the GMAW process that affect weld penetration, bead shape, arc stability, productivity, and overall weld quality are:

- *Welding consumables:* Shielding gas composition, wire electrode type, diameter, and other physical attributes
- *Equipment settings:* Shielding gas flow rate, wire feed speed, polarity, voltage, pulsing conditions
- *Gun manipulation:* Standoff distance, travel speed, travel angle, work angle, weave, welding position and progression
- *Dependent variables:* Welding current, mode of metal transfer

Knowledge and control of these variables are essential to consistently produce welds of satisfactory quality. Because they are not completely independent of each other, changing one variable generally requires changing one or more of the others to produce the desired results. The selection is further complicated by the fact that the optimal settings are specific to the application, including the type and thickness of base metal, joint geometry, weld performance requirements, and so on. Thus, no single set of parameters provides optimum results in every case. Furthermore, there are additional parameters related to specific GMAW process variations. The following describes the effects of some of the more important parameters of conventional GMAW.

Welding current is considered a dependent variable because it is not directly set when a constant voltage power source is used but rather is a function of other process variables, such as wire feed speed, wire diameter, and standoff distance. Current varies in a direct relationship to wire feed speed and diameter and in an inverse relationship to standoff distance. For example, Fig. 8 illustrates the nonlinear relationship between wire feed speed and current for selected steel electrode diameters. These relationships exist because the power source welding current output varies dramatically with slight changes in arc voltage (arc length). Welding current level has important impacts on the process. Welding current can

Fig. 6 Example of welding current waveform for pulsed gas metal arc welding

affect weld penetration, fusion characteristics, weld shape, and metal-transfer mode.

Polarity describes the electrical connection of the welding gun in relation to the terminals of the direct current welding power source. When the gun lead is connected to the positive terminal, the polarity is designated direct current electrode positive (DCEP). The vast majority of GMAW applications employ DCEP polarity, because it provides for a more stable arc, improved metal transfer, lower spatter, improved bead profile, and better penetration than direct current electrode negative (DCEN) polarity. Although relatively uncommon, a recent process variation employs variable polarity, switching rapidly between DCEP and DCEN, to tailor weld penetration and deposition rate for particular applications.

Arc voltage directly affects arc length. When all other variables are held constant, an increase in arc voltage setting will result in a longer arc. The specific power source voltage value to produce a given arc length depends on a number of factors, such as the shielding gas composition, wire feed speed, and standoff distance. Although control of arc length is more important, voltage is more easily monitored and is typically specified in welding procedures. An increase in arc length (increased voltage) tends to flatten the weld bead and increase the width of the fusion zone. Excessively long arc length can cause porosity, spatter, undercut, and poor weld shape when welding out of position. Reduced arc length tends to produce a narrower bead with a higher crown. Insufficient voltage can result in excessive short circuiting, arc instabilities, and spatter.

Travel speed is the rate at which the arc is moved along the weld joint. When all other conditions are constant, penetration is maximized at an intermediate travel speed that allows the arc energy to be directed onto the weld joint at the leading edge of the weld pool. At very slow speeds, the weld pool flows ahead of the arc, which reduces base-metal heating and hence penetration. As the travel speed is increased, the arc acts more directly on the base metal. However, further increases in travel speed impart less thermal energy to the base metal, and penetration is reduced. As travel speed is increased further, there is a tendency toward undercutting and weld bead humping. To some extent, the onset of these problems can be delayed by using a push angle along with an optimized arc length.

Travel angle is the orientation of the electrode with respect to the direction of travel. A push angle is the angle when the electrode is pointing toward the direction of travel, and a drag angle is the angle when the electrode is pointing away from the direction of travel. A drag travel angle that ranges from 5 to 15° (from perpendicular) provides maximum penetration and a narrow, convex surface. More common practice is to use a push travel angle, which provides better visibility for the operator and a weld with a flatter surface profile. For some materials, such as aluminum, a leading angle is preferred because it provides arc cleaning of base-metal oxides ahead of the molten pool, which promotes wetting and reduces base-metal oxidation.

Electrode extension is the distance between the last point of electrical contact with the contact tip and the end of the electrode. An increase in electrical extension increases electrical resistive heating of the electrode, which contributes to a greater electrode melting rate. Excessive electrode extension can reduce penetration and produce a narrow, crowned weld bead. The optimum electrode extension is generally in the range of 6 to 13 mm (0.25 to 0.5 in.) for short-circuiting transfer and 13 to 25 mm (0.5 to 1.0 in.) for globular or spray transfer.

Consumables

Proper electrode and shielding gas selection is essential to the success of any welding procedure. The electrode chemical composition is selected to achieve the desired weld-metal properties. For example, electrodes are typically specified to produce a minimum tensile strength. Other characteristics of interest may include toughness, corrosion resistance, color match, or compatibility with the base material. The composition may include deoxidizers and other agents to compensate for reactions in the

Fig. 7 Typical pulsed spray transfer

Fig. 8 Typical relationship between wire feed speed and welding current for several steel electrode diameters. DCEP, direct current electrode positive

welding arc and to influence arc stability, weld-metal fluidity, and wetting.

For steel electrodes, higher levels of silicon and manganese tend to produce a more fluid weld pool with better wetting and a flatter weld bead. Excessive fluidity, however, makes out-of-position welding difficult. Most applications employ filler metals of similar composition to that of the base metal. Gas metal arc braze welding, however, involves use of an electrode composition that has a significantly lower melting point than that of the base material, such as a copper alloy electrode used with a steel base material. Braze welding may be employed in situations where it is desirable to minimize base-metal melting, such as the sheet metal example in Fig. 9.

The electrode diameter is selected depending on the current range to be used for a given application. Table 2 illustrates typical current ranges for different steel wire diameters. The larger electrodes use higher current levels; however, the usable current ranges overlap to some degree. A larger electrode requires higher minimum current than a smaller electrode for the same metal-transfer characteristics. Higher currents produce greater electrode melting and larger, more fluid weld deposits. In general, smaller wire diameters are best for welding thin materials and for out-of-position welding, where lower current levels are preferred. Larger electrodes are generally preferred for applications requiring high deposition rates and deep penetration.

The electrode physical characteristics, including surface finish and straightness, are also important considerations. Electrode specifications establish requirements to ensure that users receive a uniform product that feeds smoothly. This includes having uniform winding on the spool or coil; smooth, clean surface finish; uniform diameter; and prescribed cast

Fig. 9 Cross section of a gas metal arc braze weld on sheet metal. Courtesy of Edison Welding Institute

Table 2 Typical current ranges for different wire diameters

Electrode diameter		Useable current range, A
mm	in.	
0.9	0.035	60–280
1.2	0.045	125–380
1.6	0.062	275–475

and helix. Cast and helix refer to the straightness, determined by laying a single coil of wire on a flat surface. A coil diameter that is too small (cast) or shows an excessive lift from the flat surface (helix) may cause wire feeding problems or excessive contact tip wear.

The shielding gas composition is selected to protect the molten metal and to affect the arc characteristics, mode of metal transfer, depth of fusion, weld bead profile, welding speed, and cleaning action. Figure 10 illustrates typical bead shape effects with various shielding gas compositions. Inert gases, such as argon and helium, are commonly used, as is the active gas carbon dioxide. It is also common to use mixtures of these gases and to employ small additions of oxygen.

Equipment

The major components of a GMAW installation include a welding gun, shielding gas supply, electrode feed unit, power source, and associated controls.

The welding gun provides electrical current to the electrode, directs the electrode to the workpiece, and directs the shielding gas to the weld area. A power cable electrically connects the gun to the power source. Different types of guns have been designed for many varied applications, ranging from light-duty guns for semiautomatic (handheld) applications to

heavy-duty guns for high-current automated applications. Light-duty guns are designed to be cooled by the surrounding air; however, as current requirements increase, a water-cooled gun may be needed. Figure 11 illustrates a typical air-cooled semiautomatic gun configuration. Guns are rated based on current-carrying capacity to operate continuously for a set period of time. Current ratings are often specified using CO₂ shielding gas and must be reduced if inert shielding is used.

The contact tip, which is usually made of copper or a copper alloy, both directs the electrode toward the work and transfers power to the electrode. Proper functioning of the contact tip is critical to the GMAW process operation. The electrode must feed easily through the contact tip while maintaining a consistent electrical contact point. Hesitation in wire feeding or variation in the contact point can create arc variations and instabilities. To achieve consistent operation, the contact tip hole is slightly larger than the wire diameter being used. The wire sliding through the tip causes wear, which can enlarge and elongate the hole. Spatter can also adhere to the tip and affect the proper operation. Routine maintenance should be performed to check and replace worn or damaged tips. Contact tip life can be affected by many factors, including the welding conditions, electrode surface condition, electrode straightness, tip design, and gun design.

The gas nozzle directs an even-flowing column of shielding gas into the weld zone to protect the molten weld metal from atmospheric contamination. Nozzle size is selected according to the application, with larger nozzles used when high-current welding produces a large weld puddle, and small nozzles used for low-current and short-circuit welding. Depending on the welding conditions, spatter can accumulate on the nozzle and disrupt the flow of shielding gas, necessitating periodic nozzle cleaning. When welding reactive materials, such as titanium, a trailing shield may also be used to protect the solidified weld bead during cooling.

The shielding gas supply system provides a constant pressure and flow rate of shielding

Fig. 10 Effect of shielding gas type on weld penetration and shape for steel

Fig. 11 Typical air-cooled semiautomatic gun configuration

gas during welding. The shielding gas source can be a high-pressure cylinder, a liquid-filled cylinder, or a bulk-liquid tank. The type and size of the gas storage source depend on economic considerations that are based on shielding gas consumption rates. Gas mixtures are available in cylinders, or mixing devices can be used to produce the desired mixtures on site. The regulator reduces the source gas pressure to constant working pressure, regardless of variations at the source. A gas flow meter, which is calibrated for the specific gas mixture, is often used to ensure a consistent gas flow rate. Hoses are used to transmit the gas from the source to the gun. Gas supply system connections should be periodically checked to ensure that they are leak-free to prevent intrusion of air into the shielding gas.

The electrode source must provide a large volume of electrode material that can be readily fed to the gun to ensure maximum process efficiency and stable operation. The source is usually in the form of a spool or coil that can hold from 7 to 27 kg (15 to 60 lb) of wire that has been wound to allow free feeding without kinks or tangles. Small spools of 0.45 to 0.9 kg (1 to 2 lb) are used for spool-type guns (Fig. 12). Large spools of up to 115 kg (250 lb) are also available, and material can be provided in drums of 340 to 455 kg (750 to 1000 lb). These large sources are often used with high-volume automated applications to allow long periods of continuous operation without stopping. For automated applications requiring precise weld wire positioning, a wire straightener may be placed between the electrode source and electrode feed unit to reduce the electrode cast.

The electrode feed unit, or wire feeder, consists of an electric motor, drive rolls, and accessories for maintaining electrode alignment and drive roll pressure (Fig. 13). The motor provides the mechanical energy to pull the electrode from the source and push it through the gun and to the work. The feed unit can be an integral part of the gun, as is the case with spool-type guns. Dual-feed (push-pull) units include a pull feeder in the gun and a separate push feeder near the electrode supply. Spool guns and dual-feed units are useful for feeding soft electrodes, such as aluminum, which are difficult to push through a conduit to the gun.

The feed motor is connected through a gear reducer to a set of wire feed rolls that transfer

Fig. 12 Semiautomatic spool gun

mechanical energy to the electrode. Various types of drive rolls are available, including knurled, U-groove, V-groove, and flat. Selection of the proper roll type and pressure is important to ensure proper feeding of the electrode without damaging the electrode surface and creating debris that can clog the gun or liner. Knurled rolls are often used with harder materials, such as steel, to avoid slippage of the wire with minimal roll pressure. The U- or V-groove rolls are often used with softer electrode materials, to allow the electrode to be gripped without deformation. Flat rolls can be used in combination with U- or V-grooves for smaller-diameter electrodes.

The electrode conduit and liner direct the electrode from the feed rolls to the gun and contact tip. The conduit/liner diameter and materials are selected to provide support to the electrode while allowing it to slide freely without hesitation, which is important to maintaining arc instability and contact tip life. A steel liner is often recommended when using hard electrode materials such as steel. Other materials, such as nylon or other synthetic polymers, are often recommended for softer electrode materials, such as aluminum. Wire liners can wear or collect debris from the wire surface, resulting in increased sliding friction. A preventative maintenance program should include periodic inspection and replacement of wire liners when necessary.

The welding power source provides the electrical power that is delivered to the electrode and workpiece to produce the arc. Output voltage levels typically range from 15 to 80 V. Depending on the application, output current

levels can range from under 100 A to well over 500 A. Because the vast majority of GMAW applications use DCEP polarity, the positive welding lead is usually connected to the gun and the negative lead to the workpiece. The input power can be either a utility line (single or three phase, 120 to 480 V) for fixed installations, or an internal combustion engine with a generator for field applications. Power conversion technology has evolved from transformer-rectifier designs to inverter designs, which allow smaller and lighter power sources for equivalent output ratings. These newer designs also allow sophisticated control of the output waveforms for particular applications.

Output characteristics can be either constant current or, more commonly, constant voltage, also known as constant potential. A conventional constant voltage power source compensates/maintains a constant arc length when the contact-tip-to-workpiece distance varies by changing the output current and hence the electrode burn-off rate. Power source manufacturers have also developed many types of power source output waveforms and control strategies. Pulse-spray power source waveforms are tailored to specific electrode type, diameter, feed speed, and gas composition. The pulse waveform is automatically adjusted in response to changes in electrode feed speed or contact-tip-to-workpiece distance. This may involve changing pulse frequency, background current, or other waveform characteristics. Power sources have also been developed for short-circuiting transfer, again tailoring the output waveform to achieve desired arc characteristics.

Fig. 13 Typical wire feeder and drive roll configuration

Welding controls are used to set the wire feed speed, voltage, and other process parameters. Power source settings and controls are a function of the power source type. Conventional constant voltage power sources have an electrode feed speed setting (which also determines the current) and a voltage setting (which affects the arc length). Power sources intended for short-circuiting transfer may have inductance and slope settings. Pulse synergic power sources often have electrode/gas selections to choose from and provide arc voltage trim adjustments. The location of the controls varies by power source type and application. Control settings can be found on wire feeders, power sources, or located remotely for ease of adjustment. Automated GMAW applications often involve a separate welding controller that coordinates power source parameters with motion control.

Process Variations

The advent of computer-based controls in combination with improved power conversion technologies has contributed to significant GMAW innovations with particular benefits for specific applications. The following briefly describes some of these variations.

Tandem GMAW makes use of two electrodes and two welding arcs in close proximity, which together produce a single weld pool (Fig. 14). This process variation makes use of two coordinated welding power sources and electrode feed units connected to a gun having two contact tips. Each arc may be separately adjusted to achieve the desired arc stability, penetration, and fill characteristics. This configuration allows significantly increased welding deposition rates and travel speeds as compared with conventional single-electrode GMAW. Tandem GMAW is generally limited to mechanized or automated implementations and is most commonly applied in the flat position, although it can be used for out-of-position welding with the proper welding procedures.

Reciprocating wire feed short-circuit GMAW involves varying the electrode feed speed and direction in coordination with control of welding current and voltage levels. Similar to conventional short-circuiting transfer, this process variation has an arcing phase where the end of

Fig. 14 Tandem gas metal arc welding uses two electrodes in close proximity.

the electrode melts and a shorting phase where the metal is transferred. Unlike conventional short-circuit welding, this process variation does not rely on a sudden rise in welding current to pinch off the molten metal. Rather, the electrode is advanced and retracted many times each second, allowing a single drop of material to be precisely deposited during each cycle. Because the welding current can be lowered during the shorting phase, spatter can be virtually eliminated. The net result is a low-spatter means to produce precise deposits, such as in Fig. 15.

Fig. 15 Reciprocating wire feeding gas metal arc welding can produce precise deposits, such as this edge buildup on stainless steel. Courtesy of Edison Welding Institute

Variable polarity GMAW makes use of a specially designed welding power source that rapidly switches polarity to control drop transfer, deposition rate, and base-metal penetration. Figure 16 illustrates a variable polarity waveform with a portion of the cycle spent on electrode negative (DCEN) polarity and a portion of the cycle spent on electrode positive (DCEP) polarity. Arc stability is maintained by the rapid switching between electrode positive and electrode negative polarities, such that the arc does not extinguish during the instantaneous zero-current condition. As Fig. 17 shows, polarity has a dramatic effect on weld penetration. During the DCEN polarity portion, most of the arc energy is directed toward electrode melting, allowing higher deposition rates and reduced penetration. During the DCEP polarity portion, the majority of arc energy goes to base-metal melting and penetration. Thus, increasing the proportion of the time spent on DCEN reduces base-metal penetration and increases deposition rate. Drop transfer also occurs during the DCEP portion, so the output waveform determines the drop size and transfer frequency.

Hybrid laser GMAW is a process variation in which laser beam delivery optics are integrated with a GMAW gun. Higher productivities are possible than conventional GMAW, as the laser beam provides added penetration and stabilizes the GMAW process at higher travel speeds. Figure 18 illustrates the greater penetration possible with hybrid laser GMAW. Better tolerance to joint fit-up variations are possible than with conventional laser welding, because GMAW provides added fill and alloying. The arc and laser are in close proximity, such that the laser keyhole and GMAW weld pool interact. This process variation may be operated either with the laser beam leading or the GMAW torch leading.

Hybrid plasma GMAW involves combining a plasma arc welding torch with GMAW. The plasma arc welding torch provides additional base-metal heat input to improve wetting or penetration. This technique has been applied to improve weld profile and speed for braze welding applications.

Fig. 16 Example of variable polarity gas metal arc welding output waveform. Courtesy of Edison Welding Institute

Narrow-groove GMAW makes use of specialized joint configurations to efficiently weld heavy sections with minimal distortion. Figure 19 illustrates a typical narrow-groove joint configuration. Narrow-groove GMAW requires the contact tip to reach down into the bottom of the joint to deposit each successive weld pass. To provide access, shielding gas is delivered with ancillary devices rather than a conventional gas nozzle. Special precautions are necessary to ensure the electrode is positioned to achieve proper side wall fusion. Several approaches have been developed to achieve side wall fusion, including tandem GMAW with each arc directed to one sidewall, and rotating contact tip, which directs the electrode to the sidewall. Figure 19 is an example of a narrow-groove weld in 125 mm (5 in.) thick plate produced at over 9 kg/hr (20 lb/hr) using a combination of tandem and electrode rotation.

Safety Considerations

The major hazards of concern during GMAW are inhalation of fumes and gases, electrical shock, and eye or skin injury from arc light radiation and hot spatter.

The type and amount of fumes and gases present during welding depend on the shielding gas type, electrode being used, the alloy being welded, and the presence of any coatings on

the base material. To guard against potential hazards, a welder should keep his head out of the fume plume. Ventilation is always required, and special precautions should be followed when welding in confined spaces where gases or fumes can collect. Fume sampling can be used to assess potential hazards. In some cases, respirators may be warranted to protect welders from hazardous fumes and gases.

Electric shock can result from exposure to high open-circuit voltages of GMAW power sources. All electrical equipment and the workpiece must be connected to an approved electrical ground. Cables should be of sufficient size to carry the maximum current required. Insulation should be protected from cuts and abrasion, and the cable should not come into contact with lubricants or other fluids that may cause deterioration. Work areas, equipment, and clothing must be kept dry at all times. The welder should be well insulated, wearing dry gloves, rubber-soled shoes, and standing on a dry board or platform while welding.

Radiant arc light, especially in the ultraviolet wavelength, is intense during GMAW. GMAW can also produce significant amounts of hot metal spatter. To protect eyes from injury, the proper filter shade should be used for the welding current level. Approved safety glasses should always be worn with GMAW to protect against hot spatter. Skin should also be protected from continuous exposure to the arc light

and hot spatter. The high-intensity ultraviolet radiation can cause rapid deterioration of cotton clothing. Leather, wool, and metal-coated cloth will better withstand exposure to arc radiation and protect skin. Ear protection both prevents exposure to excessive noise in the work area and can prevent spatter from entering the ear.

Conventional fire prevention requirements should be followed, such as removal of combustibles from the work area. Sparks and spatter can travel long distances, so care must be taken to minimize the start of a fire at locations removed from the welding operation. For further information, see the guidelines set forth in the National Fire Protection Association Standard NFPA No. 51B, "Fire Prevention during Welding, Cutting, and Other Hot Work."

Care should be exercised in the handling, storage, and use of cylinders containing high-pressure and liquefied gases. Cylinders should be secured with chains or straps during handling and use. Approved pressure-reducing regulators should be used to provide constant, controllable working pressure for the equipment in use. Lubricants or pipe fitting compounds should not be used for making connections, because they can interfere with the regulating equipment, and, in the case of oxygen service, they can contribute to a catastrophic fire. For further safety information, see ANSI/AWS Z49.1, "Safety in Welding and Cutting and Allied Processes."

Plasma Gas Metal Arc Welding*

Revised by Ian D. Harris, Edison Welding Institute

PLASMA GAS METAL ARC WELDING (GMAW), also known as plasma metal inert gas (MIG) welding, was invented at the Philips Research Laboratories in Eindhoven, Netherlands, in approximately 1969 (Ref 1). The process can be defined as a combination of plasma arc welding (PAW) and GMAW within a single torch, where a filler wire is fed through the plasma nozzle orifice. Although originally referred to as plasma-MIG welding, the preferred term is plasma-GMAW. The process can be used for both welding and surfacing.

The plasma-GMAW process is illustrated in Fig. 1. Separate power supplies are used for the PAW and the GMAW elements of the equipment (for descriptions of PAW and GMAW, see the articles "Plasma Arc Welding" and "Gas Metal Arc Welding" in this Volume). An arc is struck between the tungsten electrode and the workpiece in a similar fashion to that of a PAW system. The filler wire can be fed to the plasma arc, either with or without the GMAW arc established. Without power supplied to the filler wire, the system can be operated as a PAW system with concentric feed of filler wire. Later versions of the system incorporated an

annular electrode to replace the offset tungsten electrode in the welding torch. A new configuration of hybrid plasma-GMAW is available, with in-line rather than concentric configuration of the two heat sources, and is also described briefly in the "Gas Metal Arc Welding" article.

The equipment can be operated either with a single power source, effectively as a PAW system with concentric filler wire feed, or with two power sources, for the plasma-GMAW operation. The polarity of the tungsten electrode is direct current electrode negative, as is that of the GMAW part of the system. The heat of the plasma arc is sufficient to achieve good metal-transfer stability for the GMAW element, despite the fact that when this process is used separately, it is almost always used in a direct current electrode positive mode. The filler wire is heated by the constricted plasma arc, as well as by the cathode heating of its own arc, and by resistance heating along the wire extension. Therefore, the melting and deposition rates of the wire are higher than the rates achieved by heating with either arc alone.

Metal transfer is governed not only by plasma streaming but also by arc forces between the wire tip and the workpiece. Because the metal droplets are totally enclosed by the plasma stream, spray transfer takes place even though the GMAW element operates on negative polarity.

Advantages and Disadvantages. The advantages of the plasma-GMAW process include deposition rates and joint completion rates that are higher than those of the conventional GMAW process. The independent control of the plasma arc and current to the filler wire leads to more control of metal deposition. This capability can yield improved productivity and good flexibility for controlling heat input and arc characteristics in both welding and surfacing operations. Good control of dilution is achieved by running the system without any power applied to the filler wire. Metal-transfer stability is increased, compared to that of the conventional GMAW process, and results in lower spatter levels. The cleaning action of the plasma arc results in lower porosity in

aluminum alloys, compared to that of the conventional GMAW process.

Disadvantages include the capital cost of two power sources (although there are systems that are designed to operate with one), the greater complexity of the torch, and the increased maintenance time and cost associated with this complexity. With two power sources, more welding parameters must be set up, compared to the conventional GMAW process.

Equipment

As noted earlier, the basic equipment includes a power source for the plasma arc and a power source for the GMAW part of the system. A special torch incorporating both a contact tip for the GMAW element and a cathode for the PAW element is required. The initial design incorporated an offset tungsten electrode, as well as a concentric conduit and contact tip for the delivery of the consumable wire (Fig. 1). A later design incorporated a concentric cathode for the plasma arc (Fig. 2).

The plasma-GMAW torch can be readily fitted to existing welding equipment, such as side beams and welding carriages, to replace the GMAW process in mechanized welding operations.

Power Sources. A constant-current power source with a high-frequency circuit to initiate the pilot arc is used for the plasma arc component of the system. The power source for the GMAW component can be used as a constant-voltage or a constant-current rectifier. Power sources have welding currents that typically range from 40 to 200 A for the plasma arc and from 60 to 300 A for the GMAW element at 100% duty cycle. However, equipment with welding currents up to 800 A is available and can be used for surfacing applications.

Welding Torches. A special torch with a concentric cathode for the plasma arc and a concentric conduit and contact tip for the delivery of the consumable wire is required (Fig. 2). A water-cooled copper alloy nozzle is

Fig. 1 Schematic of plasma gas metal arc welding equipment. Source: Ref 1

used to constrict the arc and to form a collimated plasma jet that exits the nozzle orifice. A plasma orifice gas and a focusing gas from the same supply are used; the latter is delivered via channels between the plasma welding electrode and the constricting nozzle. The focusing gas results in greater arc constriction and arc stability and prolongs the life of the constricting nozzle by creating a boundary gas layer between the nozzle orifice and the plasma arc. The contact tip, plasma cathode, and the constricting nozzle are all directly water cooled to provide 100% duty cycle at the typical welding currents identified in the preceding section, "Power Sources."

Shielding Gases. Three shielding gases are used: one for the plasma (orifice) gas, one to provide additional arc constriction and arc stability, and one for supplementary shielding. The plasma gas and the focusing gas are usually argon, because an inert gas is required to prevent oxidation of the PAW electrode. The supplementary shielding gas can be argon, argon-oxygen, argon-carbon dioxide, or argon-hydrogen, depending on the nature of the workpiece being welded or, in the case of a surfacing operation, on the material being deposited. Argon is used when welding aluminum alloys, whereas argon-oxygen and argon-carbon dioxide are used when welding steels. Argon-hydrogen is used when welding stainless steels or when surfacing with them.

Procedure

Process Operating Procedure. The plasma arc is ignited using a pilot arc in a fashion similar to that of a PAW system. The main arc is transferred from the electrode to the workpiece, and the plasma jet passes through the nozzle orifice. The system can be operated in this way, with the

Fig. 2 Schematic of modern plasma gas metal arc welding torch with annular plasma arc welding electrode and additional (focusing) gas stream. Source: Ref 1

concentric cold wire being fed through the axis of the torch. A higher melting rate is achieved when power is applied to the wire through the contact tip and when both arcs are run simultaneously. The higher energy imparted to the wire by the plasma arc results in an increased wire deposition rate (Table 1). In this operating mode, deposition rates higher than those typical of the GMAW process can be achieved.

Inspection and Weld Quality Control.

Inspection requirements are similar to those of other arc welding or surfacing operations. Visual, ultrasonic, and radiographic inspection techniques are most appropriate. The dual action of the GMAW and plasma arcs results in weld quality that is sometimes higher than that achieved by the GMAW process alone. This is particularly true for aluminum alloys, because the cleaning action of the plasma arc often results in reduced porosity.

Quality control requires monitoring the welding parameters for both power sources, as well as monitoring the wire feed. In addition, the condition of the nozzle orifice (that is, the wear and concentricity of the orifice) should be monitored.

Troubleshooting. The relatively complex nature of the welding torch involves increased maintenance time. Erosion of the copper alloy nozzle orifice will cause a change in the arc shape and will affect the weld profile. Therefore, the nozzle should be checked periodically.

Applications

Material Types. The plasma-GMAW process is suitable for welding a wide variety of materials. The high heat energy supplied by the plasma and gas metal arcs makes the process suitable for high-melting-point materials, such as tungsten and molybdenum. The most common application is welding aluminum sheet and plate. Wear-resistant steels are used with the process in hardfacing applications. Austenitic stainless steels, such as types 308, 309, and 347, as well as nickel alloys, such as alloy 625, are used in cladding applications. Both solid and flux cored wires

(Ref 3) can be employed for welding and surfacing, although most applications involve solid wires.

Industries. The plasma-GMAW welding process has been used for the deposition of corrosion-resisting stainless steel and nickel-base alloys in the offshore industry, for the general fabrication of silos and tank trailers made from aluminum alloys (Ref 2), and for hardfacing applications in the excavation equipment industry as well as the dredging and offshore industries.

Typical Components and Joints. The plasma-GMAW process is suitable for welding of joints and for surfacing operations. The wide range of heat inputs available by choosing how to apply current to the consumable electrode provides additional flexibility for surfacing operations, compared to the range of heat inputs available with an external wire feed using the GTAW/PAW or the conventional GMAW process.

Single-V butt joints are commonly used for the plasma-GMAW welding of plate. A full-penetration weld can be made in a single pass on a 9.5 mm (0.375 in.) thick mild steel plate when operating the plasma and gas metal arcs simultaneously. This compares to three passes when just the PAW process is used. One would expect the same joint to require two or three passes for the conventional GMAW process.

When butt welding aluminum alloy sheet and plate in thicknesses ranging from 4.6 to 6.1 mm (0.18 to 0.24 in.), single-pass welds can be made at travel speeds that are more than twice as fast as when the GMAW process is used alone (Table 2). Welding of aluminum plate 10 mm (0.39 in.) thick in a single pass without edge preparation has been reported (Ref 4). The wire feed rate and melting rate were 14.5 m/min (571 in./min) and 80 g/min (2.82 oz/min), respectively, for the 1.6 mm (0.06 in.) diameter welding wire using the plasma-GMAW process. Lower porosity levels are achieved with the plasma-GMAW process because of the cleaning action of the plasma arc. When using mild steel and stainless steel, the plasma-GMAW process can make butt welds

comparable to those made with the GMAW process alone at almost twice the travel speed (Table 2).

The hardfacing of dredging equipment with martensitic steel was made more productive by using the plasma-GMAW process, rather than the conventional GMAW

process. Higher deposition rates were achieved, resulting in reduced labor costs for the semiautomatic welding operation. Deposition rates of up to 20 kg/h (44 lb/h) can be achieved by plasma-GMAW surfacing of mild steel with stainless steel flux cored wires (Table 3).

Personnel

Skill Level and Training. The plasma-GMAW process can be used for semiautomatic, mechanized, or automated operation. It requires a skill level comparable to that of the conventional GMAW process, although additional parameters must be set for the plasma arc. Most welding and surfacing activities are carried out with mechanized equipment. When welding parameters are set, operation is similar to that of the GMAW process.

Health and safety issues are similar to those of other arc welding processes. Electric shock, eye protection, burns, ultraviolet radiation, and fume exposure are typical concerns. The plasma-GMAW process generates more radiant heat than the conventional GMAW process.

Hybrid Laser Arc Welding

Brian M. Victor, Edison Welding Institute

HYBRID LASER ARC WELDING (HLAW), also known as laser hybrid welding or simply hybrid welding, is a metal joining process that combines laser beam welding (LBW) and arc welding in the same weld pool. The concept of HLAW was first introduced in the 1970s as “arc-augmented laser welding” that combined LBW with gas tungsten arc welding (GTAW) (Ref 1). Since then, arc processes including GTAW, gas metal arc welding (GMAW), and plasma arc welding have been used; however, GMAW has become the most popular arc process for HLAW. Historically, high-power continuous-wave lasers such as carbon dioxide (CO₂) gas lasers and solid-state neodymium-doped yttrium-aluminum-garnet (Nd:YAG) lasers have been used for HLAW. With advancements in the performance of other solid-state technologies, fiber lasers, thin-disk lasers, and semiconductor diode lasers are increasingly used for HLAW.

Advantages and Limitations

Advantages. Hybrid laser arc welding is a high-productivity welding process that typically combines GMAW with LBW in the same weld pool. This process is used with mechanized or automated welding applications. These process combinations result in a synergy that incorporates the benefits of each individual process. Hybrid laser arc welding can offer the following advantages:

- The high energy density from the laser process can provide deep weld penetration and high processing speeds.
- With appropriate parameters, HLAW can be performed in all welding positions.
- Hybrid laser arc welding can provide lower heat input and less distortion than conventional arc welding.
- Hybrid laser arc welding can produce narrow welds with small heat-affected zones.
- Because of the deep-penetration capability, HLAW can enable less filler-metal usage for a given material thickness or reduce the number of passes required for a multipass joint.
- Filler material from the GMAW process can provide alloying additions and joint filling that is not possible with autogenous laser welding.

- Hybrid laser arc welding has a greater tolerance to joint gaps than autogenous laser welding.
- The laser component of the HLAW process can maintain a consistent weld pool at high processing speeds and reduce weld humping.
- Hybrid laser arc welding is applicable to a wide range of metal alloy systems.
- For reactive metals such as titanium and zirconium, the laser can provide stabilization of the arc welding process.
- Full-penetration HLAW can be performed without a backing material or consumable insert. In some cases, full-penetration HLAW of steel can be performed without root shielding gas.
- Because HLAW is an automated process, precise welds (relative to alignment, width, and penetration) can be obtained.

Limitations. Although HLAW is a productive and advantageous welding process, there are certain limitations that restrict its use:

- Precise alignment and strict part fit-up are required to maintain weld consistency and quality with HLAW.
- Hybrid laser arc welding is only used in mechanized or automated applications.
- Because of the small focal spot diameter of the laser beam, thick-section butt joints with a gap exceeding 1 mm (0.039 in.) are difficult to weld with the HLAW process.
- Due to the low heat input and fast cooling rates produced by HLAW, mechanical properties of the as-welded condition may, in some cases, be poorer than mechanical properties from arc welding processes with higher heat inputs.
- Although combined laser arc processing has been studied for decades, the HLAW process has had limited implementation in production manufacturing until recently. This short history may be an obstacle for implementing HLAW in applications already using established welding processes.
- Due to the expensive laser equipment, capital cost for HLAW systems can be 10 to 50 times higher than conventional automated GMAW systems.
- Compared to conventional arc welding processes, additional safety measures are necessary with HLAW to protect personnel from laser hazards.

Applications and Operating Modes

Hybrid laser arc welding can be used to weld a wide range of metals, including steel, stainless steel, nickel, titanium, aluminum, copper, and other alloy systems. With the high-productivity advantages of HLAW and the broad range of alloys that can be welded, many industries currently using GMAW or submerged arc welding (SAW) could benefit from hybrid welding. The HLAW process is suitable for applications where a productivity increase can justify the high capital cost of an automated hybrid welding system. These can be high-volume production applications or low-volume applications that require an extensive amount of welding. The HLAW process can increase productivity by providing faster processing speeds or deeper penetration.

Thin-section applications, such as automotive components, can benefit from HLAW by an increase in welding speed and a reduction in filler-metal usage (Ref 2). Lap and fillet joints of steel or aluminum sheet metal can be welded at speeds on the order of 4 to 14 m/min (160 to 550 in./min) without humping or lack-of-fusion defects (Ref 2, 3).

Hybrid laser arc welding can also provide an increase in productivity for thick-section welding. In thick-section applications, HLAW can produce deep-penetration welds at travel speeds on the order of 1 to 3 m/min (40 to 120 in./min). In this case, the increase in productivity is generated by deeper weld penetration rather than a drastic increase in travel speed. Using a 30 kW ytterbium-fiber laser, full-penetration HLAW of a 28 mm (1.10 in.) square butt joint has been completed in a single pass (Ref 4). Applications such as oil and gas transmission pipelines, wind turbine towers, prefabricated steel beams, nuclear components, ship structures, heavy vehicles, construction and mining equipment, and rail cars are some example applications that can benefit from the deep penetration of the HLAW process (Ref 5–7). By generating deep weld penetration at productive travel speeds, HLAW can reduce the number of weld passes or decrease weld distortion, compared to GMAW and SAW (Ref 8). To date, the most widely known production application of thick-section HLAW is in the shipbuilding industry.

In 2002, Meyer Werft GmbH in Papenburg, Germany, implemented HLAW for production welding of steel panels and stiffeners for commercial cruise ship fabrication. Using a 12 kW CO₂ laser combined with a 450 A GMAW system, steel plates 6 mm (0.24 in.) thick were welded at speeds of 2.5 to 3.0 m/min (98 to 118 in./min), and 15 mm (0.59 in.) plates were welded in a single pass at 1.2 m/min (47 in./min). By moving to the one-sided, single-pass HLAW process, Meyer shipyard reported welding speeds three times faster than GMAW or SAW and reduced filler-wire usage by an estimated 80%. In addition, HLAW produced less weld distortion and eliminated post-weld flattening processes at Meyer (Ref 9). Hybrid laser arc welding systems using high-power fiber lasers have also been developed for the shipbuilding industry (Ref 10).

Process Description

Hybrid laser arc welding most often combines LBW with GMAW in a common weld pool (Fig. 1). In HLAW applications, the GMAW process is always used to add filler metal to the weld. However, the laser process can be used for multiple purposes, depending on the laser power density (W/cm²) at the work surface.

The applications of the HLAW process can be divided into two groups based on the mechanism for which the laser is used. One is a stabilization mode, where the laser is used to augment the GMAW process without providing a significant increase in penetration or speed. The other is a penetration mode, where the laser generates a keyhole in the metal, providing both deep penetration and high processing speeds. These two modes are described in the section “Modes of Operation” in this article.

In addition, the major process variables for either mode of operation include three sets of welding parameters: the variables for the independent LBW and GMAW processes and welding variables that are specific to the HLAW process. The process variables specific to HLAW are:

- Travel speed (typically from 1 to 3 m/min, or 40 to 120 in./min)
- Process orientation
- Process separation

These parameters of the HLAW process are discussed in the section “Hybrid Laser Welding Parameters” in this article, while specific variables for the LBW process (discussed in other articles in this Volume) include:

- Laser power (typically from 200 W to 20 kW)
- Diameter of the focused laser beam (spot size typically 0.2 to 1 mm, or 0.008 to 0.39 in.)

The variables for GMAW, as discussed in the article “Gas Metal Arc Welding” in this Volume, include:

- Arc current, voltage, and polarity
- Wire feed speed
- Electrode diameter and composition
- Electrode extension (contact tip-to-work distance)
- Shielding gas composition

Other variables, such as base-metal composition, joint design, part fit-up, GMAW torch angle, shielding gas flow rate, laser wavelength, position of the laser focus with respect to the work surface, and preheat temperature, can play important roles in hybrid welding but are variables usually defined by the application or the available equipment. For HLAW with other arc processes, the GMAW variables would be replaced by the variables of the alternative arc process. The process separation, or distance between the laser and arc, would remain a critical variable regardless of the arc process used.

Modes of Operation

Stabilization-Mode HLAW. As noted, this mode of hybrid laser welding augments the GMAW process without providing a significant increase in penetration or speed. This mode is sometimes referred to as laser-assisted arc

welding. The method of augmentation can be different depending on the material being welded and the laser power density used. For reactive metals such as titanium and zirconium, the laser can be used to provide arc stabilization. As little as 200 W can stabilize the cathode spot during pulsed GMAW of titanium (Ref 11). For welding steel, stainless steel, nickel, and aluminum alloys, a low-power-density laser spot can be used to produce a wide, shallow weld pool ahead of the GMAW process to stabilize the filler-metal deposition. In this case, the laser process is used to increase the wetting angle of the deposited metal and produce a smooth weld bead. This technique can be used to prevent weld humping at fast travel speeds, increase weld toe angles, improve side-wall fusion in groove welds, or enhance attachment of deposited metal when welding out of position (Ref 12).

Using a low-power-density laser beam for stabilized-mode hybrid welding can provide technical benefits in unique applications. However, this mode of HLAW is usually cost-prohibitive for most production manufacturing applications. Laser equipment is much more expensive than arc welding equipment in terms of price per unit of output power (cost per watt). If the expensive laser equipment is used for stabilization rather than drastically increasing productivity (speed or penetration), the return on investment for a hybrid welding system may not be attractive.

Penetration-Mode HLAW. To fully utilize the benefits of an expensive laser system, HLAW is conducted primarily in penetration mode. This is sometimes referred to as arc-assisted laser welding. In penetration-mode HLAW, the laser generates a keyhole in the metal. Both deep penetration and high processing speeds can be achieved with keyhole laser welding.

A keyhole is formed when a laser beam with sufficiently high power density causes melting and vaporization of the base metal. As the metal is vaporized, it rapidly expands and pushes away from the substrate. This expansion exerts a reactive force on the melted substrate called the evaporative recoil force. This recoil force pushes the melted metal away to form a depression. The melted metal is continually pushed out until the depression has formed into a deep keyhole.

The keyhole can be partially or fully through the thickness of the metal. In the steady-state condition after the keyhole is established, continual vaporization of the bottom and walls of the keyhole holds it open against the forces of surface tension and gravity. The relationship of laser power density and travel speed dictates the penetration and width of the keyhole for a given base metal. Power densities on the order of 10⁶ to 10⁸ W/cm² are typical for keyhole laser welding.

Hybrid Laser Welding Parameters

Knowledge of each variable and the ability to precisely control them are necessary to consistently

Fig. 1 Schematic of hybrid laser arc welding process orientations. (a) Laser leading. (b) Arc leading. GMAW, gas metal arc welding

produce hybrid welds with the desired quality. These variables can produce competing effects on the weld attributes, and balancing the performance of each variable is essential to successful hybrid welding. Table 1 lists the general effects of each HLAW variable on hybrid weld attributes. The effects listed are typical for welding butt joints over 6 mm (0.24 in.) thick or for welding thinner sections at travel speeds above 3 m/min (120 in./min).

Travel Speed. Hybrid laser arc welding is applicable over a wide range of travel speeds. Generally, the determining factor for welding speed is the productivity requirement. As travel speed increases, hybrid weld penetration will decrease. To maintain the required weld penetration at increasing travel speeds, more laser power and an increased rate of filler-metal deposition is required. If the existing laser equipment is limited in power, then a compromise must be made among travel speed, laser power, and weld penetration.

At travel speeds on the order of 4 m/min (160 in./min) or greater, joint-filling capabilities from the GMAW system can be limited. Gas metal arc welding systems are inherently limited to a maximum current output. For a given electrode diameter, there is a maximum wire feed speed at the maximum current rating of the GMAW power supply. This limitation can lead to insufficient filler-metal addition at faster travel speeds. If the required reinforcement or fillet size cannot be met for a given travel speed due to the limitations of the GMAW power supply, the travel speed, GMAW source, wire diameter, joint design, or the number of passes must be reevaluated. Additional GMAW torches with separate power supplies and wire feeders could be used to overcome deposition limitations.

Process Orientation. The HLAW process can be oriented in two directions: arc leading or laser leading. The GMAW process can be positioned behind or in front of the traveling laser keyhole. If the GMAW process travels behind the laser beam, the HLAW process orientation is referred to as laser leading. If the GMAW process travels ahead of the laser, the HLAW process orientation is referred to as arc leading. Figure 1 illustrates the laser-leading and arc-leading process orientations.

The main difference between the two orientations is the angle of the GMAW torch with

respect to the direction of travel. Torch angle can have an effect on the deposited GMAW bead. In the laser-leading HLAW configuration, the GMAW torch is traveling behind the laser beam, positioned at a “push angle.” In the arc-leading configuration, the torch is at a “drag angle,” traveling in front of the laser beam. This difference in torch angle can produce different weld surface geometries. In the laser-leading orientation, the deposited weld bead is relatively wide and flat, with large weld toe angles. With arc leading, the deposited weld bead is more narrow and convex, with sharper weld toe angles. Torch angle can be adjusted for each process orientation, but there is a limitation to how close the torch can be positioned to the beam axis, due to the beam convergence angle and obstructions from the laser-focusing optic assembly. Alternatively, the laser beam axis can be tilted while the GMAW torch is positioned normal to the work.

Another reported difference between the two process orientations is in penetration. If the laser beam is positioned in the arc depression of the GMAW process, the arc-leading configuration can provide slightly more penetration for HLAW. However, there is conflicting data reporting that the laser-leading process provides deeper penetration. In either case, the reported gain in penetration is generally considered insignificant for most manufacturing applications.

Process Separation. A key variable for HLAW is the process separation, or distance between the two welding processes. This is also known as the beam-to-wire distance or process spacing. Process separation can affect the solidification morphology and microstructure of a hybrid weld. Increasing the process separation will eventually separate the two processes into separate weld pools. Even if the weld pools of the two processes appear to be connected on the weld surface, a metallographic cross section of the hybrid weld can show that the fusion profiles from each process may have solidified separately within the thickness of the joint. This separate solidification can affect the weld microstructure and composition gradient of the GMAW filler metal through the thickness of the joint. Changing the process separation can also have an effect on the energy concentration of the hybrid process, affecting weld penetration, spatter generation, and root bead

profile in full-penetration welding. Process separation for HLAW is typically between 0 and 6 mm (0 and 0.24 in.), depending on the material, laser power, process orientation, and travel speed.

Laser Power. The relationship of laser power and focused beam diameter determines the laser power density. In penetration-mode HLAW, laser power density has the greatest effect on weld penetration. For most structural metals, approximately 1 kW of laser power is needed to provide 1 mm (0.039 in.) of penetration at a travel speed of 2.0 m/min (79 in./min). This estimate depends on the absorptivity of material being welded for a given laser wavelength and the diameter of the focused laser beam. For example, when welding low-carbon steel with a 10 kW laser, a full-penetration hybrid weld can be produced at 2.3 m/min (90 in./min) on a 9.5 mm (0.375 in.) square butt joint with no gap. Spot sizes larger than 600 μm (0.024 in.) can reduce the power density and require more laser power to penetrate a given thickness.

The depth and diameter of the keyhole are determined by the laser power and focused spot size, respectively. Large focused spot sizes, greater than 600 μm (0.024 in.), produce large-diameter keyholes with less penetration for a given laser power. Small-diameter spots, typically 100 to 600 μm (0.004 to 0.024 in.), are used more often in HLAW to generate narrow keyholes and produce welds with high aspect ratios (depth to width). Figure 2 is a video still of a steel hybrid bead-on-plate weld using 1.1 mm (0.045 in.) diameter wire. The image shows that the keyhole diameter is relatively small in respect to the width of the weld pool. This is because the GMAW process drives the weld width at the top surface of the material. Through the thickness of the material, the weld width is similar to the keyhole width. Figure 3 is a cross section of a penetration-mode hybrid weld conducted on a 12.45 mm (0.490 in.) carbon steel square butt joint. This weld was performed with 10 kW of laser power, a 333 μm (0.013 in.) laser spot size, and an 8.9 m/min (350 in./min) wire feed speed for a 1.1 mm (0.045 in.) diameter steel wire at a travel speed of 1.52 m/min (60 in./min). Note that the fusion zone resembles the superposition of a GMAW weld profile and a laser weld profile.

Table 1 Effects of hybrid laser arc welding process variables on weld attributes

Welding variable to change	Desired change in weld attribute

Process orientation	Minor effect	Minor effect	No effect	No effect	Laser leading	Arc leading	Minor effect	Minor effect
Process separation	Minor effect	Minor effect	No effect	No effect	Minor effect	Minor effect	Decrease	Increase

Shielding Gas. The primary function of the shielding gas is to protect the molten weld metal from the surrounding atmosphere. Shielding gas for HLAW should be selected based on the material being welded; however, additional considerations are necessary based on the laser wavelength and the desired GMAW arc characteristics.

During LBW with a CO₂ laser, the vapor plume or plasma generated by the laser process can absorb and scatter the laser beam. This interference can cause a loss in weld penetration. Therefore, when hybrid welding with a CO₂ laser, it is necessary to remove or suppress the plume with gas usually containing some percentage of helium. In some cases, this can be done with gas delivered by the GMAW torch. In other cases, a secondary plume-suppression gas may be necessary. When hybrid welding with solid-state lasers such as Nd:YAG, fiber, thin-disk, or diode lasers, the shorter wavelengths are not significantly affected by the vapor plume, and a secondary gas for plume suppression is usually not necessary.

Shielding gas delivered from the GMAW torch is generally sufficient to protect the molten weld metal from the surrounding atmosphere. In some cases, a second gas trailing the welding process is needed to shield the weld as it cools. A trail shield device is generally used when welding reactive metals such as titanium or in applications where discoloration due to surface oxidation is unacceptable.

For the GMAW process, the shielding gas plays an additional role in determining weld profile, arc characteristics, and mode of metal transfer. Inert gases, active gases, and blends of the two can be used for HLAW. (For information about shielding gas compositions and which gases to use for specific applications, see the article “Shielding Gases for Arc Welding” in this Volume.)

Fig. 2 In-process video image of penetration-mode hybrid laser arc welding on steel. GMAW, gas metal arc welding. Courtesy of Edison Welding Institute

Gas Metal Arc Welding Current, Voltage, and Polarity. Depending on the arc current, electrode diameter, electrode extension, and shielding gas composition used for the GMAW process, three general modes of metal transfer can be achieved: short-circuiting, globular, and spray transfer. Due to the fast travel speeds used in penetration-mode HLAW, spray transfer or pulsed GMAW are typically used. In pulsed mode, the GMAW power supply provides a controlled electrical output that pulses the welding current to detach individual droplets with each peak current pulse. Because of the advanced control provided by newer GMAW power supply technologies, most HLAW applications now use pulsed GMAW sources. However, spray transfer can be used to produce higher arc heat input for fast travel speed applications.

Arc voltage can be adjusted to increase or decrease the arc length. A longer arc length generally produces a wider melt width at the top surface of the weld. However, a long arc length can allow the deposited metal to wander from the weld centerline at fast travel speeds. A short arc length constricts the arc and limits weld pool width, reducing the wander of the deposited bead at high speeds.

The polarity of the GMAW system can be changed to affect the heat balance between the electrode and the work. However, the vast majority of GMAW and HLAW applications use direct current electrode positive (DCEP) polarity. The DCEP for GMAW provides good arc stability and low spatter generation. Direct current electrode negative and variable polarity (alternating current) have been tested with HLAW but have had limited commercial acceptance.

Fig. 3 Cross section of hybrid laser arc welding on a carbon steel square butt joint. Courtesy of Edison Welding Institute

Wire Feed Speed. The consumable GMAW electrode is fed into the welding process at a predetermined speed. This wire feed speed is selected to provide a specific volume of deposited metal for joint filling, gap bridging, or producing the required reinforcement at the cap and root of the weld. With conventional GMAW power supplies (constant voltage), wire feed speed and arc voltage are set while the power supply adjusts arc current and electrode melt rate to maintain a constant arc length. With modern pulsed GMAW power supplies (constant current), a waveform is designed for a specific wire feed speed. The pulsed waveform dictates the arc current that affects droplet frequency, droplet size, and arc voltage targets. If the wire feed speed is increased, the amplitude of the pulsed waveform is synergistically increased.

Joint Designs

Many joint designs can be welded with HLAW, including butt, groove, lap, flange, and fillet joints. Using the appropriate parameters, hybrid welding can be conducted in all welding positions. Hybrid laser arc welding can be performed on linear joints, circumferential joints, or two- and three-dimensional curvilinear joints. Figure 4 illustrates example joint designs for HLAW.

The primary difference in joint design between HLAW and conventional welding processes is that HLAW can provide both joint filling and deep penetration into the base metal. Typically in arc welding, a groove is prepared and then filled with molten metal deposited by the process. In autogenous laser welding, a square butt joint with no groove preparation is welded by penetrating through the joint thickness and fusing the two base metals together. The HLAW process is applicable to both methods of joint fusion.

A multipass V-groove joint that was previously welded with conventional GMAW could be redesigned as a single-pass HLAW joint.

Fig. 4 Example joint designs for hybrid laser arc welding. (a) Square butt. (b) V-groove. (c) U-groove. (d) Lap weld. (e) Fillet weld. (f) Dissimilar-thickness joint

By using the high energy density of the laser process, HLAW can penetrate a square butt joint in a single pass while adding filler metal to produce positive weld reinforcement. To maximize productivity gains with HLAW, the weld joint should be designed to use the available laser power and maximize penetration or travel speed while maintaining weld quality.

Because the majority of the HLAW penetration is produced by the laser, HLAW is best suited as a root-pass process for thick-section multipass operations. After the root has been fused, subsequent passes with penetration-mode HLAW will only remelt and solidify the existing root weld. The only joint filling provided by the HLAW process is the deposition from the GMAW process. If the available laser power is unable to weld the entire joint thickness in a single pass, the joint should be designed to use a deep-penetration HLAW root pass, with subsequent fill passes using a different process (Fig. 4b, c).

The limitations on part geometries that can be welded with HLAW are based primarily on the limitations of the motion system and the access to the joint. For some applications, the combined size of the laser beam and GMAW torch can be too large to fit into tight corners or inside small-diameter pipes. Due to the required process separation length, turning sharp corners with the HLAW process should be avoided. To maintain consistent quality around a sharp corner, intersecting welds could overlap at the corner. Alternatively, the hybrid weld head can be designed to have a mechanized axis that rotates the GMAW torch about the laser beam.

In penetration-mode HLAW, small changes in the repeatability of the joint can have a large effect on weld quality. A variation in joint thickness, a mismatch in height between the two parts, a gap in the joint, or misalignment with the weld path can all affect the quality of the weld. To minimize the effects on weld quality, the consistency of the weld joint preparation should be strictly controlled.

Joint Gap. Fluctuations as little as 0.25 mm (0.010 in.) in the joint gap can require adjustments in weld parameters for deep-penetration HLAW. As the gap increases, maintaining weld stability with HLAW is challenging. Gap sizes above 1.0 mm (0.039 in.) are difficult to weld in a single pass for joints 6 mm (0.24 in.) or thicker. When welding on any gap, small variations in process separation or other welding parameters can have a large impact on weld quality.

Ideally, there should be no gap in the joint, because this is the easiest condition to prepare and keep consistent along the length of the joint. However, hybrid welding on a joint with no gap can cause poor mixing of the filler metal through the thickness of the joint (Ref 13). When a gap is present, more filler metal reaches the root of the joint, but higher wire feed speeds are required to fill the volume of the gap. Welding can be performed on a joint with a designed

gap; however, ensuring that the prefabricated gap remains constant may be difficult.

Joint Mismatch. In a butt or groove joint, mismatch is the measured distance between the top surfaces of the two parts being welded. This is also called vertical mismatch or high-low. Mismatch is common in the pipe-welding industry due to out-of-roundness or eccentricity between the two pipes to be welded. In penetration-mode HLAW for a full-penetration weld, the cap of the weld can generally tolerate a large amount of mismatch because of the deposited metal from the GMAW process. However, the weld bead is relatively small at the root, and the ability to bridge a mismatch is limited. Hybrid welding of joints with a mismatch greater than 2 mm (0.079 in.) is difficult for full-penetration welding of thick sections.

Joint Thickness. The total joint thickness that can be penetrated is determined by the laser power. For a zero-gap joint, the effective throat of a finished weld is approximately the sum of the laser penetration and the deposited thickness provided by the GMAW process. To maximize the effective throat that can be produced with HLAW, the weld joint is usually designed to have a root face or land thickness that is appropriate for the available laser power. The remaining thickness of the joint can be filled by the GMAW deposition.

Dissimilar joint thicknesses can be welded with the HLAW process (Fig. 4f). If the difference in thickness is small, 2 mm (0.079 in.) or less, a bevel preparation of the thicker section may not be necessary. Usually in dissimilar-thickness joints, the mismatch should be set at the cap of the weld rather than the root. At the cap, there is a larger weld pool and therefore more tolerance to mismatch geometries. At the root, there is a limited amount of molten metal to bridge the transition between the dissimilar thicknesses.

Even when welding similar thicknesses, the actual base-metal thicknesses can vary in production. A small increase in part thickness can require more laser power to maintain full penetration. The HLAW parameters and equipment must be designed to accommodate thickness variations that can be seen in production.

Equipment and Consumables

There are four major components of an HLAW system: the laser source, the GMAW source, the hybrid welding head, and the motion system. The consumables used for HLAW are the same as the consumables used in the individual laser and GMAW processes.

Laser Sources

Continuous-wave lasers are most often used for HLAW because they generate a constant laser power for the duration of the weld. The laser source is selected based on power and

wavelength. The output power capability is chosen based on the desired weld penetration for a given application. Travel speed, power density, base-metal absorptivity, and joint design can also affect the determination of laser power.

Multiple factors influence the selection of the laser wavelength. Table 2 lists the wavelengths of common high-power laser technologies that can be used for HLAW. Semiconductor diode lasers can also be used for HLAW; however, the output power and beam quality of diode lasers is currently not suitable for deep-penetration hybrid welding applications.

Carbon dioxide (CO₂) lasers produce a wavelength of 10.6 μm and must be transmitted to the work by reflective optics. Because CO₂ lasers are limited to reflective optic delivery, HLAW applications using CO₂ lasers are typically limited to linear welds on gantry-style motion equipment. Carbon dioxide lasers can have wall-plug efficiencies exceeding 10% and can have high output powers. Carbon dioxide lasers are typically on the order of 20 kW or less for welding applications but can be focused to small spot sizes to provide high power densities.

Solid-state lasers, including Nd:YAG, ytterbium-fiber, thin-disk, and diode lasers, produce wavelengths near 1 μm . The shorter wavelength allows solid-state lasers to be transmitted through flexible fiber optic cables to the work. Fiber optic delivery enables hybrid welding of complex contours and flexibility for welding multiple-part designs.

The Nd:YAG lasers are typically limited to 6 kW or less in output power. Due to the inherent characteristics of the technology, Nd:YAG lasers exhibit poor beam quality and therefore have limited power density. Lamp-pumped Nd:YAG lasers have wall-plug efficiencies (electrical-to-optical power efficiency) of less than 5%; however, diode-pumped models have better efficiency.

Fiber and disk lasers are also referred to as high-brightness lasers due to the excellent beam quality and high power densities they can produce. Both technologies can generate output powers above 20 kW and are excellent laser sources for HLAW. Both fiber and disk lasers are diode-pumped and have wall-plug efficiencies exceeding 25%. Fiber and disk lasers have become the most cost-effective high-power lasers in terms of price per watt and

Table 2 Wavelengths of various high-power laser technologies used for hybrid laser arc welding

Laser type	Wavelength, μm
CO ₂	10.6
Ytterbium fiber	1.070
Disk (ytterbium: yttrium-aluminum-garnet, or YAG)	1.030
Neodymium:YAG	1.064

maintenance costs. As the efficiency of pump diodes continues to increase, the overall efficiency of diode-pumped solid-state lasers will continue to increase.

Gas Metal Arc Welding Sources

Modern pulsed GMAW power supplies are typically used in most HLAW applications. Pulsed GMAW sources enable advanced control of arc stability, arc length, metal transfer, droplet size, droplet frequency, and spatter generation. Modern digital power supplies also enable intimate integration with the controllers of automated motion systems that are typically used for HLAW.

Due to the fast travel speeds used for HLAW, wire feed speeds and average current levels may be higher than typical GMAW applications. For this reason, the GMAW system should be capable of the maximum wire feed speed and current rating for the desired HLAW application. Because of the high average current used in HLAW, considerable heat is generated in the GMAW torch. In addition to the heat produced by the arc, the GMAW torch receives additional heat radiated by the laser process. To reduce damage from the heat generated during hybrid welding, the GMAW torch should be water cooled.

Push-type wire feeders are conventionally used for GMAW and HLAW. Push-pull wire feed systems that use drive rolls at the wire feeder and in the torch were conventionally used for soft electrode materials such as aluminum. Because push-pull feed systems offer increased control and consistency, they are being used more often in HLAW applications for both stiff and soft electrode types, including steel, stainless steel, aluminum, nickel, and titanium.

Hybrid Welding Head

The processing head for HLAW is a combination of laser-focusing optics and a GMAW torch.

Laser-Focusing Optics. The focusing optics should be selected to produce the desired spot size at the work. The optical assembly can consist of reflective or transmissive optics. In both cases, the lenses or mirrors are very sensitive to contamination. Dust, dirt, fingerprints, scratches, or other sources of contamination on the optical surfaces can cause a loss in transmitted laser power, an increase in the focused spot diameter, a change in power distribution, a shift in the focal position, or a combination of these effects. A transmissive cover window or debris shield is typically used to protect the optic assembly from contamination. A compressed air cross-jet, or air knife, is also used between the work and the optics to protect the cover window from weld spatter and fume.

In addition to spot size, the standoff distance of the focusing optic should be considered when choosing welding optics. If a longer focal

length focusing lens is selected, the expensive optic assembly will be farther from weld spatter. However, longer focusing optics generate a larger spot size. Larger spot sizes have lower power densities and produce less weld penetration or slower travel speeds. This trade-off must be managed to provide sufficient weld productivity while reducing the risk of damaging the expensive laser optics. Focal lengths of 200 to 300 mm (7.87 to 11.81 in.) are typical for HLAW.

Gas Metal Arc Welding Torch. The water-cooled GMAW torch should be capable of handling the appropriate current rating for the desired application. The contact tips, liner, and other consumables should be selected for the appropriate filler-metal alloy and wire diameter. If a small process separation (beam-to-wire distance) is used for HLAW, the GMAW nozzle may need to be modified so that the laser beam does not strike the nozzle. Alterations to the gas nozzle should be kept to a minimum so that the flow of the shielding gas is not significantly disrupted. If a large process separation is used, the GMAW gas nozzle does not need to be modified.

Because process separation, torch angle, electrode extension, and alignment of the two processes are critical, the method of mounting the GMAW torch with respect to the laser beam is critical. Off-the-shelf hybrid processing heads can be purchased that incorporate both the optics and the torch into one assembly. Custom hybrid welding heads can also be assembled by combining standard laser-focusing optics to a standard GMAW torch with a custom mounting bracket.

Whether custom-built or commercially purchased, the components of the hybrid welding head should have certain degrees of freedom. Based on the application, the GMAW torch angle and work angle can be fixed or variable relative to the beam. The torch should be able to move laterally to align with the beam along the weld joint, vertically to adjust the electrode extension relative to the beam focus, and horizontally to adjust the process separation from the beam axis. These adjustments can be manual or mechanized. The overall assembly should be rigid and capable of withstanding the travel speed, acceleration, and changes in position that may be used during processing.

Motion Systems

The motion systems that can be used for HLAW are dictated by the application. For linear welding, a linear beam or gantry system can be used. For complex geometries, a six-axis robot is generally used. In pipe-welding applications, the hybrid head could be mounted on a track system to traverse around the circumference of the pipe. The part or the hybrid welding head can be moved to achieve welding motion. In all cases, the dynamic accuracy and path repeatability of the motion system are significant variables. In particular, the standoff

distance of the hybrid welding head and alignment with the joint are critical for HLAW.

Hybrid Laser Arc Welding Consumables

Consumable Parts. The GMAW consumables include contact tips, gas nozzles, liner, guide tubes, and drive rolls. For different wire diameters, the contact tips, liner, guide tubes, and drive rolls should be changed. The contact tips should be changed periodically as the internal bore is eroded by the moving electrode. The internal bore of the contact tip is important because the wire must feed smoothly through the tube while making good electrical contact. As the bore of the contact tip wears away, poor electrical contact can result in erratic arc characteristics.

For welding with steel wire, a spiral steel liner is typically used to guide the wire through the torch cable. For soft wires such as aluminum, nylon or synthetic fluorine-containing resin liners are used. When welding with titanium wire, graphite liners are used to reduce contamination of the weld.

The primary consumables of the laser system are the cover windows that protect the focusing optic assembly from contamination and weld spatter. Other consumables depend on the type of laser source used for HLAW.

Filler-Metal Consumables. The chemical composition of the consumable GMAW electrode must be properly selected to achieve the desired properties in the hybrid weld metal. Of particular note with HLAW is that the heat input is typically lower than GMAW, and the cooling rate is much faster than conventional arc welding processes. This means that HLAW can significantly affect the solid-state transformations in the weld zone and that an acceptable electrode composition for GMAW applications may not always be acceptable for the fast cooling rate of the HLAW process, particularly in high-strength steels or other alloys with high hardenability.

For deep-penetration HLAW with little or no joint gap, the dilution of filler metal may not be homogeneous through the thickness of the joint. In some cases, weld-metal composition can be primarily filler metal near the cap of the weld and primarily base metal near the root. Knowledge of the heat input, cooling rate, and filler-metal dilution from the HLAW process and their effects on weld-metal microstructure is essential to producing high-quality HLAW welds.

Sources of Defects

Typical defects for HLAW are porosity, undercut, concavity, root humping (root bead instability), incomplete fusion, and incomplete penetration. Other defects can occur but are driven more by the application (joint design, alloy selection, travel speed, and cooling rate) than by the nature of the process.

Porosity. Assuming there is no source of contamination (oxidation, oil, foreign metals, weld

surface, joint interface, wire surface, shielding gas), porosity is generally attributed to the keyhole laser process used in penetration-mode HLAW. The keyhole is a column of metal vapor surrounded by the liquid weld metal. Turbulence in the keyhole can introduce gas pores into the molten weld. Aluminum and titanium are particularly susceptible to weld porosity from the HLAW process.

Partial-penetration HLAW occurs when welding in penetration mode but not fully penetrating through the joint thickness. Partial-penetration HLAW is highly susceptible to internal weld porosity due to instability at the root of the keyhole. Porosity caused by keyhole instability is typically seen in the bottom half of a partial-penetration HLAW cross section. To reduce the occurrence of porosity from keyhole instability, the weld can be redesigned to fully penetrate the joint thickness. Full-penetration welds are less likely to have porosity from keyhole instability. Increasing the spot diameter or modulating the laser power has been shown to reduce porosity from keyhole instability in partial-penetration laser welding.

Undercut and Concavity. Geometric defects such as undercut and concavity are typically caused by a gap in the joint that could not be filled by the deposited wire. Undercut at the toes of the weld surface can also occur due to the high travel speeds. In full-penetration welding, the molten weld can drop through the joint. This results in concavity or undercut at the top surface and excessive root reinforcement on the back surface of the weld.

Root Humping. In full-penetration HLAW of steel, improper welding parameters can result in irregularities in the profile of the root bead. This defect typically appears as a longitudinal humping profile at the weld root on the back side of the joint. This defect most often occurs in steel, but it has been seen in stainless steel, nickel, and titanium alloys as well. The physical phenomena that cause this defect are not fully understood; however, increasing the laser power reestablishes a stable full-penetration keyhole and eliminates the root-humping defect. Root-humping defects usually coincide with undercut or concavity defects at the weld cap.

Incomplete Fusion. Deep-penetration hybrid welds generally have very narrow weld profiles. Small deviations in joint alignment can cause the laser beam to miss the weld joint and result in an incomplete fusion defect. This can be a particularly troubling defect because the weld may appear to have complete fusion from a visual inspection of the top and bottom surfaces, but in the center of the thickness, the weld may not fuse the entire joint.

Incomplete Penetration. If there is a loss in laser power or an unexpected increase in the joint thickness, the hybrid weld may not fully penetrate the thickness, resulting in an incomplete-penetration defect. Loss in laser power or changes in the power distribution are usually the causes for incomplete penetration.

Contamination of the cover window or other optical surfaces can cause changes in laser power density at the work. The gas nozzle, air knife, or GMAW torch can clip the beam and reduce the laser power that reaches the work. If the process spacing has been reduced to zero, the deposited droplets from the GMAW process can impinge on the keyhole and decrease penetration depth.

Quality Control and Inspection

Hybrid laser arc welding is an automated process that requires strict controls on repeatability of the parts and of the welding system. To ensure the parts are repeatable, upstream processes should be addressed to accommodate the HLAW process. Improving upstream preparation of the parts and weld joints will only improve the productivity gains possible with HLAW.

Even with strict control on upstream processes, weld joint preparations are never perfect. To adjust for variations in joint fit-up, gap, and mismatch, real-time seam tracking and joint sensing should be implemented. With advanced control systems, the welding parameters and joint alignment can be adjusted on-the-fly to compensate for the variations in the joint. If a complex control system is not feasible, a path check could be conducted with a camera system coaxial to the laser beam to verify the joint alignment prior to welding.

To ensure consistent weld quality and penetration, periodic laser power measurements should be conducted. Scheduled preventative maintenance should be conducted on the GMAW and laser systems to ensure optimal working condition. Periodic inspection should also be conducted on the welded parts to ensure weld quality.

Inspection by destructive analysis could evaluate fusion profile, hardness, tensile strength, fatigue performance, or impact toughness of the hybrid weldment. Inspection by nondestructive evaluation (NDE) could search for centerline defects, incomplete fusion, porosity, solidification cracking, and incomplete penetration. The NDE methods typically used for HLAW are radiographic testing and ultrasonic testing.

Safety

The greatest safety concerns are from the laser welding equipment. Because high-power laser beams are invisible to the human eye, the hazards may not be readily apparent to inexperienced personnel. With exposed laser beams, personnel may be exposed and permanently injured before the existence of the hazard is even recognized. For this reason the American National Standards Institute specification ANSI Z136.1, "Safe Use of Lasers" (latest edition), requires that each facility using lasers designate an individual as the laser safety officer. This individual should be familiar with laser safety, ANSI Z136.1, and

potential hazards at the designated facility. Special precautions must also be taken to protect personnel from arc welding hazards.

Training. Employers of facilities using HLAW are responsible for providing training to all operators, engineers, technicians, maintenance, and service personnel. ANSI Z136.1 requires that training in the potential hazards and control measures be provided to all personnel involved in laser use. ANSI Z136.1 provides a model safety training program in Appendix D of the standard. Refer to the article "Safe Welding Practices" in this Volume and ANSI Z136.1, "Safe Use of Lasers," for more information on training.

Electrical Hazards. Both laser equipment and GMAW equipment employ high voltages and currents capable of lethal shock. Only qualified and authorized personnel should install and service equipment with the appropriate procedures, tools, and protective equipment. Refer to the article "Safe Welding Practices" in this Volume for more information on electrical hazards.

Eye Hazards. Eye injury is readily caused by laser beams. With laser beams operating in the visible or near-infrared spectrum, a 5 mW beam can inflict permanent retinal damage. Proper safety precautions must be taken to protect personnel from direct, scattered, reflected, and diffuse laser radiation. Depending on the laser wavelength employed, different safety measures and personal protective equipment are required. Consult ANSI Z136.1 for the appropriate safety measures for specific laser wavelengths.

The GMAW process produces intense visible and ultraviolet (UV) light. Appropriate protective equipment is required to protect personnel from this intense radiation generated by the electric arc. Eye protection is required for each of the welding processes used in HLAW to protect personnel from both laser and arc radiation. Refer to the article "Safe Welding Practices" in this Volume and ANSI Z136.1, "Safe Use of Lasers," for more information on eye hazards.

Skin Hazards. Skin exposure to the primary laser beam can result in severe burns and must be prevented by safety enclosures and operator training. There is no personal protective equipment rated to protect personnel from direct exposure to the primary beam. Enclosures should be designed to prevent operators or spectators from placing any body part near the beam path. Unless a sufficient enclosure is constructed, exposure to reflected and scattered laser light is possible. Intense UV light produced by the GMAW process can cause skin damage. Spatter and hot metal parts are burn hazards for HLAW personnel. Refer to the article "Safe Welding Practices" in this Volume for more information on skin hazards.

Fume Hazards. Both the laser and GMAW processes produce welding fumes. Fume hazards are dependent on base-metal composition, filler-metal composition, shielding gas composition, and welding parameters. Welders, operators, spectators, and other personnel in the welding area must be protected from overexposure to

fumes and gases produced during welding. Refer to the article "Safe Welding Practices" in this Volume for more information on fume hazards for various welding applications.

Flux Cored Arc Welding*

Revised by Michael T. Merlo, RevWires LLC, a Heico Wire Group Company

FLUX CORED ARC WELDING (FCAW) was introduced in 1957 to 1958 by two different manufacturers in the United States, and it represented the first improvement in continuous welding over the solid wire gas metal arc welding (GMAW). The same equipment and process variables employed in GMAW were used by the FCAW process. A unique engineering breakthrough in this process was the formation of a carbon steel tube around fluxing and alloying powders by filling the tube in the middle of its construction, closing it, and drawing it to a predetermined size.

In the early years, flux cored wires were manufactured with diameters of 3, 2.8, and 2.4 mm ($\frac{1}{8}$, $\frac{7}{64}$, $\frac{3}{32}$ in.) and were used for flat and horizontal welding positions only. There were two varieties of products made: one requiring gas shielding and one requiring no external gas shielding. The latter used denitrification to neutralize the effect of air intrusion (the "nitrogen boil"), and the former used the columnar flow of shielding gas to minimize air intrusion into the weld pool. In the late 1960s, smaller sizes were introduced, such as 2, 1.5, and 1.1 mm ($\frac{5}{64}$, $\frac{1}{16}$, and 0.045 in.) diameters. In the early 1970s, formulations were developed to allow welding in all positions, such as vertical up and overhead. This allowed flux cored wires to be used in applications formerly limited to covered electrodes and the shielded metal arc welding (SMAW) process.

Common shielding gases employed were carbon dioxide (CO_2) and a blend of 75%Ar-25% CO_2 . As manufacturing processes improved, both gas-shielded and self-shielded wires were introduced in diameters as small as 0.75 and 0.90 mm (0.030 and 0.035 in.). The gas-shielded products evolved to where formulations using gas blends of 85 to 90% Ar/balance CO_2 were designed and used in common applications.

Process Features

Flux cored welding electrodes are supplied in two distinct product types:

- Gas-shielded flux cored arc welding (FCAW-G) process
- Self-shielded flux cored arc welding (FCAW-S) process

The gas-shielded flux cored process (Fig. 1) uses an externally applied gas to assist in shielding the arc from oxygen and nitrogen in the atmosphere. The most deleterious effect of air intrusion is the nitrogen boil, wherein the insolubility of nitrogen in liquid steel causes it to boil out and create gross surface porosity. The columnar flow of shielding gas, typically CO_2 or blends of argon and CO_2 , protects the molten weld pool from atmosphere in the same manner as in the GMAW process. Additional protection from the intrusion of air is provided

by the fluxing and slag-forming powders within the core ingredients, which form a molten slag cover over the weld pool.

The use of CO_2 shielding gas leads to what is known as an active gas shielding (i.e., a gas that reacts with the elements in the molten puddle to form compounds). The effect of CO_2 shielding on the carbon content of the molten puddle is very unique. It can be carburizing or decarburizing. If the initial carbon content of the weld metal is low ($<0.05\%$), the CO_2 will carburize the molten puddle. If the initial carbon content of the weld metal is high ($>0.10\%$), the molten puddle will show a tendency to lose carbon. The use of CO_2 also promotes deeper weld bead penetration and a more fluid weld puddle from the exothermic reactions. The CO_2 disassociates

Fig. 1 Gas-shielded flux cored arc welding. Source: Ref 1

* Revised from D.W. Meyer, Flux-Cored Arc Welding, *Welding, Brazing and Soldering*, Vol 6, ASM Handbook, ASM International, 1993, p 886-889

($2\text{CO}_2 \rightarrow 2\text{Co} + \text{O}_2$) in the welding arc, and the O_2 reacts with the added deoxidizing elements within the tubular volume of the wire (as well as the iron in the base metal in steels).

Additives to the core ingredients can be used to stabilize the transfer, generate smaller droplets, and promote less spatter around the weldment. The use of argon with CO_2 , typically 75 to 80% Ar, provides an arc plasma with less heat of reaction (because of much less CO_2) and a lower-penetration weld bead. Argon (due to its higher energy of ionization) is more of a cooling gas than CO_2 ; hence, the weld pool solidifies much more quickly. The higher ionization promoted by argon stabilizes the welding arc, resulting in smaller droplet transfer and lower spatter levels. These blends also promote lower fume generation rates, because the addition of argon lowers the available oxygen from the CO_2 and reduces the amount of oxide formation, a key component of welding fume particles.

Argon blends are preferred for all-position welding, because the cooling effect of the argon promotes faster freezing of the weld pool; that, in turn, facilitates welding in the vertical up and overhead positions. Simultaneously, the fluxing and slag-forming agents in the core can be adjusted to assist in the freezing of the molten slag, further facilitating welding in all positions. Alloying agents, such as manganese, silicon, magnesium, and titanium, are added to the core ingredients for purposes of grain refinement, oxygen reduction, and strengthening of the weld deposit. Other alloys, such as nickel, chromium, molybdenum, and copper, can be added to produce higher-strength, low-alloy weld metal, which possesses improved strength and toughness properties over standard carbon steel weld metal.

Self-Shielded Flux Cored Arc Welding. In the FCAW-S process, alloying, slag-forming, and fluxing ingredients in the core protect the weld pool from atmospheric contamination, that is, the nitrogen boil. Because both oxygen and nitrogen can harm the weld pool by oxide contamination and porosity, respectively, different means of neutralization are employed. Combinations of lithium, magnesium, and aluminum, in elemental and chemical compound forms, either limit nitrogen solubility or combine with it to form nitrides, preventing the nitrogen boil. Elements such as manganese, magnesium, aluminum, and titanium are used to deoxidize the weld pool, combining with oxygen to form oxides that help form a protective slag covering the weld pool.

It should be noted that oxides of aluminum, along with nitrides of aluminum and magnesium, can be quite detrimental to the toughness of the resultant weld deposit. Several manufacturers have developed formulation technology that suppresses nitrogen solubility, reducing the residual level of aluminum oxides in the weld metal. These products have quite high levels of Charpy V-notch (CVN) impact toughness at subzero temperatures. There are also newer formulation technologies that provide all-position welding capability, in addition to

the high-CVN impact values. Unlike products from years ago that produced large droplet, or globular, transfer during welding, these newer products exhibit small droplet, spraylike transfer, facilitating all-position welding with lower spatter emission.

Advantages and Limitations. There are many advantages to the FCAW process. Both FCAW-G and FCAW-S provide the high productivity of continuous welding combined with the benefits afforded by the presence of slag-forming, fluxing, scavenging, and alloying agents. Advantages include but are not limited to:

- Higher deposition rates in all-position welding than SMAW or GMAW
- Less training and operator skill required than for GMAW or SMAW
- Simpler and more adaptable, in terms of welding equipment and positions, than submerged arc welding
- Deeper penetration than with SMAW; better sidewall penetration than GMAW
- More tolerant of rust, mill scale, and other oxide or hydrocarbon contaminants than GMAW

The specific advantage of high productivity with the FCAW process is the dominant basis for its use. However, the process does present some limitations that must be dealt with as a result of its high productivity. Some relative disadvantages are:

- Slag must be removed from the weld and properly disposed of.
- Fume generation rates, directly proportional to deposition rates, are higher than the lower-deposition-rate processes (GMAW and SMAW); fume extraction may be required.
- The process is not as portable as SMAW; shielding gas may be required, and suitcase feeders with a spool of wire may weigh up to 23 kg (50 lb).

Applications

Flux cored arc welding enjoys widespread use in many industries. Since its inception in 1957, the FCAW process has been adopted by virtually every industry seeking productivity and quality improvements in the welding operation. Both the FCAW-G and FCAW-S processes are used to fabricate structures from carbon and low-alloy steels. Both process variants are used for shop fabrication, but the FCAW-S process is preferred for field use. The acceptability of the FCAW process for structural use is illustrated by the fact that prequalified joints are included in the structural welding code of the American Welding Society (AWS).

Gas-shielded flux cored electrodes are commonly used to weld carbon, low-alloy steel, and stainless steels in the construction of

pressure vessels and piping for the chemical processing, petroleum refining, and power generation industries. In addition, flux cored electrodes are used to weld some nickel-base alloys.

Flux cored electrodes are also used in the automotive and heavy-equipment industries in the fabrication of frame members, axle housings, wheel rims, suspension components, and other parts. Small-diameter flux cored electrodes are used for automotive body repair.

Gas-shielded flux cored wires are used in the fabrication of mining machinery, off-road equipment, earth-moving machinery, pipe and superstructures for offshore drilling platforms, structural steel, water towers, oil storage tanks, military and commercial ships, rail cars, automobile components, hot water heaters, truck frames, wind towers, machine tools, automobile and truck wheels/rims, barges, farm machinery, and locomotives.

Self-shielded flux cored wires are used in many of the same applications but are also used for field erection of oil and gas pipelines, fabrication of high-rise structures, and welding of automobile body components. Because self-shielded electrodes have less penetration than the gas-shielded variety, they lend themselves quite readily to welding with minimal burn-through on lighter-gage steels, such as automotive body sections, various sheet metal applications, and certain structural joints.

Carbon steel flux cored electrodes are commonly used to weld grades of steel such as ASTM A516, A517, and A572, while the low-alloy types are used for low-temperature steels, such as ASTM A302 chromium-molybdenum steels, and high-strength steels, such as ASTM A514. Use of self-shielded electrodes has been dominant in field applications, such as pipeline construction and high-rise building construction, because gas-shielded electrodes require a shielding gas source near the welding arc. The use of gas cylinders in these instances has proved unwieldy, hence making self-shielded products the favorite choice.

Equipment

The FCAW process uses semiautomatic, mechanized, and fully automatic welding systems. The basic equipment includes a power supply, wire feed system, and welding gun. The required auxiliary equipment, such as shielding gas, depends on the process variant used and the degree of automation. The use of fume-removal equipment may be considered for welding applications indoors or in enclosed areas, as deemed necessary by safety and health professionals. Such systems should be designed for the specific application and area involved.

Typical semiautomatic equipment is shown in Fig. 2. The equipment used in the FCAW-G process is typically identical to GMAW equipment.

The recommended power supply for the semiautomatic FCAW process is a constant-voltage

Fig. 2 Semiautomatic flux cored arc welding equipment. Source: Ref 1

direct current machine. Most power supplies used for semiautomatic FCAW have output ratings of 600 A or less. A power supply rated at 60% or more duty cycle is the best choice for most industrial applications, whereas a duty-cycle rating as low as 20% may be sufficient for maintenance and repair applications.

Constant-current power supplies are used in certain situations, such as field welding applications, where portable constant-current SMAW power supplies are readily available. The addition of a contactor and a voltage-sensing wire feeder makes this an adequate welding system. However, such a system is only recommended when the use of a constant-voltage system is not feasible, because constant-current systems produce an inherently less-stable welding arc than constant-voltage systems.

Wire feeders for constant-voltage FCAW systems are generally simple devices that provide a constant wire feed speed. The power supply provides sufficient current to maintain an arc at the voltage that is preset at the power supply. A change in wire feed speed results in a change in the welding current.

In a constant-current system, the wire feeder is somewhat more complex. The welding current is preset at the power supply. The wire feeder has a voltage-sensing feedback loop that allows it to adjust the wire feed speed to maintain the desired welding voltage. The wire feeder generally contains systems to close the contactor and open

the shielding gas solenoid valve (FCAW-G process only) when welding is started.

Because flux cored wires are easily deformed by excessive feed roll pressure, knurled feed rolls are generally used in the FCAW process. Some wire feeders use a single drive roll paired with an undriven pressure roll. Others have one or two pairs of drive rolls. It is generally believed that systems having two pairs of drive rolls require the least drive roll pressure to provide dependable feeding. Excessive pressure with smooth rolls can crush the wire to an oval shape, causing it to jam in the liner or the contact tip. Excessive pressure with knurled rolls can wear notches into the wire surface that carve a trough into the contact tip, causing feeding and electrical burnback problems.

Both air-cooled and water-cooled welding guns are used in the semiautomatic FCAW process. Air-cooled guns are generally preferred, because they are simpler to maintain, lighter in weight, and less bulky. Water-cooled guns may be required when welding currents over 500 A are used, especially when the shielding gas is rich in argon, because argon arcs radiate more heat to the gas cup on the gun. As a rule of thumb, the use of argon blends will typically reduce the current-carrying capacity of a gun by 50%, rendering a 400 A gun useful at a maximum of 200 A.

Air-cooled guns designed for gas-shielded welding should not be used for self-shielded

welding, because the gun depends on the flow of shielding gas for proper cooling. Although curved-neck guns are the most common, straight guns are used to a limited extent.

A trigger switch on the welding gun is closed to initiate wire feeding, welding current flow, and shielding gas flow. The electrode is delivered from the wire feeder to the gun through a flexible conduit. Standard conduit lengths are 3, 3.7, 4.6, and 7.7 m (10, 12, 15, and 25 ft). Other lengths may also be available.

Mechanized and automatic FCAW equipment is not substantially different from that used in the semiautomatic FCAW process. The power supply should be rated for 100% duty cycle. Power supplies capable of outputs up to 1000 A may be required for some applications. Constant-current systems are very seldom used for mechanized and automatic welding.

The wire feed system is separated into a drive motor assembly and a welding control device, the latter of which often has a system to automatically start the travel mechanism when wire feed, current flow, and shielding gas flow are initiated. The welding control device is often equipped with a voltmeter and ammeter, as well.

The welding gun in mechanized and automatic systems is often mounted directly to the drive motor assembly, eliminating the need for a conduit. The gun is usually straight, but curved-neck guns are also used. Both water- and air-cooled guns are used, depending on the welding current level and shielding gas.

Most of the commonly available air-cooled guns can be used at levels up to 500 A with CO₂ shielding gas. When argon-rich shielding gas is used, the same gun may only be suitable for use at levels up to 300 A. Water-cooled guns are generally used at higher current levels.

Various travel mechanisms are used, depending on the applications. These mechanisms include side-beam carriages, tractor-type carriages, and robots.

Fume-Removal Equipment. In many cases, the amount of fumes generated by the FCAW process is sufficient to require fume-removal equipment. Although such equipment can be as simple as exhaust fans in the shop roof, additional local fume collection is often necessary. These systems can be either collection hoods (located above the welding gun) or fume-extractor guns. These guns are more efficient at collecting fumes but are heavier and more bulky than standard welding guns. To be effective, fume-collection hoods must be repositioned each time the welding location is moved.

Base Metals

Carbon and Low-Alloy Steels. Most carbon and low-alloy steels can be welded by the FCAW process if suitable electrodes are available and if the steels can accommodate the process. Steels for which electrodes are available include the following.

Electrode Diameters

Flux cored electrodes are produced in diameters ranging from 0.030 to 1/8 in. (0.8 to 3.2 mm). All-position electrodes are usually available in diameters of:

- 0.030 in. (0.8 mm)
- 0.035 in. (0.9 mm)
- 0.045 in. (1.2 mm)
- 0.052 in. (1.4 mm)
- 1/16 in. (1.6 mm)

Electrodes for flat and horizontal welding are usually available in diameters of:

- 1/16 in. (1.6 mm)
- 5/64 in. (2.0 mm)
- 3/32 in. (2.4 mm)
- 7/64 in. (2.8 mm)
- 1/8 in. (3.2 mm)

Other diameters are supplied through special purchasing agreements between end users and the manufacturers. The 0.030 and 0.035 in. (0.8 and 0.9 mm) diameters are typically made in the self-shielded versions, with gas-shielded, all-position, flux cored electrodes commonly marketed in the 0.045, 0.052, and 1/16 in. (1.2, 1.4, and 1.6 mm) diameters. These diameters lend themselves quite readily to all-position welding applications.

Electrode Classification

Carbon and Low-Alloy Steel Electrodes. Carbon steel flux cored electrodes are classified by AWS A5.20, "Specification for Carbon Steel Electrodes for Flux Cored Arc Welding." The layout of this classification system is defined

in Fig. 4; an "X" indicates a position where a designator would be. For example, the designator indicating minimum tensile strength can be a 6, to denote 60 ksi (415 MPa), or a 7, to denote 70 ksi (480 MPa). The assignment of the final designator depends on the shielding requirements and features of the electrode, as well as the recommended welding polarity. These are described in Table 2. The designations EXXT-G and EXXT-GS are designed to allow the classification of electrodes that are not covered by any of the other classifications. There are also optional supplemental designators, allowing the addition of a "J" for lowering the temperature of CVN testing requirements by 11 °C (20 °F) and for adding the diffusible hydrogen designator, which indicates the diffusible hydrogen level that the electrode meets, such as H2, H4, H8, and H16 (representing 2.0,

4.0, 8.0, and 16.0 mL of hydrogen per 100 g of weld metal).

Low-alloy steel electrodes are classified under AWS A5.29, "Specification for Low Alloy Steel Electrodes for Flux Cored Arc Welding." This specification uses a classification system very similar to that used in specification AWS A5.20, except that a chemical composition designator is added to the designation. An electrode classified according to this specification will have the form EXXTX-X. All of the positions before the dash have the same meaning as those in specification AWS A5.20. The position behind the dash is the chemical composition designator, which consists of a letter and a number. The same optional supplemental designators are used in AWS A5.29 as in A5.20. Therefore, it is possible to have a classification that looks like

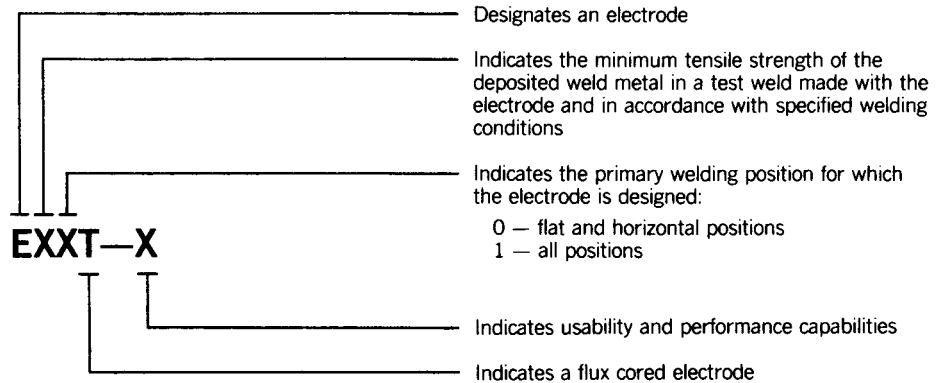

Fig. 4 Classification system for carbon steel flux cored electrodes. The letter "X" as used in this figure and in electrode classification designations in AWS specification A5.20-79 substitutes for specific designations indicated by this figure. Source: Ref 3

Table 2 Usability type designators for flux cored electrodes

Type(a)(b)	Shielding(c)	Single or multipass(d)	Transfer	Impact toughness requirement	Polarity(e)	Special characteristics
T-1	Gas	Multipass	Spraylike	20 ft · lbf at 0 °F (27 J at -18 °C)	DCEP	Low spatter, full slag coverage
T-2	Gas	Single	Spraylike	No requirement	DCEP	Low spatter, full slag coverage, high deoxidizers
T-3	Self	Single	Spraylike	No requirement	DCEP	High speed
T-4	Self	Multipass	Globular	No requirement	DCEP	High deposition, low penetration, crack resistant
T-5	Gas	Multipass	Globular	20 ft · lbf at -20 °F (27 J at -30 °C)	DCEP(f)	Improved toughness, crack resistant, thin slag
T-6	Self	Multipass	Spraylike	20 ft · lbf at -20 °F (27 J at -30 °C)	DCEP	Improved toughness, deep penetration
T-7	Self	Multipass	Globular	No requirement	DCEN	Crack resistant, good slag removal
T-8	Self	Multipass	Globular	20 ft · lbf at -20 °F (27 J at -30 °C)	DCEN	Improved toughness, crack resistant
T-9	Gas	Multipass	Spraylike	20 ft · lbf at -20 °F (27 J at -30 °C)	DCEP	Toughness requirements are at -20 instead of 0 °F (-30 instead of -18 °C).
T-10	Self	Single	Globular	No requirement	DCEN	High speed
T-11	Self	Multipass	Spraylike	No requirement	DCEN	General purpose
T-12	Gas	Multipass	Spraylike	20 ft · lbf at -20 °F (27 J at -30 °C)	DCEP	1.60 max Mn to meet ASME, enhanced toughness
T-13	Self	Multipass	Globular	No requirement	DCEN	Designed for aluminized and galvanized coated steels
T-14	Self	Multipass	Globular	No requirement	DCEN	Designed for thin-gage galvanized steels
T-G	Not specified	Multipass	Not specified	No requirement	Not specified	Not specified
T-GS	Not specified	Single	Not specified	No requirement	Not specified	Not specified

(a) A "C" designator is added when the electrode is designed for CO₂ shielding and an "M" designator when designed for Ar-CO₂ blends. (b) Addition of the "J" designator requires Charpy V-notch impact values to meet 20 ft · lbf (27 J) at -40 °F (-40 °C). (c) Gas-shielded electrodes are classified using CO₂ shielding; however, Ar-CO₂ mixtures are commonly used in practice. (d) Multipass electrodes are suitable for single-pass or multipass welding; single-pass electrodes are suitable for single-pass welding only. (e) DCEP, direct current electrode positive; DCEN, direct current electrode negative. (f) T-5 electrodes are classified using DCEP; however, they are sometimes used with DCEN in practice. Source: Ref 3

EXXTX-X J HX. The letter “X” that follows “EXXTX” denotes the alloy type of the electrode being classified, as follows:

Designator	Alloy type
A	Carbon-molybdenum steel
B	Chromium-molybdenum steel
Ni	Nickel steel
D	Manganese-molybdenum steel
W	Weathering steel
K	Other low-alloy steels
G	Not specified

Specification AWS A5.29 classifies only the EXXT1-X, EXXT4-X, EXXT5-X, and EXXT8-X electrode types, and the usability designator has the name meaning as that in specification A5.20. Minimum tensile strengths of up to 830 MPa (120 ksi) are included in specification AWS A5.29. Impact toughness requirements are based on the strength, usability, and chemical composition requirements of the electrode.

Stainless steel electrodes are classified under AWS A5.22, “Specification for Flux Cored Corrosion Resisting Chromium and Chromium-Nickel Steel Electrodes.” Classifications to this specification have the form EXXTX-X. The first three positions are the chemical composition designator, which corresponds to the American Iron and Steel Institute (AISI) designations (such as 308, 316, and 410) of steels having a similar composition. The final position is the shielding-type designator:

- T1 types are designed for use with CO₂.
- T-2 types are designed for use with Ar-2O₂ shielding gas.
- T-3 types are self-shielded.
- T-4 types are for use with 75 to 80% Ar/balance CO₂.

Also, a T-G type is included for electrodes that are not covered by the other shielding-type designators.

Nickel-Base Electrodes. A specification for nickel-base flux cored electrodes has been

published, AWS A5.34. Now that these products have their own classification document, flux cored nickel-base electrodes have found their way into many applications, such as cladding vessels for power generation, welding dissimilar metals on offshore platform components, and joining nickel-base materials to themselves on scrubbers and other highly corrosive weldments.

Submerged Arc Welding

Lee E. Allgood, The Lincoln Electric Company

SUBMERGED ARC WELDING (SAW) is an arc welding process in which the arc is concealed beneath and shielded by a blanket of granular fusible material called flux that is placed over the joint area ahead of the arc. Filler metal is obtained primarily from an electrode wire that is continuously fed through the blanket of flux into the arc and pool of molten flux.

The distinguishing feature of submerged arc welding is the granular material (flux) that covers the weld area and prevents arc radiation, sparks, spatter, and fumes from escaping. The flux is of major importance in achieving the high deposition rates and high-quality weld deposit characteristics. In addition to shielding the arc from view, the flux provides a slag that protects the weld metal as it cools. The slag may also deoxidize and refine the weld metal, insulate the weld to reduce the cooling rate, and help to shape the weld contour. Figure 1 shows a schematic diagram of a typical submerged arc weld.

Principles of Operation

During welding, the heat of the arc melts some of the flux along with the tip of the continuously-fed electrode, as illustrated in Fig. 2. The tip of the electrode and the welding zone are surrounded and shielded by molten flux covered by a layer of unfused flux. The electrode is automatically held a short distance above the workpiece, with an arc between the electrode and the workpiece. As the electrode progresses along the joint, the lighter molten flux rises above the molten metal in the form of a slag. The slag then freezes over the newly solidified weld metal, continuing to protect the metal from possible contamination by nitrogen and oxygen while at elevated temperatures. After cooling and removing any unfused flux for reuse, the solidified slag may be easily removed from the weld.

Automatic welding generally uses electrodes ranging in diameter from 2.4 through 4.8 mm (3/32 through 3/16 in.), with 4 mm (5/32 in.) being perhaps the most commonly used size. Semiautomatic welding is limited in size to maintain flexibility of the cable through which the electrode is fed. The normal diameter for semiautomatic welding is between 1.6 and 2.4 mm (1/16 and 3/32 in.) with 2.0 mm (0.78 in.) being the most commonly used.

Advantages of SAW include:

- The process virtually eliminates weld spatter, thus simplifying weld cleaning.
- There is little or no arc radiation, eliminating the need for the operator to use a welder's helmet. It also eliminates surrounding-area weld flash, hence the need for protective screening.

Fig. 1 Schematic of a typical submerged arc weld

Fig. 2 Submerged arc weld pool schematic

- Submerged arc welding significantly reduces fume generation. In comparison to open-arc processes, virtually no fume is generated.
- The flux acts as a scavenger and deoxidizer to remove contaminants such as oxygen, nitrogen, and sulfur from the molten weld pool, thus helping to produce very clean weld deposits.
- Deposits that are low in hydrogen are readily achievable.
- Very high deposition rates are possible, thus significantly increasing welding speeds and reducing total arc times.
- High current density produces high arc penetration, allowing for reduced edge preparation. Figure 3 is a macrophotograph of a submerged arc weld produced with two plates that were square butted together with no edge bevel.
- Submerged arc welding is readily adapted to semiautomatic, machine automated, and fully automatic modes of operation.
- Multiple electrodes may be used in the same weld pool resulting in deposit rates unattainable by any other arc welding process.

Limitations of SAW include:

- Most welding is performed in the 1F, 2F, 1G, and to a limited extent, the 2G positions (Fig. 4, Ref 1).
- Slag must be removed from each pass (layer) in weld joints involving multiple weld passes, although this is no different than for most arc welding processes.
- High heat inputs for SAW somewhat unites the process to thicker materials, arbitrarily 6.4 mm (0.25 in.). Special conditions may allow welding thinner materials.
- Submerged arc welding is generally not suitable for welding nonferrous materials such as aluminum, magnesium, and their alloys.

Process Applications

If a steel is suitable for welding with gas metal arc welding, flux cored arc welding, or shielded metal arc welding, procedures likely can be developed to weld the steel with SAW (Ref 1). The main limitations of SAW are plate thickness and position. Because SAW is a high-heat-input and high-deposition-rate process, it

Fig. 3 Square-edge preparation on 12.5 mm (0.5 in.) plate

is generally used to weld thicker steels. Although the welding of 1.6 mm (0.062 in.) thick steel is possible, most SAW is done on plate over 6.4 mm (0.25 in.) thickness.

Types of Metals Submerged arc welding is most commonly used to join plain carbon steels. Low alloy and alloy steels can be readily welded with SAW if care is taken to properly control the heat input to prevent creating undesirable hardness in the heat-affected zone (HAZ). Alloy steels and heat treated steels can be welded using controlled heat input (Joules/min.) and interpass temperature procedures to avoid undesirable grain coarsening and/or cracking in the HAZ.

Heat input as well as interpass temperature control may be essential to developing specific mechanical properties in the weld deposit. Welding of stainless steels is possible and practical on many AISI grades of steel. However, it is not recommended for fully austenitic grades or where ferrite content is controlled to less than 4%. Silicon content may be considerably higher for other arc welding processes and may cause hot-short cracking in austenitic grades of material (Ref 1).

Industrial Uses for SAW. Submerged arc welding is ideally suited for any application involving long, continuous welds. The ability to readily weld thick plates, sometimes with simple joint configurations, makes SAW the method of choice for welding components or assemblies found in:

- Bridge girder fabrication
- Structural steel components
- Machinery components such as gear cases, gears, structural bases, hydraulic cylinder end-caps, and so on
- Shipbuilding
- Earthmoving, construction, and agricultural equipment
- Mining and mineral processing equipment
- Food processing equipment
- Pressure vessels
- Air receiver and compressed gas cylinders
- Pipe fabrication

Submerged arc welding is also suited for buildup and/or overlay with alloyed materials. Typical applications include steel mill and

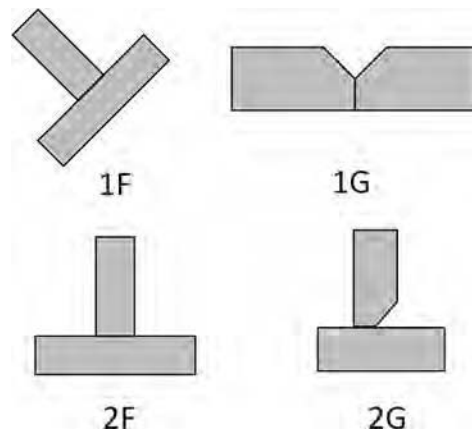

Fig. 4 Typical submerged arc welding positions

paper processing rolls, pressure vessel cladding, and hardfacing wear parts (Fig. 5). This is frequently done during fabrication of new components as well as the restoration to serviceability of worn components.

Joint Configurations. The most common weld deposits made with SAW are groove, fillet, lap, plug, joggle, and surfacing (buildup) deposits.

For groove or butt welds, the deep-penetration capability of SAW can play a role in specific joint selection. Plate up to 9.5 mm (0.38 in.) thick can be completely welded from one side using a square butt joint with an 0.8 mm (0.03 in.) root opening incorporating flux, copper, or ceramic backing. Plates in the thickness range from 6.4 to 19 mm (0.25 to 0.75 in.) that are square-edge butted with no gap may be welded without using backing by making one pass from each side, as shown in Fig. 3 (Ref 1).

Beveled joints may be used on any material 10 mm (0.38 in.) or greater. These joints may involve one pass from each side or multiple passes from either or both sides. When multiple passes are used, each pass should be such that slag is easily removed (Ref 1).

Fillet and lap welds with leg sizes up to 7.9 mm (0.31 in.) can readily be made in the horizontal 2F position (Fig. 6) using either semiautomatic or full-automatic methods. Welds larger than this can be made using multiple-pass techniques. In the flat (1F) position, it is possible to similarly produce welds of 12.7 mm (0.50 in.) leg size.

Submerged arc plug welds are made in the flat position only. The electrode is placed in the center of a prepared hole, and the arc is allowed to remain turned on until the hole is filled.

Ensuring High-Quality Welds. As with all arc welding processes, there are a number of steps that should be taken to produce high-quality welds. Make sure that the plate surfaces and the abutting surfaces to be welded are prepared such that:

- Organic materials including oil, grease, paint, and some paint primers are removed.
- Paint primers are kept uniform in thickness and as thin as possible.

Fig. 5 Submerged arc welding buildup on cylindrical object

- Rust in the weld area, especially red rust, is removed.
- The surfaces and abutting areas are free of moisture.
- Slag is removed from previous layers and any tack welds.
- Welding flux is clean and dry. This is very important when reusing unfused flux.
- An established welding procedure should be followed. This is especially important in repetitive work and mandatory to comply with most codes and standards, such as the American Society of Mechanical Engineers (ASME), the American Welding Society (AWS), and so on.
- A welding procedure should at least include electrode diameter, flux and electrode type, amperes and/or wire feed speed volts, type of current, travel speed and contact tip to work distance (CTWD), see (Fig. 7). This is sometimes referred to as electrical stick-out (ESO).
- Work should be securely grounded to the power source and, whenever possible, welding direction should be away from the ground.
- If preheating is required, the necessary temperature should be reached through the thickness of the section to be welded and (as a rule of thumb) at least 50 mm (two inches) on either side of the joint line.

Automatic SAW Power Source and Equipment

Power Supply. The power supplied to the contact tip may be direct current (dc) or alternating current (ac). Both dc and ac power have advantages and disadvantages.

In the United States, dc power has been the predominant type of power used for single-arc SAW. The dc power may be of a constant voltage or variable voltage (also known as constant current) type. In the past, both types have been supplied by motor generator or transformer

rectifier-type welders. More recently, inverter power sources have been designed for SAW. In Europe and the Far East, ac is more commonly used for single-arc SAW. In all cases, a suitable wire-feeding device is connected to the power supply. Figure 7 illustrates a simplified block diagram of a typical setup.

Advantages of the dc system include:

- Arc stability at both low and high travel speeds
- Better arc striking
- Usually uses three-phase input power, which keeps primary current draw balanced across each phase

Disadvantages of the dc system include:

- May encounter magnetic interference (arc blow), resulting in poor bead shape and possible porosity
- Multi electrode applications will create magnetic interference between themselves.

Advantages of the ac system include:

- Freedom from magnetic arc interference (arc blow)
- Higher deposition rates for the same current

Disadvantages of the ac system include:

- Arc ignition and arc instability may occur, especially at lower current settings. On a 60 Hz system, the arc extinguishes and reignites 60/s.
- May require voltages as high as 80 volts to insure acceptable arc ignition.
- Because these are single phase devices, larger input power lines are required.
- The high single-phase primary current draw can create significant supply line imbalances.
- Phasing and/or power sources for multiarc applications involve complex connections.
- Paralleling power sources for high current applications involves complex transformer connections.

Power Inverter Technology. Recent advances in power inverter technology, digital solid-state controls, and software control of power output have dramatically altered the nature of SAW power sources and related equipment. Figure 8 illustrates a modern power source, control unit, and wire drive.

These power sources differ from traditional motor generator or transformer-type power sources in the following ways:

- Three-phase power input is balanced at higher efficiencies irrespective of output mode.
- Either ac or dc power and constant current or constant voltage modes can be output from the same power source.
- Easy paralleling of power sources for high current outputs
- The ac output can be square wave, which increases arc stability (Fig. 9).
- To switch between ac and dc output, no external or internal wiring changes are required. Dc output may be either constant current or constant voltage.
- The ac output may be unbalanced, thus permitting controlled changes in penetration and deposit rate.
- The source is readily compatible with programmable logic controllers.

Control System Requirements. If constant voltage output is used, the wire is fed at a controlled, constant speed. The required welding current is determined based on the size of the electrode, the contact-tip-to-work distance, and the speed of the feeder. This is frequently the choice for small, high-travel-speed welds.

If constant current (variable voltage) output is used, the feeder monitors the arc voltage to adjust the wire feed speed and maintain a given arc length, while the power source maintains the desired current. This is usually the choice where large weld puddles are involved.

SAW Fluxes

Fluxes are described in several different ways, including method of manufacture, alloying effect, basicity index, and diffusible hydrogen potential.

Fig. 6 Fillet welds, 8 mm (0.31 in.)

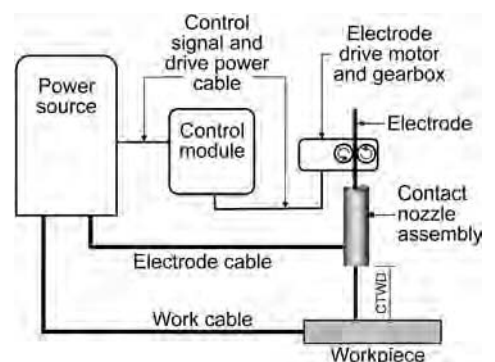

Fig. 7 Typical submerged arc welding equipment layout. CTWD, contact-tip-to-work distance

Fused fluxes are manufactured by melting, drying, and then grinding the raw materials. Agglomerated fluxes are manufactured by binding the raw materials together and heating them as a ceramic. Because of the lower manufacturing temperatures, agglomerated fluxes may contain alloys and high-melting compounds. Slag that has been produced by SAW is sometimes ground and used as a welding flux. Because of the inherent risks in this process, the usage is typically limited to overlay welding or less-critical applications. *Reground fluxes may require requalification to the appropriate material specification.* Fluxes can be produced over a wide range of particle sizes. Typically, smaller particle sizes are preferred for smaller welds, and larger particle sizes for larger weld puddles.

Fluxes may be categorized as active or neutral with regard to alloying weld metal. Active fluxes generally add alloy to a weld deposit and specifically may change the level of alloying based on the amount of flux that is melted with

respect to the electrode and base metal melted. They are particularly effective at resisting weld defects due to dirty steel and are mainly used for limited-pass welding. When using these fluxes, more care must be taken to keep welding conditions the same, because the amount of alloy deposited changes with the amount of flux melted. They are also known to increase the alloy level of multiple-pass welds as subsequent layers of weld metal are added.

Some fluxes contribute significant amounts of various alloys and are used for hardfacing and specific alloy steel applications. Other fluxes add chromium and are used to compensate for chromium that is lost during welding of stainless steels. Neutral fluxes are typically used for multiple-pass applications.

The neutral/active behavior of a given flux is expressed by the Wall neutrality number (N) (Ref 2, 3) and is defined by:

$$N = 100 \times (|\Delta\%Si| + |\Delta\%Mn|) \quad (\text{Eq 1})$$

where $|\Delta\%Si|$ is the absolute value of the change in the weight percent of silicon, and $|\Delta\%Mn|$ is the absolute value of the change in the weight percent of manganese when welds are made at 28 and 36 V. Fluxes that contribute alloying ingredients other than manganese and silicon are characterized by the expected composition or properties of the resulting weld metal.

Another common method used to describe submerged arc fluxes is the basicity index (BI). The basicity index is a measure of the ratio of strongly bound metallic oxides to weakly bound metallic oxides and roughly relates to the amount of oxygen in the weld metal. The Boniszewski basicity index (Ref 4) is defined by:

$$BI = \frac{(\text{CaO} + \text{CaF}_2 + \text{MgO} + \text{K}_2\text{O} + \text{Na}_2\text{O} + \text{Li}_2\text{O}) + \{\text{BaO} + \text{SrO} + 1/2(\text{MnO} + \text{FeO})\}}{\{\text{SiO}_2 + 1/2(\text{Al}_2\text{O}_3 + \text{TiO}_2 + \text{ZrO}_2)\}} \quad (\text{Eq 2})$$

Fluxes with a high basicity index (>2) generally produce weld metal with higher toughness properties in multiple-pass welds. Fluxes with a medium basicity index (1 to 2) generally produce weld metal with higher toughness in single-pass or two-run welds. Fluxes with a low basicity index (<1) are generally used where high impact toughness is not a requirement.

Fluxes exhibit more influence on submerged arc weld-metal hydrogen than do solid electrodes, so fluxes are sometimes classified in terms of the diffusible hydrogen of weld metal. Submerged arc weld metal can be produced with diffusible hydrogen levels of less than 2 mL/100 g to over 15 mL/100 g weld metal. Some fluxes must be dried prior to use to produce low weld-metal hydrogen values. Different welding fluxes will contain different amounts of moisture. Different welding fluxes will have different relationships between moisture in the flux and hydrogen in the weld. It is difficult to generalize this relationship, so the consumable manufacturer should be consulted with regard to appropriate flux storage and drying conditions.

Fig. 8 Inverter with digital control

Fig. 9 Alternating current (ac) square wave and sine wave output

Electrodes for SAW

There are three different types of electrodes manufactured for SAW welding:

- **Solid:** These are drawn to specific sizes and are the most commonly used type. Solid electrodes are available for welding carbon steel, low-alloy steel, stainless steel, and nickel-base alloys. A thin copper coating is usually applied to the carbon steel electrodes to enhance atmospheric corrosion resistance and improve electrical contact. The most commonly used sizes range from 1.6 to 6.4 mm (0.062 to 0.25 in.).

- **Cored:** These are electrodes with a metallic sheath and a filling of metals and fluxing agents. They are often used to add alloy to a weld puddle to provide a specific weld-metal composition. Size availability ranges from 2 to 4 mm (0.078 to 0.156 in.).
- **Strip:** These are made from solid strip to an appropriate chemistry. They are available in widths from approximately 25 to 100 mm (1 to 4 in.). Thickness ranges are usually from 0.5 to 1.0 mm (0.02 to 0.04 in.). These electrodes are primarily used for cladding, buildup, overlaying, and hardfacing applications. The advantage of these electrodes is that low penetration and low dilution with parent plate (or previous layers) can be achieved at moderately high deposition rates. A major disadvantage is that special feeder drive rolls and contact nozzles are required.

Weld-Metal Considerations

A weld consists of melted parent plate and electrode and may also contain alloying elements from the flux. The weld-metal composition and mechanical properties are dependent on the welding procedure, the joint preparation, the consumables used, and any postweld heat treatment. Submerged arc weld metal is classified based on tensile strength, impact toughness, and sometimes chemical composition of the weld metal. Weld metal is classified based upon producing welds using specific procedures as detailed in

AWS specifications. Provision is made for classification by using either a multiple pass procedure or a two run procedure.

Classification of Multiple-Pass Plain Carbon Weld Metal. The classification of electrodes and fluxes for welding carbon steels is detailed in "Specification for Carbon Steel Electrodes and Fluxes for Submerged Arc Welding," ANSI/AWS A5.17 (Ref 2). The classification of solid electrodes is based on the chemical composition of the electrode. Flux is not classified alone but is based on the mechanical properties and diffusible hydrogen of weld metal produced with a given electrode. The classification system used to describe flux-electrode combinations for mild steel welding is shown in Fig. 10. References in that figure are to the appropriate figures and tables in AWS A5.17.

Classification of Multiple-Pass Low-Alloy Weld Metal. The classification of low-alloy steel welding electrodes and fluxes is detailed in "Specification for Low-Alloy Steel Electrodes and Fluxes for Submerged Arc Welding," ANSI/AWS A5.23 (Ref 3). The classification of solid electrodes is based on the chemical composition of the electrode. The classification of composite electrodes (cored wire) is based on weld deposit composition. Flux is not classified alone but is based on the mechanical properties, chemical composition, and diffusible hydrogen of the weld metal produced with a given electrode. The designator system for flux-electrode combinations of low-alloy steel is shown in Fig. 11. References in that figure are to the appropriate figures and tables in ANSI/AWS A5.23/A5.23M.

Classification of Two-Run Weld Metal.

The classification of submerged arc weld metal produced in the two-run welding method is also detailed in "Specification for Low-Alloy Steel Electrodes and Fluxes for Submerged Arc Welding," ANSI/AWS A5.23 (Ref 3). The classification of electrodes is identical to that for multipass welding. The classification of the flux-electrode combination is based on the mechanical properties and diffusible hydrogen of the weld metal produced using a specified two-run technique. The mechanical properties of a flux-electrode combination welded with a two-run technique will most often be very different than those obtained with a multipass welding technique. This is due to the reheating of the weld metal as subsequent weld passes are applied to the weldment. The designator system for flux-electrode combinations of low-alloy steel is shown in Fig. 12. References in that figure are to the appropriate figures and tables in ANSI/AWS A5.23/A5.23M.

Stainless Steel Electrodes for SAW. The requirements for classification of stainless steel electrodes are detailed in "Specification for Bare Stainless Steel Welding Electrodes and Rods," ANSI/AWS A5.9 (Ref 5). The classification of the filler metal is based on the chemical composition. There is no provision for classifying a flux-electrode combination in this specification.

Nickel and Nickel Alloy Electrodes. The requirements for classification of nickel and nickel alloy electrodes are detailed in "Specification for Nickel and Nickel Alloy Bare Welding Electrodes and Rods," ANSI/AWS A5.14 (Ref 6). The classification of the filler metal is based on the chemical composition. There is no provision for classifying a flux-electrode combination in this specification.

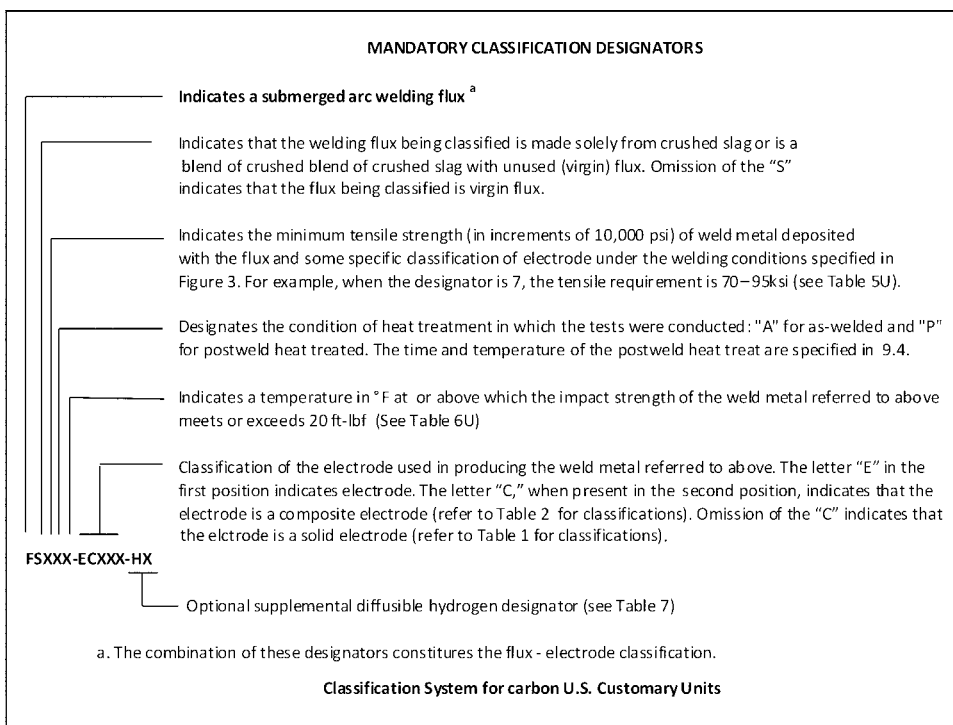

Fig. 10 Flux-electrode classification system for U.S. customary units. Source: Ref 2

SAW Process Parameters

In addition to the previously listed conditions for SAW, there are a number of considerations, including proper fit-up of the work and an appropriate welding procedure, that must be carefully controlled, just as with any automated arc welding process. The following is a discussion of several important factors.

Fit-Up of Work. Assembled parts to be welded should be fit-up accurately as specified to assure uniformity from assembly to assembly. Some key factors are:

- Whether fit-up of the workpieces is to be "tight" or with a specified gap, edge-preparation uniformity from piece to piece is important.
- Tack welding should be consistently uniform, and if a slag-forming process is used, the slag should be removed.
- Fixturing or clamping of the assembly should be sufficient to minimize distortion during welding and to establish a consistent weld.

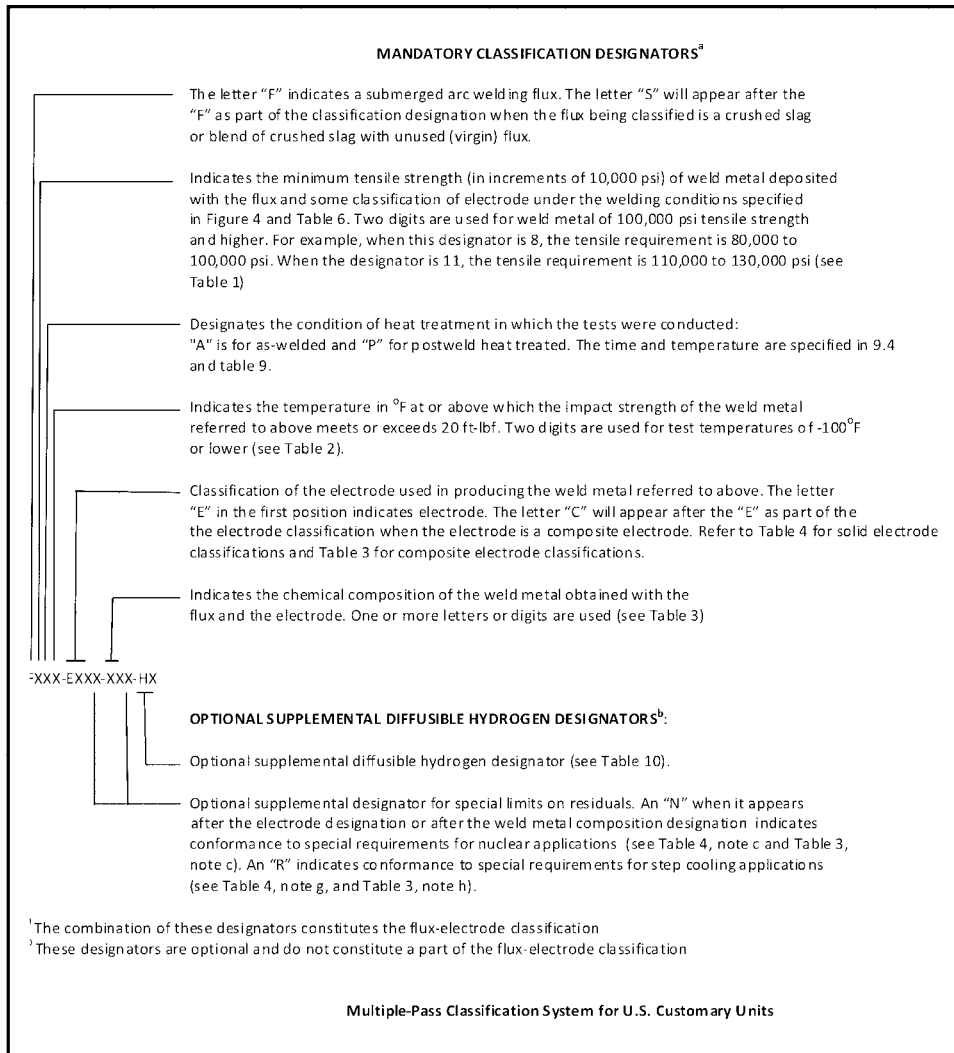

Fig. 11 Flux-electrode classification system for U.S. customary units. Source: Ref 3

- Travel motion alignment relative to the workpiece must be uniform. The use of automatic seam tracking may be beneficial for nonlinear seams.
- If groove welds are to be completely welded from one side, suitable joint backing is essential.

Welding Procedure Components. Appropriate welding procedure requires careful control of:

- Electrode-flux combination
- Electrode size
- Type of current (dc or ac)
- Current
- Voltage
- Type of voltage (variable or constant)
- Polarity if dc is used
- Frequency, balance, and offset if ac square wave is used
- Electrical stickout (ESO) (also referred to as contact-tip-to-work distance, Fig. 16)
- Travel speed
- Position of weld
- Number of passes
- Preheat and/or interpass temperature

These components act together with a joint design to constitute a specific welding procedure. Published procedures are available for many joint configurations and provide a good starting point for developing new welding procedures (Ref 1). Indiscriminant changes in any procedural component can result in a final weld that may not be acceptable in terms of serviceability or appearance. A brief description of the effects of some important procedural components follows.

Welding current has a direct influence on deposition rate, joint penetration, and the resulting internal and external bead shape. The type of current in conjunction with electrode size and ESO affects the deposition rate, penetration, and base-plate dilution. The effect of current variation on weld bead profiles is shown in Fig. 13. Welds made at excessively low

current (Fig. 13a) will tend to have little penetration and may result in a less stable arc. Welds made at excessively high current (Fig. 13b) will have deep penetration, high dilution, and an overall undesirable bead shape. Correct current (Fig. 13c) will produce a well-shaped bead.

The direction of current flow will also affect the weld bead profile. The current may be direct with the electrode positive (reverse polarity), electrode negative (straight polarity), sinusoidal ac, or variable polarity ac. When dc welding is the only choice available, electrode positive (dc +) is generally preferred for most applications because of greater arc stability. However, electrode negative (dc-) is used to increase deposition rate and reduce penetration. Electrode negative (dc-) is frequently used for fillet welding where joint penetration is undesirable or not needed. Because electrode negative (dc-) produces shallower penetration and therefore less base-plate dilution, it is often used for surfacing (buildup) applications.

Deposition rate for conventional alternating current is between that of dc straight and dc reverse polarity. Conventional ac (sine wave) alternating current is often used when welding current exceeds 1000 amps.

Alternating current is frequently used when arc blow is encountered, including in multiple-electrode applications.

Inverter and software-based power sources with digital control can provide a very stable square wave output that allows the user to control the percent of the cycle that is on the positive or the negative side. Referred to as percent balance, this allows for a significant increase in deposit rate over conventional ac sine wave output at equal amperes. An example of this increase is shown in Fig. 14 for a commonly used electrode size.

Arc Voltage. Like current, arc voltage will affect the bead shape and may affect the weld deposit composition when using active and alloy fluxes. Changes in voltage while holding the current constant can affect the resulting bead shape, as shown in Fig. 15. Excessively high voltage (Fig. 15b) will produce a hat-shaped weld, which has low resistance to cracking.

Setting voltage toward the high side will produce a longer arc length with a correspondingly wider, flatter bead with less penetration. However, when the voltage is excessively high, the weld bead appearance will mimic that of very low voltage. Lower voltages will shorten the arc length and increase penetration. Excessively low voltage will produce an unstable arc and a crowned bead as well as uneven surface contours (Fig. 15a).

Electrical stickout is variously referred to as ESO or contact-tip-to-work distance. It is the distance between the point at which current is input to the electrode and the work (Fig. 16). While not precisely correct, it is typically measured as the distance from the end of the electrode contact tip to the work surface or previous layer surface in multilayer welds.

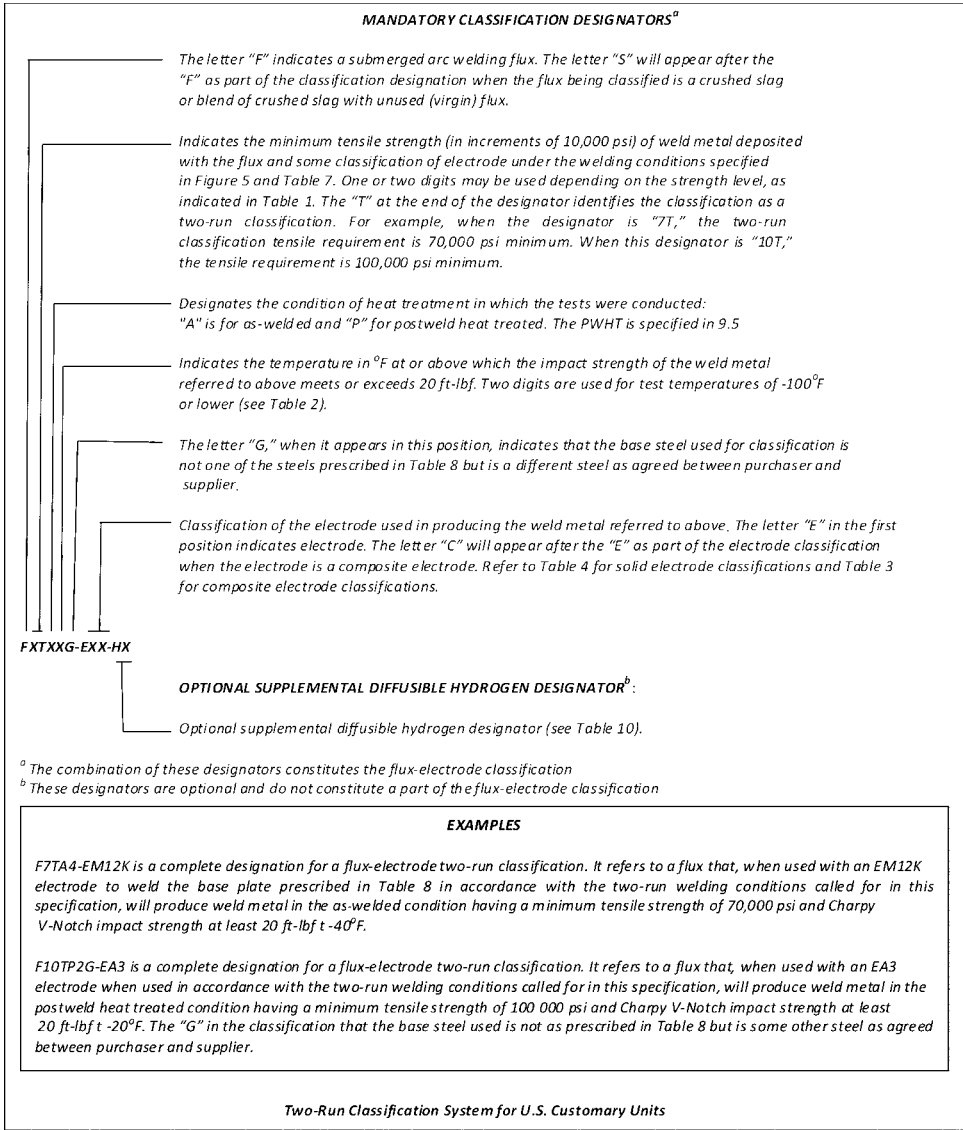

Fig. 12 Flux-electrode classification system for U.S. customary units. Source: Ref 3

Fig. 13 Effect of welding current on bead shape

The current flowing in the electrode between the contact tube and the arc will cause some resistance heating, resulting in a voltage drop across that length of electrode. This resistance heating and subsequent voltage drop can be used to obtain higher deposition rates.

Normal electrode extension for solid SAW wire is approximately 7 to 12 times the electrode diameter. As this length increases, so does the amount of resistive heating and the melt-off

rate. This (I^2R) heating will create an increased drop in arc voltage and necessitate an increase in voltage output from the power source to maintain the desired voltage across the arc. Extending the electrode 20 to 30 times the diameter can increase deposition rates by more than 50% (Ref 1).

As the electrode is extended, keeping the electrode aligned to the weld seam can become a problem. Special insulated contact nozzles are

commercially available to keep the proper electrode alignment.

Travel Speed. With any given welding procedure, travel speed determines and controls the volume of weld metal deposited per incremental length. There are other effects from travel speed changes with an otherwise fixed welding procedure:

- Heat input is directly affected by travel speed and thus must be carefully considered when there are specific heat-input requirements.
- The proper travel speed will result in a good bead shape and slag removal. Travel speed also affects penetration.
- Excessively high travel speeds will promote a crowned weld bead as well as increase the tendency for undercut and porosity.
- Excessively slow travel speeds can cause an undesirable increase in the total weld puddle size. This can cause slag inclusions and wavy edges because the molten metal is not properly contained by the slag.

Figures 17 and 18 illustrate how the type of current and travel speed can interact to produce the same weld volumes. Voltages were adjusted as appropriate for the increase in deposit rate. Heat input for the three welds is within a 10% spread between the slowest- and highest-speed welds.

Flux depth should be just deep enough that the arc does not "flash through" the flux blanket. A flux blanket that is too thick can act as a dam and affect the overall bead appearance. In deep-groove welds, an excess amount of flux can result in a humped weld with poor fusion and trapped slag.

Too little flux will result in the arc flashing through the flux. This will result in poor weld surface appearance, arc instability, and may even cause weld porosity by allowing air to be drawn into the arc.

Defects in SAW

The fact that SAW is a high-heat-input process under a protective blanket of flux greatly decreases the chance of weld defects. However, defects such as lack of fusion, slag entrapment, solidification cracking, hydrogen cracking, or porosity can occur.

Insufficient Fusion and Slag Entrapment. Lack-of-fusion defects and slag entrapment are most commonly caused by improper bead placement or welding procedure. Improper placement can cause the weld metal to roll over and trap slag underneath. A crown-shaped bead caused by excessively high or low welding voltage may also contribute to slag entrapment and lack of fusion.

Solidification Cracking. Cracking along the center of the bead is usually due to improper bead shape, poor joint design, high joint restraint, or poor welding procedures. A bead width-to-depth ratio greater than 1 will decrease cracking tendencies (Fig. 19). If the weld bead is too deep,

Fig. 14 Weld deposit rate versus current. ac-SW, alternating current-square wave; dc, direct current

Fig. 15 Effect of voltage on bead shape

Fig. 16 Contact-tip-to-work distance (CTWD) or electrical stickout

increased shrinkage stresses related to solidification may cause centerline cracking. Joint design can also contribute to excessive shrinkage stresses and cracking. Because cracking is related to stresses in the weld, high-strength materials will have a greater tendency to crack. Therefore, special care must be taken to generate proper bead shape, preheat temperatures, and interpass temperatures, in addition to correct electrode and flux combinations, when welding these materials.

Hydrogen-Induced Cracking. Unlike solidification cracking, which appears immediately after welding, hydrogen cracking may occur from several hours to several days after welding has been completed. To minimize hydrogen cracking, all possible sources of hydrogen (for example, water, oil, grease, rust, thick primer paint, and dirt) present on the plate or joint should be removed. The flux, electrode, and

Groove-level full requires 0.340 lb/ft (0.505 kg/m) of deposited weld metal. Adding a cap of 5/8 × 1/16 in. (15.9 mm × 1.59 mm) requires an additional 0.089 lb/ft (0.132 kg.m) deposit.

Fig. 17 Prepared welding groove

plate should be clean and dry. Care should be taken to avoid moisture contamination of fluxes and electrodes. Fluxes and electrodes should be stored, handled, and redried, if necessary, as recommended by the consumable manufacturer.

Other considerations to reduce hydrogen-cracking tendency include:

- Electrodes with surface rust should not be used.
- Consumables designed to produce weld deposits that are very low in diffusible hydrogen should be considered, especially when welding high-strength steels.

- Follow proper preheat and interpass temperatures as well as postweld hold times and temperatures (Ref 1).
- Keep weld-metal layers as thin as possible, and allow as much time as possible for hydrogen to escape. Hydrogen escapes more readily with increasing time and temperature. Reduction of the distance that hydrogen must travel to escape will also assist in hydrogen removal from the weld metal.

Porosity caused by trapped gas is uncommon in SAW because of the protection provided by the flux. When porosity does occur, it may be in the form of internal porosity or visible holes on the weld bead surface. The gas bubbles that generate porosity originate either from a lack of protection from the atmosphere or from contaminants such as water, oil, grease, and dirt. To reduce porosity in SAW, in addition to proper flux coverage, all water, grease, dirt, and any other organic material should be removed from the plate and

the joint. Porosity that occurs at one end of the joint and becomes worse with subsequent passes may be caused by arc blow. Switching to ac polarity or changing the ground location may improve this situation. Occasionally, porosity can occur as the result of nitrogen being absorbed in plate edges prepared by plasma cutting. This problem can usually be eliminated by light grinding of the edges before welding.

Training and Safety

Welder Training. Submerged arc welding is an automatic or semiautomatic process carried out primarily in the flat or horizontal position with the arc obscured from view. Both forms of the process are largely controlled by welding procedure settings. The welder, or weld operator, is responsible for slight adjustments in equipment settings. Depending on the level and sophistication of fixturing, the welding operator may have to align the electrode to the

work and track the weld joint. Semiautomatic welding will require training to properly align the welding torch to the workpiece and to develop the skill to provide the appropriate travel speed.

A welder who is expected to establish welding procedures must understand how the various elements of a procedure interact with each other and influence the weld.

Workplace Health and Safety. Submerged arc welding has the advantage over other arc welding processes in that it is essentially devoid of arc radiation and smoke and fume generation. Nonetheless, good ventilation should be provided, and care should be taken in handling flux to avoid the generation of dust.

The heavy protective clothing and gear associated with open-arc processes is not required. Light protective clothing may be worn. Hot slag and flux can cause burns to exposed skin, as can contact with hot workpieces. Eye protection should be worn at all times.

Protection against electric shock should be provided by assuring that all equipment is properly installed and grounded. Welding cables should be maintained in good condition, with proper connections at each end. Specific practices as outlined in "Safety in Welding and Cutting and Allied Processes" (Ref 7) should always be followed.

Manufacturers' material safety data sheets should be carefully read and understood. *Note that there is one for the electrode and one for the flux.*

Gas Tungsten Arc Welding*

Lee E. Allgood, The Lincoln Electric Company

THE GAS TUNGSTEN ARC WELDING (GTAW) process was developed in the late 1930s when a need to weld magnesium became apparent. The GTAW process is also referred to as the tungsten inert gas (TIG) process and as Heliarc (Ref 3), the original registered trade name, and thus became commonly referred to as TIG welding.

The GTAW process derives the heat for welding from an electric arc established between a tungsten electrode and the part to be welded (also called the workpiece). The arc zone must be flooded with an inert gas to protect the tungsten electrode and molten metal from oxidation and to provide a conducting path for the arc current. In 1941, Russell Meredith and V.H. Pavlecka developed the first practical torch for holding a tungsten electrode and delivering an inert gas shield to protect the electrode, weld pool, and adjacent hot metal (Fig. 1). The inert gas is fed through a nozzle

surrounding the tungsten electrode, which provides a means of shielding the arc as it is moved along a weld joint. Torches used for higher currents are usually water cooled (Fig. 2).

The melting temperature necessary to weld materials in the GTAW process is obtained by maintaining an arc between a tungsten alloy electrode and the workpiece (Fig. 1, 3). Weld

pool temperatures can approach 2500 °C (4530 °F). The inert gas sustains the arc and protects the molten metal from atmospheric contamination. The inert gas is normally argon, helium, or a mixture of helium and argon. Although the process was developed with helium, argon soon became the most widely used shielding gas because of its lower cost, greater density, and smoother arc operation. Helium produces a higher-energy arc and so is still used for certain applications.

A typical setup for GTAW consists of an inert gas supply (argon, helium, or a mixture of these), including pressure regulators, flow meters, and hoses to deliver the gas to the arc. The gas(es) may be supplied from a cylinder(s) or liquid container(s). An illustration of a complete GTAW arrangement is shown in Fig. 4.

Gas tungsten arc welding may readily be automated for automatic, machine, or robotic welding (Fig. 5), but additional equipment is required, such as a means of mechanically moving the torch in relation to the work and feeding filler electrode into the weld pool. A fully automatic system may require a programmer consisting of a microprocessor to control weld current, travel speed, and filler electrode feed rate as well as a programmed travel path.

Applications

Various GTAW applications are shown in Fig. 6 and 7. Gas tungsten arc welding can be used for those alloys where high-quality welds and freedom from atmospheric contamination are critical. Examples of these are reactive and

Fig. 5 Robotic welding. Note wire feed device supplying “cold” wire. Courtesy of The Lincoln Electric Company

refractory metals such as titanium, zirconium, and niobium, where very small amounts of oxygen, nitrogen, or hydrogen can reduce both the ductility and corrosion resistance. It can be used to join stainless steels (austenitic, ferritic, and martensitic types) and many nickel-base superalloys where high-quality welds are required. Both aluminum and magnesium alloys are readily weldable.

The GTAW process is well suited for welding thin sheet (Fig. 7c) and foil of all weldable metals because it can be controlled at the very low amperages (2 to 5 A) required for these thicknesses. Gas tungsten arc welding is an excellent process for root-pass welding with the application of consumable inserts or open-root techniques on pipe and tubing (Fig. 7). Gas tungsten arc welding should not be used for welding metals and alloys with very low melting points, such as tin-lead solders and zinc-base alloys, because the high temperature of the arc makes it difficult to control the weld puddle.

The GTAW process is especially suited when the highest weld quality is required. The operator has excellent control of heat input, and visibility is not limited by fumes or smoke from the process. Other advantages include (Ref 4):

- High-quality, low-distortion welds
- Free of the spatter associated with other methods

- Applicable with or without filler wire
- Applicable with a range of power supplies
- Suitable for almost all metals, including dissimilar ones
- Precise control of welding heat

Limitations of GTAW include (Ref 5):

- Lower deposition rates than consumable electrode arc welding processes
- Used manually, it requires slightly more welder dexterity and eye/hand coordination than gas metal arc welding or shielded metal arc welding for manual welding.
- Less economical than consumable electrode arc welding for thick sections greater than 9.5 mm (0.38 in.)
- Problematic in drafty environments because of possible difficulty in shielding the weld zone properly

Additional problems with the process may include:

- Possible tungsten inclusions if the electrode is allowed to contact the weld pool
- Contamination of the weld metal if proper shielding of the filler metal by the gas stream is not maintained
- Low tolerance for contaminants on filler or base metals

- Contamination or porosity, caused by coolant leakage from water-cooled torches
- Arc blow or arc deflection, as with other processes when using direct current

Principle of Operation

In the GTAW process, an electric arc is established in an inert gas atmosphere between a tungsten electrode and the metal to be welded. The arc is surrounded by the inert gas, which may be argon, helium, or a mixture of these two. The heat developed in the arc is the product of the arc current times the arc voltage, where approximately 70% of the heat is generated at the positive terminal (anode) of the arc. Arc current is carried primarily by electrons (Fig. 8) that are emitted by the heated negative terminal (cathode) and obtained by ionization of the gas atoms. These electrons are attracted to the anode, where they generate approximately 70% of the arc heat. A smaller portion of the arc current is carried by positive gas ions that are attracted to the cathode, where they generate approximately 30% of the arc heat. The cathode loses heat by the emission of electrons, and this energy is transferred as heat when the electrons enter or interact with the anode. This is one reason why a significantly greater amount of heat is developed at the anode than at the cathode. Because the greater amount of heat is generated at the anode, the GTAW process is normally operated with the tungsten electrode or cathode negative (negative polarity) and the workpiece or anode

positive. This puts the heat where it is most needed, at the work.

Arc Polarity

The GTAW process can be operated in three different modes: electrode negative (straight polarity), electrode positive (reverse polarity), or alternating current (ac) (Fig. 9). In the electrode negative mode, the greatest amount of heat is developed at the work. For this reason, electrode negative (straight polarity) is used with GTAW for welding most metals. Electrode negative (straight polarity) has one disadvantage in that it does not provide cleaning action on the work surface. This is of little consequence for most metals, because their oxides decompose or melt under the heat of the arc so that deposited metal will wet the joint surfaces. However, the oxides of aluminum and magnesium are very stable and have melting points well above that of the metal. They are not removed by the arc heat and remain on the metal surface, restricting wetting, which, in turn, contributes to poor weld appearance.

In the electrode positive (reverse polarity) mode, cleaning action takes place on the work surface by impact of gas ions. This removes the thin oxide layer while the surface is under the cover of an inert gas, allowing molten metal to wet the surface before more oxide can form. The disadvantage of this mode is that the greater portion of heat is developed at the positive tungsten electrode and the smaller portion at the work. This means that to obtain the same heat at the work with electrode positive as with

electrode negative, the current must be increased by a factor of 2.3. This current increase, plus the fact that more heat is developed at the positive electrode, means that the electrode operating on positive polarity must dissipate approximately five times as much heat as an electrode operating on negative polarity. Usually, an electrode for positive polarity use is approximately four times the diameter of an electrode used for negative polarity. In the ac mode, the desirable features of both direct current (dc) modes are obtained at a reduced current level.

With GTAW-ac welding, the current flow goes to zero twice every cycle, and the arc must be restarted twice every cycle. When the electrode becomes negative, restarting occurs readily, but when the electrode becomes positive, restarting may be delayed, resulting in lower current. If the current does not start on the positive half-cycle, complete rectification occurs, and there will be no cleaning action. Continuous high frequency superimposed on the ac will assure that the arc is restarted early in each positive half-cycle to provide the cleaning action and minimize the unbalance. This is the reason that sine-wave-based GTAW power sources include a high-frequency generator.

When 60 Hz ac is used, cleaning is obtained on each positive polarity half-cycle, and some heat is developed at the work. The area cleaned on the positive polarity half-cycle will remain clean during the negative polarity half-cycle while shielded with inert gas. Most of the welding heat is delivered to the work during the negative polarity half-cycle. However, some power sources, when operated in the ac mode, must be modified when rectification occurs (as in the case of GTAW-ac of magnesium and aluminum).

Rectification and Cleaning Action with Alternating Current

When welding aluminum or magnesium with ac, an unbalanced wave form (Fig. 10) occurs because the hot tungsten electrode will emit electrons more readily than the clean metal surface. If this happens, more current will flow when the electrode is negative (Fig. 10), and

rectification will occur. This causes the arc to look and audibly sound unstable.

Rectification will occur with older, sine-wave ac welding power supplies. More advanced GTAW machines include solid-state controls that allow adjusting the ac so as to favor either the positive or negative polarity half-cycle (Fig. 11). This feature is particularly useful

Fig. 11 Alternating current (ac) wave shapes with square-wave gas tungsten arc power supply. dc, direct current

when welding aluminum and magnesium, because the control can be set to favor the positive half-cycle for maximum cleaning. When the electrode is negative, more heat is generated in the weld pool where it is needed. The smaller amount of current when the electrode is positive is acceptable, as long as sufficient current flows to provide adequate cleaning of the surface. The lower current flow also means less heating of the tungsten electrode.

Some power sources also produce a square-wave ac rather than sinusoidal ac. When maximum cleaning is desired, the electrode positive mode is favored; when maximum heat is desired, the electrode negative mode is favored. In general, square-wave power sources are much less susceptible to arc rectification than sine-wave power sources, although it still sometimes occurs.

Equipment

Power Supplies

Power supplies for GTAW are usually of the constant-current type with a drooping (negative) volt-ampere curve (see the article “Arc Welding Power Supplies and Controls” in this Volume for more details on power sources in general and for inverters in particular). Saturable reactors and thyristor-controlled units are the most common. Advances in the electronics industry have readily been adapted by the welding community, resulting in sophisticated, lightweight power supplies. Transistorized dc power supplies are common. There are newer inverter-based power sources that will deliver dc, pulsed dc in addition to sine-wave ac, and square-wave ac. The output frequency can also be varied (Fig. 12). Higher frequencies can be beneficial in welding thin materials.

For many years, inverter power supplies were only capable of supplying dc. This limited the

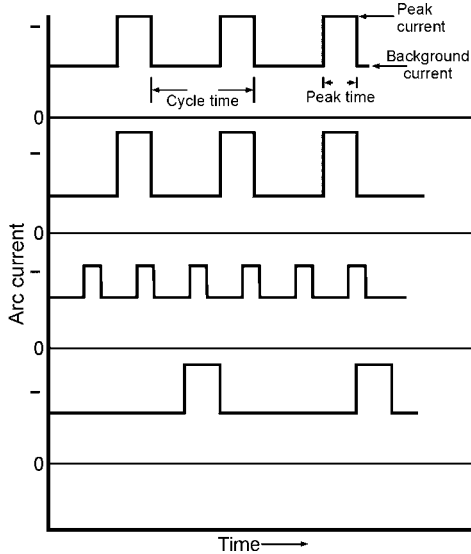

Fig. 12 Pulsed-wave shapes attainable with gas tungsten arc welding power supply

use of inverters for welding aluminum, which is normally gas tungsten arc welded using ac. By using two inverters running at opposite polarity and alternately switching them on and off, a pseudo-ac output is generated. Some inverters still generate ac in this manner. Today (2011), there are more sophisticated methods of generating ac. The ability to generate ac is what really makes the inverter suitable for welding aluminum using GTAW. The fact that the arc voltage never truly goes through zero means that the ac arc is much more stable than it was in the past.

Most inverter-based GTAW power supplies do not need the traditional high-frequency (HF) circuit, which had been added to improve arc initiation and arc stability. The elimination of continuous HF reduces the amount of radio-frequency interference generated by the power supply. In addition to having a very stable output, they also have faster response times than conventional silicon-controlled rectifier power supplies. Figure 13(a) illustrates the typical response of a thyristor-controlled welding

machine, while Fig. 13(b) shows an inverter-controlled arc welding machine.

The two figures show that the inverter-controlled machine reaches a steady-state output in approximately one-third the time of the thyristor-controlled machine, and without the typical starting current overrun and arc instability.

Advanced inverter-based machines also offer an additional major advantage. Figure 9 schematically shows typical penetration patterns for the three basic modes of GTAW: ac, dc negative, and dc positive. Advanced ac output inverter-type welders offer the additional ability to significantly alter the bead shape by adjusting the balance (Fig. 14a) or frequency of the balanced ac square wave (Fig. 14b).

Figure 15 illustrates an advanced 300 A rated ac/dc inverter. The compact size of 439 mm high by 269 mm wide by 620 mm deep (17.3 by 10.6 by 24 in.) and net weight of 34 kg (75 lb) make it highly suitable for portable as well as stationary use. Note that a graphical image of the output settings is displayed by this machine. This helps to simplify making output settings.

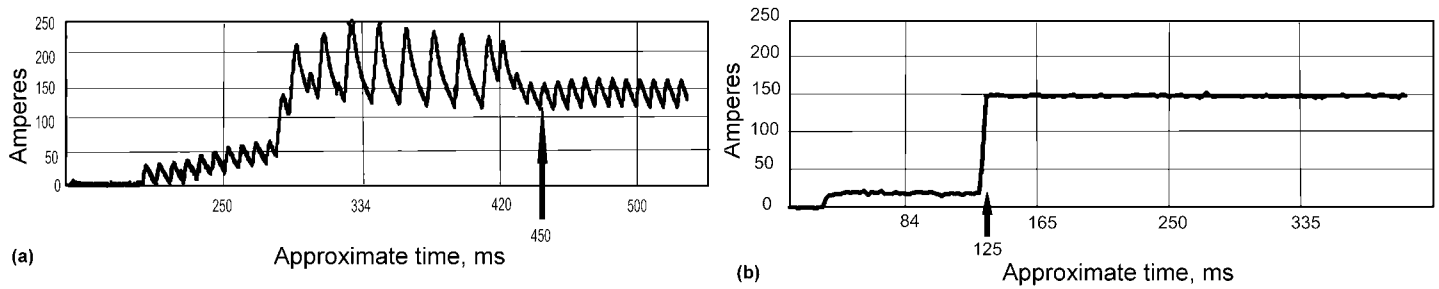

Fig. 13 Current profiles with (a) thyristor-controlled and (b) inverter-controlled welding machines

Fig. 14 Effect of alternating current (ac) waveform on weld profile. (a) Effect of altering balance. (b) Effect of altering frequency (with balanced square wave)

High Frequency. In GTAW, the term *high frequency* can have dual-usage meanings:

- The imposition of a separate high-frequency spark on the welding voltage
- On square-wave-output power sources, an ac output voltage greater than 60 Hz

Historically, the term is used to indicate that a separate high-frequency voltage is being generated and imposed on the welding circuit to enhance arc ignition, reignition, and stabilization. The frequency may be in the range of 20 MHz. Most machines have controls that permit continuously “on” operation or for initial arc starting only. The latter is useful to avoid having to bring the electrode into physical contact with the workpiece, which can cause tungsten contamination at the arc start point. In sine-wave ac output machines, continuous high-frequency operation is essential to assure arc stability by continuously assisting arc ignition as the sine-wave output approaches the zero point. This is essential to minimize or eliminate rectification when welding aluminum or magnesium (Fig. 10a). Some machines also permit adjusting the strength of the generated spark.

The imposed high frequency is usually generated by a spark-gap transformer. This may result in radiating signals that can interfere with radio, television, and electronic devices in general. *It is important that the manufacturer’s installation and grounding instructions be consulted and carefully followed.*

With advanced-design square-wave-output machines, the term is used to indicate that the ac output voltage frequency can be higher than 50 Hz. The output voltage frequency can usually be adjusted to anywhere from 20 to 300 Hz (Fig. 12, 14b). These machines also provide for a high-frequency spark for initiating the arc for the same reason as mentioned earlier. A major advantage of these machines is that continuous high frequency is not required to assure arc stability on ac, even when welding aluminum- or magnesium-base materials.

Torch Construction and Electrodes

The welding torch holds the tungsten electrode that conducts the current to the arc, and

Fig. 15 Advanced 300 A, alternating current/direct current inverter for gas tungsten arc welding

it provides a means of shielding the arc and molten metal. The major components of a typical welding torch are shown in Fig. 16.

Welding torches rated at less than 200 A are normally gas cooled (that is, the shielding gas flows around the conductor cable, providing the necessary cooling). Water-cooled torches are used for operation at higher welding currents and/or high arc-on times. Water-cooled torches are commonly used for mechanized, automatic, and robotic welding applications. The cooling water may be supplied to the torch from a recirculating system that uses a radiator or chiller to cool the recirculated water.

Electrode Selection. In selecting electrodes for GTAW, six factors must be considered: material to be welded, electrode material, size, tip shape, electrode holder, and nozzle to be used.

Electrodes for GTAW are typically available in diameters from 0.25 to 6 mm (0.010 to 0.250 in.) and in standard lengths ranging from 75 to 600 mm (3 to 24 in.). Electrodes are classified by the American Welding Society (Ref 6). The classifications are pure tungsten and tungsten alloys of thorium, cerium, lanthanum, or zirconium oxides (Table 1). All classified electrodes are color coded, as shown in Table 1.

Pure Tungsten (EWP). Pure tungsten electrodes (green), which are 99.5% pure, are the least expensive but also have the lowest current-carrying capacity on ac power, low resistance to contamination, and the highest

consumption rate. Pure tungsten is used primarily for ac welding.

Zirconia Tungsten (EWZr-1 and EWZr-8). Tungsten electrodes containing zirconia (brown and white, respectively) have properties between those of pure tungsten and thoriated tungsten electrodes regarding arc starting and current-carrying capacity. These electrodes are recommended for ac welding of aluminum over pure tungsten or thoriated electrodes.

Ceriated Tungsten (EWCe-2). Ceriated tungsten electrodes (gray) were introduced in the late 1980s. Ceriated tungsten electrodes operate well with either ac or dc polarity. These electrodes feature good starting and arc stability and also last longer than their thoriated tungsten counterparts.

Lanthanum Tungsten (EWLa-1, 1.5, and 2). Tungsten electrodes containing lanthanum (marked black, gold, and blue, respectively) have characteristics similar to ceriated tungsten. These tungsten electrodes can be used for both ac and dc applications. As the percentage of lanthanum increases, the arc stability, starting capability, and tip life improve. These electrodes can be used in place of thoriated tungsten with traditional and inverter-based power sources.

Thoriated Tungsten (EWTh-1 and 2). Tungsten electrodes containing 1% Th (yellow) or 2% Th (red) have greater electron emissivity than pure tungsten and therefore greater

Fig. 16 Schematic showing exploded view of key components comprising a typical gas tungsten arc manual welding torch

Table 1 Chemical composition requirements for tungsten electrodes

Classification symbol (ISO 6848 classification)	Chemical composition requirements		Impurities, mass percent	Tungsten, mass percent	Color code and RGB color value(a)
	Principle oxide	Mass percent			
EWP (WP)	None	Not applicable	0.5 max	99.5	Green #008000
EWCe-2 (WCe20)	CeO ₂	1.8–2.2	0.5 max	bal	Gray (formerly orange) #808080
EWLa-1 (EWLa10)	La ₂ O ₃	0.8–2.2	0.5 max	bal	Black #000000
EWLa-1.5 (WLa 15)	La ₂ O ₃	1.3–1.7	0.5 max	bal	Gold #FFD700
EWLa-2 (WLa 20)	La ₂ O ₃	1.8–2.2	0.5 max	bal	Blue #0000FF
EWTh-1 (WTh10)	ThO ₂	0.8–1.2	0.5 max	bal	Yellow #FFFF00
EWTh-2 (WTh-2)	ThO ₂	1.7–2.2	0.5 max	bal	Red #FF0000
(WTh 30)	ThO ₂	2.8–3.2	0.5 max	bal	Violet #EE82EE
EWZr-1 (WZr3)	ZrO ₂	0.15–0.50	0.5 max	bal	Brown #A52A2A
EWZr-8 (WXr 8)	ZrO ₂	0.7–0.9	0.5 max	bal	White #FFFFFF
EWG	The manufacturer must identify all additions.	The manufacturer must state the nominal quantity of each addition.	0.5 max	bal	The manufacturer may select any color not already in use.

Note: Intentional addition of doping oxides other than indicated for a particular classification is prohibited. (a) Red, green, and blue (RGB) color values and color samples can be found at the following website: <http://msdn.microsoft.com/en-us/library/ms531197.aspx>. Source: Ref 6

current-carrying capacity and longer life. Arc starting is easier, and the arc is more stable, which helps make them more resistant to contamination from the base metal. They maintain a well-sharpened point when welding dc negative polarity. The most commonly used electrode is EWTh-2.

Caution with Thoriated Electrodes. Thorium (thoria) is a radioactive material. Appropriate safety precautions should be taken when using thoriated electrodes. The statement in Fig. 17 was developed by the International Institute of Welding Commission VIII on Health and Safety (Ref 7). The grindings from thoriated electrodes also may be considered as hazardous waste in some states, and disposal may be subject to environmental regulations.

Electrode Tip Shape. The electrode material, size, and tip shape (Fig. 18) will depend upon the welding application, material, thickness, type of joint, and quantity. Electrodes used for ac or electrode positive polarity will be of larger diameter than those used for electrode negative polarity. The shape of the electrode tip can affect the resulting weld shape. Electrodes with included angles from 30 to

120° are stable and give good weld penetration and depth-to-width ratios. Electrodes with smaller included angles (5 to 30°) are sometimes used for grooved weld joints to eliminate arcing to the part sidewalls. For aluminum, aluminum alloys, magnesium, and magnesium alloys, a hemispherical end shape may prove to be the most suitable (end radius equal to one-half the electrode diameter).

Shielding Gases

The original GTAW process used helium as the shielding gas for welding magnesium and aluminum. Today (2011), argon is the predominant shielding gas. Mixtures of the two are sometimes used for specific situations.

Argon is the least expensive of the inert gases used for shielding gas tungsten arc welds, which is only partially responsible for its widespread use. Argon has a low ionization potential (2.52×10^{-18} J, or 15.7 eV), making it easier to form an arc plasma than with other shielding gases. Argon is approximately 1.4 times heavier

than air, so it displaces air, resulting in excellent shielding of the molten weld pool.

Helium has an ionization potential of 3.92×10^{-18} J (24.5 eV), which results in more difficult arc initiation and requires operation at a higher arc voltage and hence higher heat input for a given current. This higher heat input can be very beneficial when welding copper, aluminum, and other high-conductivity materials. Helium shielding used with direct current electrode negative is very effective for welding thick aluminum.

Gas Purity. Most materials can be welded using a welding-grade torch gas with a purity of 99.995% or 50 ppm impurities. However, some reactive materials (for example, titanium, molybdenum, and tantalum) require that the contaminant level be less than 50 ppm. This may require certified gas purity or the use of gas filters and purifiers.

Gas Flow Rates. The density of argon is approximately 1.4 times that of air and 10 times that of helium. For this reason, argon is heavier and will blanket a weld area and be more resistant to cross drafts than helium. Helium, being much lighter than air, tends to rise rapidly and cause turbulence, which can bring air into the arc atmosphere. Because helium costs approximately three times as much as argon, and the required flow rate is two to three times that for argon, the cost of using helium as a shielding gas can be as much as nine times that of argon. Typical flow rates for argon are 9.4 to 14.2 L/min (20 to 30 ft³/min).

Backup Purge and Shielding the Weld. Protecting the molten weld pool from the atmosphere is very important in GTAW. Atmospheric contamination can result in weld cracks, porosity, scaling, and an unacceptable granular appearance. The gas cup on the welding torch is the primary outlet of shielding gas for most GTAW applications. Backside shielding is especially important on thin-material butt welds, fillet welds joining thin-walled tubing, and root-pass welds on pipe because the presence of oxygen can reduce weld-metal penetration and result in the effects mentioned previously. Copper backing bars and ceramics are sometimes used to hold shielding gas against the back surface of the molten weld

“Thorium oxides are found in thoriated tungsten electrodes up to 4.2% (ISO 6848-WT 40 electrode). Thorium is radioactive and may present hazards by external and internal exposure. If alternatives are technically feasible, they should be used.

“Several studies carried out on thoriated electrodes have shown that due to the type of radiation generated, external radiation risks—during storage, welding, or disposal of residues—are negligible under normal conditions of use.

“On the contrary, during the grinding of electrode tips there is generation of radioactive dust, with the risk of internal exposure. Consequently, it is necessary to use local exhaust ventilation to control the dust at the source, complemented, if necessary, by respiratory protective equipment. The risk of internal exposure during welding is considered negligible since the electrode is consumed at a very slow rate.

“Precautions must be taken in order to control any risks of exposure during the disposal of dust from grinding devices.

“The above statement is based on a considered view of the available reports. Commission VIII will continue to keep these aspects under review.”

Fig. 17 CAUTION with thoriated electrodes. Statement of appropriate safety precautions when using thoriated electrodes, developed by the International Institute of Welding Commission VIII on Health and Safety. Source: Ref 7

Fig. 18 Electrode end shapes. ac, alternating current; dc, direct current

and support the molten underbead (Fig. 19). Reactive materials and special applications may require more elaborate shielding. This can be in the form of a simple trailing device (Fig. 20) that provides the inert shielding gas or may be as elaborate as a special welding chamber equipped with gas purifiers and analyzers or vacuum chambers. Note the absence of oxidation coloring on the titanium welds shown in Fig. 6(e). For repetitive parts that are automatically welded and where backside protection is not required, a trailing shield can be very effective. A trailing shield with backside protection may be required for some automated applications where currents and travel speeds may be higher.

Gas flow rate in a backup bar or closed tube can be fairly low because the space is small and enclosed; it may be approximately 2.4 L/min (5 ft³/h). Flow rate in a trailer shield may be equal to or greater than the flow rate in the torch, such as 9.4 to 23.6 L/h (20 to 50 ft³/h). Trailer shields may be curved to fit around circular joints.

Filler Metals for GTAW

In general, composition of the filler metal used for a specific GTAW procedure should match that of the material to be welded, especially if the filler material is readily available. The American Welding Society filler-metal specifications in Table 2 provide specific filler-metal requirements (Ref 8).

The thickness of the part to be welded will determine the need for filler-metal additions. Properly designed and prepared, lap welds, butt welds, and edge welds on material thinner than 2 mm (0.08 in.) may be autogenously welded without filler-metal additions. Autogenous welding of aluminum and magnesium is not generally recommended because there is a possibility of cracking, especially crater cracking. Filler metal, when needed, can be added

Fig. 19 Backup bar

Fig. 20 Trailing shield. GTAW, gas tungsten arc welding

manually from straight lengths (Fig. 21) or automatically from a roll or coil. The filler metal is normally added cold. Filler metal may also be added by hot wire addition with automatic applications (Fig. 22).

Welding Inserts

The purpose of an insert is to preplace filler metal that will subsequently become part of the finished weld and therefore must be of a suitable material type. Welding inserts are used to produce a smooth, uniform backbead. The insert is normally a separate piece of material, although integral internal inserts are sometimes used. Smooth backbeads can be produced in a mechanized system or in manual systems when highly skilled welders are available. Inserts can be commercially obtained in several different configurations.

GTAW Welding Procedures

When a formal welding procedure specification record is required for a particular welded part to comply with specific agency requirements, such as the American Welding Society, American Society of Mechanical Engineers, or others, there are a number of selections and variables that must be considered. These include:

- Type and thickness of material
- Service requirement
- Joint design
- Position in which weld will be made
- Cleanliness of material to be welded
- Filler metal required if the weld is not autogenous
- Filler-metal diameter
- Tungsten type and diameter
- End shape of tungsten and end diameter
- Current type and amperes
- Arc voltage
- Composition of shielding gas
- Gas cup diameter
- Shielding gas flow rate

Current Range and Type

The useable current range for a given-sized electrode varies somewhat with the type of shielding gas, the type of equipment, and the type of current being used (Table 3) (Ref 6). The type of current used for specific GTAW applications is perhaps more important, with more choices than for other open-arc welding processes. Table 4 provides a helpful guide for current type selection.

GTAW Manipulation

As with any open-arc welding process, a skilled welder can easily make adjustments for some joint or part alignment issues that may occur, sometimes “on-the-fly” without having to stop and make setting changes. For critical, manual GTAW, some power sources permit remote current adjustment via a foot pedal or

(d) Amperage should be approximately 25% higher than when DCEN is used. (e) Unless work is mechanically or chemically cleaned in the areas to be welded. Source: Ref 1

torch-mounted thumb-operated device. The welder's skills can also make some variations by controlling travel speed and/or manipulating the torch. Arc oscillation can be used in both manual and mechanized welding. The benefits in manual welding are basic to the control of the weld when adapting to changes in the weld joint and gap. In automated welding, the oscillation is typically produced by moving the entire welding torch mechanically and is preset to provide width of oscillation, rate, and dwell time at the end of each oscillation.

Filler-Metal Feeding

Most GTAW is accomplished by the welder manually feeding a straight length of filler electrode, as shown in Fig. 21. Even with manual GTAW, the filler electrode can be automatically power fed into the arc using special devices that can be incorporated and synchronized with the welding torch motion.

Mechanized or torch-mounted GTAW can incorporate either cold or hot wire feeding:

- *Cold wire*: Employs coiled wire fed from an independent wire feeder into the leading edge of the weld pool at a preset but adjustable rate. Figure 5 shows a setup using cold wire feeding. Note the wire supply, the feeder, and the feeding tip arrangement.
- *Hot wire*: Employs a heated filler metal to increase the deposition rate of the process. The wire is resistance heated to near the melting temperature and fed into the trailing edge of the weld pool. The higher deposition rates obtained with hot wire improve productivity. The process is suitable for making overlays as well as welds (Fig. 22).

Automatic and Robotic Welding

Generally, the factors that must be considered for manual GTAW also must be considered for automatic and robotic (A/R) GTAW. The main difference between manual and A/R GTAW is that travel speed, current, and wire feed rates can be greater for A/R welding. With higher travel speeds and higher current, the weld deposit would remain hot enough to oxidize after the torch passes, and for this reason, the use of a trailer shield is recommended for all materials. A trailer shield must be used with reactive and refractory metals such as titanium and niobium (columbium) and is strongly recommended with stainless steel and nickel- and cobalt-base alloys.

Successful A/R welding requires that parts be uniformly and consistently fit up from part to part. Only if this condition exists can the welding truly be automatically controlled. Weld programmers' programmable logic controllers and robotic controllers can control all the parametric functions for a GTAW application: arc current, voltage, travel speed, electrode feed

rate, and gas flow. These devices can be used to start and stop arc current, travel, wire feed, and gas flow and to control these items within fixed predetermined limits. These devices can also vary welding parameters along joints where thickness, type of joint, or other factors require a change. Most modern GTAW power supplies are capable of having current controlled by various external devices, thus allowing predetermined, multiple procedural changes.

Safety When Using GTAW

Gas tungsten arc welding is an electric arc welding process, just as are manual electrode, flux cored electrode, and gas metal arc welding, and therefore, as a minimum, the safe practices followed for these processes should be followed. There are three basic safety documents, and all personnel, welders, and supervisors alike should understand and be familiar with the safe practices discussed in these documents. These documents are:

- “Safety in Welding and Cutting,” ANSI Z49.1 (Ref 8)
- “Fire Prevention in the Use of Welding and Cutting Processes,” ANSI Z49.2 (Ref 8)
- “Safe Handling of Compressed Gases in Containers,” 11th ed., Compressed Gas Association (CGA) P-1 (Ref 9)

To protect personnel from injury or death, everyone must be aware of and understand all the possible hazards of arc welding and follow procedures and precautions to avoid these hazards. Just as for other open-arc welding processes, the possible hazards may be grouped into four categories:

- Electrical shock
- Fumes and gases
- Arc radiation
- Fire and explosion

With GTAW, there is a fifth potential hazard. If thoriated (thorium-base) electrodes are to be used, there is a potential for radioactive contamination, and all necessary precautions (Fig.17) should be strictly taken.

Electrical Shock

Electric shock can kill, and all personnel require protection from possible dangerous electrical shock:

- The electrode and work (or ground) circuits may be electrically “hot” when the welder is on. Never permit contact between “hot” parts of the circuits and bare skin or wet clothing. Use dry, hole-free gloves to insulate hands.
- Always insulate personnel from the work and ground by using dry insulation. When welding in damp locations, on metal floors,

gratings, or scaffolds, and when welding requires positions such as sitting or lying, make certain the insulation is dry and large enough to cover the full area of possible physical contact with work and ground.

- Always be sure the work cable makes a good electrical connection with the metal being welded. The connection should be as close as possible to the area being welded.
- Ground the work or metal to be welded using a good electrical connection.
- Maintain the welding torch, work clamp, welding cable, and welding machine in good electrical operating condition.
- Never dip the end of the torch in water to cool it. This can also crack the gas cup and contaminate the torch.
- Never simultaneously touch electrically “hot” parts of torches connected to two welders, because voltage between the two can be the total of the open-circuit voltage of both welders.
- When changing or installing electrodes in the GTAW torch, make sure the power is turned off at the welder.
- When working above floor level, provide protection against falling in the event of electric shock.
- Never allow GTAW with wet or damp gloves. They can allow shocks from the high frequency when it is being used.

Fumes and Gases

Welding may produce fumes and gases hazardous to health, and breathing these fumes and gases should be avoided. Precautions include:

- When welding, the welder should keep his head out of the fumes.
- Provide enough ventilation and/or exhaust at the arc to keep fumes and gases away from the breathing zone of the welder.
- When welding with consumables that require special or additional ventilation (such as those having significant amounts of manganese, chrome, etc.) or for welding on galvanized, lead-, or cadmium-plated steel and other metals that produce toxic fumes, local exhaust is recommended, and even greater care may be required, such as a fresh air supply to the welder by an air-supplied respirator.
- Do not allow welding in locations near chlorinated hydrocarbon vapors coming from degreasing, cleaning, or spraying operations. The heat and radiation of the arc can react with solvent vapors to form phosgene, a highly toxic gas, or other irritating products.
- Shielding gases used for arc welding can displace air and cause injury or death by suffocation. Always provide enough ventilation, *especially in confined areas*, to ensure that breathing air is safe.

- Everyone should read and understand the manufacturer’s instructions for the equipment and the consumables to be used, including material safety data sheets.

Arc Radiation

The total radiant energy produced by the GTAW process can be higher than that produced by the shielded metal arc welding process, because the quantity of welding fumes (smoke) produced is significantly lower and the arc is more exposed. Generally, the highest ultraviolet radiant energy intensities are produced when using an argon shielding gas and when welding on highly reflective materials such as aluminum. The range of suggested filter glass shades for GTAW, as presented in AWS/ANSI Z49.1, may be used as a guide (Ref 8):

Current range, A	Filter plate shade range number
0–50	8–10
50–150	8–12
150–500	10–14

The actual filter plate used will depend on the person and the location of the arc. It is recommended that the operator start with the darker shade and then go to lighter shades until the operation is sufficiently visible. However, do not go to a shade lighter than the lowest number for a given current range.

Dark leather or wool clothing (to reduce reflection that can cause ultraviolet burns to the face and neck underneath the helmet) is recommended for GTAW. The greater intensity of the ultraviolet radiation may cause rapid disintegration of cotton clothing (Fig. 21).

Provide adequate screening to protect other personnel, who may at times be close to the welding, from radiation exposure by using suitable screening.

Fire and Explosion

Remove fire hazards from the immediate area. If this is not possible, cover them to prevent any possible welding sparks from starting a fire. Remember that welding sparks and hot materials from welding can easily go through small cracks and openings to adjacent areas. Have a fire extinguisher readily available.

All personnel should read and follow the instructions on compressed gas cylinders, on associated equipment, and in the CGA publication P-1, “Precautions for Safe Handling of Compressed Gases in Cylinder” (Ref 9). Use only compressed gas cylinders containing the correct shielding gas for the process used and with properly operating regulators designed for the gas and pressure used. All hoses, fittings, and so on should be suitable for the application and maintained in good condition.

Always keep cylinders in an upright position and securely chained to a power source undercarriage or fixed support. Cylinders should be located:

- Away from areas where they may be struck or subjected to physical damage
- A safe distance from arc welding or cutting operations and any other source of heat, sparks, or flame

Never allow the electrode, electrode holder, or any other electrically “hot” parts to touch a cylinder.

The welder should keep his head and face away from the cylinder valve outlet when opening the cylinder valve. Valve protection caps should always be in place and hand tight, except when the cylinder is in use or connected for use.

Acknowledgments

Special thanks are given for the contributions from Lynn Welding of Newington, Conn.

(www.lynnwelding.com), and Innofab Source of Tempe, Ariz. (www.innofabsource.com). As with all welding processes, technology has advanced significantly from the 1993 edition of this Handbook. This article expands the excellent presentation made by Grant Ken-Hicken of the Sandia National Laboratory that appeared in the 1993 edition (Ref 1). Thanks are also given to The James F. Lincoln Arc Welding Foundation (Ref 2) for contributing much information to this article on GTAW.

Gas Tungsten Arc Welding with Penetration-Enhancing Compounds

Ian D. Harris, Edison Welding Institute

GAS TUNGSTEN ARC WELDING (GTAW)—also referred to as the tungsten inert gas (TIG) process—is used in aerospace, power generation, oil and gas, and other industries for single-pass welds and the root passes of multiple-pass welds in sheet, plate, pipe, tube, fittings, and castings. The advantages of using the GTAW process include high-quality welds, precise control of welding parameters and heat input, and low equipment costs.

The productivity of GTAW is limited for many applications because of low deposition rates, shallow penetration (typically 3 mm, or $\frac{1}{8}$ in.), or inconsistent penetration caused by small variations of trace elements such as sulfur in the base material, especially in austenitic stainless steels (lower part of Fig. 1). To overcome these problems and reduce the cost of

fabrication and construction of a variety of products, the Edison Welding Institute (EWI) and the National Joint Council (Ref 1–3) developed compounds to enhance the penetration of the GTAW process. The EWI-trademarked process is DeepTIG for GTAW.

Penetration-enhanced GTAW processes have been referred to variously as Flux TIG, A-TIG, and GTAW with a penetration-enhancing compound (PEC). In all cases, the process uses a material that is not a flux but rather an oxide or mixture of oxides. Similar products are available in Canada (such as the Catalyst from Liburdi), Europe (originating from research at the Paton Welding Institute in Kiev, Ukraine, in the mid-1970s), and purportedly in India and China. Most are based on oxides, but little information on specific composition is available in the open literature. The EWI compounds are based on mixtures of oxides of silicon, titanium, and chromium, whereas the Catalyst from Liburdi is based on titanium oxide only. The U.S. patent (Ref 4) is held by EWI.

welding. A simple square-edged, closed-butt joint preparation is often used for the GTAW weld with a penetrating compound. In many applications, full penetration can be achieved with a square-edged, closed-butt joint, reducing joint preparation costs, filler material costs, heat input, distortion, and welding times. Thicker sections can be welded using a penetrating compound on a square-butt land for the root pass and the weld completed in a conventional groove preparation. The GTAW DeepTIG products are recommended for mechanized and orbital welding with and without filler metal. They also have proven useful in manual welding applications where maximum penetration is not required. Standard GTAW equipment, shielding and backing gases, and consumables are used. The DeepTIG compound is not intended to provide shielding for either the face or the root of the weld.

Advantages and Disadvantages

Shipbuilders and industrial users have confirmed the performance and cost benefits of using the penetration-enhanced GTAW process. For example, the GTAW-DeepTIG process increases weld penetration by as much as 300% for mechanized or automatic applications. The process also reduces heat-to-heat variation in penetration and distortion, based on achieving the desired penetration at a lower welding current. The DeepTIG process can also promote grain refinement in some alloys. The mechanical properties, weldability, corrosion resistance, and safe use of these fluxes have been extensively tested and found suitable for a wide range of applications. The penetration-enhanced GTAW process can reduce welding time by 50% in most applications. For example, typical application in stainless steels and nickel alloys that are welded manually in five passes may require only one or two passes using a GTAW with a penetrating compound. Welding times for these applications could be reduced from approximately 23 min for the manual

Fig. 1 Schematic of the mechanism of increased penetration (top) with penetration-enhancing compounds. There is a reversed weld-pool flow and increased penetration based on the higher surface tension.

Principles of Operation

The principles of operation are illustrated (Fig. 1) by the change of surface tension and fluid flow in the cross-sectional view of a weld pool resulting from the effect of active oxides in DeepTIG (or other PEC product). For simplicity, the DeepTIG name is principally used henceforth. The effect of the oxygen overwhelms the changes in penetration caused by sulfur, resulting in an inward fluid flow and increased surface tension, as shown in the upper part of Fig. 1. Penetration-enhancing compounds for GTAW can increase weld penetration by as much as 300% (Fig. 2) and produce consistent penetration regardless of heat-to-heat variations in base-metal composition.

The DeepTIG penetrating compound is a mixture of inorganic powders suspended in a volatile medium such as acetone or isopropyl alcohol. The mixture is applied to the base metal adjacent to the weld joint prior to

procedure to 3 min for a single-pass DeepTIG GTAW procedure.

Typical reasons for using a penetration-enhanced GTAW process include one or more of the following:

- High potential for reduced rejection rates
- Improved productivity
- High level of repeatability
- Reduced number of weld procedure specifications
- Reduced heat input and distortion compared to conventional GTAW
- Reduced joint preparation requirements
- Reduced wire consumption for making the weld

When the penetration-enhanced GTAW process is used for welding of austenitic and superaustenitic materials, there is little to no observable impact on microstructure morphology (Ref 5–8). Conversely, when used on duplex and superduplex stainless steels, the microstructure shifts to a finer prior-ferrite grain size with a larger volume fraction of austenite. One critical item noted following welding was that, for both duplex and superduplex, the weld-metal nitrogen content remained unchanged following welding. Typically, these alloys lose 10 to 30% of their nitrogen content during welding. Superduplex stainless steels welded in conjunction with penetrating compounds have been shown to exhibit improvements in both mechanical and corrosion properties. The use of commercially available oxide-based DeepTIG products for superduplex stainless steel yields a smaller observable (prior-ferrite) grain size when compared to welds produced without the use of penetration-enhanced GTAW.

Previous work (Ref 5–8) showed that the use of penetration-enhanced GTAW for various grades of duplex stainless steel grades offers a competitive advantage over that of conventional GTAW welding. In austenitic stainless steels (>95% austenite), for example, the use of DeepTIG increased penetration without affecting the primary solidification microstructure. In other stainless steels (~50% austenite), penetration was increased and weld quality was improved with a smaller prior- δ -ferrite grain size and a more consistent austenite/ferrite balance in the solidified weld metal. Some of the research suggests that this small grain size and austenite/ferrite balance occurs over a wide range of heat inputs, thus increasing the weldability window for duplex and superduplex alloys.

Preliminary welding procedures have been developed for full-penetration welds in 6 mm (0.25 in.) thick 300-series stainless steel square-butt joints. Faster travel speeds are possible by maintaining constant arc energy and maintaining a short arc length. To date, travel speeds have been tested up to 300 mm/min (12 in./min.) and used in the field up to 150 mm/min (6 in./min.). A residual slag that

typically remains on the top surface of the weld pool can be removed by grinding or mechanized wire brushing. The slag need not be removed prior to subsequent passes. This slag will float to the top of each subsequent pass and remain visible on the finished weldment. If the weld face appearance is important, slag removal is recommended prior to deposition of a cosmetic cap pass or deposition of subsequent passes in a multipass weld.

Equipment, Procedures, and Applications

Equipment. The welding equipment used for penetration-enhanced GTAW is the same as that used for conventional GTAW (Fig. 3). Maintenance of a short arc length (1.2 mm, or

0.050 in.) is critical to ensure maximum penetration during welding. Arc length is a critical variable in the repeatability of welds made with the penetration-enhanced GTAW products; hence, the use of arc voltage control and mechanized equipment is well recommended.

Penetrating compounds for GTAW are commercially available in kit form or in larger quantities. Kits include materials safety data-sheets and instructions on how to apply the penetrating compound to a joint. Also, the DeepTIG PEC is available from EWI in a wire that allows increased penetration by using a compound addition to the wire in a single product. This is currently available for stainless steels with an SS-7 core, yielding results similar to that shown in Fig. 4.

Procedure. Process operating procedure is very similar to that for conventional GTAW,

Fig. 2 Effect of welding current on penetration with and without the penetration-enhancing compound (DeepTIG, Edison Welding Institute)

Fig. 3 Penetration-enhancing compounds pasted onto the surface of a butt joint in a pipe for gas tungsten arc welding. Courtesy of the Edison Welding Institute

Fig. 4 A 6 mm (0.25 in.) thick type 304 stainless steel welded with penetration-enhanced gas tungsten arc welding (DeepTIG wire at 195 A). Courtesy of the Edison Welding Institute

and similar procedures are recommended. If a powder-based product is used, it should be applied using a carrier and mixed to a consistency that allows it to be easily applied to the joint when it is fit up. The product will not give the penetration increase desired if removed before welding, so care must be taken to avoid accidental contact before welding. With the product deployed in a wire, this is not a concern.

Inspection and weld quality control is very similar to conventional GTAW, and similar procedures are recommended. Troubleshooting is very similar to conventional GTAW, and similar procedures are recommended for the equipment used.

Applications. Penetrating compounds from EWI are available for the following joint materials:

- DeepTIG SS-7 for stainless steels (e.g., types 304, 316, 347, 409, 410, duplex, and superduplex)
- DeepTIG NI-139 for nickel-base alloys (e.g., alloys 600, 625, 690, 718, 800) (Fig. 5)
- DeepTIG CS-325 for carbon and low-alloy steels (e.g., A36, SA-178C, 2¼Cr-1Mo, X80)

Typical components and joints using the SS-7 penetrating compound in the GTAW of stainless steel include:

- Sterilization chambers and pressure vessels

- Coil ends joined together in steel production
- Nuclear fabrication
- Oil and gas (316L and duplex alloys 2205 and 2507) components such as umbilical center-tubes, plumbing on skids (injection pumps), hydraulic control panels, Christmas trees (plumbing)

The United States Navy has approved the use of the SS-7 product for GTAW of stainless steels. One shipbuilder is using penetration-enhanced GTAW to fabricate piping for Navy aircraft carriers and for commercial tankers. Another shipbuilder has used the SS-7 compound to improve the quality and reduce the costs of pipe welds on Navy destroyers.

A boiler manufacturer has used DeepTIG compounds for boiler tube production applications. An orbital GTAW equipment manufacturer uses the SS-7 compound for orbital GTAW of stainless steel tubing. Another manufacturer uses it for fabricating large medical instrument sterilizers. Another application is for fabrication of duplex and superduplex tubing (Fig. 6) for down-hole umbilicals associated with oil and gas equipment. Aerospace manufacturers and suppliers have used penetrating compounds for fabrication of various components.

Welds produced by GTAW with penetrating compounds perform commensurate to or better than conventional GTAW welds. Property improvements include:

- Increased strength
- Decreased volume of weld metal and heat-affected zone
- Increased corrosion resistance
- Improved bead shape and nugget size
- Improved austenite content in SAF 2507

- Smaller grain size in SAF 2507

In duplex and superduplex alloys, property improvements include:

- Improved microstructure, corrosion, and mechanical properties
- Weld metal retained a majority of the base-metal nitrogen
- Weld-metal properties exceeded industry requirements
- Refined primary delta grain size
- Small grains expand welding process window

The NI-139 compound is used in the aerospace industries for welding nickel-base alloys. One example is in turbine engine manufacture for nonrotating components (Fig. 7).

Boiler tube and pipe applications include welding carbon and alloy steels with the CS-325 compound. One example is a turbine barrel (Fig. 8).

Personnel

Skill level and training are the same as those for conventional GTAW, especially when mechanized or robotic welding is employed. The only significant difference is a short arc length, preferably with arc voltage control (AVC). The use of AVC makes the technique a little more difficult to achieve when welding manually, and the deeper weld pool requires more vigilance for the welder to control.

Health and safety issues are the same as those for GTAW. Electric shock, eye protection, burns, ultraviolet radiation, and fume exposure are typical concerns. A minor amount

of fume generation will occur with the use of the compounds. Appropriate measures should be considered to reduce welder exposure to welding fumes. ANSI Z49.1-99, *Safety in Welding, Cutting, and Allied Processes*, should be reviewed before welding.

Plasma Arc Welding

Ian D. Harris, Edison Welding Institute

PLASMA ARC WELDING (PAW) can be defined as a gas-shielded arc welding process where the coalescence of metals is achieved via the heat transferred by an arc that is created between a tungsten electrode and a workpiece. The arc is constricted by a copper alloy nozzle orifice to form a highly collimated arc column (Fig. 1). The plasma is formed through the ionization of a portion of the plasma (orifice) gas. The process can be operated with or without a filler-wire addition.

Principles of Operation

Once the equipment is set up and the welding sequence is initiated, the plasma and shielding gases are switched on. A pilot arc is then struck between a tungsten alloy electrode and the copper alloy nozzle within the torch (non-transferred arc mode), usually by applying a high-frequency open-circuit voltage. When the torch is brought in close proximity to the workpiece or when the selected welding current is initiated, the arc is transferred from the electrode to the workpiece through the orifice in the copper alloy nozzle (transferred arc mode), at which point a weld pool is formed (Fig. 1).

The PAW process can be used in two distinct operating modes, often described as the melt-in mode and the keyhole mode:

- *The melt-in-mode* refers to a weld pool similar to that which typically forms in the gas tungsten arc welding (GTAW) process, where a bowl-shaped portion of the workpiece material that is under the arc is melted.
- *In the keyhole mode*, the arc fully penetrates the workpiece material, forming a nominally concentric hole, or keyhole, through the thickness. The molten weld metal flows around the arc and resolidifies behind the keyhole as the torch traverses the workpiece.

Current and Operating Modes

The PAW process uses three current modes: microplasma (melt-in mode), medium-current

plasma (melt-in mode), and keyhole plasma (keyhole mode). This categorization is primarily based on the level of welding current. The microplasma mode is usually defined in the current range from 0.1 to 15 A. The medium-current plasma mode ranges from 15 to 100 A. The keyhole plasma mode is above 100 A. There is a certain degree of overlap between these current ranges. For example, keyholing can be achieved at 70 A on a 2 mm (0.08 in.) sheet. Equipment is available for welding currents up to 500 A, although a 300 A maximum is typical. Microplasma and medium-current melt-in modes are used for material up to 3 mm (0.12, or 1/8, in.) thick, whereas the keyhole plasma mode is used for greater thicknesses and higher travel speeds.

In addition to operating in a continuous and steady direct current electrode negative (DCEN) mode, the PAW process can be carried out using DCEN pulsed current, as well as in the variable polarity mode, which uses both direct current electrode positive (DCEP) and electrode negative polarity switching. The pulsed-current mode (both DCEN and DCEP/DCEP) is most often used when current levels (typically, above 100 A) are employed for keyhole plasma welding. Pulsing the current widens the tolerance region of acceptance welding parameters, primarily by further

Fig. 1 Plasma arc welding process, showing constriction of the arc by a copper nozzle and a keyhole through the plate

stabilizing the formation of the keyhole itself (Fig. 2).

The electrode positive component of the variable polarity plasma arc (VPPA) welding process promotes cathode etching of the tenacious surface oxide film when welding aluminum alloys, allowing good flow characteristics and consistent bead shape. Pulsing times are typically 20 ms for the electrode negative component and 3 ms for the electrode positive polarity. The VPPA welding process is used very effectively in specialized aerospace applications.

The PAW process is generally applied when the high penetration of the keyhole welding mode can be exploited to minimize the number of welding passes and hence welding time. The time saved can reduce the direct labor element of the welding operation. At the other end of the scale, the microplasma operating mode is used to weld small, thin-section components (as low as 0.025 mm, or 1 mil, thick), where the high arc constriction and low welding

Fig. 2 Tolerance to variation in welding current and plasma gas flow rate in pulsed- and continuous-current keyhole welding; boundaries show the welding parameter combinations at which specific defects are likely to occur. Welding parameters: nozzle bore, 2.36 mm (0.0929 in.); electrode diameter, 4.8 mm (0.19 in.)

current can be beneficial in controlling heat input and distortion.

Advantages and Disadvantages

The advantages of the PAW process are primarily intrinsic to the keyhole mode of operation, because greater thicknesses of metal can be penetrated in a single pass, compared with other processes, such as GTAW. This greater amount of penetration allows a reduced amount of joint preparation. In some materials, for example, a square-grooved butt joint preparation can be used for thicknesses up to 12 mm (0.5 in.). The process can produce high weld integrity (similar to GTAW) while minimizing weld passes and hence welding times and labor costs. The columnar shape of the arc results in a greater tolerance to variations in torch standoff distance, when compared with the conical arc shape of a GTAW arc. The tungsten electrode used in the PAW process is protected from contamination by the constricting nozzle (Fig. 1). The longer arc length allows better viewing of the weld pool, which is important in manual welding.

Disadvantages include the greater capital equipment cost, when compared with its main rival, the GTAW process. Although high arc constriction achieves higher penetration, it also reduces the tolerance of the process to joint gaps and misalignment, when compared with the broader, conical arc of the GTAW process. The greater complexity of the PAW torch design and the greater number of parts requires more scheduled maintenance. The accurate set-back of the electrode tip, with respect to the nozzle orifice, is required to maintain consistent results. However, this task is facilitated by a general-purpose tool designed for nozzle removal and replacement and for electrode set-back adjustment.

Equipment

A basic PAW system consists of a power source, a plasma control console, a water cooler, a welding torch, and a gas supply system for the plasma and shielding gases (Fig. 3).

The power source, which supplies the main power for the welding system, is usually supplemented with a sequence controller and control console. The sequence controller sequences the timing of gas flow, arc initiation, main welding current control, and any up-slope and down-slope parameters. In its simplest form, the plasma control console controls the gas flow for plasma and shielding gases from separate flowmeters and incorporates the high-frequency pilot arc initiation circuit. The welding torch can be manual or mechanized and is water cooled to avoid torch overheating and to maximize component life.

In most PAW installations, plasma and shielding gases are supplied from separate gas cylinders, although bulk gas can readily be

used. The gas supply is usually routed through the plasma control console, where the individual flow rates are set by the operator.

The power source should be of a constant-current design. Transistorized power sources are most common, although inverter power supplies are also available. It should have a minimum open-circuit voltage of 80 V to ensure the reliable initiation and transfer of the main arc current. The power source can be adjusted for welding current, and it should have the capability to adjust the up slope and down slope of the current. It may be equipped with thumbwheels or potentiometers to select the parameters for pulse current operation, that is, peak and background current levels, as well as peak and background times.

Welding Torches

Like those of the other arc welding processes, PAW torches are available in a range of sizes for different power ratings and in manual and mechanized versions. The design principles are the same in each case. A tungsten alloy electrode is held in a collet within the torch body. To avoid one of the most common defects in plasma torches, it is critical to hold concentricity between the tungsten electrode and the orifice in the design and manufacture of the torch. The electrode assembly is set inside a plenum chamber and the plasma gas is supplied to this chamber. A threaded copper alloy nozzle forms the front of this chamber

and contains the nozzle orifice that is used to constrict the plasma arc. A shielding gas nozzle, usually of an insulating ceramic material, is threaded onto the front end of the torch and surrounds the constricting nozzle, creating an annulus through which the shielding gas is supplied. The torch is connected electrically to the power source, and the electrode forms the negative pole of the circuit for direct current welding. The gas hoses that supply the plasma and shielding gases and the water hoses that supply and remove water from the torch are all connected to the torch body or handle. These hoses are enclosed in a flexible sheath that extends from the torch to the components of the welding system.

Most constricting nozzles have a single orifice in the center. However, multiple-nozzle orifices can be used with higher-power torches to achieve further arc constriction. The most common version of this type of nozzle has a central orifice flanked by a smaller orifice on each side. The common centerline of the three orifices is arranged at 90° to the weld line during operation.

Electrodes

The nonconsumable electrode employed is usually a 2% thoriated tungsten electrode, that is, tungsten with 2% thorium oxide. The electrode specification is covered in AWS A5.12-92. The electrode size is selected according to the welding current level that will be used.

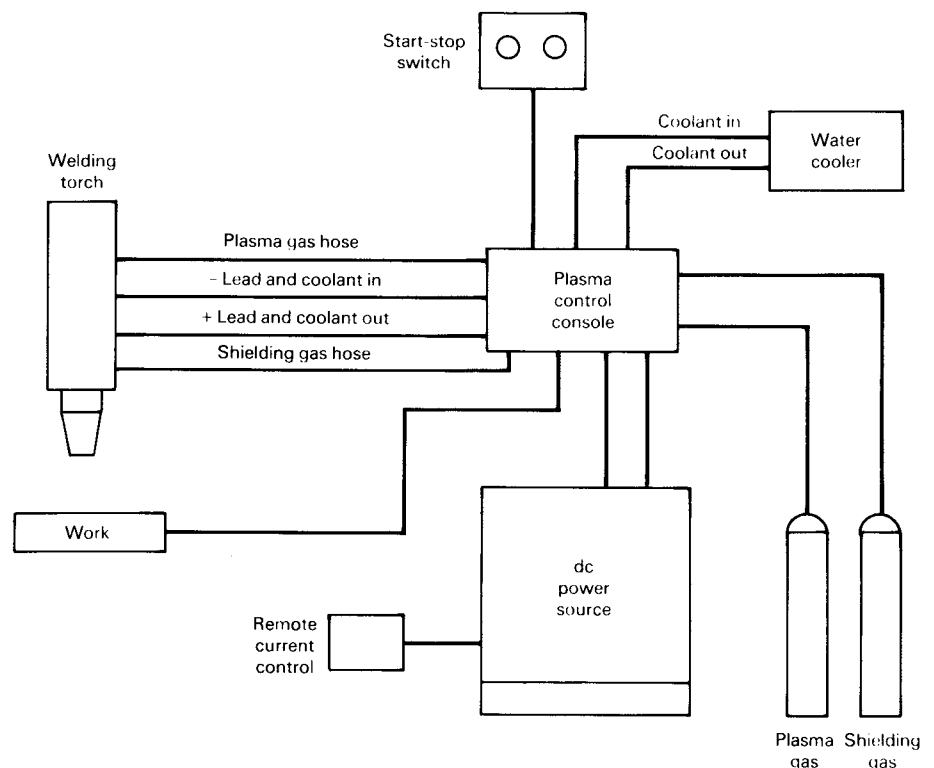

Fig. 3 Typical equipment for plasma arc welding. dc, direct current

The electrode is ground with a tapered point on the end, the angle of which depends on the selected welding current level. Electrode sizes and tip angles for a range of welding current levels are shown in Table 1.

Tungsten electrodes that contain oxides of rare-earth elements in place of the thorium oxide can also be used. These electrodes have been shown to have greater tip life. However, they are more expensive and their usefulness in plasma arc welding may be limited because of the high level of protection provided to the electrode tip preparation by the nozzle. In low-current microplasma welding applications, their better emissivity provides easier arc transfer and better overall performance.

If a finer wire is required, to fit the joint or to avoid undercut at the weld toes, then wires suitable for gas-shielded arc welding (for example, those used for GTAW) should be employed. The appropriate American Welding Society specification series is AWS A5.XX.

Plasma (Orifice) and Shielding Gases

The plasma gas is used to generate the arc, whereas the shielding gas is used to provide the weld pool with supplementary shielding from atmospheric contamination while it solidifies and cools. The plasma gas is almost always argon. Gas properties affect both weld shape and quality. Flow rates, particularly of the plasma gas, are also important, because they control the extent of plasma constriction. The flow rate can vary from 0.1 L/min (0.026 gal/min) for

microplasma welding up to 10 L/min (2.6 gal/min) for keyhole plasma welding. Considerable care is needed to regulate the gas flow rate if keyhole closure is required, because the flow rate must be sloped out to 1 to 2 L/min (0.26 to 0.52 gal/min) within approximately 1 s. Gas flow control is best achieved by electronic means.

The design and current rating of welding torches are based on argon plasma gas. Argon provides effective shielding, being heavier than air, and is cheaper than helium. Shielding gas selection is based on the type of base metal (Table 2).

Helium and argon-helium mixtures can be used as shielding gases to increase the thermal conductivity of the gas and hence the heating effect on the weld pool. Helium results in wider weld pools than argon, because it produces a higher arc voltage. Hydrogen additions to argon shielding gas tend to promote slightly narrower weld pools through arc constriction and achieve a very clean weld pool appearance, because it is a reducing gas. Although helium and hydrogen can be added to argon in the shielding gas to give higher heat input, the use of gases with higher heat contents in the plasma gas can result in torch overheating and potential damage.

Applications

The PAW process is commonly used to weld stainless steels in a wide range of thicknesses. The process can also be used with carbon and alloy steels, aluminum alloys, titanium alloys,

copper and nickel alloys, and more specialized materials, such as zirconium and tantalum. The thicknesses that can be welded in a single pass range from 0.025 mm (1 mil) for microplasma applications to 12.5 mm (0.5 in.) for the VPPA welding of aluminum. Direct current pulsing can be used on most materials.

The PAW process is often carried out in an autogenous mode, that is, without filler wire. When edge beveling is used, a filler wire is required to complete the joint. A filler wire can also be used with the keyhole mode of operation to avoid undercut at high welding speeds. Wire composition depends on that of the parent materials in the joint. The same continuous-wound wire that is used in GTAW operations is suitable.

The industries that use the PAW process can be categorized as those that weld thin-section sheet using microplasma or medium-current plasma welding and those that weld plate using keyhole plasma welding.

A wide range of small devices and assemblies made from thin stainless steel sheet, including bellows assemblies and associated fittings, are welded using the microplasma operating mode. The narrow weld bead that can be produced provides sheet-metal fabrications with a good cosmetic appearance. Furthermore, the high welding speed that can be achieved, coupled with the good tolerance to stand-off variations resulting from the columnar nature of the arc, makes the process attractive for high-volume production work.

Microplasma, as well as medium-current plasma modes, can be used to spot weld guide wires and lamp filaments, as well as in other applications that require highly repetitive autogenous welds. This type of application allows a user to limit the number of high-frequency arc starts that would be required with tungsten inert gas welding.

Keyhole plasma welding is extensively used to weld stainless steel pipe and tankage. The process is applied to individual strokes from plate to make stainless steel vessels in

the food and chemical processing industries. Circumferential welding of strakes also can be used to create these products. Longitudinal seam welds in stainless steel pipe with wall thickness of ≥ 3 mm (≥ 0.12 in.) are ideally suited to keyhole plasma welding, because joint preparation is minimized and single-pass welding can be consistently achieved without the use of weld-backing devices. Pipes with wall thickness greater than 5 to 6 mm (0.20 to 0.24 in.) employ the keyhole mode of operation for the root pass. Depending on the material type and wall thickness, melt-mode PAW, GTAW, gas metal arc welding (GMAW), or submerged arc welding (SAW) are used to complete the joint. High-alloy composition piping is similarly manufactured.

The manufacturing of stainless steel tube from strip was one of the first applications of the PAW process. Because the process can reliably produce full-penetration welds without the use of backing, it is extensively used on tube mills, because a lack of access precludes welding from the inside.

The VPPA welding process has been very effective for welding large space shuttle orbiter sections of aluminum alloys, particularly the external fuel tank. The cathodic cleaning action of the electrode positive portion of the current cycle breaks up tenacious surface oxide film on the aluminum. The process can be used on thicknesses up to 12.5 mm (0.5 in.) with square-grooved butt joints, and it can be used for the root pass on thicker sections with edge beveling. It is anticipated that this technique will be extensively employed in building aluminum alloys structures in a modular space station.

Typical Components and Joints

The most common joint configuration used with the PAW process is a butt joint. The microplasma mode is used with overlapped butt (microlap) joints and with joints that have integral weld metal as a result of flanged, butted edges on very thin metals (Table 3). Corner joints with edge welds are also commonly welded using the microplasma and medium-current modes. An example is shown for thin-walled type 304 stainless steel tubing (Fig. 4) with edge welds between tubes with a wall thickness of less than 0.5 mm (0.020 in.).

Because the keyhole operating mode fully penetrates the workpiece, it is used exclusively on square-grooved butt joints and single-V joints with a root face (Table 3). For square-grooved butt joint preparation, the thickness that can be welded in a single pass depends on the fluid flow characteristics of the workpiece material for a given heat input from the plasma torch. Thus, alloys of titanium and zirconium can be butt welded with square-grooved preparation at greater thicknesses than steels and stainless steels. Generally, it is an industry-accepted practice to use square-grooved preparation without edge beveling for stainless steels up to 6 mm (0.24 in.) in thickness.

A 4 or 5 mm (0.16 or 0.20 in.) root face and a single-V preparation, usually with a 60° included angle, are used on steels thicker than 6 mm (0.24 in.) (Table 4). The root is welded in the keyhole mode, and the rest of the joint is completed with a filler wire addition by melt-mode PAW, GTAW, GMAW, or SAW, depending on the material type, joint volume to be filled, and the mechanical property requirements

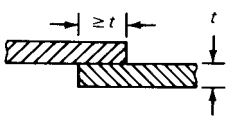

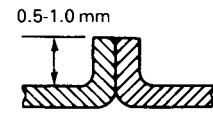

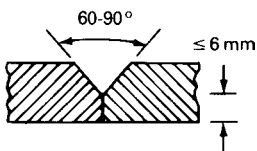

of the joint. An example is shown for 8 mm (0.3 in.) thick type 304L stainless steel (Fig. 5).

In the PAW process, fixturing for part fit-up is more critical than it is for the GTAW process, primarily because of the narrower, more-constricted arc in PAW. The backing bar design and shielding gas techniques employed for GTAW are appropriate for microplasma and medium-current modes. During keyhole welding, however, the arc passes right through the workpiece, forming an efflux plasma (Fig. 1) that normally extends 10 mm (0.4 in.) below the back face of the joint. This characteristic must be accommodated when designing backing systems. Failure to allow sufficient gap can result in turbulence in the efflux plasma, causing weld pool disturbance and porosity.

When welding longitudinal seams in tube or pipe, the weld can be started and stopped on run-on and run-off tabs, precluding the need for keyhole closure. However, when using the keyhole mode on circumferential seams of vessels or on butt joints in tubes or pipes, the keyhole will overlap the start of the weld to produce a complete joint. Keyhole closure without porosity has been an area of difficulty, particularly when butt welding tubes, and it represented an important concern for more-widespread use of the process. Modern electronic controls for simultaneous reduction in gas flow and current slope-out provide a more reliable method for keyhole closure.

Plasma arc welding with wire feed is also a suitable process to rebuild parts or produce parts in a layer-by-layer method known as additive manufacturing. The process can be used to add features to existing parts or to produce a whole new part, a generic example of which is shown in Fig. 6.

Table 3 Joint configurations for plasma welding sheet and tubular components

Thickness range		Joint type	Joint configuration	Process variant	No. of runs	Comments
mm	in.					
0.5–1.0	0.02–0.04	Micro-lap		Microplasma	1	Edges fully fused to produce additional weld metal; good clamping essential
0.5–1.5	0.02–0.06	Flanged edge		Microplasma	1	Edges fully fused to produce additional weld metal
3.0–6.0	0.12–0.24	Square but		Keyhole plasma	1	Grooved backing bar required to prevent disturbance of the efflux plasma. Additional (cosmetic) run using melt mode may be employed
6.0–15	0.24–0.60	Single-V butt		Keyhole plasma	2 or more	Keyhole technique used for root run only. Joint completed with the melt mode plus filler wire

Operations

Procedures

Process Operating Procedure. Welding parameters, such as welding current, arc voltage, travel speed (for mechanized/automatic operation), and plasma and shielding gas flow

Fig. 4 Edge joints in thin type 304 stainless steel tubes. Courtesy of Edison Welding Institute

rates, are set by the procedure and implemented by the welder. Torch parameters include the correct electrode vertex angle and set-back distance, as well as the correct orifice diameter for the welding current level.

The operating sequence for the PAW process was described in the section “Principles of Operation” at the beginning of this article. After the weld pool or keyhole is formed, the torch is traversed across the workpiece at the preset welding speed. Welding is terminated by the down slope of the welding current, with simultaneous sloping of the plasma gas flow rate if keyhole welding and keyhole closure are desired. Slope control for the keyhole mode is shown in Fig. 7.

Most PAW is done in a mechanized or automated operation that does not require much operator intervention, except initially to set the parameters and to position the workpiece and torch. When current pulsing and keyhole closure operations are involved, numerous parameters must be set, which requires strict attention to detail, accurate part fit-up, and careful alignment of the torch relative to the joint.

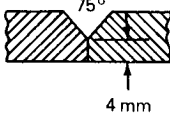

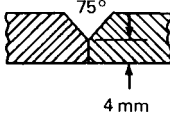

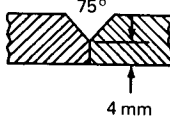

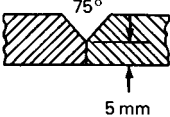

Inspection and Weld Quality Control. All of the common nondestructive evaluation techniques are applicable to plasma arc welds. Radiography and ultrasonic inspection are the most common techniques used. The fact that most plasma arc welding is carried out in the

keyhole mode means that there is a penetration bead on the root side of the joint. Visual inspection for full penetration, as well as for correct width and profile of both the penetration bead and the weld surface profile, can readily be accomplished. Smooth, even underbeads can be achieved through good procedure development with tolerances improved through current pulsing.

Troubleshooting. When troubleshooting a PAW operation, all of the previously defined basic parameters of the welding schedule should be checked. Welding discontinuities can result from incorrect electrode set-back or from a worn or damaged nozzle orifice. The concentricity of the diameter of the nozzle orifice and the alignment of the electrode and nozzle orifice are very important. Worn nozzles should be replaced. The condition of the tungsten electrode tip should also be checked.

An undercut is one of the most common defects in the PAW process. Depending on material type, thickness, and preset welding parameters, a two-sided undercut can occur above certain threshold welding speeds. This can only be eliminated by increasing welding current. A one-sided undercut can result from misalignment of the torch, the electrode/orifice and multiport nozzles, or from the mismatched fit-up of the workpieces. Correct alignment is essential.

Personnel Requirements

The skill level and training requirements for the PAW process are generally similar to those for the GTAW process. When manual welding, the columnar nature of the plasma arc allows

greater variation of the torch-to-workpiece distance without altering the size and shape of the weld pool. The fact that the electrode is protected from contamination by the nozzle means that tungsten contamination and tungsten inclusions in the weld metal are more readily

avoided than they are in the GTAW process. From the viewpoint of an operator, disadvantages include the greater complexity of the torch, in terms of nozzle orifice and electrode set-back considerations, and the correct setting of two gases (plasma and shielding gas).

When mechanized welding is carried out, which is usually the case for the keyhole mode, the operator is required to set a greater number of parameters (compared to GTAW), particularly if current pulsing and keyhole closure operations are required. Specific operator training is required for pulsed keyhole operation, and particularly for VPPA operations, which are usually carried out in the vertical position, welding upward, and thus require a high level of operator competence. Computerization of welding parameter selection is the trend for VPPA welding and other mechanized or automated PAW operations.

The health and safety issues related to the PAW process are very similar to those of other gas-shielded arc welding processes, especially GTAW. These include electrical shock; electromagnetic radiation hazards, particularly ultraviolet radiation; burns from hot metal parts; and welding fumes and gases, including ozone. Precautions must be taken to capture grinding dust when preparing tungsten electrodes. The volume of welding fumes produced is low and is similar to that produced by the GTAW process. Hexavalent chromium and ozone are concerns when welding stainless steels and aluminum alloys, respectively. Like the GTAW process, the low level of general welding fumes associated with PAW results in a comparatively higher level of ozone. However, the rapid decay of ozone within a short distance of the arc, coupled with the high degree of mechanization and automation typical of the keyhole plasma welding operation, means that operator exposure is generally very low. The microplasma mode, which is more commonly used manually, employs such low current levels that fume and ozone levels are very low.

Electroslag and Electrogas Welding*

Revised by S.D. Brandi, Escola de Politecnica da USP; S. Liu, Colorado School of Mines; and R.D. Thomas, Jr., R.D. Thomas and Company

ELECTROSLAG WELDING AND ELECTROGAS WELDING are two related procedures that are presently used to weld thick-section materials in the vertical or near-vertical position between retaining shoes. Primarily applied for joining steels of thicknesses over 50 mm (2 in.), electroslag welding (ESW) involves high energy input relative to other welding processes, resulting in generally inferior mechanical properties, specifically lower toughness of the heat-affected zone (HAZ). However, the high deposition rate and relatively low cost of the process make it attractive for heavy structural fabrication. The as-welded properties of electrogas welding (EGW), usually applied to steels under 50 mm (2 in.), are generally superior to those of electroslag welds, and the process is commonly applied to the field erection of storage vessels and other less critical structures.

Electroslag welding is a vertical welding process producing coalescence with molten slag that melts the filler metal and the surface of the work to be welded. Confined by cooling shoes, the molten weld pool is shielded by the molten slag, which moves along the full cross section of the joint as welding progresses. The conductive slag is maintained in a molten condition by its resistance to electric current passing between the electrode and the work (Ref 1). Electroslag welding can be considered a progressive melting and casting process in which the heat of a bath of molten flux is used to melt the filler metal and the edges of the plates to be welded. Electric arc occurs only at the beginning of the process, and once a molten bath is achieved, the arc is extinguished. During the process, flux is added periodically or continuously to maintain an adequate slag covering over the pool of molten metal. Two or more retaining shoes hold the molten metal in place until it has solidified. In normal operation with a constant potential power source, the electrode melts off while dipping only partly through the flux bath and gathers in the molten metal puddle. In the case of low-carbon steel,

the temperature of the bath is reported to be in the vicinity of 1925 °C (3500 °F), while the surface temperature is approximately 1650 °C (3000 °F) (Ref 2). The major process variables are welding current and voltage. Welding current is directly responsible for the electrode melt rate, while voltage influences the base-metal penetration and weld bead width. Both variables are sensitive to the physical properties of the welding flux, such as electrical resistivity and fluidity.

Electrogas welding is a method of gas metal arc welding (if a solid wire is used) or flux cored arc welding (if a tubular wire is used), wherein an external gas is supplied to shield the arc and molding shoes are used to confine the molten weld metal for vertical-position welding (Ref 2). Electrogas welding may or may not use an added flux. In the solid wire process, CO₂ shielding gas is commonly used and no flux is added. With the flux cored process, the core ingredients provide a small amount of flux to form a thin deposit of slag between the weld and the shoes. Self-shielding electrodes eliminate the need for external shielding gas. A major difference

between ESW and EGW is that the former relies on slag conduction to carry the welding current and the latter uses arc conduction. Despite the differences, similarities between ESW and EGW in terms of equipment, joint preparation, and welding procedures are such that they can be grouped into one category and described as allied processes.

Fundamentals of the Electroslag Process

Heat Flow Conditions

Electroslag welding is quite similar to in situ casting, with large volumes of molten metal and high heat content. When compared with other arc welding processes, electroslag welds have a long thermal cycle with very slow cooling rate. Electroslag welding generally consumes from 100 to 200 kJ/mm (2500 to 5000 kJ/in.), as compared to 10 to 40 kJ/mm (25 to 1000 kJ/in.) found in most arc welding processes. Figure 1 shows a typical thermal cycle

Fig. 1 Typical thermal cycle of an electroslag weld bath relative to that of an arc welding pool

* Adapted from R.D. Thomas, Jr., and S. Liu, Interpretive Report on Electroslag, Electrogas, and Related Processes, *Welding Research Council Bulletin*, No. 338, Nov 1988. Used with permission of the Welding Research Council

of an electroslag weld bath compared with that of an arc welding pool. As a consequence of the thermal experience, weld-metal solidification in ESW is extremely slow, resulting in a coarse primary solidification structure. The heat absorbed into the base metal also creates an extremely large HAZ (Fig. 2).

A heat balance diagram of a typical electroslag weld (Fig. 3) illustrates that approximately 60% of the heat is absorbed by the workpart,

close to 25% of the total heat is expended in the melting of the electrode, and approximately 10% of the heat is used to superheat the molten metal (Ref 3). The amount of heat extracted by the cooling shoes varies, depending on the thickness of the plate and on the welding conditions. In the welding of steel plates 90 mm (3.5 in.) thick, less than 10% of the heat of the molten slag and metal pool is transferred to the cooling shoes. In thinner plates, however, the

cooling shoes play a more significant role in the heat balance.

Mathematical models are used to estimate the three-dimensional temperature field in the slag, metal pool, and base-metal regions in an electroslag weldment, and to predict HAZ size and grain growth in the HAZ. Figure 4 shows an example of the calculated temperature distribution for a base plate 25.4 mm (1 in.) thick, 470 mm (18.5 in.) long, and 610 mm (24 in.) wide, at the time that corresponds to half the total time required for completion of the weld (Ref 4). The maximum temperatures reached in the slag and weld pool were 1960 and 1630 °C (3550 and 2960 °F), respectively. The temperature distribution in a weldment along planes parallel and normal to the parent plate surface can also be represented in the form of isometric temperature plots (Fig. 5).

The energy balance in the slag phase is summarized in Table 1. A major portion of the heat generated in the slag layer was transferred to the cooling shoes (36.1%). Approximately 22 and 15% of the heat was used in base-metal heating and electrode melting, respectively. The heat-generating patterns are highly sensitive to the geometric location of the electrode in the slag. With careful control of the process variables (such as gap distance and convective flow suppression) by external application of the electromagnetic field, reductions of two or three times the usual heat input could be practical.

To distribute the energy uniformly across the thickness of the weldment, empirical rules have been developed (Table 2) to determine the preferred number of electrodes, the wire spacing, and the traverse (oscillation) distance (Fig. 6). Oscillation speeds depend on the plate thickness, usually allowing a traverse time of 3 to 5 s; a dwell time at the end of each traverse ensures adequate penetration at the plate edges.

Metal Transfer and Weld Pool Morphology

The droplet transfer rate and the length of time each droplet is in contact with the slag layer profoundly affect the chemical composition and the metallurgical properties of the weld pool.

Droplet Formation. In steady-state operation, the molten filler metal transfers into the weld pool in a globular mode. Current and voltage oscillograms indicate that despite the droplet size decrease observed with increasing voltage, welding current has no significant effect on the size of the droplets. Rather, the length of time that a droplet is in contact with the slag layer decreases considerably with increasing current. On the other hand, the length of time a droplet is in contact with the layer of slag increases with voltage, because

Table 2 Effect of joint geometry on multiple-wire butt electroslag welding

Steel plate thickness		Number of wires	Oscillation	Square butt gap opening	
mm	in.			mm	in.

the electrode tip is further away from the molten metal pool. The extent of interaction between a metal droplet and the slag layer determines the chemical composition of the weld pool.

Weld Pool Morphology. In an electroslag weldment, solidification begins at the fusion line, surfaces adjacent to the retaining shoes, and progresses toward the center of the weld. Because the process is continuous in a vertical or near-vertical-up position, solidification also progresses from the bottom toward the top part of the joint. The angles at which the columnar grains meet at the center of the weld depend on the shape of the weld pool, which can be described by the weld pool form factor. Form factor is defined as the ratio between the width, *w*, and the maximum depth, *h*, of the pool (Fig. 7). Welds having a high form factor (>2.0) will have grains meeting at an acute angle at the center line, while welds with a

low form factor (<1.0) will solidify with grains meeting at an obtuse angle. Low form factor is highly undesirable because of the potential accumulation of residual elements at the center of the weld joint. High welding current usually results in a low form factor, while low welding current usually results in a high form factor and shallow metal pool. High voltage promotes shallow pools and low voltage. Figure 7 shows two examples of different pool morphologies and form factors as a function of the welding current and voltage.

An additional factor controlling the weld puddle morphology is the welding flux conductivity. Actually, the bulk of the electrical energy is converted into thermal energy in a thin layer of the slag contiguous to the electrode tip, which acts as the heat source in ESW (Ref 3). High-conductivity fluxes generate less heat and result in less base-metal penetration and shallower weld pools.

Out-of-Position (Nonvertical) ESW

Electroslag welding has been successfully done in joints that are inclined from the vertical position. The stability of the process and the quality of the weld joint are both functions of the angle of inclination. Weld morphology, including penetration, HAZ, and weld-metal microstructure, is sensitive to the welding parameters. Preferential thermal radiation heating of the upper weld surface is considered the cause of asymmetric penetration and HAZ geometry (Ref 7).

Weld Pool Penetration and Magnetic Field Coupling

Magnetic field is not generally applied in ESW. For electroslag overlays, however, some use of magnetic field to promote fluid flow and to drive the molten slag layer from the hotter region to the colder region to eliminate undercutting has been reported (Ref 8). However, the effect of magnetic stirring, which induced convective fluid motion in the weld pool and disrupted the solidification and growth of the columnar dendrites, can be seen in Fig. 8 (Ref 9, 10). Mechanical vibration on electroslag

weld pools generally does not cause significant microstructural modification. However, some refinement of the as-deposited grains can result when the slag/molten metal interface is disturbed. The use of a quartz-shielded electrode guide tube as an extended stirrer has been reported to form a deeper weld pool, with the form factor decreasing from 3 to 1.5 (Ref 11, 12). Other techniques for refining weld-metal microstructures include ultrasonic cavitation and the use of chemical inoculators.

Constitutive Equations for Welding Current, Voltage, and Travel Rate

The power input per unit length of a weld is the primary variable that influences the degree of base-metal melting, the amount of filler-metal deposition, and the thermal history of the weldment. In ESW, current and travel speed are not independent variables, as in the other arc welding processes. For a constant voltage power supply, the current and power are both functions of the resistance of the slag pool. Hence, they are functions of the electrode feed rate, the mechanics of electrode melting, and the nature of the electrical and thermal transport at the electrode/slag interface. To control the welding process, a constitutive equation has been proposed (Ref 13):

$$I = BW^{1/2}V^{1/3} \tag{Eq 1}$$

where I is the welding current, W is the electrode feed rate, V is the welding voltage, and B is a proportionality constant. Equation 1 expresses the functional relationship between the various process variables and has the primary objective of selecting a voltage and current range that provides sufficient energy input for base plate penetration without excessive overheating of the HAZ. The relation can be empirically determined from Fig. 9. The total energy input per unit area of weld surface, E , can also be determined:

$$E = B \frac{L_g}{2\pi r^2(L+g)} \cdot \frac{V^{5/3}}{I} \tag{Eq 2}$$

where L is the width of the base plate, g is the root gap opening, and r is the radius of the welding electrode. Note also that this equation takes into consideration the electrode-to-joint geometry, which is related to the electrical and thermal transport in the process.

Unlike arc welding processes, in which an increase in current results in greater energy input and deeper penetration, the reverse occurs in ESW. An increase in current requires an increase in electrode burn-off rate, which increases the welding speed and decreases the energy input per unit area of weld. An excessive increase in the current at constant voltage, however, can shift the process from penetration to no penetration of the base plate. The process control boundaries for ESW can be easily developed (Fig. 10). Boundaries A through D enclose an operating space that exhibits good process stability and base-metal melting. Outside the indicated boundary, the process often appears to operate well but with inadequate base-metal penetration (Ref 13).

A change in electrode geometry and nature (cored) may result in a different constitutive equation (Ref 9, 15):

$$I = B'W^{0.35}V^{1.63} \tag{Eq 3}$$

where B' is the proportionality constant. The total energy input, E , is:

$$E = B' \frac{L_g - 2w_g t_g}{[L + (g - 2t_g)](w_e t_e)} \cdot \frac{V^4}{I^2} \tag{Eq 4}$$

where w_g is the width of the consumable plate guide, t_g is the thickness of the consumable plate guide, w_e is the width of the consumable electrode, and t_e is the thickness of the consumable electrode.

Effect of welding parameters on weld metal pool shape

Parameter	Effect of parameter increase on weld-metal pool dimension(a)		
	Pool width (w)	Pool depth (h)	Form factor (F = w/h)

Temperature Relations between the Slag Bath and Electrode in ESW

Because the electrode is partially immersed in the slag bath, the current density presents a maximum value at the electrode tip and decreases substantially in the direction of the metal pool and the slag bath free surface. Therefore, heat is transferred to the periphery of the slag bath and to the periphery of the metal pool.

Experimental evidence (Ref 3) showed that metal droplets were heated to a temperature higher than the slag. Assuming only the heat transfer from the melted slag to the electrode wire, the temperature at the electrode tip, assuming a non-preheated electrode, can be calculated:

$$T_e = T_s \left[1 - \exp\left(-\frac{2\alpha S_{wet}}{c\gamma rW}\right) \right] \tag{Eq 5}$$

where T_e is the electrode temperature, T_s is the slag temperature, S_{wet} is the wet stickout (electrode depth into the slag bath), α is the heat-transfer coefficient, $c\gamma$ is the volumetric specific heat, r is the distance from the heat source, and W is the wire feed rate.

Figure 11 presents a plot of a carbon steel electrode tip temperature change as a function of the slag bath temperature and wet stickout for an electrode feed rate of 220 m/h (722 ft/h). In Fig. 11, an increase in the wet electrode stickout augments the electrode tip temperature for a constant slag temperature. An ESW usual wet stickout is 2 cm (0.79 in.) for a 2 mm (0.08 in.) electrode diameter. For this electrode stickout, the electrode tip temperature increases when the slag temperature is increased. In this condition, the electrode is heated but below the melting temperature.

Figure 12 depicts the electrode tip temperature as a function of electrode feed rate and slag temperature for a wet stickout of 2 cm (0.79 in.). Melting of the electrode is possible only for a slag temperature higher than 2000 °C (3632 °F) and an electrode feed rate below 80 m/h (260 ft/h) (for a slag temperature of 2200 °C, or 3992 °F), considering a carbon steel melting temperature of 1450 °C (2642 °F).

The results of Fig. 11 and 12 indicate the presence of another electrode heating mechanism, Joule heating. In this case, and neglecting the effect of heat conductivity along the wire and the heat transfer between wire and slag, the equation for the electrode temperature is (Ref 3):

$$T_e = \frac{i^2 \rho_e S}{c\gamma W} \tag{Eq 6}$$

$$S = S_{dry} + S_{wet} \tag{Eq 7}$$

where i is the current density, S is the total stickout, S_{dry} is the dry stickout (distance between electrode contact and the slag bath surface), and ρ_e is the electrode electric resistivity.

Figure 13 presents the effect of Joule heating of a 2 mm (0.08 in.) electrode wire diameter and a 2 cm (0.79 in.) wet stickout for different electrode feed rates.

ESW Thermal Cycles Equations

A quasi-stationary (pseudostationary) temperature field for an ESW can be achieved according to (Ref 3):

$$t_{qs} > \sqrt{\frac{7.5ar}{v_{welding}^3}} \tag{Eq 8}$$

where t_{qs} is the time to achieve a quasi-stationary state in a distance, r , and a is thermal diffusivity.

Fig. 11 Electrode temperature in a slag bath using a constant electrode feed rate (220 m/h, or 722 ft/h) and three different slag temperatures

Fig. 12 Electrode temperature in a slag bath using a constant wet stickout of 2 cm (0.8 in.) and different electrode feed rates for three different slag temperatures. Electrode diameter: 2 mm (0.08 in.)

With this time and the welding speed, is it possible to calculate the distance from the beginning of welding where a quasi-stationary condition is achieved. This information is important to the:

- Shape and size of the weld-metal pool and, consequently, the solidification conditions and fusion zone microstructure
- Repeatability of thermal cycles in the HAZ, which means a constant microstructure for a fixed distance along the weld length and, consequently, constant mechanical properties for each point

- One maximum temperature field, which determines residual stresses and distortion
- Three heat sources, distributed and aligned in a linear geometry and traveling slowly, are used to simulate ESW thermal cycles. These three heat sources are located in:
- q_1 : Located at the surface of the slag bath and the atmosphere and is responsible for approximately 25% of the total heat input
 - q_2 : Located in the middle of the slag bath and is responsible for approximately 50% of the total heat input

- q_3 : Located in the middle of the metal pool and is responsible for approximately 25% of the total heat input

The temperature at a point of interest in the HAZ y -distance from the weld centerline is calculated (Ref 3):

$$T(x, t) = T_0 + \sum_{i=1}^3 \left(\frac{q_i}{2\pi\lambda h} \exp\left(-\frac{v_{\text{welding}}^2 t_i}{2a}\right) K_0\left(r_i \sqrt{\frac{v_{\text{welding}}^2}{4a^2} + \frac{b}{a}}\right) \right) \quad (\text{Eq 9})$$

$$q_i = \frac{\eta V_i I_i}{v_{\text{welding}}} \quad (\text{Eq 10})$$

$$r_i = \sqrt{\left(y - \frac{b}{2}\right)^2 + v_{\text{welding}}^2 t_i^2} \quad (\text{Eq 11})$$

where T_0 is the initial plate temperature (preheat temperature); q_i is the heat input of wire i ; λ is the thermal conductivity; h is the plate thickness; t is the time when a given heat source (number of electrodes) traverses the cross section containing the point of interest; a is the thermal diffusivity; $K_0(u)$ is the second-kind, zero-order Bessel function; v_{welding} is the welding travel speed; η is the thermal-transfer coefficient; r_i is the distance of heat source i to the point of interest in the HAZ; y is the distance from the weld centerline; and b is the root gap.

Figure 14 shows two carbon steel thermal cycles calculated by assuming $q_1 = q_3 = 0$, plate thickness of 50 mm (2 in.), root gap of 24 mm (0.9 in.), $I = 480$ A, $V = 35$ V, and $v_{\text{welding}} = 0.02$ cm/s (0.008 in./s).

ESW Consumables

ESW Fluxes

Similar to the fluxes used in other welding processes, ESW fluxes are formulated to refine the weld metal, to coat the surface of the retaining shoes and the completed weld metal, and to protect the molten metal from oxidation. However, several physical and chemical properties distinguish ESW fluxes from the others used in arc welding. Electroslag welding fluxes are invariably fused, rather than agglomerated. Compared with the arc welding fluxes, fluxes for ESW are higher in resistivity, because the arc is extinguished soon after the process becomes stable. Sometimes, an agglomerated starting flux with high conductivity is used to initiate the process and form the weld pool. After that, a running flux of high resistivity is added to generate heat for melting the filler metal and to maintain steady welding operation. In fact, for high-current welding the use of starting flux is often omitted.

Fig. 13 Electrode temperature due to Joule heating. Wet stickout of 2 cm (0.8 in.) and a 2 mm (0.08 in.) electrode diameter

Fig. 14 Thermal cycles calculated by Eq 9 for two distances. Plate thickness of 50 mm (2 in.); root gap of 24 mm (0.9 in.); $I = 480$ A; $V = 35$ V; $v_{\text{welding}} = 0.02$ cm/s (0.008 in./s)

A typical running flux for low-carbon steels has the following composition (Ref 11):

Constituent	Content, wt%
SiO ₂	25
MnO	10
CaF ₂	15
Al ₂ O ₃	25
CaO	15
MgO	10

Electrical Resistivity. A flux of high resistance (or low conductivity) will draw less current, resulting in a colder weld pool and lower base-metal penetration. It will also allow the wire to drive deeper into the pool. On the other hand, a flux of low resistance may draw excessive current, raising the temperature of the bath until the process stabilizes with a shorter electrode extension. However, if resistance is too

low, then arcing may occur between the electrode and the slag bath surface, especially at higher voltages. This condition is aggravated in fluxes that show steeply increasing conductivity with rising temperature. In terms of process conditions, lower slag resistivity may result in operation at lower voltage.

Fluidity. In addition to its heat-generating ability, the molten slag must also have sufficient fluidity to cause rapid convection and good circulation, needed to distribute heat throughout the weld joint. Fluidity of a slag depends mainly on its chemical composition and operating temperature. The melting point of a flux must be below that of the base metal for weld pool refining, and its boiling temperature must be higher than the operating temperature to avoid loss by vaporization. Any preferential loss (of one or more ingredients) will alter the bath composition, which may greatly change the slag fluidity and electrical conductivity, resulting in improper shielding. If the composition of the fluxes is altered during operation, the change in energy imparted to the slag may cause an increase in temperature and in conductivity during welding of long seams, which may give rise to arcing on the top surface of the slag bath.

Low fluidity will tend to trap slag inclusions in the weld metal; excessive fluidity will cause leakage through the small space between the work and the retaining shoes. For joining thin plates, higher-fluidity fluxes are desirable to obtain good circulation in the relatively small bath.

Metallurgical Compatibility. Finally, the slag should be metallurgically compatible with the alloy being welded. For steel welding, the fluxes are generally mixed oxides of silicon, manganese, titanium, calcium, magnesium, and aluminum (Ref 1). These oxide components play an important role in the shielding and refining of the weld pool. Calcium fluoride (CaF₂) is added to basic oxides or silicate systems to achieve the proper resistivity and fluidity. Increasing CaF₂ decreases viscosity, melting point, and resistivity. Additions of TiO₂ also decrease resistivity, while Al₂O₃ increases it. However, TiO₂ also increases slag viscosity (Ref 2, 3). Special applications, such as inclusion control or sulfur removal, may require the addition of rare-earth compounds (Ref 16).

Slag detachability after weld-metal solidification is not a major problem in ESW. The addition of large quantities of TiO₂, however, will often result in difficult slag removal. Fluoride additions generally improve slag detachability.

ESW Electrodes

Various ESW techniques are available, depending on the type of electrodes and the feeding mechanism. The electrodes can be solid

wires, tubular flux cored wires, large-section solid electrodes, and large-section cored electrodes. The guides or nozzles can be consumable or nonconsumable. The conventional method uses nonconsumable guides (also known as snorkels), which are maintained approximately 50 to 75 mm (2.0 to 3.0 in.) above the molten flux. In this case, a mobile feeding head is used and is raised vertically to match the weld pool travel speed. If the electrode feeding mechanism is stationary, then the nozzle will be "consumed," becoming part of the weld metal when it is reached by the slag pool. Accordingly, the materials used in consumable guides generally match the chemical composition of the electrode or base metal. A consumable guide can either be a thin-walled tube or an assembly of plates or rods with conduits to feed the electrode wire. Fin-shaped guide tubes are prepared by welding webs to circular-section guide tubes to obtain more uniform weld pool heating (Ref 1, 3, 6). Among the different types of electrodes, only the wire type and the large-section cored electrodes require the use of nozzles for delivering the electrode into the root gap. Bare guides sometimes need insulation along their lateral surfaces if they cannot be precisely aligned within the weld joint. One solution is to insert insulating plugs at critical locations in the assembly. Flux-coated consumable nozzles are available to minimize the problem of insulating the electrode assembly. Figure 15 shows several shapes of electrodes and guides used in ESW.

Metallurgical and Chemical Reactions

Fusion Zone Compositional Effects

In ESW of carbon and low-alloy steels, the major reactions involve manganese, silicon, carbon, and impurities such as oxygen, sulfur, and phosphorus. In the welding of high-alloy steels, reactions involving chromium, titanium, aluminum, and other elements are important. The extent and control of reactions are determined mainly by the concentrations of the elements in the liquid metal and by the concentrations of their oxides in the slag. The temperature in the reaction zone, the metal droplet/slag surface area, and the duration of contact between the molten metal and slag are other factors that affect the final weld-metal composition. The concentration of elements in the metal and slag is determined by the electrode wire and flux compositions and by the renewal of the slag pool (that is, the frequency with which the make-up flux is added to the pool).

Thermochemistry. In the case of slags containing high MnO and SiO₂, the reactions between the metal and slag can be described as:

In Eq 12 and 13, $[M]$ and (NO) represent the activities of the metal M in the weld pool and of the oxide of element N in the slag layer. However, for all practical purposes, concentrations of the metallic element and oxide can be used instead of their activities in thermodynamic calculations. When electrodes containing high silicon are used, the reduction of manganese oxide by silicon must also be taken into account:

The lower the temperature, the more intense the reaction between manganese oxide and silicon. Changes in welding conditions, such as power input and temperature distribution, will have a definite effect on the recovery of alloying elements.

Like silicon, aluminum is often employed as a deoxidizer for steels and, to a lesser degree, as a microalloying element. The deoxidation reaction is:

The reaction of aluminum with nitrogen is also important because it has a strong affinity for dissolved nitrogen in the weld pool and because aluminum nitride is responsible for the pinning of grain boundaries and grain growth control.

Titanium is widely used to alloy and modify steels. In welding, it is oxidized by the slag:

Similar to aluminum, titanium also reacts with carbon, nitrogen, and oxygen to form TiN, TiC, Ti(C,N), TiO, and TiO₂ particles that may remain trapped in the weld metal, moderating excessive grain growth.

The oxidation of carbon may take place as a result of carbon reacting with dissolved oxygen and metal oxides in the liquid metal:

Other minor constituents, such as vanadium and niobium, are oxidized by the slag at the expense of FeO to form a series of oxides, such as VO, V₂O₅, NbO, and Nb₂O₅.

When ESW is used to surface machine parts, metal-cored tubular wire electrodes are often used to provide high contents of alloy elements, such as chromium, molybdenum, vanadium, or titanium, in the deposited metal. When silicate fluxes are used, the oxidation of chromium takes place according to the following main reactions:

The welding consumables (fluxes and welding electrodes) and base metal are the major contributors of tramp elements, such as sulfur and phosphorus, to the weld pool. In addition, the temperature and welding conditions in ESW are not optimal for dephosphorization. As a result, increased migration of phosphorus from the slag to the weld pool occurs not only at the initiation of the weld but also at points where the electroslag process is resumed after an interruption. Sulfur in carbon steel welds is considerably more dangerous than phosphorus because it is the main cause of hot cracking. More recently, desulfurization slags with approximately 60 to 85 wt% CaF₂ and 15 to 40 wt% CaO have been adopted in ESW. Substantial desulfurization can also be achieved when carbon is added to a lime-fluorspar system.

There is also indication that in ESW the slag bath receives oxygen continuously from the surrounding atmosphere. With higher oxygen potential, the slag will also tend to oxidize the

weld metal. Therefore, some modified electroslag processes include an inert gas cover on top of the slag layer to ensure a more deoxidized weld pool.

Electrochemistry. In addition to the thermochemistry of the process, electrochemistry plays an important role in ESW (Ref 17, 18). Because the anode and cathode reactions all occur in one pool, the weight of electrode melted is approximately equal to the weight recovered in the weld pool. Current efficiency can then be expressed as a function of electrode melted and element concentration change. Anodic current efficiency data show that the bulk of the current at the anode is carried by the oxidation reactions of iron, chromium, manganese, and silicon (Ref 19), which also indicates that electrochemical reactions account for a large fraction of the charges transferred. The major charge-carrying reactions at the cathode are the reductions of iron, aluminum, chromium, manganese, and silicon cations from the flux. Furthermore, the current efficiencies for electrochemical reactions involving chromium, manganese, silicon, molybdenum, oxygen, and aluminum increase with increasing current density. The concentration changes are directly proportional to the welding current and to the current efficiency for the reactions, and they are inversely proportional to the electrode melt rate.

Weld-Metal Inclusions

Due to the almost "equilibrium" operating conditions of ESW as compared with other arc welding processes, inclusion separation is expected to be more complete. The larger volume of molten metal, less turbulent weld pool, slower cooling, and slower solidification rate in ESW contribute to a cleaner weld metal with relatively few submicron-sized inclusions.

Solidification Structure

The morphology of steel electroslag weld deposits was first characterized and summarized by Paton (Fig. 16). Yu et al. (Ref 20) further characterized the solidification substructure of low-carbon structural steel electroslag weldments and related them to the weld pool form factor:

- *Group 1:* Transition from cellular to columnar dendrites occurs at a short distance from the fusion line. Welds from this group show shallow molten metal pools with high form factor.
- *Group 2:* Cellular-to-columnar dendrite transition occurs further away from the fusion line, with a fine columnar grain zone at the center of the weld.
- *Group 3:* Characterized by a shallow angle of inclination (approximately 10°) between the columnar grains and the fusion line. The transition from dendritic to columnar

dendrites occurs close to the centerline of the weld. The grains meet at the center at an obtuse angle.

- *Group 4:* Dendritic-to-columnar dendrite transition occurs close to the centerline, with equiaxed grains at the center of the weld.

The deep pools and low form factor generally found in groups 3 and 4 welds are also responsible for the high sensitivity to centerline cracking and radial hot cracking of these welds.

Solid-State Transformations

The cooling rate of an electroslag weld metal is so much slower than those of other welding processes that reasonably coarse microstructures are found. During the austenite-to-ferrite transformation, primary ferrite and grain-boundary ferrite are the principal constituents, along with carbides, mostly in the form of pearlite. In low-alloy steels, acicular ferrite, martensite, bainite, and retained austenite can be found only in those welds that have considerable amounts of alloying ingredients.

Electroslag Process Development

High-Productivity Electroslag Processes

Responding to the technological challenge of the need for a large volume of deposited metal and low heat input, many high-speed ESW techniques have been developed (Ref 9–12, 15, 21–25). There have been essentially two approaches:

- Narrowing the gap to decrease the volume of metal deposited (thereby shortening the time needed to form the weld joint)
- Increasing the welding speed

With either approach, the productivity is increased and the heat can be distributed throughout a longer section of the weld.

With respect to the narrow-gap approach, the extent of gap cross-sectional area reductions is limited by the stability of the process and the size of the electrode and guide tube. Too narrow a gap may cause arcing between the electrode and the base metal. Solid flux blocks may be inserted at regular intervals to avoid arcing between a solid strip electrode in a thin-channel consumable guide and the base metal. Gaps as small as 12 mm ($\frac{1}{2}$ in.) have been reported (Ref 26). Narrow-gap welding, however, can result in higher base-metal dilution.

The use of powdered filler metal has been reported to increase the deposition rate in ESW (to over 24 kg/h, or 53 lb/h) with reduction in the specific heat input and to refine the weld-metal and HAZ microstructure. The supply of metal powder (ferrous, mainly) to the weld metal can be obtained by a flow of argon gas (Fig. 17). Welding speed as high as 230 mm (9 in.) per minute has been reported. Notch impact testing results measured with samples taken 1 to 2 mm (0.04 to 0.08 in.) from the fusion line showed good Charpy impact toughness.

Metal powder cored strip electrode for consumable guide ESW has also been used (Ref 9, 17). The average weld deposition rate is approximately two to three times higher than the solid wire process, over 38 kg/h (85 lb/h). The specific heat input of these welds was lower, at 0.8 kJ/mm^2 (520 kJ/in.^2). Rather than

add metal powder to increase the deposition rate and absorb the excess thermal energy in the molten metal bath, a separate filler wire can be used (Ref 27). This is shown in Fig. 18. This setup resembles the feeding of a cold wire into plasma arc welding or gas tungsten arc welding processes. Not only is the productivity of the process increased, but the HAZ width is also reduced.

Narrow-Gap Improved Electroslag Welding

Narrow-gap improved electroslag welding (NGI-ESW) is a variant process of standard ESW with the aim of improving the toughness of the fusion zone and HAZ, the productivity, and the soundness of the weld bead. Compared to the range of process variables between both welding processes, for a 5 cm (2 in.) thick steel plate, NGI-ESW presents lower root opening (approximately 40%), higher welding current (67% more), higher welding speed (approximately twice the speed of standard ESW), and lower welding heat input (75% less energy per length) (Ref 28–34).

Similar to standard ESW, a molten slag and a molten welding pool are created, but in this case, the weld-metal dilution is approximately 50%. The consumable guide and the insulators, when melted, are mixed with the welding and slag pools, respectively. An ESW neutral fused flux is used, with controlled oxygen content in the weld metal (180 to 200 ppm). The consumable guide is made of low-carbon steel to improve the soundness of the weld bead. The filler metals used in NGI-ESW are metal-cored wires, according to AWS 5.25 ESW filler-metal specification.

The consumable guide in NGI-ESW is designed to distribute heat in a more uniform way. Usually, it has two shapes: the standard, with a cylindrical-type shape, and the sandwich,

Fig. 18 Schematic of electroslag welding process using separate filler wire to increase deposition rate and absorb excess thermal energy in molten metal bath. Source: Ref 28

with a rectangular shape (Ref 34). These two shapes are presented in Fig. 19.

The consumable guide shape is important to uniform heat flow and also deposition rate and weld bead soundness, in particular, lack of fusion. Figure 20 compares the effect of two consumable guide shapes in the uniformity of heat flow (presented by arrows and two isothermals) and in the presence of cold spots, which generate a lack of fusion. The standard EWS shape is more prone to a lack of fusion when compared to NGI-ESW.

The NGI-ESW process presents reduced sensitivity to weld imperfections and improved toughness in the HAZ. These goals are achieved with higher productivity and substantial cost savings (Ref 34).

Electroslag Surfacing

Surfacing by means of weld overlays has a long history. Electroslag surfacing can be done in either the vertical or flat position. Where the area to be surfaced is small relative to the base metal, vertical electroslag surfacing is usually used. Adapting the vertical orientation of ESW to produce composite metallic structures involves replacing one of the parent-metal plates with a water-cooled mold. An interesting application is tool steel ingots that are given a soft steel electroslag-welded deposit on each end to facilitate the rolling operation.

For large areas, such as plates for tube sheets or cylindrical pressure vessels, electroslag surfacing is conducted in the flat position. Excellent process stability is one of the characteristics of the process. Even with electrodes as wide as 150 mm (6 in.), the quality of the surface weld is still comparable to that of welds produced by other processes. To minimize the undercutting problem and improve bead smoothness, Kawasaki Steel (Ref 6) developed the Maglay process, which uses an external magnetic field to control the flow of molten slag and metal. Dilution can also be controlled, to less than 10%. Forsberg (Ref 28) reports the development of a similar process, which uses strips of 60 to 90 mm (2.4 to 3.5 in.) width

Fig. 19 Example of consumable guide designs for a steel plate. (a) Standard type for standard electroslag welding. (b) Sandwich type for narrow-gap improved electroslag welding. Source: Ref 34

and emphasizes the higher deposition rate and lower dilution ratio.

Electrogas Welding

Electrogas welding can be classified as a gas metal arc welding process. It was introduced in the early 1960s to perform single-pass welding of relatively thin plates in the vertical position. As shown in Fig. 21, the process is very similar to ESW, with the exception of the presence of an arc and the weld pool shielding mechanism (Ref 6). In most cases, shielding gas is used together with a bare or flux cored wire to provide a shielding gas on top of the molten pool of slag and weld metal. Self-shielded flux cored wires are often used without a separate gas shield. The production rate can be as high as 34 kg/h (75 lb/h), depending on the joint configuration and plate size. Special flux cored wires that contain fewer slagging ingredients must be formulated for EGW, because slag buildup on the molten weld-metal surface can affect arc stability and cause slag entrapment. The thicker the plate being welded, the less flux needed. When bare wire is used, small amounts of granular flux are usually added at the start. The slag needed for protection is produced from the deoxidizers in the electrode wire. For steel welding, the most common shielding gas is carbon dioxide. Additions of argon (75 to 80 vol%) to carbon dioxide seem to improve the arc stability and weld-metal properties. Flow rates are usually of the order of 14 to 19 L/min (30 to 40 ft³/h).

Heavy aluminum weldments are produced by EGW using argon-helium gas shielding with flow rates of 28 to 38 L/min (60 to 80 ft³/h).

In addition to its higher deposition rate, EGW presents the advantages of lower heat

Fig. 20 Example of consumable guide designs for a steel plate. (a) Standard type for standard electroslag welding. (b) Sandwich type for narrow-gap improved electroslag welding. Source: Ref 34

Fig. 21 Schematics comparing primary components of two vertical welding processes in which molten weld pools are confined by cooling shoes. (a) Electroslag welding. (b) Electrogas welding (EGW)

input, more refined microstructure, and improved HAZ properties. Consequently, post-weld heat treatment is not mandatory in many EGW applications. The process also offers easy restarting if the weld is interrupted (complicated in ESW). However, as the thickness of a plate increases, the shielding gas often fails to cover the entire joint area, leading to unacceptable porosity. Thick plates favor the choice of ESW because electroslag welds exhibit fewer inclusions and defects.

Multipass ESW and EGW

The metallurgical problems encountered in single-pass electroslag and electrogas processes can be largely overcome by multipass welding. An example is a thick steel square-butt electroslag weld joint with a fixed copper chill bar or water-cooled copper tube inserted at midwall, and a weld being produced with a moving shoe on one side. The copper chill is then removed, and the opposite side is welded. In practice, however, several problems may appear. One is related to the removal of the copper chill, gripped by the shrinkage that occurs during the first weld pass. Another is the problem of ensuring penetration by the second pass into the first pass. Unless the plate edges are machined and carefully fitted up, slag leakage may also occur.

Reference 29 reports the use of a copper chill bar that penetrated to the root of one side of a double V-joint preparation while EGW proceeded from the opposite side. An alternative method is to manually deposit the root pass, to avoid the problem of close fit-up tolerances needed for complete penetration. Where welding can only be approached from one side,

conventional backing bars are used, and the copper shoe protrudes into the joint to mold the initial pass, followed by the surface pass deposited in the conventional manner. This technique is satisfactory for EGW, but slag retention in the cavity formed by the protruding shoe and the base plates is a challenge in the electroslag process.

The consumable nozzle electroslag process can be used to make a multipass electroslag weld with a pass from each side. A tightly fitted spacer bar is placed at midwall. The electroslag weld pass from the first side partially penetrates the spacer bar, and the second pass from the opposite side consumes the remaining spacer and penetrates the first pass.

These process modifications do not solve the problem of the wide HAZ on the surface of the plates being welded, because toughness and fatigue properties at or near the outer surface of a weld are essential for the integrity and performance of the structure.

Electroslag and Electrogas Process Applications

Carbon and Low-Alloy Steels

The joining of heavy-section steels is the most common application of both ESW and EGW. As previously stated, ESW is commonly done on plates of thickness 50 mm (2 in.) and greater. In fact, economy is greatly increased if the section thickness is greater than 100 mm (4 in.). The range of application of EGW is between 9.5 and 75 mm (0.375 and 3 in.). When compared with arc welding processes, minimum distortion, vertical position, and

minimum joint penetration are the major advantages. Typical applications include fabrication of pressure vessels, nuclear components, power generation equipment, rolling mills, heavy presses, bridges, ships, and oil drilling rigs (Ref 30). Other structural applications reported are blast furnace shells (carbon steel) and a wind tunnel structure (HY-100 steel) (Ref 31, 32).

Structural Steels

A considerable number of highway bridges were fabricated using ESW prior to its ban in bridge construction. Some failures have been attributed to defects such as hydrogen cracking, lack of fusion, low HAZ fatigue properties, and so on. However, properly made welds were found to meet the radiographic standards required for impact and fatigue loading of structural members (Ref 33). In the case of low-alloy steels for structural applications, austenitizing postweld heat treatments have been considered necessary for electroslag welds. However, when proper attention is given to consumable (flux and electrode) selection, a stress-relieving heat treatment is generally sufficient to obtain good impact properties (Ref 34).

Shipbuilding. Electroslag and electrogas welding can be used for the welding of components and for on-ship welding. One application is the propeller shaft bracket assembly for natural gas and oil tankers. Stem frame parts, heavy rudderstock plates, longitudinal and vertical hull stiffeners, and shaft struts are often electroslag welded (Ref 35).

Pressure Vessels. Thick-wall pressure vessels used in the chemical, power generating, petroleum, and marine industries are manufactured using ESW. Plates are rolled to form the shell of the pressure vessel, and the longitudinal seam created is then welded. Lifting lugs on the vessels, nozzles, and branch pipes are also electroslag welded to thick-walled vessels. Due to the high heat input, the welding practice must be critically controlled. Where code requirements are specified, a normalizing heat treatment is also performed.

Penetrating members, such as nozzles and pipe fittings, are often costly to weld into thick-wall pressure vessels by conventional processes. A unique method employing both welding and casting techniques has been proposed by Norcross (Ref 36). A cylindrical water-cooled mold is tightly affixed to the outside surface of the vessel, and weld metal is cast in place. The hole of the nozzle is then machined to provide an opening into the vessel, at the end of which pipes or other attachments can be easily welded (Fig. 22). Even large-diameter penetrating members can be made by this method, by casting hollow cylinders after first tapering the vessel wall to allow the

Fig. 22 Application of electroslag welding to incorporate penetrating members such as nozzles onto thick-wall pressure vessels. Source: Ref 38

starting zone of the electroslag weld to be machined away (Ref 37, 38).

Heavy Machinery. Large presses and machine tools are often manufactured from plates that are larger than the mills can produce, so ESW is used to join large plates together. Motor frames, press frames, gear blanks, turbine rings, crane rails, and crusher bodies are some of the common applications. In the transmission pipeline industries, ball valves and stop-gate valves are often electroslag welded.

Dissimilar Metal Joining

Electroslag remelting has been used to develop transition pieces for heavy-wall steam piping where low-alloy chromium-molybdenum steel pipe is to be joined to austenitic stainless steel pipe. Two round ingots, one of the ferritic alloy and one of the austenitic stainless steel, are welded together to form the electrode for electroslag remelting. As the electrode is melted in the molten slag bath, the composition gradually changes from one to the other, depositing a graded alloy billet that is later pierced and formed into a transition piece (Ref 38–40).

Joining and Repairing of Castings

Electroslag welding is also used to weld cast components. Instead of producing a large casting, many small castings of lower cost and simpler fabrication are produced and welded together. One such application is described by Brosholen et al. (Ref 41) to construct a cast

steel propeller shaft bracket. Cast iron has been electroslag welded using a cored wire containing either white or gray cast iron powders and a graphite nozzle (Ref 42). Defective thick sections of cast steels can be repaired by ESW, by drilling a series of connecting holes into the defect zone. A close-fitting water-cooled copper mold is inserted in one of the drilled holes while welding proceeds in the adjacent hole. On completion of that weld, the mold is moved to the next hole before the molten slag has cooled, which allows ESW to start in the vacated hole (Ref 43, 44).

Tool and Die Surfacing and Welding

The slow thermal cycles involved in ESW are favorable for depositing hardenable alloys. For large forging hammers and forming dies, hard wear-resisting alloys can be spilled to the surface of a carbon steel backing using multiple electrodes and current-pulsing techniques (Ref 45–47).

Stainless Steel and Nickel-Base Alloys

Two halves of large 38 tonne (42 ton) cast stainless steel pumps for nuclear electric power facilities have been successfully joined by circumferential welding of their equatorial surfaces and have been qualified to rigid nuclear code requirements. As-welded electroslag welds in austenitic stainless steels were found to be insensitive to knife-line attack after sensitization for 1 to 5000 h at temperatures ranging from 450 to 750 °C (842 to 1382 °F) in tests (Ref 48). It has also been demonstrated that ESW is suitable for welding 25 mm (1 in.) thick alloy 600 plates and 25 mm (1 in.) and 114 mm (4.5 in.) thick plates of alloy 800. Matching filler metals and Inconel filler-metal 82 produced sound welds with excellent elevated-temperature strength and stress-rupture results. Because stainless steels and nickel-base alloys do not undergo allotropic transformations, electroslag welds do not require a high-temperature postweld heat treatment.

Aluminum

Both ESW and EGW have been used to join thick sections of aluminum. One such application is to join 240 mm (9.5 in.) thick electrical conductors (busbars). Instead of the typical copper shoes, graphite shoes are used to obtain satisfactory weld surfaces and edge penetration (Ref 49). Gagan et al. (Ref 50) reported erratic penetration encountered in ESW of thick-section aluminum due to the magnetic fields generated by the welding process, which required special shielding screens around the weld zone. The high conductivity of aluminum and the prompt formation of a refractive oxide are also of concern. High-fluoride-content fluxes and an inert gas shield in EGW typically produce good results in welding thick-section

aluminum. For ESW of aluminum containing 4.5 wt% Mg, the following flux has been suggested (Ref 51):

Constituent	Content, wt%
MgF ₂	1–30
MgCl ₂	5–60
LiF	5–60
KCl	5–6

As welding progresses, additions are made to the flux containing 30 wt% each of KCl, LiF, and MgCl₂, and 10 wt% MgF₂. This flux is reported to work well for ESW of aluminum with copper shoes (Ref 51).

Titanium

The reactivity of titanium requires that residual elements such as hydrogen, oxygen, and nitrogen be minimized in ESW. A slag bath high in halides and containing virtually no oxides, and an inert gas (argon) shield over the bath, are required. Plate electrodes seem to produce better results (Ref 3, 52). Commonly, fluxes are halide compounds based on CaF₂ with rare-earth additions to produce welds low in oxygen, nitrogen, and hydrogen. Devletian (Ref 53) reported that because the high resistivity of titanium promotes rapid ohmic heating of the titanium consumables, stable welding operation generally requires large-diameter electrodes for nonconsumable guide welding, and nozzles or guide plates for consumable guide welding.

Problems and Quality Control

Fusion Zone

As discussed earlier in the section “Solidification Structure” of this article, both cellular and columnar dendrites are observed in the solidification structure of an electroslag weldment. Particularly in the cases of welds with low form factor, in which the transition from cellular to columnar dendrites occurs close to the centerline of the weld and the grains meet at an obtuse angle, centerline cracking and radial hot cracking are more frequently observed. These defects can be attributed to the combined effects of temperature gradient, solidification rate, degree of restraint in fit-up of the weld, high welding speed, and low form factor. In general, a long, straight-sided columnar grain structure (the result of high welding speed) tends to be weaker under load than the more equiaxed and finer grain structure of a slow-speed weld. At the same time, the cellular structure may be coarser and higher in segregation for the case of low welding speed. Figure 23 shows a proposed mechanism of solidification cracking.

Fig. 23 Schematic indicating projected mechanism of solidification cracking in an electroslag weldment. Source: Ref 54, 55

Partially Melted Zone

Liquation cracking is associated with the melting of heavily segregated grain boundaries near the fusion line region. Carbon and manganese are the most common alloying elements involved in the formation of compounds such as (Mn,Fe)S that lower the melting temperature of the grain boundaries. Phosphorus, nitrogen, and boron are some of the other embrittling agents found in ferrous alloys. During cooling, residual stresses may build up and rupture these weakened boundaries. Under the slow heating and cooling conditions experienced by an electroslag weld, the susceptibility of a ferrous alloy to liquation cracking is increased. It has been reported that liquation cracks can be eliminated in heavy electroslag welds by microalloying the steels with cerium, titanium, and other elements to combine with sulfur and form small high-melting-point inclusions (Ref 56).

Temper Embrittlement

Thick-section 2.25Cr-1Mo steel plates used in pressure vessels for petroleum and chemical service at elevated temperatures are susceptible to temper embrittlement in service. The problem has been attributed to the presence of residual elements such as phosphorus and antimony. Bruscati (Ref 55) established an X factor to describe the effect of the residual elements:

$$X = \frac{10P + 5Sb + 4Sn + As}{100} \quad (\text{Eq 23})$$

where X is in parts per million. Acceptable weld-metal ductility can be obtained if the manganese and silicon contents and the X factor are low. Reduction of these elements can be achieved using basic fluxes. Another indicator, the Watanabe number, J , shows that welds and base metal are not susceptible to temper embrittlement if J is less than 200 (Ref 57):

$$J = (\text{Si} + \text{Mn})(\text{P} + \text{Sn}) \times 10^4 \quad (\text{Eq 24})$$

Hydrogen Cracking

Generally speaking, ESW is performed under perfect slag shielding conditions, and the rate of cooling of the weld metal is low. Therefore, the occurrence of hydrogen-induced cracking is minimal. However, under circumstances that require the use of a moist argillaceous material to prevent the slag from leaking out of the joint region, an atmosphere high in water vapor is present. Microcracks, and sometimes blowholes, may result in the weld metal. Grain-boundary separation, observed in some electroslag welds, can be completely eliminated by postweld heat treating at 300 °C (570 °F) immediately after welding, which indicates that by allowing hydrogen to diffuse out of the specimen, the integrity of the welds can be maintained. This effect is further evidenced by the higher cracking incidence at the bottom part of an electroslag weld. In addition, diffusible hydrogen content is high at a region close to the weld start, decreasing to a relatively constant value at short distances from the starting point. By increasing the depth of the pool, the cooling rate is reduced, and hydrogen escapes by diffusion before it causes damage (Ref 58).

Weld Distortion

When compared with welds produced using other processes, electroslag welds do not present significant distortion problems. Measurements show that both transverse and angular distortion are present and that the gap distance changes as welding progresses. However, the distortion is only of the order of 1 to 2%. Angular distortion occurs because of the rapid cooling of the welded portion of the joint, which tends to draw the parts together, reducing the gap distance. Material ahead of the weld is separated by a gap, so heating has no effect. Material in the weld is either liquid or so hot that it is soft. Neither can support much of a load. As the weld progresses, the very bottom of the weld (coldest metal) resists motion. A contraction of 3 mm (0.125 in.) at the top of a weld 1.3 m (4.3 ft) long is normal. This separation must be allowed during joint setup to avoid jamming the guides and disrupting the normal progress of welding. Parts to be joined must be fitted up so that the gap is wider at the top of the joint. For improved dimensional accuracy, welding must be done at the maximum travel speed attainable.

Postweld Heat Treatment. As discussed in the section "Solidification Structure" of this article, most of the as-welded electroslag weldments have very coarse as-cast structure in the weld metal and coarse grains in the HAZ. As a result, such electroslag weldments may not qualify for many critical applications.

For example, in the case of ferritic steels, normalizing is generally required to refine the weld-metal and HAZ structure. In the case of electroslag-welded nuclear transport flasks, normalizing is frequently followed by tempering (Ref 59). In some low-alloy steels, subcritical postweld heat treatments (for example, stress relief) may not be useful because they can be either detrimental or harmful to mechanical properties, particularly notch toughness. As an example, stress-relief 2.25Cr-1Mo steel weldments at 760 °C (1400 °F) significantly increased the fusion zone and HAZ toughness, but they coarsened the carbides in the base metal, reducing its toughness (Ref 60). Quenched and tempered material, when joined by ESW, must be heat treated after welding to obtain adequate mechanical strength in the weld and HAZ. Kapadia (Ref 61) examined the need to stress relieve components that will be exposed to fatigue loading and determined that in butt welds in the as-welded condition, the outside surfaces cool and contract before the center. Thus, compressive residual stresses are present, which improve fatigue life. Stress-relief heat treatments actually reduce this beneficial effect.

Stud Arc Welding*

STUD ARC WELDING (SW), also known as arc stud welding, is a commonly used method for joining a metal stud, or fastener, to a metal workpiece. The process has been used as an alternative metal-fastening method since the 1940s. Millions of specially designed and manufactured metal studs are welded by this process every week in such diverse industries as construction, shipbuilding, automotive, and hard goods, as well as in miscellaneous industrial applications.

This article serves as a basic information source for those interested in accomplishing one-sided, no-hole attachment of metal fasteners. The SW process represents an alternative to other welding processes and is also a substitute for other fastening procedures, such as drilling and tapping, bolting, and self-tapping screws.

Process Overview

Stud arc welding is similar to many other welding processes, including arc and percussion welding, in that the base (weld end) of a specifically designed stud is joined to a base material by heating both parts with an arc that is drawn between the two. Equipment that is unique to this process regulates the arc length and arc dwell time. After an arc is struck, the stud weld end and the workpiece surface are brought to the proper temperature for joining and, after a controlled period of time, the two heated surfaces are brought together under pressure, creating a metallurgical bond capable of developing the full strength of the stud.

There are two basic types of stud arc welding, which are differentiated by the source of welding power. One type uses direct current (dc) power provided by a transformer/rectifier or a motor generator similar to that used in the shielded metal arc welding (SMAW) process. The second type uses power discharged from a capacitor storage bank. The process based on a dc power source is known as stud arc welding, whereas the process that utilizes capacitors is known as capacitor discharge stud welding (CDSW).

Both the SW and CDSW processes overlap in some areas of application. Generally, the SW process is used in applications that require similar stud and workpiece metals, the workpiece thickness is greater in relation to the stud diameter, and an accommodation

must be made for the stud flash (fillet). The term *flash* is preferred to the term *fillet*, because the metal that forms the flash during the stud arc welding process is expelled, rather than added, as occurs with other welding processes.

In contrast, the CDSW process is used extensively when welding to thin sheet metal and is used frequently with dissimilar workpiece and stud alloys. It is also used in cases where marks on the opposite side of the workpiece must be avoided or minimized. With this process, the stud diameter is limited to smaller sizes. The CDSW process is more fully described in the article "Capacitor Discharge Stud Welding" in this Volume. The factors on which process selection should be based are fastener size, base-metal thickness, base-metal composition, and reverse-side marking requirements (Table 1).

Equipment. As shown in Fig. 1, the basic equipment used for stud arc welding consists of a control system, which regulates the arc time and controls gun movement; a fixed or portable stud-welding gun, which holds the stud in position during the welding process to create the proper arc length and joining pressure; and connecting cables, which must be connected to a separate source of dc power. The other items that are needed to weld the workpiece are the studs themselves and ceramic arc shields, or ferrules. The equipment used for stud welding is comparable, in terms of size, portability, and ease of operation, to the equipment used in the SMAW process. Although the initial cost of stud-welding systems varies with the method selected, stud size, and productivity requirements, it is generally competitive with other fastening methods on an in-place or finished part cost basis.

A stud-welding control system that has been integrated in a transformer/rectifier power source is shown in Fig. 2. This type of equipment, which is the most widely used, is called a power/control system. It can weld studs with diameters up to 28.5 mm (1 1/8 in.). Either a single gun or dual guns can be used. Although a light-duty control system can weigh 11.3 kg (25 lb), the system shown in Fig. 2 weighs approximately 450 kg (1000 lb) and can be put on a wheeled cart for mobility.

A typical stud-welding gun (Fig. 3) is usually available in at least two sizes: standard duty, for

use with studs up to 16 mm (5/8 in.) in diameter, and heavy duty, for use on larger-diameter studs. The weight of the gun can vary from approximately 1.8 kg (4 lb), for a standard-duty gun, to 6.8 kg (15 lb), for heavy-duty models.

Table 1 Stud-welding process selection

Parameters	Stud arc welding	Capacitor discharge stud welding	
		Gap and contact methods	Drawn arc method
Stud shape			
Round	A	A	A
Square	A	A	A
Rectangular	A	A	A
Irregular	A	A	A
Stud diameter or area			
1.6 to 3.2 mm (1/16 to 1/8 in.)	D	A	A
3.2 to 6.4 mm (1/4 to 1/4 in.)	C	A	A
6.4 to 12.7 mm (1/4 to 1/2 in.)	A	B	B
12.7 to 25.4 mm (1/2 to 1 in.)	A	D	D
Up to 32.3 mm ² (0.05 in. ²)	C	A	A
Over 32.3 mm ² (0.05 in. ²)	A	D	D
Stud metal			
Carbon steel	A	A	A
Stainless steel	A	A	A

Fig. 1 Stud arc welding control system. The control system must be connected to a direct current power source for welding. In most applications, the stud (electrode) should be negative.

Fig. 2 Typical integrated power/control system for stud arc welding

Operation. The stud arc welding process utilizes the same principles as any other arc welding procedure. First, the stud, which acts as an electrode, is inserted into a chuck on the end of the gun, surrounded by a ceramic ferrule, and positioned against the workpiece (Fig. 4a). Next, the gun trigger is depressed, which starts

the automatic weld cycle by energizing a solenoid coil within the gun body that lifts the stud off the work and draws an arc. The arc melts the end of the stud and a portion of the workpiece (Fig. 4b). After a preset arc time (set on the control unit), the welding current is shut off and the solenoid is de-energized (Fig. 4c).

A main-spring in the gun forces the stud into the molten pool of metal, producing a full-strength weld, which is shown in Fig. 4(d) after the gun has been lifted off the stud and the ceramic ferrule removed. The result is a full-penetration, full-strength stud-to-workpiece weld, as shown in Fig. 5. This weld is similar to that obtained with other types of arc-welding processes.

Studs and Ferrules. With the exception of special processes, the stud arc welding of steel, stainless steel, and aluminum studs requires the use of a specifically designed weld stud and ceramic ferrule.

Studs. A wide range of studs are made by stud-welding manufacturers for the SW process. They vary in size and weld-base configuration, depending on the application requirements. The typical stud styles that are available include threaded, unthreaded, headed, and rectangular studs (Fig. 6). The steel stud diameters that are commonly welded using the SW process range from 2.7 to 25.4 mm (0.105 to 1.00 in.).

Full-strength welds result when using studs made from low-carbon steel that conforms to ASTM A-108 grades C-1010 through C-1020, although other steel grades can be used on a special-application qualified basis (Ref 2). Stainless steel studs are typically made from the austenitic series, including AISI 302, 302 HQ, 304, 305, 308, 309, 310, 316, 321, and 347, in both normal-carbon and low-carbon varieties. Stainless steel 303 is not an acceptable stud alloy. Aluminum studs are usually made from aluminum-magnesium alloys, including 5183, 5356, 5556, 5086, and 5456 (Ref 3).

Steel and stainless steel arc-welded studs that are larger than 6.4 mm (0.250 in.) in diameter use a welding flux to stabilize the welding arc and to deoxidize the weld area. The most commonly used flux is commercially pure aluminum, which is installed onto the weld end of the stud by thermal spraying, staking, or pressing a slug into a drilled hole in the end of the stud (Fig. 7). Studs that are 6.4 mm (0.250 in.) and under usually do not require fluxing.

Aluminum studs do not have to be flux loaded. Instead, the weld end of the stud has a conical or cylindrical tip that is shaped into the parent metal to help initiate the arc and control the arc length. To prevent the oxidation and embrittlement of the stud/plate weld zone during aluminum stud arc welding, the weld area is purged with an inert gas during the weld cycle. Argon gas is commonly used for this purpose, although helium also can be used. The typical gas flow rates for aluminum studs of various diameters are shown in Table 2.

When stud arc welding low-carbon and stainless steel studs, the stud (electrode) should be negative. Aluminum stud arc welding should be set up so that the stud is positive.

Obtaining a full-quality stud arc weld requires a sufficient amount of total energy

Fig. 3 Typical standard-duty gun for stud arc welding

Fig. 5 Macrosection of low-carbon steel stud weld

settings for various SW stud diameters. The ideal settings in each weld position for a particular stud and workpiece should be established by beginning with typical settings and then varying them within the allowable range to meet the required conditions.

Typical settings are based on good weld conditions, such as a clean workpiece, good ground, and others. Also necessary is a proper dc power source, which should have the following characteristics:

- High open-circuit voltage (70 to 100 V)
- Rapid output current rise
- Drooping output volt-ampere curve
- High current output over a short time

Stud arc welding requires a very short weld time (Table 3), but a very high current input, when compared with other types of arc welding. Usually, the duty cycle for this process is much lower than that of other welding processes. Constant-voltage types of dc power sources are not suitable for stud welding. Many of the available dc power sources are acceptable for stud welding, including those supplied as integrated power/control systems by the stud-welding manufacturer. These integrated systems use both three-phase and single-phase incoming alternating current power. Both standard and special voltage units are available. Single-phase units are relatively low-cost, portable systems that are usually suitable for smaller-diameter (≤ 12.7 mm, or $\frac{1}{2}$ in.) stud arc welding. Three-phase units are preferred for larger-diameter studs, because they provide a balanced load on incoming power lines and have smoother arc characteristics. A transformer/rectifier power source, combined with an integral stud-welding control system, is shown in Fig. 2.

Weld cable length and cable size also can affect the total output of a power source. Basically, a larger welding cable size minimizes current loss that is due to cable length, resistance, and heating. Thus, when the distance from the power source to the gun increases significantly, or when the number and size of studs applied per minute are large, larger welding

Fig. 4 Stud arc welding process. (a) Gun is properly positioned. (b) Trigger is depressed and stud is lifted, creating an arc. (c) Arcing period is completed and stud is plunged into molten pool of metal on base material. (d) Gun is withdrawn from welded stud and ferrule is removed.

input to the weld joint in order to produce melting and complete metallurgical bonding of the stud and workpiece. The energy input or weld current that is necessary depends on the stud diameter. Other parameters in the stud arc welding process are arc voltage, arc time, and plunge. Arc voltage is a function of the arc length, which is set as "lift," or the length the stud is drawn away from the workpiece during weld-cycle initiation. Plunge is the length of stud that extends past the end of the ceramic

ferrule and is available for melt-off during the weld cycle.

Studs are reduced in length during the weld cycle. Table 3 shows the typical reductions for steel and aluminum studs as a result of welding.

There is a range of setting combinations for all stud diameters. The same total energy input can be obtained by varying current input and arc time. For example, a low current input can be compensated for, to some extent, by increasing weld time. Table 3 also shows typical weld

cables should be used. Smaller dc power sources suitable for stud arc welding can be wired in parallel to produce the necessary current range.

Ferrules, or ceramic arc shields, are used in most stud arc weld applications. They are available in a wide variety of sizes and shapes to fit specific stud base designs and applications. For example, there are specific designs for welding studs through metal deck, to the fillet or heel of an angle, to round pipes or bars, or in a vertical position. A ferrule is placed over every stud at the weld end, where it is held in place by a grip on the stud-welding gun. The ferrule is used only once and must be removed from the stud after welding is completed to allow the inspection of the completed weld. Typical ferrule configurations are shown in Fig. 8.

Ferrule design is important, because it controls certain functions during welding. For example:

- Vents on the bottom of the ferrule allow weld gases to escape from the weld area and restrict the inflow of air to minimize weld porosity and oxidation.
- The internal cavity of the ferrule confines and shapes the molten metal into a flash (fillet) around the stud periphery.
- Heat in the weld area is concentrated and contained.
- Flash and weld spatter are minimized.

Although the dimensions of the flash are controlled by the ferrule configuration, the flash diameter and height must be taken into consideration when designing mating parts. Manufacturer specifications on finished stud flash dimensions should be followed, and test welds should be made to establish part fit. Flash

(a) Stud arc welded aluminum studs require inert gas shielding; see Table 2.

dimensions can be accommodated by any of the five methods shown in Fig. 9.

The typical dimensions for flash clearance are shown in Table 4. It should be noted that the flash (fillet) of a stud weld is not the same as the fillet that is produced by conventional welding techniques. It may have areas of nonfusion on its vertical leg or shrink fissures, which have no adverse affect on weld strength or ductility (Ref 4). Consequently, it is not subject to

the profile and inspection criteria used for a conventional weld fillet.

Base Plate Material and Thickness. To obtain full strength, the stud arc welding of low-carbon steel, stainless steel, or aluminum studs should be made to a base material of sufficient thickness so that the stud fails in tension or torque, rather than by pulling a hole in the base-metal workpiece. In the case of stainless or low-carbon steel studs, the base-metal thick-

ness should be at least one-third that of the stud diameter. For aluminum studs, the aluminum base plate material should be at least half that of the stud diameter. Thinner base plates can be used if strength is not the primary design characteristic that is required. On thinner materials, the studs will pull a hole in the plate at strength levels below their maximum. If the plate is too thin, then the stud will burn a hole through it. The recommended base plate thickness for full-strength development and the minimum thicknesses required to prevent burning through the base plate are given in Table 5.

The most widely used combinations of base plate and stud materials are shown in Table 6. With low-carbon steel studs, no preheat or post-heat treatments are needed when welding to low-carbon steel or austenitic stainless steel base plate materials. As carbon content in the base plate increases into the medium range, heat treatment for stud welding may be required. Welding to high-carbon base plate is not suggested. When base plate/stud combinations are questionable, an application qualification test is suggested (Ref 5). Details on this procedure are provided in the section "Stud-Welding Quality Control, Qualification, and Inspection" in this article. For best results when welding stainless steel studs to low-carbon steel plate (especially) when working stress levels are very high or there are repetitive loading cycles), the studs should either be manufactured from annealed-in-process materials or postmanufacture annealed before use.

Good welding practice requires that the base plate material at the weld spot be cleaned. Common contaminants that can result in unsatisfactory welds if not removed include paint, heavy mill scale, heavy rust, oxidation, oil or grease, and plating, such as galvanizing and anodizing on aluminum. Removal methods vary according to the contaminant, the base material, and the end use. Wire brushing and grinding may be satisfactory on heavy structural steel but can be destructive to thin-gage metals or anodized aluminum, because they may reduce the thickness to a point where burn-through or less-than-full-strength welds result.

Suggested cleaning methods include grinding, wire brushing, or needle scaling on heavy materials; using solvents to clean grease and oil; and using a noncontaminating stainless wire brush or a nonmetallic foam disk to clean aluminum and milling. Because anodizing is difficult to remove from aluminum without reducing the metal thickness, consideration should be given to anodizing the base plate and stud after the welding operation.

Similarly, the weld end of the stud should be free from materials that would contaminate the weld, including paint, rust, galvanizing, and others. Studs cannot be coated with any nonconductive material that would interfere with the flow of welding current. Light copper flashing and nickel or chrome plating usually do not cause welding problems.

Because a high-amperage, short-time current is typical in the stud arc welding process, it is also important that the grounding spot(s) on the base material be clean, that the ground be tight, and that all cables be in good condition and have tight connections.

The position of the ground(s) also can influence stud-welding quality. This depends on the geometry of the base-metal shape and is the result of electromagnetic arc deflection, or arc blow (Ref 6). Occurrences are more common when studs are very near a free edge or are on long and narrow base plates, hollow pipe sections, or irregular peripheries, and can be corrected by moving the ground to a central position or using multiple grounds. Because

current flow is usually away from the ground toward the heavier or larger area of the base plate, arc blow is characterized by a lack of flash or fillet on the side of the stud nearer the edge, end, or smaller area.

Stud Strength. Fasteners will develop full material strength when they have been stud arc welded to compatible base plate alloys. Tables 7 to 9 show the tension and torque loads for various threaded stud diameters, based on minimum specified stud strengths (Ref 2, 3, and 6). For unthreaded stud fasteners, the yield strength and tensile or ultimate strength is calculated by:

$$\text{Yield strength} = A_s F_y$$

$$\text{Tensile strength} = A_s F_u$$

where A_s is the area of the stud shank (in.²), F_y is the specified stud material yield strength (minimum psi), and F_u is the specified stud material ultimate strength (minimum psi).

For threaded studs, the area is based on the mean effective thread area, which is calculated by:

$$A_s = 0.7854 [D - (0.9743/N)]^2$$

where D is the nominal diameter of the stud, and N is the number of threads per inch.

Process Variations and Special Equipment. There are several specific applications

that lend themselves to special variations of the stud arc welding technique. One application is the welding of studs to thin base materials that are less than the minimum thicknesses listed in Table 5. Although full weld base strength is usually not achieved, the resulting strength level is suitable for the application loadings involved. This process variation, which is called short-cycle stud arc welding, does not use a ceramic ferrule. Instead, higher weld current is used with very short times, which minimizes penetration of the stud into the base plate. Normally, this variation is used with stud diameters ≤ 9.5 mm (≤ 0.375 in.) in situations where backside marking is not considered detrimental.

The second special process is gas-shielded arc welding, which also does not use a ceramic ferrule. Instead, the stud-welding area is shielded by an inert gas, usually argon. This process can be used with both steel and aluminum but is more widely used with the latter material. The welding variables fall into a very narrow range, and conditions for application usually include tight tolerances and a tightly controlled setup. Consequently, the stud arc welding equipment most often consists of a fixed-gun production unit. A typical application is the welding of aluminum studs with special end configurations to aluminum kitchen utensils.

Special equipment is frequently used with the short-cycle and/or gas-shielded arc welding processes, because the application parameters must be tightly controlled and involve large quantities of studs applied in a production environment. Equipment manufacturers assemble many types of special equipment for production-line use. The equipment can be used with automatic stud feed, automatic stud and ferrule feed, computer-programmed indexing, robotic stud-welding guns, and other mechanisms. A typical automated stud arc welding production unit is shown in Fig. 10. A unit can involve simple, column-mounted, single-gun systems or sophisticated, multigun, multiple-feed units that cost thousands of dollars.

Fixturing and Tooling for Stud Arc Welding

Regardless of the stud-welding method employed, certain “expendable” accessories are required. These include such items as a chuck or collet to hold the particular stud being welded, a ferrule grip for the fastener, a foot that holds the ferrule grip, legs that attach to the gun and adjust to accommodate various stud lengths, and other minor items. The operating life of these items is variable, depending on the care and maintenance they receive. For example, a chuck may last for 5000 to 25,000 welds. Legs last indefinitely, whereas ferrule grips and feet usually have a shorter usage life.

Table 7 Mechanical properties of low-carbon steel stud arc welded fasteners

Fasteners have 380 MPa (55 ksi) minimum ultimate strength and 345 MPa (50 ksi) minimum yield strength.

(a) UNC, unified coarse thread series; UNF, unified fine thread series. (b) Mean effective thread area is based on a mean full diameter midway between minor and pitch thread diameters. (c) In practice, a stud should not be used at or higher than yield load. A factor of safety should be applied, and 60% of yield is commonly used, although other values may be used at discretion of user. (d) Torque figures are based on the assumption that excessive thread deformation has not affected the proportional range of torque/tension relationship. An average torque coefficient of 0.20 was used in these calculations. (e) Shear load is based upon 0.75 times ultimate load. The user should apply an appropriate safety factor to these figures. (f) Value given in in. · lbf

Table 8 Mechanical properties of stainless steel stud arc welded fasteners

(a) UNC, unified coarse thread series; UNF, unified fine thread series. (b) Mean effective thread area is based on a mean full diameter midway between minor and pitch thread diameters. (c) In practice, a stud should not be used at or higher than yield load. A factor of safety should be applied, and 60% of yield is commonly used, although other values may be used at the discretion of user. (d) Torque figures are based on the assumption that excessive thread deformation has not affected the proportional range of torque/tension relationship. An average torque coefficient of 0.20 was used in these calculations. (e) Shear load is based upon 0.75 times ultimate load. The user should apply an appropriate safety factor to these figures. (f) Value given in in. · lbf

Accessories are relatively in-expensive items that should be planned for when preparing budgetary estimates on any given project.

The extent and sophistication of tooling for stud welding reflects the required production rate and the total number of studs to be welded. Locating the stud arc welding centers can be as simple as laying out the workpiece and center punching the locations either directly or through a template, as shown in Fig. 11. The studs are then placed in the punch marks, the

stud-welding gun is held vertically, and the weld is initiated. Although operator skill is a factor, careful welders can achieve a perpendicularity of $\pm 5^\circ$ and a location tolerance of approximately 1.2 mm (0.046 in.). Often, the cover plate in a base plate/cover plate assembly can be used as the template for marking.
