A permanent template becomes more practical when an increasing number of studs are to be welded on repetitive locations. Stud arc welded fasteners can be welded directly

through temperature-resistant material which should be spaced off the work by 1.65 to 6.35 mm (0.065 to 0.250 in.) to allow expelled weld gases and weld spatter to escape without restriction, which could adversely affect weld quality. This type of template arrangement is shown in Fig. 12. Note that the template holes are drilled slightly larger than the outside dimension of the ceramic ferrule. Before the template is prepared, it is good practice to consult the manufacturer specifications for the

Table 9 Mechanical properties of aluminum stud arc welded fasteners

Fasteners have 290 MPa (42 ksi) minimum ultimate strength and 205 MPa (30 ksi) minimum yield strength.

(a) UNC, unified coarse thread series; UNF, unified fine thread series. (b) Mean effective thread area is based on a mean full diameter midway between minor and pitch thread diameters. (c) In practice, a stud should not be used at or higher than yield load. A factor of safety should be applied, and 60% of yield is commonly used, although other values may be used at discretion of user. (d) Torque figures are based on the assumption that excessive thread deformation has not affected the proportional range of torque/tension relationship. An average torque coefficient of 0.20 was used in these calculations. (e) Shear load is based on 0.60 times ultimate load. The user should apply an appropriate safety factor to these figures. (f) Value given in in. · lbf

Fig. 10 Typical automatic stud-feed hand-gun system for portable operation using templates or fixtures on the workpiece

ceramic ferrule dimensions to be used with the stud being welded. Location accuracy, in this case, can be as tight as ± 0.78 mm (± 0.031 in.).

Even greater accuracy can be obtained, both in the vertical and horizontal directions, by adapting the template hole to fit a drill jig bushing tightly and by inserting the template adapter (or a ferrule tube adapter) through the bushing to the workpiece. The ferrule tube adapter also can be used for welding down into deeply drilled holes or into tight-fit areas (Fig. 13).

With closely spaced studs, the foot grip is sometimes modified so that after welding the initial stud at a center-punched location, the foot can be held against the reference stud to weld the next or adjacent stud on the required spacing.

Fig. 11 Center punching base material through a template

The verticality of the weld stud can be ensured by several methods. The most accurate is obviously a fixed gun on a slide mechanism

Fig. 12 Welding through a template using a ferrule with stud arc welding fasteners

Fig. 13 Portable stud arc welding gun equipped with accessories for welding studs through or into a drilled or formed hole

of the type used for automatic-feed, high-production work. This type is also the most expensive. A portable gun can be mounted on a machine slide or drill press by fabricating a bracket (Fig. 14) in cases where production quantities do not justify the expense of automatic equipment.

Other methods of ensuring verticality are to use a bushing-type template, a bubble level mounted on the rear of the gun, or a bipod foot arrangement, as shown in Fig. 15. With the stud and ferrule acting as one fixed point, the two bipod screws are adjusted to obtain perpendicularity. Vertical variations that are less than $\pm 1^\circ$ can be achieved with proper accessories and adjustments.

A wide range of accessories is available for welding studs of different lengths or for welding studs into areas with limited access. Two widely used special accessories are shown in Fig. 16 and 17. For unusual situations, the manufacturer should be consulted to suggest or, possibly, design stud-welding accessories.

Stud-Welding Quality Control, Qualification, and Inspection

Because of its broad use for many years and the relative simplicity of its applications, stud welding in the downhand position is considered to be a prequalified procedure; that is, it is only necessary to weld two studs satisfactorily in the downhand position to qualify both the process and the operator. The two qualification studs can be bend tested, torque tested, or tension tested. The physical test is satisfactory if no failure occurs in the weld or the heat-affected zone.

Stud-welding code requirements (for example, Ref 2 and 7) define the necessary tests for prequalified stud welding to the flat or downhand position, as well as other positions. The limit on the flat position is defined as 0 to 15° slope on the surface to which the stud is applied. Beyond 15° , a ten-stud test is required. Again, each of the ten studs in the nonflat position must be bend, tensile, or torque tested. Bend testing is 90° from the original axis, whereas torque and tension testing are conducted until failure. Failure must occur in the stud shank or in the work-piece material, not in the weld or the heat-affected zone. All failures require retesting. Satisfactory testing qualifies the welder and the process.

Typical bend, torque, and tensile testing setups are shown in Fig. 18 to 20. Qualification records, including stud drawings, ceramic arc

Fig. 16 Typical offset assembly used when stud arc welded fasteners must be welded below an obstruction

Fig. 14 Inexpensive method of mounting portable hand gun to machine slide or drill press to obtain fixed-position accuracy

Fig. 15 Use of an adjustable bipod foot assembly to provide three-point contact, ensuring perpendicularity of stud to workpiece

Fig. 17 Typical leg-extension accessory for welding long studs (up to 1.83 m, or 6 ft). Note the use of a split foot and ferrule grip; the gun does not have to be stripped the full length of the stud when the stud is welded.

Fig. 18 Typical bend testing setup. Studs that must undergo application qualification should be bend 90° without weld failure (15° for aluminum studs). Testing for preproduction or testing during production for inspection purposes requires bend testing to 30° from original position (15° for aluminum studs). For threaded studs, torque testing in accordance with Fig. 19 should be used. Source: Ref 2

shield drawings (if used), weld settings, and position, should be kept.

Either two-stud or ten-stud testing should be conducted on a production piece or on a separate piece of the same type and thickness ($\pm 25\%$) of material that will be used in the application, in the same position in which the studs will actually be applied.

In addition to physical testing, the studs that are welded for qualification also must be visually inspected, whether there are two or ten. Visual inspection consists of verifying that a full 360° weld flash (fillet) is formed around the stud base. There should be no gaps or

undercuts in the flash or in the wetted area. As mentioned previously, flash can be irregular in both height and evenness and it can contain shrinkage fissures or cracks. Because flash is expelled, not deposited, metal, it should not be subject to the usual inspection criteria for a weld fillet.

The final visual inspection should be a measurement of the after-weld length. With stud arc welding, the after-weld length of the stud will be shorter by the lengths shown in Table 3. A consistent after-weld length, combined with acceptable visual inspection and physical testing, are assurances of satisfactory welds. Figure 21 shows typical stud arc weld appearances for both acceptable and problematic welds.

Passing the two-stud preproduction or the ten-stud application qualification test approves the procedure and operator. Production stud welding is then allowed to proceed. However, at the start of each new production period, a two-stud test is again required before production can begin. Similarly, a change in stud diameter, equipment, settings, or operator requires requalification.

During production, welding inspection and testing should be used on a continuous basis to confirm acceptable quality. This can be done on a reasonable number of studs, depending on the welding conditions and stud appearance. After the visual inspection of all stud welds,

physical testing of at least one weld per hundred is usually suggested. Any weld that does not show a full 360° flash or wetness should be tested. Welds without a full flash can be repair welded, but repaired welds are also required to be physically tested.

In the case of unthreaded studs, the quality inspection test can be to bend 15°. The studs can be straightened after testing, if required. Threaded studs can be subjected to a torque test to approximately 80% of the yield torque load, rather than a bend test. Failure in the weld or heat-affected zone is cause to reject the weld being tested. Failure also requires that the quantity of studs welded from the previous test to the present test be carefully inspected for weld deficiencies. Additional tests may be necessary to confirm weld quality.

If the quality inspection test studs must be straightened for end use, then they should be returned to the vertical position by using a bending tool. Continuous slow pressure should be applied during the straightening process.

Temperature at the time of stud welding and during stud testing is an influential parameter. Stud welding should not be conducted at temperatures below $-18\text{ }^{\circ}\text{C}$ ($0\text{ }^{\circ}\text{F}$). When the temperature is below $0\text{ }^{\circ}\text{C}$ ($32\text{ }^{\circ}\text{F}$), one additional stud per hundred welded should be tested to verify weld quality. Below $10\text{ }^{\circ}\text{C}$ ($50\text{ }^{\circ}\text{F}$), welded studs should be tested using the bending tool, rather than by hammer testing. In colder

Fig. 19 Typical torque testing arrangement. Studs that must undergo application qualification or preproduction testing should be torqued to destruction without failure in the weld. Proof torque testing during inspection of threaded studs should be applied at 60 to 66% of the yield torque load for the stud size testing. Refer to Tables 7 to 9. Source: Ref 2

Fig. 20 Typical tension test fixture. For qualification of application or preproduction testing, either bend or torque testing can be substituted for tension testing.

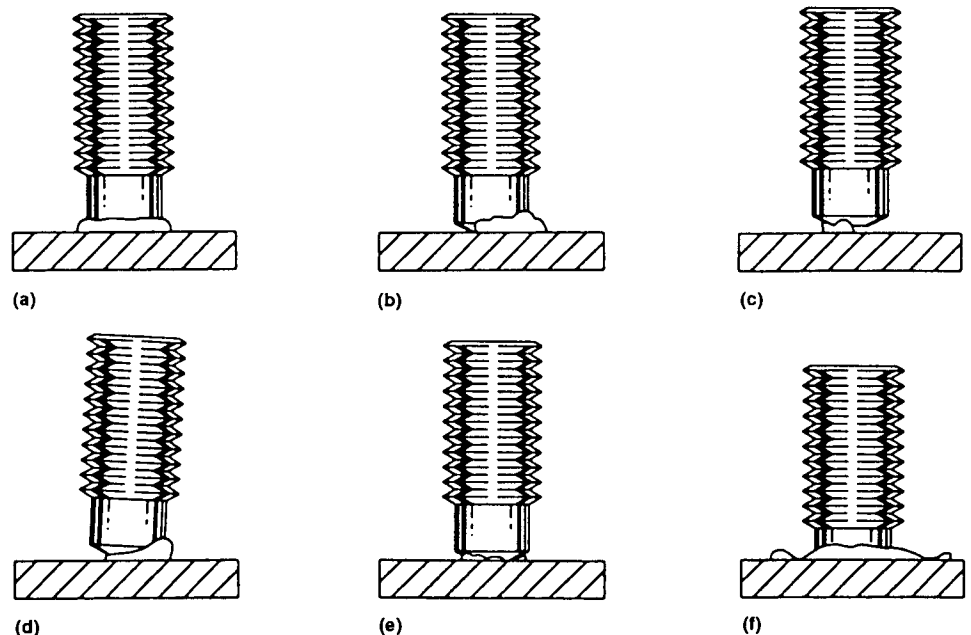

Fig. 21 Stud arc weld characteristics for satisfactory and unsatisfactory welds. (a) Satisfactory; good flash formation, wetting entire periphery of stud base. (b) Unsatisfactory; plunge too short, not enough material allowed for burn-off. Stud must project an adequate length beyond the ferrule. This condition can also be caused by bad grounding practice. (c) Unsatisfactory; hang up caused by inadequate arc length lift or by misalignment of stud, restricting free movement. (d) Unsatisfactory; misalignment of stud by poor gun position. (e) Unsatisfactory; cold weld, resulting in nonuniform or incomplete flash around stud periphery. (f) Unsatisfactory; hot weld, where molten material is expelled violently from weld, resulting in poor flash formation

welding temperature conditions, threaded studs should always be tested by torque, rather than by bending. Impact testing at low temperature produces brittle failures. This is not a function of weld quality but of the ambient temperature at the time of welding and testing. Data resulting from extensive tests conducted on studs welded and tested at various temperatures have shown that it is the temperature and manner of testing that influences the failure mode, rather than the temperature at the time of welding (Ref 8).

Another factor, besides temperature, that can affect weld quality is cleanliness of the weld area. Although stud arc welding does provide some cleaning action during welding, it is not sufficient to remove heavy contaminants. Coatings or rust on studs also can cause poor welds. Plating, except for a copper flash, nickel plating, or chromium plating, should be removed from the stud end prior to welding. This includes such materials as paint, zinc, and cadmium. Stud arc welded fasteners are usually capped during plating so that the weld end is left clean.

The plating or contaminant removal methods should be compatible with the base-material thickness and composition. For example, a heavy paint or rust cover on thick structural steel can be removed by grinding, needle scaling, sand blasting, or chipping, and the weld surface will still be acceptable for stud welding. Stainless steel, brass, aluminum; or other polished surfaces should be cleaned with appropriate solvents or other cleaning methods that will not destroy the material finish or contaminate the weld area. For example, a carbon-steel wire wheel or brush should not be used to clean stainless steel or aluminum-base material.

Studs and ferrules should be kept clean and dry prior to welding. Although cold conditions will not adversely affect either, they should be protected from exposure to adverse weather conditions, high humidity, marine atmospheres, and other extremes. When ferrules absorb water, the steam generated during the welding process can cause very poor welds and excessive weld spatter. Ferrules exposed to moisture should be oven dried at a temperature between 101 and 120 °C (215 and 250 °F) for 2 h before use.

The condition of weld cables, connections, and ground clamps can affect weld quality. These items should be checked frequently and either repaired or replaced, so that the cables are not frayed, connections are tight and clean, and ground clamps are properly functioning. Ground clamps should be tightly connected to the work-piece or work platen and attached to areas that have been cleaned of all deleterious materials that would prevent good current flow.

Stud-Welding Safety Precautions

Any welding process can be dangerous if proper safety precautions are not followed.

Equipment should be properly installed according to the directions of the manufacturer and maintained in good condition. Operators should be thoroughly trained in the use of the stud-welding process. They also should be familiar with the installation, operation, and maintenance procedures for the equipment being used.

Electrical shock is a potential cause of injury or death. Stud-welding systems should be properly installed and grounded using electrical connections made according to national (Ref 9) and local code guidelines.

Neither operators nor anyone else in the welding area should ever touch live electrical parts, or weld in wet areas, or wear wet gloves or clothing. In addition, all workers should ensure that they are insulated from shock.

All electric cables and connections should be kept in good condition. They should be inspected on a regular basis and frayed sections, broken insulation, or broken connectors should be repaired or replaced at once. Stud welding frequently uses long cable lengths, particularly on construction sites, where the cables are subject to abuse by tow-motors, trucks, material storage, or foot traffic. It should be ensured that these conditions do not result in cable damage.

Although weld spatter and arc flash are minimal with the stud-welding process, they do occur and precautions should be taken. All combustible or volatile materials should be removed from the weld area so that sparks or spatter cannot reach them. Gas cylinders should be stored and secured properly and checked to ensure that they do not contact any electrical cables in the welding circuit. Proper protective clothing should be worn, including boots, aprons, and gloves, as necessary. Eye protection is always necessary. Eye glasses with spectacle frames, side shields, and lenses with shade number three absorption filters should be worn by the operator at all times (Ref 10). Helpers or workers within 1.5 m (5 ft) of the weld area also should wear clear safety glasses with side shields. Fire-suppression equipment should be available in or adjacent to the weld area for immediate use in emergencies.

Ventilation of the welding area is necessary. Fumes from welding and cleaning materials, such as solvents, as well as paints, epoxies, and galvanizing or other coatings, can be harmful. Ventilation can be either forced or natural, depending on the job conditions. Material suppliers should provide material safety data sheets on any items being used in the welding area, and proper precautions for potentially dangerous contents should be followed.

Pinch points where fingers or hands can be caught should be avoided during material handling or where moving parts are involved in the welding process.

The instructions of the manufacturer should be followed when maintaining and servicing

the stud-welding equipment. If possible, all electric supplies should be disconnected and locked out during maintenance or troubleshooting work.

Finally, certain welding operations produce elevated noise levels during the weld cycle. Operators and other workers near the equipment should use hearing protection that can adequately protect them, in accordance with Ref 11.

Capacitor Discharge Stud Welding*

CAPACITOR DISCHARGE STUD WELDING is a stud arc welding process in which the tip of the stud melts almost instantly when energy stored in capacitors is discharged through it. The three basic modes of capacitor discharge (CD) stud welding are initial-gap welding, initial-contact welding, and drawn-arc welding. Figure 1 shows current-versus-time curves for the three process variations.

The initial-gap mode (Fig. 2) is begun with the stud held away from the work surface by the welding head. At the beginning of the weld cycle, the stud is forced against the work surface, melting the tip, the face of the stud, and the adjoining work surface upon contact with the work surface. The weld is completed using the gun forces (i.e., spring pressure or air pressure) to plunge the stud into the molten materials, forming a strong welded bond between the stud and the work surface. The weld cycle time (Fig. 1) for this process is from 4 to 6 ms, and the penetration of the weld zone into the work surface is normally from 0.10 to 0.15 mm (0.004 to 0.006 in.).

Fig. 1 Typical current-versus-time curves for the three capacitor discharge stud welding methods. Source: Ref 1

The initial-contact mode (Fig. 3) begins with the weld stud in contact with the work surface. The weld cycle is initiated with a surge of current that disintegrates the weld tip, thus melting the stud face area and the work surface that it immediately contacts. The stud is forced into the molten material, forming a strong homogeneous weld. This process has a weld cycle time of approximately 6 ms, much like the gap process.

The drawn-arc mode (Fig. 4) begins with the stud in contact with the work surface. When the weld cycle is initiated, a current surge is applied to the weld tip and the stud is retracted from the work surface, drawing an arc that melts the face of the stud and the work surface directly beneath it. The stud is then plunged into the molten pool of material, forming a welded connection. The weld cycle time for this process is longer than for the other two processes, and the heat-affected zone is thicker than it is in the preceding two processes.

Advantages and Disadvantages. A major reason for using the CD stud-welding process is that it provides a strong welded fastener with either a minimum or no reverse side marking of the work material. Another reason is that it is cost-effective, especially for small-diameter fasteners. This process also allows fasteners to be welded to very thin sections of work material, as well as to thick sections (as thick as necessary), with reliable results. Furthermore, the process allows the welding of many dissimilar material combinations, such as aluminum studs to zinc die castings. The disadvantages of using the CD process are the limited stud diameters available and the fact that the work surface must be clean of mill scale, dirt, oxidation products, and oil.

Applications

The CD process is normally used for fastener sizes of 4-40 through 1/4-20, with lengths from 6.4 to 38.1 mm (1/4 to 1.5 in.). Although there are limited uses of 1/16-18 and 3/8-16 diameter studs in special applications, only the more-common stud diameters are considered in this article. The work material thickness can typically range from 0.25 mm (0.010 in.) to as thick as the application requires. The determining factors for making successful welds are the stud diameter, the materials being used, the strength required, and the amount of allowable reverse side marking. See Table 1 for guidance on the expected strength parameters.

The stud and workpiece materials can be common low-carbon steel, stainless steel, or aluminum. Also used are medium-carbon steel, lead-free brass and copper, Inconel, titanium, René 41, zirconium, gold, silver, and platinum. Table 2 shows some of the more popular combinations of materials. Various studs and plate materials can be combined, except when aluminum-base material is used.

Capacitor discharge stud welding is used in many industries in a large variety of applications because it is one of the most versatile and reliable processes available. The food processing industry uses this process on stainless steel utensils and machinery, aluminum

Table 1 Standard capacitor discharge stud fastener load strengths

Stud material	Stud size	Maximum fastening torque(a)		Ultimate tensile load		Maximum shear load

cookware, and appliances. The aerospace industry applies the process to aircraft engines, aircraft parts and instrument areas, and components for outer space vehicles. The appliance industry uses CD welding for its cabinets, trims, and other components. The building industry uses it for doors, facia, subassemblies, and other exposed finished areas. The insulation industry uses it in securing insulation to heating and air conditioning duct work, as well as on apparatus at power plants, schools, and other major buildings. The automotive industry uses the process to secure trim and various components to cars and trucks. The ship-building industry uses it in fabricating components in

ship kitchens, in insulation applications aboard ship, and in other areas where components and instruments must be secured. The electrical industry uses this process when securing components inside various controllers and equipment, as well as in trim parts for cabinets. The sign industry uses it on both structural and component members of large and small signs.

Equipment

The equipment used for CD stud welding can be either portable or stationary production-type

units. The portable units consist of the basic controller that uses standard 110 V alternating current (ac) power input to charge the capacitors and a lightweight gun-shaped tool used for placing and welding the fasteners. The production-type units typically require 240/480 V ac three-phase incoming power and a compressed air supply. The production units are normally used for higher rates of productivity, close-tolerance work (down to ±0.13 mm, or 0.005 in.), critical reverse side marking requirements, automatic stud feeding, automatic feeding of the part to be welded, automatic location of the stud on the part, and exotic materials.

The production rate of portable equipment normally ranges from 4 to 6 studs/min, depending on the application. Material handling and other factors could cause this rate to be either slower or faster. The production rates for the permanent production equipment can range from 3 to 20 studs/min, depending on the application, special requirements, and tooling.

When the initial-gap or initial-contact modes of stud welding are used, welds are made on all materials without the use of shielding gases or ceramic arc shields. When using the drawn-arc mode while working with aluminum, a shielding gas would be necessary. This mode is also less flexible when working with exotic materials.

Personnel Responsibilities

The CD stud-welding process is easy to operate and maintain. The operator must first ensure that his unit is connected to the proper incoming voltage. The operator then determines whether the weld gun is connected to the negative and the ground is connected to the positive. Straight polarity is used for welding in nearly all applications. The operator places a given diameter of fastener into the stud gun. The gun is then placed on the work surface. The operator closes the trigger of the gun and the welding process begins. After the welding process is completed, the operator lifts the gun off the welded stud.

The operator needs to inspect the welds to ensure that the settings were correct. The controller voltage, which is set according to the recommendations of the equipment manufacturer, depends on the material and diameter of the fastener to be welded, as well as on the thickness and type of base material being used.

There are also other parameters that should be considered. If it is desirable to reduce spatter and smoky conditions in the weld area, then wetting the weld area with a wetting agent just prior to making the weld is recommended. If a wetting agent is used, then it is best to add a few drops of liquid hand soap to a pint of plain water and to spray or brush the solution into the

weld area. This will produce a clean weld with reduced, if not eliminated, spatter in the weld area. However, the noise of welding increases when a wet weld is made.

Weld inspection is normally done by bending the fastener by applying either a torque or tensile force to it. If a tensile force is applied, then care should be given to the diameter of the hole used to secure the plate material. A hole that is as small as possible should be used to accommodate the flange of the stud. If a large hole is used, the tensile factors may be reduced, because the plate material could yield prematurely. Prior to production welding,

it is recommended that sample welds be made on similar materials and tested to destruction. During production, operators should visually inspect the welds periodically. If weld inconsistency occurs, the process should cease, and the cause should be determined and eliminated.

A common occurrence that contributes to inconsistency is movement of the plate material during the short weld cycle. This can occur when working with materials that are less than 3.2 mm (0.125 in.) thick. There should not be a gap between the workpiece and the backup material of the fixture or table being used.

Proper fixtures and attention to their clamping system can alleviate this problem.

Introduction to Resistance Welding

RESISTANCE WELDING (RW), invented in 1886 by Professor Elihu Thomson, is conceptually one of the simplest and most commonplace of welding processes. When an electric current flows through a conductive material, such as a pure metal or alloy, there is some inherent resistance to the free flow of electrons through the conductor. Mathematically stated, the thermal power (dQ/dt) produced when current (I) flows through a conductor of resistance R is given by $dQ/dt = I^2R$, where the unit of power is watts (or Joules/second). This production of thermal energy is formally known as Joule heating, or informally as I^2R heating. The process is most commonly used to weld two overlapping sheets or plates.

In a resistance weld, the local rate of Joule heating exceeds the rate at which heat can be dissipated by or from the workpieces being joined. The resulting increase in temperature may cause melting or merely heat the parts sufficiently to allow forging them together into a solid-state weld. In practice, a pair of electrodes clamps the workpieces together under controlled pressure. The electrodes conduct electrical current to the workpieces from the power supply, promote good local contact between the workpieces (both mechanical and electrical), and precisely constrict the flow of current to the joint location. The electrode pressure also acts to contain any molten metal produced at the joint location, impeding it from being expelled from the joint, which would result in gross porosity. Finally, the electrodes (which may be water cooled) extract the welding heat, promoting rapid cooling of the joint.

Resistance welding encompasses many variations on the basic theme of local Joule heating while an external pressure is applied. This article introduces some aspects of the most generally applied RW processes, followed by separate articles on specific RW processes, power supplies, procedure development, and quality control. In addition, while the dominant heating mechanism in all RW processes is Joule heating, there are also some secondary thermoelectric effects that may apply in specific instances (see the section “Overlooked Fundamentals of Resistance Welding” in this article).

Resistance Welding Processes

William Mohr, Edison Welding Institute

As noted previously, the rate of heat production (dQ/dt) during Joule heating is proportional to I^2R . The resistance depends on the material and is also a function of temperature. The electrical resistivity of metals and alloys usually increases greatly when they are heated. For instance, the resistivity of steel can increase by a factor of 10 or more from room temperature to 800 °C (1470 °F). So, passing current through a locally hot material tends to further heat the hottest regions. Because current flow is necessary to the process, highly resistive materials, such as ceramics, are not good candidates for RW (as explained by Ohm’s law in the form $I = E/R$). Such materials require lethal voltages to generate sufficient current. Low-resistivity materials, such as copper, where excessive current is required for sufficient heating, are also not good candidates for RW.

Pressure is applied even before the current is activated to ensure good electrical contact between the workpieces. Accurate control and timing of the electric current and application of pressure is an essential feature of RW. The actual temperature rise at the joint depends on the interrelationship of the three variables: current (squared), resistance (as a function of temperature and position), and the time duration of current flow. These variables are further affected by:

- Cooling effect of the electrodes
- Effect of electrode follow-up behavior on resistance (at the various interfaces)
- Effect of current shunting, where the current flow takes another path rather than through the desired weld area

An example of current shunting can occur when a thick section is being welded to a thinner section by indirect spot welding (see the article “Resistance Spot Welding” in this Volume). Current shunting also can occur through nearby previous welds when welds are close together. As the second weld heats up with an increase of

resistance, more of the current preferentially can go through the previous weld, which has a lower resistance through the section.

During RW, initial electrical heating typically occurs due to the higher resistance of the interface between the parts to be joined, rather than the base metals or the electrodes or the connections of the electrodes to the base metal. This resistance can come from surface roughness between the parts or from surface coatings. In some processes, the resistance can be provided by the shape of the parts to be joined or, rarely, by the resistance of one of the base metals.

Resistance-welded joints require cooler metal around the heated area to restrain the expansion of the hot area, whether or not it becomes molten. The strength of the bond also depends on the cleanliness of the mating surfaces, although the process is more tolerant of the presence of oxide layers and contaminants than other welding processes. Resistance welding processes require specialized machinery, but they have the major advantages of not requiring filler metals, shielding gases, or flux.

The three major RW processes are resistance spot welding, resistance seam welding, and projection welding. Other methods of RW include:

- Upset welding is a solid-state variation of RW. Rather than fusion (melting followed by coalescence), the primary method of creating a joint during upset welding is on forging (“upsetting”) with some resistance heating to improve plastic deformation during upsetting.
- Flash welding creates the heat for welding at the faying surfaces of the joint not only by resistance to the flow of electric current but also by arcing (“flashing”) across the interface (see the article “Flash and Upset Welding” in this Volume).
- Capacitor discharge stud welding, where a stud serves as a weld member, is a process similar to flash welding.
- High-frequency RW concentrates the surface current of the part to heat the base metal and cause the coalescence of metal.

These processes are described in more detail in separate articles in this Volume.

Types of Resistance Welds

Resistance welds must allow for the passage of electrical current to provide heating of the interface to be joined and for force to constrain the heated material and form the bond as it cools. This section briefly reviews some of the general design aspects of resistance-welded joints. Most of the processes discussed as follows are used for lap joints, where the weld joins faces of the material rather than edges.

Spot welds are most easily made between identical materials of the same thickness, employing identical electrodes on both sides, because this allows the heating to be symmetrically generated in each workpiece. Symmetrical heat balance such as this is advantageous because it locates the center of the molten zone on the interface between the sheets.

Spot welds can be made in series with more than two sheets joined in a single event. This requires attention to the surface condition of the faying surfaces to get the resistance at each of the multiple interfaces to be broadly similar. Welding of more than two sheet layers is most easily performed with thinner outside sheets and a thicker center sheet, because the heating profile at the two interfaces between thin-thick sections would be more uniform (see the article "Resistance Spot Welding" in this Volume for a schematic of the temperature profile across a spot weld).

When RW of workpieces that are not inherently heat balanced, the electrode combination can be changed to localize the heat more toward one side of the stack. Effects can be obtained from using a larger-diameter electrode on one side or a higher-conductivity material on that side. Another process change that can also improve the situation includes heating the joint more rapidly (to increase the heating effect of the interfacial resistance over that of the bulk resistance of the workpieces).

It is often desirable to minimize the visible effect of the spot weld on one of the surfaces. The use of a larger electrode for that side or dividing the job of providing mechanical force and electrical current contact between two locations can be used for this (see the article "Resistance Spot Welding" in this Volume).

Seam welds provide fluid-tight lap welds that are often used for pressurized vessels with mild internal pressure, such as exhaust system catalytic converters for vehicles. They are created as a series of overlapping spot weld nuggets, with each nugget cooling before the following nugget is initiated.

Parameters that affect weld quality and integrity of resistance seam welds are the materials to be joined, their thicknesses, the overlap distance, the electrode width, and the access available for the electrodes. The electrodes are usually copper alloy disks or wheels, which roll along the intended seam, although a variation with conventional cylindrical spot welding electrodes has also been used (stitch welding). The required workpiece clamping force is provided by the electrodes rather than through

separate fixtures. The axis of rotation of one wheel may be slightly nonparallel to allow clearance of adjacent members, but the difference should not be more than 6° , and the contact surface will still need to be parallel to the surface of the workpiece it contacts.

The presence of adjacent spot weld nuggets allows much of the current to be shunted through the previous spots, so the welding parameters for seam welding tend to have much higher current pulses than spot welding, with other parameters such as electrode force changed to compensate for this.

Projection welds localize the heating for RW at the contact between the workpieces by employing a small raised bump or projection on one of the members being joined. This has an advantage compared to conventional spot welding for welding materials with low contact resistance, such as galvanized sheets and copper alloys, or in cases where the heat balance is severely skewed away from the faying surface, such as when one of the materials is much thicker than the other. Projections are usually placed in the thicker of two dissimilar pieces, on the basis that the thicker piece will be more difficult to melt at the faying surface.

The projection must be designed to remain raised during the initial heating phase of welding but soften and compress or collapse by the end of the welding cycle. Projection design is thus connected with the design of the heating cycle. The low elevated-temperature strength of aluminum alloys tends to make them unsuitable for projection welding.

For sheets, the spherical dome projection punched into the sheet is most common. Thicker parts will usually have machined projections, although they can be punched in moderate thicknesses. For some applications, such as crossed wires, the configuration of the mating parts already provides a sufficient projection.

Designs with extended or multiple projections can be used, even providing a continuous length of weld for pressure-retaining components. In circularly symmetric geometries, an annular projection may be used for its ability to provide a single-shot, fully circumferential joint, such as hermetic cans for transistors.

When using extended or multiple projections, the fit-up tolerance must be tightened so that all of the projection areas can participate equally.

Butt Welds. Resistance welding can be used to create butt joints rather than lap joints, using processes such as flash welding, upset welding, and high-frequency induction (HFI) welding, as is widely used for the production of welded tube. All of these processes require electrical heating and displacing the two sides of the joint toward one another.

Material will often be extruded at and near the bond line during resistance butt welding. Many applications require the removal of this flash, for instance, by a cutting operation just after completion of welding.

Design of the preweld geometry in these processes requires a determination of the shortening

between the current-carrying clamps to achieve the desired final dimensions of the welded component. The components of this shortening are the loss of material directly at the bond line (the material extruded into the flash) and the upsetting and thickening of the adjacent base metal. Flash welding, in particular, has a significant fraction of shortening occurring by loss of material at the bond line. An estimate of flash weld shortening for steels, both in tubular and bar form, is provided in Ref 1.

Some welding processes add plastic deformation processes after butt welding to provide an accurate size and shape to the final component. For instance, HFI tube will commonly be sized to an accurate outer diameter after welding.

Overlooked Fundamentals of Resistance Welding*

G.A. Knorovsky, Sandia National Laboratories

Much knowledge has been accumulated concerning many aspects of RW since its invention by Elihu Thomson in 1886. This work discusses two factors that have not been well documented in the standard reference texts. As noted earlier, the principal heat source in RW is Joule (I^2R) heating. However, there are other heating effects that may also occur during RW. The second factor discussed in this section is the effect of the current pulse on the subsequent motion of the welding head (the so-called electrode "follow" behavior). While both of these effects are often unimportant, they may become critical when the RW process is being applied at its limits. Examples taken from sheet metal and microwelding applications are given.

Thermoelectric Effects

Although Joule (I^2R) heating is the predominant heating mechanism acting in RW, two types of thermoelectric effects may also be operative: the Peltier effect and the Thomson effect. To combine all three effects, two different situations are examined: one typical of an industrial sheet-metal-type weld and one typical of an electrical interconnection.

Peltier Effect. The Peltier effect occurs when the flow of current through a bimetallic junction causes energy to be absorbed or released at that junction. The Peltier effect is the inverse of the more widely known thermocouple (Seebeck) effect, where temperature difference between the ends of a bimetallic pair of conductors

* Adapted from Overlooked Fundamentals of Resistance Welding, *The Metals Science of Joining*, 1992

causes an electric potential difference to occur. The Peltier effect is associated with changes in potential energy due to the different energy levels of conduction electrons within the two materials. When a conduction electron changes energy levels, it gains or loses potential energy.

Kinetic energy of the electrons is essentially constant, because it is governed by the (current) flow. The potential energy, gained or lost from the different energy levels of two materials, is converted into a thermal effect. Mathematically, the thermal effect from the Peltier-effect heat is expressed as:

$$dQ_p/dt = -\Pi_{ab}J$$

where dQ_p/dt is the rate of heat released (i.e., the thermal power) per unit area due to current flow from material "a" to material "b." The symbol Π_{ab} is the Peltier coefficient for current flow from material "a" to material "b." J is the current density (in units of amperes/unit area, as opposed to I , given in amperes).

In the Peltier effect, note that the heat effect can be either positive (release) or negative (absorption), depending on the direction of current flow. This is distinct from the Joule heating effect (dQ_j/dt), which is based on the square of current density (J^2), such that thermal energy is only positive ($dQ_j/dt = J^2\rho$) and therefore released. The release or absorption of some thermal energy, depending on current flow direction in the Peltier effect, is the explanation why direct current resistance welds are sometimes polarity sensitive (Ref 2). It also offers an explanation as to why one electrode usually wears faster than its nominally identical counterelectrode.

The Peltier coefficient is related to the Seebeck coefficient (the proportionality constant $S_{ab} = dV/dT$), which relates output voltage (V) to hot versus cold junction temperature difference (in degrees Kelvin) for a thermocouple of materials "a" and "b" by:

$$\Pi_{ab} = TS_{ab}$$

Hence, the Peltier effect tends to be more important at higher temperatures. Finally, while the Peltier coefficient for a bimetal pair is governed by both members of the junction, data are compiled for individual materials. The paired material coefficient is obtained by subtracting values of the individual material coefficients:

$$S_{ab} = S_b - S_a$$

Data are available (Ref 3) for pure materials, thermocouple materials, and other materials where the thermoelectric coefficients have been used to measure solid-state phenomena (dilute magnetic alloys). Unfortunately, thermoelectric data are not available for many commonly resistance-welded materials, such as aluminum alloys and stainless steels.

The Thomson effect (named after William Thomson, Lord Kelvin, not Elihu Thomson) is similar to the Peltier effect but instead acts in a single conductor and refers to heat absorbed or

released when electric current flows through a conductor that contains a temperature gradient. The explanation of these effects lies in the conservation of energy and how the energy levels of conduction electrons vary with location (such as when crossing a bimetallic interface, in the case of the Peltier effect) and temperature.

The Thomson effect is governed by:

$$dQ_t/dt = -\mu J\nabla T$$

where dQ_t/dt is the rate of heat release per unit volume, μ is the Thomson coefficient, J is the current density (a vector), and ∇T is the temperature gradient (also a vector). Absorption of heat (dQ_t/dt negative) occurs if the current flow and thermal gradient vectors are parallel and μ is positive.

Of the three thermoelectric-effect coefficients, the Thomson coefficient is the only one that can be measured directly for a single material. The three thermoelectric coefficients can be shown to be interrelated by:

$$\mu = T dS/dT$$

$$\Pi = TS$$

where T is the absolute temperature. Note that these relationships of the Thomson coefficient to the other thermoelectric coefficients (which really are only measurable in pairs), allow values of S and Π for single materials to be tabulated without arbitrarily defining one material to be of zero potential.

Relative Contributions of Joule, Peltier, and Thomson Effects. Given these three effects, what are their relative contributions for typical RW scenarios? Because the Peltier effect is two dimensional and the Joule and Thomson effects are three dimensional, it is difficult to compare all three directly. It is possible to compare the Joule and Thomson effects, because they can be combined into a single equation relating rate of heat production per unit volume to current:

$$dQ/dt = \rho J^2 - \mu J \cdot \nabla T$$

or alternatively:

$$dQ/dt = J(\rho J - \mu \nabla T)$$

Typical values of ρ range from ~ 1 to ~ 100 $\mu\Omega\text{cm}$ for metals (Ref 4), with copper at room temperature having a value of 1.6 and iron at 1000 °C (1830 °F) having a value of 110 (data beyond 1000 °C are hard to obtain). With typical welding currents, J has values in the range of 10 to 100 kA/cm^2 (Ref 5), and the product ρJ would then tend to range between 0.01 and 10 V/cm . Likewise, the absolute value of μ typically ranges from approximately 1.5 to 35 $\mu\text{V/K}$, while the temperature gradient (∇T) ranges from 0 to approximately 50,000 K/cm , and the product can vary from zero to ~ 1.5 V/cm .

Comparing the relative sizes of these two products, it is seen that under certain circumstances

the Joule heating can overwhelm the Thomson heating (or cooling), while in others the two can be comparable in magnitude. Because the Thomson coefficient (μ) and resistivity (ρ) are both of approximately the same magnitudes for common metals, whichever of the two is larger—current density or thermal gradient—will determine which effect predominates. Another important consideration is that both effects cause voltage drops, which must be isolated when trying to measure apparent resistance across a weld. In symmetrical geometries with differential measurements, the Thomson effect voltage should cancel; however, the Peltier effect may cause asymmetrical thermal gradients in apparently symmetrical geometries.

To compare the Joule and Peltier effects, it is necessary to realize that the Peltier heat is not a function of the volume of the material that the current is flowing through. That is, if a given current density flows through two sheets of steel, one of which is 10 cm (4 in.) thick and the other 1 cm (0.4 in.), the Joule heat released will be 10 times as great in the former. On the other hand, if the two sheets are different materials and a Peltier effect occurs, it will be the same no matter how thick the materials are. Thus, a good comparison between Joule and Peltier heating is to find the thickness of materials needed to release the same amount of energy via either mechanism. This is expressed by the equality:

$$|dQ_p/dt \text{ (in J/cm}^2\text{-s)}| = dQ_j/dt \text{ (in J/cm}^3\text{-s)}\Delta z$$

where Δz is the overall couple thickness in centimeters, or alternatively:

$$|\Pi_{ab}J| = J^2(\rho_a\Delta z_a + \rho_b\Delta z_b) = J^2(\rho_a + \rho_b)\Delta z/2$$

where the subscripts refer to the two materials in the couple (each of equal thickness), and thus:

$$\Pi_{ab} = J(\rho_a + \rho_b)\Delta z/2$$

and finally:

$$\Delta z = 2 \Pi_{ab}/[J(\rho_a + \rho_b)]$$

Picking a couple made of iron-copper, at 0 and 1000 °C (32 and 1830 °F) the appropriate constants and calculated Δz values are compiled in Table 1.

It is seen that while the thicknesses calculated are small, they are nonnegligible. Also, the thickness is inversely proportional to current density. For the example chosen, it appears that the effect decreases at elevated temperatures; this is not necessarily always the case. As a counterexample, choose a nickel-molybdenum couple, both of which have relatively large (and opposite sign) Peltier coefficients. The appropriate constants and calculated Δz values are compiled in Table 2. At 1000 °C (1830 °F), the Peltier heat for this couple is approximately twice as important as at 0 °C (32 °F). Again, note that the Peltier effect coefficient has units of a voltage, and it too can lead to measurement errors in nonsymmetrical situations.

Example 1 (Automotive). As an example illustrating all three effects, consider the case where two sheets of 1 mm (0.04 in.) thick low-carbon steel are to be joined. This is typical of an industrial sheet-metal-type weld (although a direct current power supply is assumed, rather than the more typical alternating current).

The Resistance Welder Manufacturers' Association's (RWMA) recommended practice (Ref 6) suggests an electrode contact spot of 0.635 cm (0.25 in.) diameter, 10 cycles of weld current of 9500 A, use of RWMA class 2 electrodes, and 2200 N (500 lbf) electrode force. This corresponds to a current density of 30,000 A/cm². There are no data for the thermoelectric coefficients of class 2 electrode material, so the data for pure copper are used. Similarly, the data for pure iron instead of low-carbon steel are used. In Fig. 1 and Table 3, values of heat generation are calculated for volumes of 1 cm² (0.16 in.²) cross section of the appropriate thickness. Only the left half of the weld geometry is pictured. The right half should be symmetric for the Joule effect and antisymmetric for the Peltier and Thomson effects. Temperature distributions are assumed, and calculations of heat effects are made at three points in time during the weld.

At the beginning of the weld (Fig. 1), the initial temperature is uniform at 0 °C (32 °F). At the start of melting, a linear temperature distribution exists between the central temperature at 1500 °C (2730 °F) and the electrode/material interface at 200 °C (390 °F). This then reduces linearly to 0 °C (32 °F) in the electrode material over a distance of 6.35 mm (0.25 in.). At the end of current flow, the melting isotherm is located ¾ of the part thickness from the centerline (the fusion zone is considered to be isothermal at 1500 °C, or 2730 °F), the electrode/material interface is at 400 °C (750 °F), and a linear temperature gradient exists between these points. The electrode material is again assumed

to cool linearly with a distance to 0 °C (32 °F) over 6.35 mm (0.25 in.).

The temperatures chosen at the electrode/part interface correspond to available data (Ref 7). Positive current is assumed to flow from left to right. A negative sign in Table 3 implies that heat is absorbed; positive indicates that heat is generated. The actual values used for the Thomson and Joule coefficients are averages over the temperature ranges applicable. If the coefficient was not well behaved (i.e., not continuous), an interval over which an average value was computed is noted. Wherever a calculation temperature exceeds 1000 °C (1830 °F), it has been extrapolated by curve fitting (except for the resistivity of iron).

Note that the signs of all Peltier and Thomson terms are reversed on the other side of the center line (C_l) and that there is no Peltier effect at the iron/iron interface. Also note that because of the nonmonotonic temperature dependencies of the Peltier and Thomson coefficients of iron, the Peltier and Thomson heat effect behave in a complex manner with temperature. Observing the results in Table 3, it is clear that the Joule effect is quite dominant under all conditions, with the thermoelectric effects never constituting more than a relatively small fraction of the overall heat production. From the viewpoint of efficiency, it is interesting to note that at the beginning of the weld, more heat is generated in the electrodes than in the weldment. (This is why RW electrodes are often water cooled.)

Example 2 (Battery Terminal). Another example, typical of an electrical interconnection, is a 0.1 mm (0.004 in.) nickel ribbon being joined to a 3 mm (0.12 in.) diameter by 4 mm (0.16 in.) high molybdenum terminal pin (typical of a long-life, lithium-containing, D-sized battery). Experiments designed to develop a weld schedule for this connection suggest that a current of 1800 A through an electrode

contact spot 2 mm (0.08 in.) in diameter (~60,000 A/cm²) for a time period of 20 ms will yield successful welds. A molybdenum electrode (negative polarity) contacts the nickel ribbon, and a copper alloy electrode contacts the molybdenum pin. An electrode force of 50 N (11 lbf) is used.

Because the weld geometry is not symmetrical, the entire geometrical sequence is shown in Table 4. Again, the values of power are calculated per cm² cross section of appropriate length, with temperatures assumed as follows. Initially, a uniform temperature of 0 °C (32 °F) exists; at the start of melting, the nickel/molybdenum weld interface is at 1450 °C (2640 °F), while the molybdenum/nickel electrode interface is at 1000 °C (1830 °F), and the molybdenum/copper weld interface is at 425 °C (795 °F) (the electrodes linearly cool to 0 °C over a distance of 5 mm, or 0.2 in.). At the end of current flow, melting has propagated from the nickel/molybdenum interface into the nickel ribbon to a distance of 0.075 mm (0.003 in.), the molybdenum/nickel electrode interface is at 1300 °C (2370 °F), and the molybdenum/copper electrode remains at 425 °C (795 °F). Interpolations between the points given are linear (Fig. 2), and the values calculated refer to averaged coefficients over the temperature ranges where gradients exist. Wherever a calculation temperature exceeds 1000 °C (1830 °F), it has been extrapolated by curve fitting (except for the resistivity of molybdenum). These simplified assumptions are based on some finite-difference calculations

Table 1 Resistivities, Peltier coefficients, and calculated equivalent Joule heat thickness for iron-copper couple

Metal	Coefficient					
	At 0 °C (32 °F)			At 1000 °C (1830 °F)		
	ρ, μΩcm	Π, μV	Δz, cm	ρ, μΩcm	Π, μV	Δz, cm

100,000 J, A/cm ²	0.01	0.02

Fig. 1 Example 1 geometry and thermal profiles

(Ref 8), which were qualitatively verified by metallography.

In comparison with example 1, these calculations are quite different. First, in contrast to the automotive sheet steel, where the electrodes were generally much better conductors than the weldment, here one of the electrodes dissipates nearly as much heat as the molybdenum terminal. This is not surprising, because it is the same material, sees approximately the same temperature range, and is about the same length. The data in Table 4 are not normalized for the electrodes and terminal pin versus the nickel ribbon (5, 4, and 0.1 mm, or 0.20, 0.16, and 0.004 in., respectively), which makes it hard to see that the Peltier and Thomson effects are really quite significant in this case. Dividing the electrode entries by 50 and the terminal pin entries by 40 does this, allowing the heating contributions to be compared on an equivolume basis. Such a comparison is fair only at the beginning, because otherwise the resistivity change with temperature is not correctly factored in.

The resistivity values used to calculate the electrode and terminal entries in Table 4 were averaged over the temperature intervals shown in Fig. 2, while the temperatures at the nickel/molybdenum and molybdenum/nickel interfaces are much higher, and hence, the resistivity

used to calculate the Joule effect heating should be higher. For the case of molybdenum, the resistivity changes by approximately an order of magnitude between 0 and 1450 °C (32 and 2640 °F). A reasonable comparison for the first melt and end values can then be made by multiplying the “begin” value by the resistivity change, with temperature divided by the thickness disparity, 10×/50× (or 10×/40× for the terminal) to see the Joule heating effect of molybdenum at temperatures near the melting point of nickel. For example, at the end of the weld, it is calculated that approximately 1850 J/s of heat are being supplied by Joule heating in a 0.1 mm (0.004 in.) thickness of the molybdenum electrode and terminal on either side of the nickel ribbon. The nickel ribbon itself is providing 6400 J/s of heat at the ribbon/terminal interface and 5600 J/s of cooling at the electrode/ribbon interface. It is clear that this will have a substantial effect on the thermal balance. The Thomson effect is also significant compared to Joule heating before the thermal gradients in the nickel ribbon begin to diminish.

Effect of the Interfacial Resistance. The interfacial resistance must also be considered to complete the analysis. Data from Ref 5 suggest that the surface contact resistivity for copper alloy versus mild steel at room temperature

is on the order of $7.7 \times 10^{-4} \Omega/\text{cm}^2$ ($1.25 \times 10^{-4} \Omega/\text{in.}^2$). This suggests that the initial heating rate at the surface (per cm^2) for example 1 is on the order of 700,000 J/s! This resistance would correspond to that of an iron bar of 1 cm^2 (0.16 in.^2) area nearly 90 cm (35 in.) long. Clearly, this rate cannot be sustained for long, because the surface asperities that constrict the current and are the main cause of surface resistivity will rapidly heat and collapse, causing the surface resistivity to drop to a small value.

Nevertheless, it is clear that the early stages of heating are overwhelmingly controlled by surface resistance. The nickel-to-molybdenum weld finite-difference calculations mentioned earlier that incorporated the Joule and Peltier effects also incorporated a surface resistivity term. These results, plotted in Fig. 3, clearly demonstrate the importance of both the surface resistance and the Peltier effect. Temperature-dependent physical properties were used, except that the Seebeck coefficient (which controls the Peltier coefficient) was held constant at an average value. Additionally, the surface resistivity (chosen as $100 \mu\Omega/\text{cm}^2$) was set to zero when the interface warmed to half the homologous melting point.

The calculated interfacial temperatures (both weld and electrode) show clearly that the initial temperature rise is independent of the polarity chosen, but that subsequent to reaching the melting temperature, the Peltier effect becomes evident. It was found that after the initial transient, the weld interface temperature for the wrong choice of polarity was less than the electrode interface temperature.

Electrode “Follow” Behavior

The second neglected fundamental discussed here deals with the requirements for assuring good electrode “follow” behavior. Normally, the recommended design to achieve good follow behavior involves the use of low-inertia welding heads. In reality, because an RW head acts like a sprung mass, much like an automobile suspension system, a more complicated specification involving damping is necessary.

Fig. 2 Example 2 geometry and thermal profiles

An appropriate analogy would be driving a high-performance sports car on a bumpy road with its shock absorbers (dampers) removed. With this automotive analogy in mind, it is clear that a low inertia is an insufficient design requirement for acceptable follow in resistance weld head design.

The dynamic model of a resistance weld head is illustrated in the simplified schematic of Fig. 4, showing the various masses, springs, and bearings. For complex real systems, analytical calculation of the motion of a given point or points is a complex and time-consuming procedure, even using available powerful finite-element analysis programs. Indeed, sometimes the best procedure is to perform an experimental modal analysis, and use the results to understand the various motions possible, their resonant frequencies, and their relative importance. This procedure, while involved, is greatly facilitated by the computerized analysis and modeling procedures now available to vibration specialists.

Modal analyses on small welding heads were far less common, certainly when the resistance welders commonly used in industry were developed. However, by examining the dynamic behavior of a simple linear single-degree-of-freedom spring-mass-damper system, considerable insight can be gained into the behavior of more complex systems. The mathematical analysis of such a system is well developed and tractable yet exhibits much of the character of the behavior of more complex systems. It is often observed that in multiple-degree-of-freedom systems, the lowest-order modes are dominant.

There are two important regimes in vibration analysis: forced and free. Forced vibration refers to a regime where the system is driven by a periodic external force. If the periodic force is sinusoidal, this is referred to as harmonic motion. An alternating-current-type welder, where current pulses occur at periodic intervals, would exemplify this regime. Free

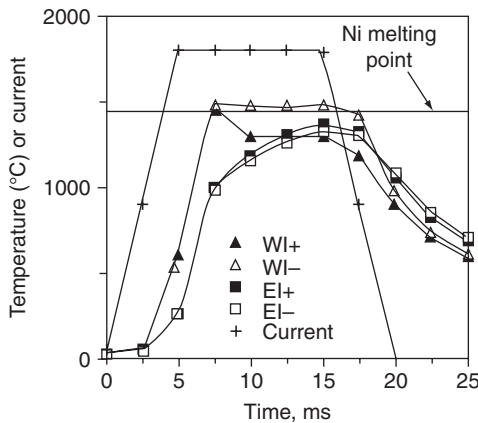

Fig. 3 Calculated temperatures at weld interface (WI) and electrode interfaces (EI) for geometry shown in Fig. 2 as a function of molybdenum electrode polarity

vibration refers to a situation where the system is given some initial stimulus to which it responds. A capacitive discharge or direct current welder is more characteristic of this type.

Referring to the simple single-degree-of-freedom system, the simplest type of free vibration to analyze is one where the system is removed from equilibrium (by stretching or compressing the spring) and then released. The solution of Newton's second law of motion in the form:

$$m \cdot (d^2x/dt^2) + b \cdot (dx/dt) + k \cdot x = 0$$

where m is mass, b is the damping coefficient, k is the spring constant, and subject to the appropriate boundary conditions, will describe how the system evolves with time. Many elementary texts on differential equations, for example Ref 9, use this as an introductory example of Laplace transformation solution methods.

The behavior of the system under conditions of underdamping, critical damping, and overdamping is shown in Fig. 5. While the rate of return to the equilibrium condition is fastest for the underdamped case, in many cases the oscillation is undesirable. For an undamped system, sinusoidal oscillation takes place at the so-called natural frequency of the system, which is given by:

$$f_a = (1/2\pi) \cdot (k/m)^{0.5}$$

For cases where less than a critical amount of damping takes place, oscillatory behavior still takes place, but the system eventually returns to equilibrium, and the damped natural frequency is slightly modified by the damping term:

$$f_d = f_n(1 - \zeta^2)^{0.5}$$

Fig. 4 Schematic of typical small resistance weld head

where $\zeta = b/(2[k/m]^{0.5})$. It can be shown that the logarithm of the ratio of successive amplitudes (the so-called logarithmic decrement; $\delta = \ln(\Delta x_i/\Delta x_{i+1})$, where Δx_i is the peak displacement from equilibrium for swing "i" in a given direction) can be used to conveniently measure the damping in a system via the equation:

$$\delta = \ln(\Delta x_i/\Delta x_{i+1}) = 2\pi\zeta/[(1 - \zeta^2)^{0.5}]$$

which simplifies to $\delta = 2\pi\zeta$ for $\zeta \sim 0.3$ or less.

When the critical amount of damping is present ($\zeta = 1$), oscillatory motion ceases, the system returns to equilibrium in the shortest period of time, and the natural frequency concept becomes irrelevant. Higher values of damping merely slow the return to equilibrium. Measurement of a typical small RW head in the author's laboratory gave a value of $\zeta \sim 0.09$.

The next most complex step involves shocking a system initially at equilibrium. If the shock involves applying a step function force (F_0), it may be shown (Ref 10) that the system responds as shown in Fig. 6. This situation is very close to what happens in a resistance welder, except that the force applied by the thermal expansion of the sample is not a square wave, and it decays to zero after some period of time. The ordinate of Fig. 6 is expressed in multiples of the equilibrium static displacement that the step force would produce. For insufficient damping, the dynamic response is nearly twice the static displacement that should result.

Fig. 5 Free response of system with variable damping. Upper curve is overdamped; oscillatory curve is underdamped.

Fig. 6 Time response of system to step function load F_0 applied at time zero. ω_n is $2\pi f_n$.

Another important method of displaying the resulting displacement of a system that has been shocked is the response spectrum curve. This shows the maximum displacement that will occur sometime during the response of an undamped single-degree-of-freedom system (although it does not show actual displacement versus time) as the time of application of the shock varies with respect to the natural period (inverse of the natural frequency) of the system. The response spectrum diagram of a half-cycle sinusoid is shown in Fig. 7. It is clear that in order to respond in an accurate manner (i.e., near the static response value or ordinate = 1), one must choose a value of $t/\tau_n > 2.3$. The value where $t/\tau_n = 1/3$ apparently gives the correct response magnitude, but it is delayed in time, with the response being achieved long after the shock is over.

The implication of these diagrams (an excellent compilation is given in Ref 11 along with actual time response curves) is that the time of application of the shock must be long with comparison to the natural period of response of the system. Furthermore, gentler shocks are more accurately followed, and the effect of damping is generally positive in controlling the overshoot of the system (as long as it is not excessive).

It has been known for many years in the field of camshaft design that the third derivative of displacement (sometimes called the "jerk") must be controlled (Ref 12) in order to have a positionally accurate motion control not prone to excessive vibration. (By making the assumptions of uniform I^2R heating and R linearly increasing with temperature, it is possible to relate expansion versus time to current versus time, from which it can be shown that the initial third derivative of the displacement is proportional to the square of the slope of current versus time.)

Also important is a cam ramp time that is long in comparison to the natural period of the cam follower mechanism, and a cam that is stiff enough to resist the force applied to it by the follower. Poor dynamic design of a cam and follower can lead to follower "jumping" or loss of control, even when the spring-loaded follower should be able to accelerate fast enough to follow the nominal acceleration profile of

Fig. 7 Response spectrum diagram to half-sine force input (shown inset). τ is the natural period of the system.

the cam. One other desirable feature is that enough damping must be present to damp out any vibrations generated before the system has to actuate again (i.e., during the dwell time when the cam is not actively controlling the motion of the follower).

Returning to RW, capacitive-discharge-type power supplies provide a very difficult shock load for a mechanical system to follow. From measurements made on a typical small welding head, the compliance and mass of the upper arm and its mounting slide result in a calculated natural frequency of only 25 Hz. However, this assumes that the slide carrying the upper electrode can actually move during the period of the weld. If one assumes a cantilever mount (i.e., the slide mount essentially remains motionless during the force application period) and relies on the elastic deflection of the electrode arm to follow the part expansion, then the natural frequency calculated from beam theory (Ref 10) is approximately 2.5 kHz. For a load application period of a few (1 to 5) milliseconds, this gives a ratio of t/τ_n of $(0.001 \text{ to } 0.005)/(1/2500) = 2.5 \text{ to } 12.5$, which is excellent—excellent, that is, for a gentle half-sinusoid load profile (or the even gentler classical cycloidal motion typical of camshafts). However, the deflection that must be accommodated by elastic bending of the electrode holder will cause the opposed electrodes to lose parallelism (similar to a rocker-type head, which the slide-type head was supposed to improve upon) and hence promote spatter because of nonuniform loading of the pressurized molten zone.

Even though forced vibrations have not been discussed, it is clear that for alternating-current-type power supplies, the natural mechanical response frequency of the system must not be too near twice the power frequency or any of its harmonics if a resonance situation is to be avoided. It is unfortunate that silicon-controlled rectifiers do not chop the tails off of sinusoidal current pulses rather than the beginnings, because chopped alternating current pulses are clearly not a gentle load to follow. Fortunately, each one is a relatively small contribution to the overall heat input.

To summarize, it is recommended that RW power supply and head designers should take a page from the book of camshaft designers. They should attempt to better tailor the electrical pulse (and the expansion resulting) to the capabilities of the mechanical system that must control it. Additionally, the effect of damping on the mechanical response of a resistance weld head needs to be further investigated if the initial measurements of it are indicative of general practice.

ACKNOWLEDGMENTS

In this work on certain important but often overlooked aspects of RW, the author of this

section would like to acknowledge, in particular, the assistance of A.J. Russo, for performing finite-difference calculations incorporating the Peltier and Thomson effects, and Arlo R. Nord, for conducting experimental modal vibration testing and analysis of small resistance weld heads. Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly-owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-AC04-94AL85000.

Resistance Welding Power Supplies and Controls

Donald F. Maatz, Jr. and Tom Morrisett, RoMan Engineering Services

HEAT DURING RESISTANCE WELDING is generated by the flow of electrical current through the parts being joined. The main process variables are welding current, welding time, electrode force, and electrode material and design. High welding currents are required to resistance heat and melt the base metal in a very short time. The time to make a single resistance weld is usually less than 1 s. For example, a typical practice for welding two pieces of 1.6 mm (1/16 in.) mild steel sheet requires a current of approximately 12,000 A and a time of 1/4 s, while 3.2 mm (1/8 in.) sheet requires approximately 19,000 A and 1/2 s.

The function of the direct current (dc) power source or alternating current (ac) transformer for resistance welding is to deliver a predetermined amplitude of current to the welding electrodes that are clamping the workpiece. Current flows from the power source to one electrode, through the workpiece to the opposing electrode, and returns to the power source. The electrodes concentrate current into a small, usually circular area. The flow of this constricted current generates heat, concentrated largely at the interface(s) of the workpiece details to be joined.

Heat Input

The rate of heating must be sufficiently intense to cause local electrode/workpiece interface melting. The opposed electrodes apply a pressure and, when sufficient melting has been achieved, the current is interrupted. Electrode force is maintained while the molten metal solidifies, producing a sound, strong weld.

If both the local resistance of the workpiece and the welding current magnitude were constant, then the total quantity of heat, Q , developed in the workpiece would be given (in joules) by:

$$Q = I^2 R t$$

(Eq 1)

where I is the effective value of current in amperes, R is the resistance of the workpiece in ohms, and t is the duration of flow of current in seconds.

However, the resistance is not constant. Contact resistances decrease in magnitude, and the bulk resistance of the work column increases as its temperature rises. Furthermore, resistance variations of the workpiece may cause variations in the current amplitude, depending on the nature of the power source. Under these circumstances, the total quantity of heat, Q , is given by:

$$Q = \int_0^t i^2 r \cdot dt$$

(Eq 2)

where i is the instantaneous value of current expressed as a function of time, and r is the instantaneous resistance that is changing with time, t .

Equipment

Equipment Selection. The design of resistance welding machines resembles that of a "C" frame press (Fig. 1). The power source

Fig. 1 Schematic showing primary components of a resistance welding machine

transformer secondary winding is connected to the electrodes on cantilevered arms, one of which provides for adjustable electrode force. Throat depth is the distance from the frame to the electrodes. Throat gap is the vertical distance between the two parallel secondary conductors. The total area of the secondary circuit (throat depth times throat gap, also known as the loop area) exerts a profound influence on output performance of an ac-operated welder. Any increase in inductance, whether due to geometry or magnetic materials within the secondary, will degrade performance and lower the power factor. Direct-current-operated welders are less susceptible to the loop area circuit inductance but nevertheless exhibit limited inductance effects.

The input to resistance welding power sources is usually 230 or 460 V utility power delivering single-phase or three-phase ac at 60 Hz. All systems require transformers to step down the line voltage to a relatively low value, with a proportional increase in current. The simplest systems consist of a transformer connected to single-phase power. More advanced sources produce a dc welding current through secondary rectification.

Single-Phase Systems. A single-phase system is shown in Fig. 2. The expected waveforms and current paths are also shown in this figure. Early single-phase systems employed ignitron tubes rather than silicon-controlled rectifiers (SCRs). The SCR began replacing ignitrons in the automotive industry as early as the late 1960s. By the 1970s, feedback systems for single-phase ac welders were available. A block

diagram for a single-phase ac welder with a feedback system is shown in Fig. 3. The earliest systems only employed local manual adjustment and were not available with remote adjustability, because this capability came about only after plantwide networks came into widespread usage. These early controls featured feedback systems that were based on an electronic signal feedback, such as the so-called dynamic resistance of the workpiece during welding, or simply systems that maintained a constant current or voltage at the workpiece. Later systems included the ability to "close the loop" around electrode displacement and other mechanical signals as well as the previously available electronic signals.

Older Rectification Systems. Single-phase dc systems have long been available. Figure 4 shows such a system and its expected waveforms for current and voltage at several places within the circuitry. These systems are based on ac weld controls, with the direct current brought about by rectification at the secondary of the welding transformer. The output current from this approach provided a direct current with a large "ac ripple," as also shown in Fig. 4. Welders with high secondary inductance provide lower ac ripple.

In primary rectification systems, a special three-phase transformer is designed with a very large iron core. Each dc pulse is limited in duration, and each is reversed in polarity to prevent saturation of the core. In the majority of applications, a weld is produced by a single impulse of direct current. For heavy gages, a pulsation

welding strategy consisting of a series of dc impulses of alternating polarity is separated by "cool time." The result is a very low-frequency alternating current. Hence, the term *frequency converter* is commonly applied to this type of power source. Figure 5 shows a three-phase half-wave primary rectified power source.

Secondary rectification systems are available in single-phase full-wave, three-phase half-wave, and three-phase full-wave forms; the latter is most commonly used. Three-phase full-wave systems consist of three single-phase transformers (or one three-phase transformer), with rectifiers connected to the secondary windings (Fig. 6). With this system, current pulse time is limited only by thermal considerations, and polarity is fixed.

The energy efficiency of a resistance welder depends on the efficiency of delivered energy at the electrodes. Energy is dissipated in the form of heat, because of resistance in the conductors. The current, I , which produces the heat of welding, is simply the secondary voltage divided by the total machine impedance, Z , plus that of the weld:

$$I = \frac{E}{Z} \quad (\text{Eq 3})$$

where Z is the vector sum of the resistance and the reactance:

$$Z = \sqrt{R^2 + X^2} = \sqrt{R^2 + (\omega L)^2} \quad (\text{Eq 4})$$

where R is the total resistance of the circuit, and $X = \omega L$ is the total reactance of the circuit (where ω equals $2\pi f$, where f is frequency, and L is the inductance).

Resistance welders designed for single-phase utility power are lowest in investment cost but highest in energy cost. The high-magnitude alternating current results in large inductive losses and a low power factor. Three-phase primary rectification and three-phase full-wave secondary rectification power sources reduce the power demand to approximately one-half and operate at a higher power factor.

The rapidly pulsing weld zone temperature inherent with a single-phase source is least desirable from a welding standpoint. In addition, copper electrodes deform from clamping impact, force, and heat, causing the occurrence of "mushrooming" (an increase in electrode contact area), which lowers current density. Mushrooming also reduces resistance in the current path. The welding current will increase because current is controlled indirectly in resistance welding machines by adjusting secondary voltage (that is, increasing or decreasing conduction time). See Fig. 7 for an example of changing conduction time. From Eq 3, a decrease in impedance causes an increase in the current. Therefore, all resistance in the work path influences the current magnitude produced by a given secondary voltage. This influence is small if total system impedance is high but significant if the system impedance is low.

Fig. 5 Circuit diagram of three-phase half-wave resistance welding power source with primary rectification

Fig. 6 Circuit diagram of three-phase full-wave resistance welding power source with secondary rectification

A three-phase primary rectification system exhibits the greatest degree of this self-compensating effect, followed to a somewhat lesser degree by the three-phase secondary rectification category.

Finally, a thermoelectric effect is associated with passing current from a copper alloy electrode to a workpiece of a given material. This phenomenon is important when welding aluminum or magnesium alloys with a single impulse. Reversing the current polarity for each successive weld, an inherent characteristic of the three-phase primary rectification system, provides the maximum electrode life between dressings.

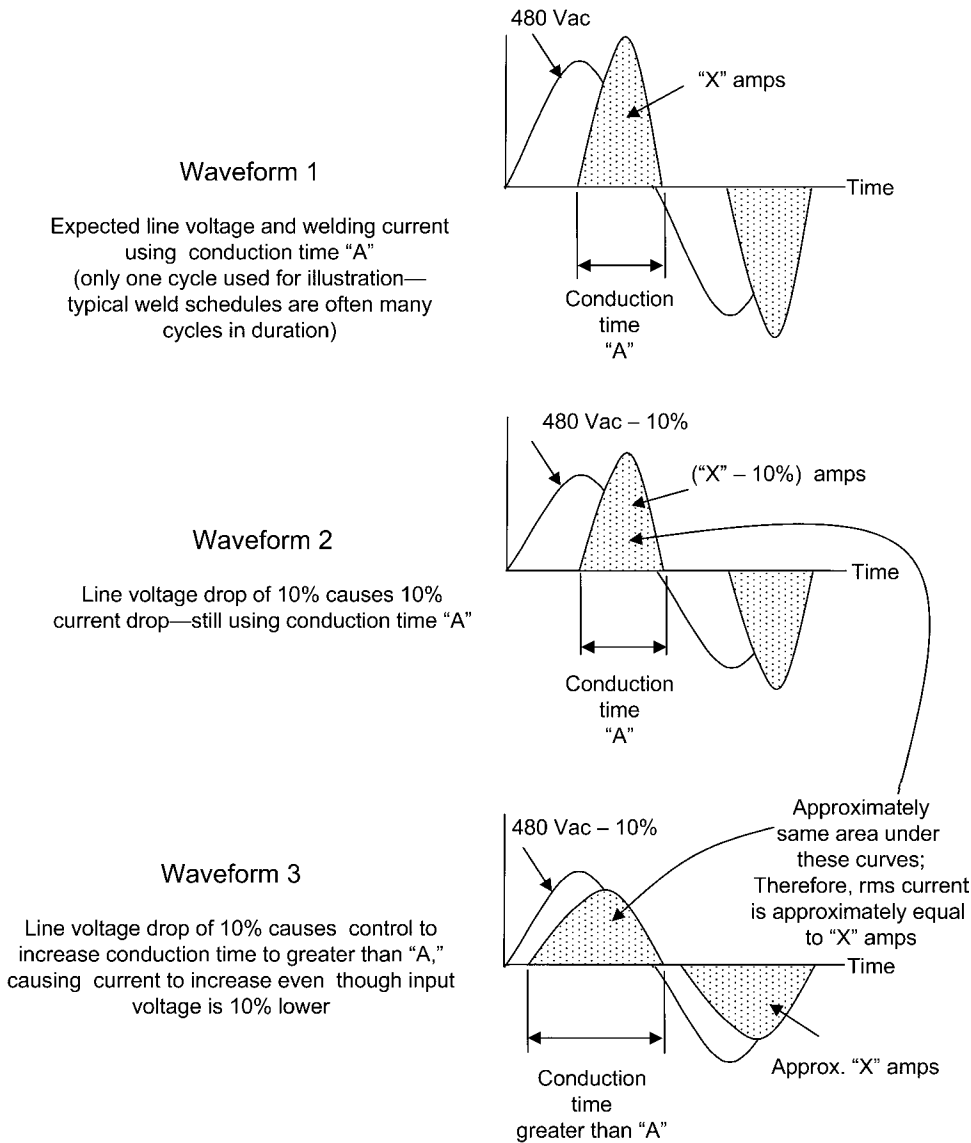

Fig. 7 Automatic voltage compensation example. Vac, volts alternating current; rms, root mean square

Newer Systems. Since the early-to-mid-1980s, newer technology has appeared that has transformed resistance welding control. Automatic voltage compensation (AVC, but known by many names) was one of the earliest feedback-type systems to be applied to large numbers of welding controls. Voltage compensation enables the welding control to take action when the input line voltage to the welder varies during the period welding is to be performed. Waveform 1 of Fig. 7 portrays the expected welding situation, where line voltage is shown as being 480 Vac, and the weld current driven in the welding transformer secondary is assumed to be "X" amperes. Waveform 2 shows an assumed instantaneous line voltage drop of 10%, resulting in weld current also dropping 10%. The AVC capability of a weld control monitors the input voltage and, in the

event of a short- or long-term voltage change, compensates for a loss (or rise) in anticipated welding current magnitude by changing the time period during which primary current is conducted through the welding transformer. In waveforms 1 and 2, the assumed conduction time is "A," meaning that for each half-cycle of weld time, the device that conducts current into the primary of the welding transformer will be on for a period equal to time "A." In waveform 3, the weld control, sensing the drop in input voltage, has increased this time to a level greater than "A," resulting in a longer half-cycle current duration but with a peak current level less than had been observed in waveform 1. The purpose of increasing the conduction time is to provide a root mean square (rms) current in waveform 3 that is equal to the rms current in waveform 1. In practice, this means that

the area under the current waveforms in waveform 1 and waveform 3 have equal areas.

By the mid-1980s, medium-frequency direct current (MFDC) controls were available. These controls provide direct current rather than the heretofore typical alternating welding current (Fig. 8). The MFDC name refers to the fact that a medium frequency (400 to 1200 Hz) is derived from the rectified three-phase power lines by using an inverter to generate an ac waveform. The medium-frequency waveform is then supplied to a specially wound welding transformer, which itself has a rectified secondary output, thus providing a dc welding current. Figure 8 shows the waveforms associated with each section of an MFDC welder.

Typically, MFDC welding controls also incorporate a feedback mechanism called constant current (CC) control. The CC responds to the actual current measurement in either the welding transformer primary or secondary circuit and can respond to dynamic changes in welding loop ac impedance (resistance to current flow in an ac circuit) or resistance in a dc welding loop. The AVC can monitor and respond only to the welding controls input voltage and is more limited in scope than the CC feedback system.

The CC level is usually entered into the weld control by the user as a setpoint. The setpoint can be manually entered but may be remotely entered by supervisory equipment, such as a programmable controller, robots, or other digital control systems/networks. The CC feedback system functions by comparing either the primary or secondary welding transformer current with the desired current setpoint (Fig. 9). If the measured weld current is below the control setpoint current level, the control automatically increases the output to force the measured current to match the setpoint current. Various weld control manufacturers use different software algorithms to achieve this result, and algorithms vary from relatively simple to rather complex.

The advantage of CC lies in the fact that power developed in the weld varies at the square of the welding current level. Therefore, a 10% drop from the required welding current level, if not corrected, will result in a 19% drop in weld power.

Constant current may also be used on ac weld controls, but the method suffers somewhat due to the limitations imposed by 60 Hz weld current adjustment. Typically, several weld cycles (16.67 ms per cycle at 60 Hz) must be measured prior to taking current modification action, and if the weld time is short (say 6 to 7 cycles), there is little time over which the control can compensate the measured current to match the setpoint current. Aggressive control action, such as attempting to achieve the desired current in a limited number of cycles, may cause overshoot (i.e., weld current in excess of the setpoint level) and hunting, where the weld current oscillates above and below the setpoint level. A nonaggressive algorithm may result in not achieving parity between current

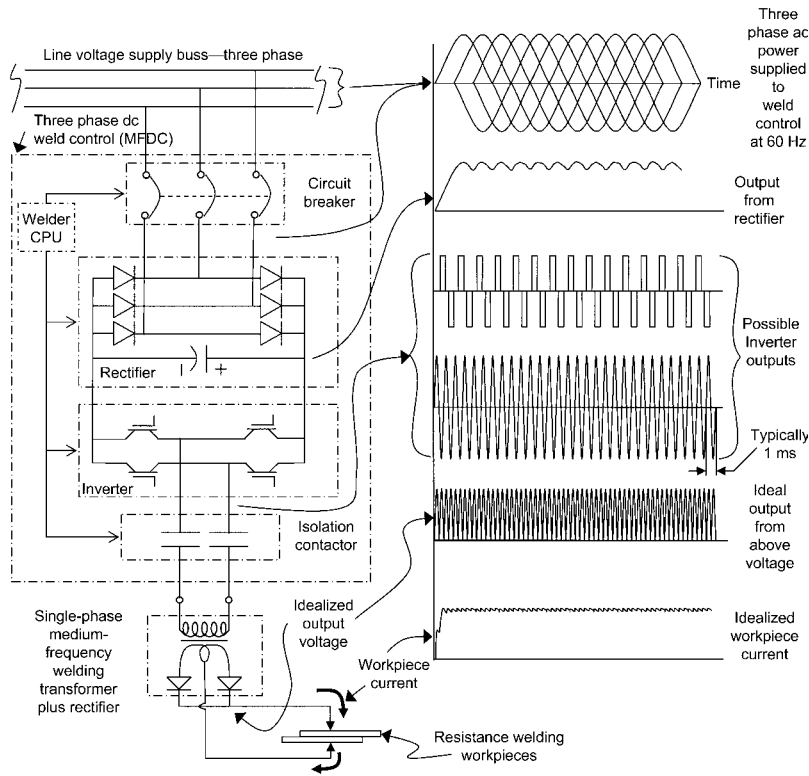

Fig. 8 Medium-frequency direct current (MFDC) resistance welding control block diagram and waveforms without feedback. CPU, central processing unit; ac, alternating current

measurement and setpoint within the weld time used to perform the weld. Because each weld control supplier typically has a proprietary method for adjusting their CC algorithm, minor differences in response may be expected.

Duty Cycle. Resistance welding is inherently an intermittent process with a series of very short current periods followed by “off” or “cool” periods. Therefore, this type of power source is rated on a 50% duty cycle and a 1 min integrating period. The relationship between kVA rating at 50% duty cycle and kVA demand at actual duty cycle is as follows:

$$kVA_{50\%} = kVA_{Demand} \sqrt{2 \cdot (D.C.)} \quad (Eq 5)$$

where D.C. is the duty cycle in percent, entered in the form of a decimal. Duty cycle is defined by:

$$D.C. = \frac{N \cdot T}{60 \cdot f} \quad (Eq 6)$$

where N is the number of welds per minute, T is the weld time in cycles, and f is the frequency in hertz.

Resistance Spot Welding

Murali D. Tumuluru, United States Steel Corporation

RESISTANCE SPOT WELDING (RSW) is a process in which faying surfaces are joined in one or more spots by the heat generated by resistance to the flow of electric current through workpieces that are held together under force by electrodes. The contacting surfaces in the region of current concentration are heated by a short-time pulse of low-voltage, high-amperage current to form a fused nugget of weld metal (Fig. 1). When the flow of current ceases, the electrode force is maintained while the weld metal rapidly cools and solidifies. The electrodes are retracted after each weld, which usually is completed in a fraction of a second.

In RSW, the weld nugget (melted and resolidified region) forms at the faying surfaces (Fig. 1) but does not extend completely to the outer surfaces. The weld should be at a sufficient distance from the edge of the workpiece (edge distance) so that there is enough base metal to withstand the electrode force and to ensure that the local distortion during welding does not allow expulsion of metal from the weld.

Resistance spot welding is a common form of resistance welding. Most ferrous alloys can be resistance spot welded if the appropriate equipment is used with suitable welding conditions. This is particularly true for thin sheet or strip steel products, whether uncoated or coated. Weldability and the thickness of the metals joined are key factors in determining whether two materials can be resistance spot

welded. Many nonferrous alloys can be resistance spot welded also, as indicated in Table 1.

Spot welding is the most widely used joining technique for the assembly of sheet metal products, such as automotive body-in-white assemblies, domestic appliances, furniture, building products, enclosures, and, to a limited extent, aircraft components. Many assemblies of two or more sheet metal stampings that do not require gastight or liquidtight joints can be more economically joined by high-speed RSW than by mechanical methods. Containers frequently are spot welded. The attachment of braces, brackets, pads, or clips to formed sheet metal parts such as cases, covers, bases, or trays is another common application of RSW.

Major advantages of spot welding include high operating speeds and suitability for automation and inclusion in high-production assembly lines as well as other manufacturing operations. Repetitive spot welding can be carried out by the use of robots, as is commonly done in automotive assembly plants. With automatic control of current, timing, and electrode force, sound spot welds can be produced consistently at high production rates and low unit labor costs using semiskilled operators. However, RSW is primarily used for sheet products generally ranging in thickness from 0.7 to 3 mm (0.03 to 0.12 in.). For RSW, accessibility from both sides of the joint is essential to be able to hold the workpieces and pass current

for welding. On-line nondestructive testing of resistance spot welds is still unreliable, and methods for nondestructive testing of joints are still evolving.

Process Description

The four basic resistance welding processes (spot, projection, seam, and flash welding) are

based on electrical resistance to build up the heat necessary to produce a weld. For a given current, the amount of heating is proportional to the electrical resistance (R) of the conductor, as shown in Fig. 2. Heating is greatest at the interface of the two surfaces being joined, because the resistance at the interface (R_i) is larger than the resistance of the metal (R_m) or at the surface contact resistance (R_c) between the metal and electrode. Heating of metals also typically increases resistivity and thus promotes more rapid heating.

In spot welding, the size and shape of the electrodes determine the size, shape, and

position of the weld nugget. For example, if the two electrodes have identical face diameter between two workpieces of equal thickness, the weld nugget forms exactly at the interface between the workpieces, and electrode indentation is equal on both sides (Fig. 3a). In contrast, if the upper electrode face has a large, flat area compared to the lower electrode face, current density on the top surface is reduced. This reduces the heating effect of the top electrode and concentrates the center of heating and the resultant weld nugget toward the smaller electrode face (Fig. 3b). Such a weld nugget may be appropriate if the top surface were an

appearance piece requiring minimum electrode indentation.

In another situation, heat imbalance is used to improve welds on workpieces of unequal thickness (Fig. 4). The lower electrode face is smaller than the upper, which ensures that the weld nugget will grow into the thinner workpiece. Without such imbalance, the nugget may grow entirely in the thicker of the two workpieces. Thus, various methods of spot welding are available to ensure solid welds despite the configuration of the workpieces.

The simplest type of spot weld is a direct, single-spot weld (Fig. 5). In a direct weld, the

Fig. 2 Resistance and heating profiles in spot welding. (a) The larger resistance at the interface (R_i) results in (b) greater heating and melting for a fusion weld at the interface between the two workpieces. R_c , surface contact resistance; R_m , resistance of the metal

welding current flows from the transformer to the electrode, through the weld to the second electrode, then back to the transformer. If the electrode cannot reach the bottom side of a workpiece, the one side of the transformer or an electrode may be connected to a mandrel or shunt bar, as shown in Fig. 5(b) and (c).

A series of direct spot welds also can be done when the two electrodes are connected to opposite ends of the transformer secondary but both contact the same workpiece (Fig. 6). Two welds are formed simultaneously with the same weld current. The current flows from one weld to the other through a copper shunt bar located below the lower workpiece. Series spot welds are done if the welding guns cannot reach the bottom side of a workpiece.

The disadvantage of a series weld occurs when the thicker section acts as the shunt (Fig. 6b) in dissimilar gage joining. Sixteen-gage steel sheet (1.52 mm, or 0.0598 in.) or heavier metal conducts too much of the secondary current through the top sheet, never allowing it to reach the weld interface to form a weld. This shunt current creates undesirable surface heating at the electrodes. Series welding is appropriate only for steel sheet metal of 18 gage (1.2 mm, or 0.0473 in.) or less. Therefore, when the top sheet is sixteen gage or heavier, indirect welding is used (Fig. 7). The heat balance during indirect welding is not as good as that in direct welding, but the method avoids the critical imbalance of series welding.

Fig. 4 Smaller electrode diameter to concentrate welding zone closer to a thinner section

Equipment

The equipment needed for RSW can be simple and inexpensive or complex and costly, depending on the degree of automation. Spot welding machines are composed of three principal elements:

- **Electrical circuit:** Consists of a welding transformer, tap switch, and a secondary circuit
- **Control circuit:** Initiates and times the duration of current flow and regulates the welding current
- **Mechanical system:** Consists of the frame, fixtures, and other devices that hold and clamp the workpiece and apply the welding force

Fig. 6 Series direct spot weld. (a) Good conduction through the shunt and formation of two welds. (b) Current shunting in heavier-gage top section, which prevents weld formation and causes overheating at the contact points of the two electrodes

Specifications for resistance welding equipment have been standardized by the Resistance Welding Manufacturers Alliance (RWMA), which is a subcommittee of the American Welding Society. The RWMA also issues specifications for resistance welding equipment.

The transformer used in direct energy resistance delivers the power to the workpiece by changing the input high-voltage, low-amperage, alternating current (ac) in the primary winding to a low-voltage, high-amperage current in the secondary winding (Fig. 8a). This system forms the basis of pedestal, or gun-type, welding machines, where the output of the secondary transformer is applied directly to the welding electrodes.

More complex secondary circuits and electrode configurations are for making single or multiple welds with multiwelder machines (see subsequent information). Multiwelder machines are used in various high-production industries, such as automotive or appliance and sheet metal assembly (Fig. 9). To minimize the size and cost of multiwelders, transformers can be designed with two or more secondary circuits supplied from the same primary circuit. This design is achieved by using transformers in which the primary current is supplied to two or more separate secondary windings.

Split or multiple secondary transformers are generally used to produce four or more welds at the same time. One controller is used for control of the timing and current supplied to the electrode, which means that it is not possible, under these circumstances, to achieve individual control or setting of the welding conditions for each pair of welding electrodes. Difficulties can arise in optimizing the necessary welding conditions to maximize the electrode life for each welding station under these conditions. In addition, the possibility exists for developing shunt currents, or an out-of-balance welding current, between each secondary circuit.

Power Supplies. Midfrequency direct current (MFDC) is the newest type of power source being used in the resistance welding industry. The frequency used in an MFDC power source is normally 1000 to 1200 Hz. The transformer secondary has diodes that

Fig. 5 Direct spot welding of single welds. (a) Electrodes directly above and below the weld zone. (b, c) Direct weld with conduction through a platen

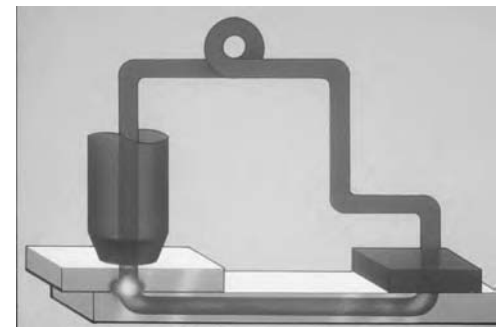

Fig. 7 Indirect spot weld. Current flows along the length of the bottom section (rather than through it, as in the case of direct spot welds).

convert current to 1000 to 1200 Hz direct current (dc) for welding. This type of power source was developed to reduce the size of the welding transformer, so that it could be incorporated into a welding gun that would go on the end of a robot. The reduction in the transformer size allows smaller robots to be used and improves the electrical efficiency over a standard 60 Hz ac power source. The improved electrical efficiency accounts for the popularity of MFDC power sources, especially in countries where

(a)

(b)

Fig. 8 Pedestal spot welder. (a) Schematic of primary and secondary transformer coils. Matteson, Taylor Winfield Technologies

power is expensive. The higher frequency makes better use of the transformer core, resulting in smaller-sized (therefore lighter) transformers.

An advantage of MFDC power sources is that the welding control cuts the waveform at a higher frequency. This allows for adjustment in the firing angle 20 times more often than in a 60 Hz system. The disadvantages of MFDC power sources are high cost and power limitations, both of which are improving every year. Seam welding is now becoming possible where spot welding had been the capability from a duty-cycle standpoint.

Secondary Impedance. The electrical characteristics of a spot welding machine are best defined in terms of their effect on the impedance of the secondary circuit. The latter is composed of two components:

- *Reactance:* Determined primarily by the depth and height of the throat of the machine and the amount of steel in the throat. Another critical factor is the frequency of the applied current.
- *Resistance:* Depends on the length and cross section of the conductors. Conductor material and operating temperature must also be considered.

Cables can be classified into three types: air-cooled jumper cables, water-cooled jumper cables, and kickless cables. In any application, it is necessary to ensure that the type and dimensions of cables are chosen to achieve the best balance between the total circuit resistance and the electrode life to be obtained with a multiple spot welder.

Single-Weld Configurations

Most pedestal and portable gun-welding machines employ direct welding, where the current flows directly through the welding electrodes and the workpiece to produce a single weld. In areas of difficult access, indirect welding may be necessary. Indirect welding is generally used when welding is carried out using either stationary or indexing welding guns and when access to the sheets being welded is limited to one side. In this case, the backing electrode generally consists of a large bar or platen, and the welding current flows from one side of the transformer secondary to the active electrode, through the welded area, and then along the platen/bar electrode or connecting jumper cable to the dummy electrode, which is connected to the other leg of the transformer secondary.

Higher welding currents are generally necessary when using dummy welding guns, which can lead to a shorter electrode life. The extent to which larger currents are required depends largely on the distance between the welding electrode and the dummy return electrode. In a multi-welder, this distance can be either fixed or variable, depending on whether a stationary or indexing head is used. Both types of welding heads can lead to losses due to stray current paths and extensive shunting of the current through jigs and fixtures. These factors must be considered in any design concept for a multiwelder station.

Two-Weld Configurations

Because of the need to minimize the number of transformers and the overall size and cost of

Fig. 9 Multigun welder with small double- and triple-piston air-operated guns and compact package transformers. Courtesy of R. Matteson, Taylor Winfield Technologies

a multiwelder, it is necessary to use configurations whereby two welds are made in one stroke of an electrode. Parallel, series, or push-pull welding configurations are used for this purpose.

In parallel welding, two or more direct welds, usually closely spaced, are made simultaneously with all upper electrodes connected to one side of the transformer and all bottom electrodes connected to the other side of the transformer (Fig. 10). Parallel welding has the advantage of lower shunt currents, thereby allowing shorter interweld spacings to be used. However, if two or more circuits are fed from a common transformer secondary winding, the current in each circuit will not be equal unless the impedances of each circuit are identical. This is often difficult to achieve in practice, and the electrode life obtained can therefore be different for each of the electrode pairs connected to the same transformer.

Series and Push-Pull Welding. As noted, two simultaneous welds can also be produced by means of series welding in which the secondary circuit is connected to two contoured electrodes that contact the workpiece from the same side, and a current backup bar/platen is used on the reverse side (Fig. 6a). Series spot welding circuitry ordinarily requires a large secondary loop because of the need for conducting the welding current around the large working area.

When direct welds are needed in the center of a deep workpiece, a set of transformers is used in a push-pull configuration (Fig. 11). The upper set of transformers matches the lower set, and it eliminates the need for long cable loops to the electrodes, resulting in lower secondary impedance. A longer electrode life can be obtained in push-pull welding compared to series welding.

It should also be noted that current shunting (Fig. 6b) between the electrodes occurs in both series and push-pull welding configurations, but to a lower extent in the latter. The magnitude of the shunt currents depends on interelectrode

distance and the type of material being welded. In all cases, current shunting will lead to a lower electrode life when welding zinc-coated steels, due to the need to use higher welding currents to compensate for the shunt currents (this can also lead to additional electrode sticking problems) and to the rapid falloff in weld size that occurs under conditions where current compensation is insufficient or nonexistent.

To some extent, the effects of both high secondary circuit impedance and current shunting can be overcome by using a constant-current facility fitted into the welding machine control circuit, but there is a limit to the effectiveness of these controls in a production situation. In addition, dc welding systems can be used in which secondary inductance/reactance effects are minimized. However, the effectiveness of using dc depends on the method used to develop the dc waveform and on the extent of the superimposed ac ripple on the dc waveform.

Machine Construction

Welding operations in highly automated production lines are based primarily on multiple spot welders and robotic cells. In addition, manual welding operations can be used to manufacture either subassemblies, which are fed into the main production/assembly lines, or, in many instances, finished products. These differing end uses require welding machines of varying designs and characteristics. The RSW machines can be divided into three basic types:

- Pedestal-type welding machines
- Portable welding guns
- Multiple spot welding machines incorporating lightweight gun welding units

Pedestal-type welding machines form the basis of most resistance spot or projection welding operations. Standard machines are either of the rocker arm type, as determined by the rocker action of the moving upper

electrode arm, or stationary, direct-acting machines. The latter outnumber the former because rocker arm machines are difficult to align due to the movement of the electrode in an arc motion. As the electrode wears, various skidding actions can be created between the upper and lower welding electrodes, depending on the extent of the electrode wear. This can change the point at which the electrodes meet relative to the fulcrum point of the moving arm. If the electrodes meet at a point above the fulcrum point, they have a tendency to slide outward from the machine. On the other hand, if the electrodes meet on a line below the fulcrum of the moving arm, the electrodes show a tendency to slide inward toward the machine. These relative movements can be different between the top and bottom electrodes, a consequence of which is a reduction in electrode life, particularly if welding coated steels. Other advantages of direct-acting machines include a lower electrode assembly mass, faster "followup" during welding, and a degree of rigidity that is impossible to obtain with an ordinary rocker arm machine. Press-type direct-acting machines have an upper electrode and welding head that move vertically in a straight line. The welding head is guided in bearings or guideways of sufficient proportion to withstand the offset loads imposed upon them. All of these factors tend to increase the electrode life obtained in a particular welding cell.

Portable welding guns are used in RSW when it is impractical or inconvenient to transport the work to the machine. The portable welding gun consists of water-cooled electrode holders, an air or hydraulic actuating cylinder, hand grips, and an initiating switch. The gun usually is suspended from an adjustable balancing unit, and the welding force is supplied by an air cylinder. Because of the high secondary losses of portable machines, transformers used in these machines have a secondary voltage two to four times as great as the voltage of transformers used in stationary machines of equal rating.

Fig. 10 Parallel welding for multiple spot welds with one transformer connected to multiple electrodes

Fig. 11 Two sets of push-pull transformer arrangements for direct spot welding

Welding current is transmitted between the transformer terminals and gun terminals through a secondary cable, usually of the low-impedance or kickless type. The reactance of this type of cable is near zero, which results in a high power factor and reduced kilovolt-ampere demand. For safety reasons, the current initiating switch is usually operated at low voltage. Recent developments in encapsulated transformers and high-speed fail-safe devices enable the transformer to be integral with the welding gun. This results in lower secondary losses and is particularly preferred in robotic applications.

Gun welders typical of portable manually operated and robotic welding cells can be classified into two basic types:

- S-type (scissors)
- J-type (direct action or C/J type)

Two important features that influence the performance of these types of welding guns are the rate of force buildup and the extent to which the arms of the gun deflect under load. These features characterize the welding gun in terms of rigidity and the mechanics involved in their operation. An S-type gun uses a lever action to transmit the force applied by the cylinder head to the welding electrodes. However, due to an unbalanced pivot point, the force measured at the electrodes is less than that applied at the cylinder. With J-type welding guns, the force applied by the pneumatic cylinder is transmitted directly to the welding electrode. The rigidity of the framework of the welding gun is characterized by the extent to which the electrode arms deflect on application of the electrode force. This is an important factor in determining weld quality and the amount of skidding that can occur between the two welding electrodes. It should be noted that extensive skidding can lead to elliptical welds and/or decreased electrode life.

Welding guns are typically actuated by pneumatic cylinders. The electrodes move the entire range of the cylinder when the gun opens and closes. Clamping force is normally controlled by a pressure regulator, and the electrode force is measured using load cells. Pneumatic guns typically have two cylinders; one is used for short opening and the other creates a full opening between the top and the bottom electrodes.

The new trend in welding guns is the use of motor-controlled servo guns. The servo gun can provide a predetermined electrode opening anywhere in the full range of gun travel. Electrode force can be programmed to any desired value during a welding cycle or can be varied from weld to weld and different material-thickness stackups. Pneumatic guns close at full clamping force, which creates a high impact force on the electrode tips. The servo gun controls the rate at which the electrodes come together. The servo gun can also ramp up to the clamping force at a predetermined rate

that can be programmed. This controlled movement of the electrode lessens the impact between the electrode and parts to be welded, thereby extending the electrode life. This is perhaps one big reason that automotive manufacturers have started using servo guns. Another advantage of servo guns is that they make it possible to use a combination of multicurrent and electrode force control. This makes it possible to control the heat input into the base materials, thereby achieving fusion between the sheets and, at the same time, preventing weld-metal expulsion. The use of multistep force control has made it possible to weld advanced high-strength steels (minimum tensile strength >590 MPa, or 85 ksi) and combinations of high- and low-strength steels as well as sheets of dissimilar thickness (Ref 1).

Welding Electrodes

Electrodes in RSW perform the following major functions:

- Conduct the welding current to the workpieces
- Transmit the amount of force needed to the workpieces in the weld area to produce a satisfactory weld
- Rapidly dissipate the heat from the weld zone

During the welding operation, the electrodes are subject to great compressive stresses at elevated temperature and must be frequently dressed and periodically replaced. Because the current conducted to the workpieces must remain localized within a fixed area, the electrodes must resist these stresses without excessive deformation or mushrooming. The electrode force, in addition to forging the heated workpieces together, influences the passage of current to the localized area.

Maintenance. The shape, dimensions, and surface condition of the electrode tips or contact surfaces are important for consistent weld quality in RSW. The shape and dimensions of electrode tips are affected by mechanical wear and deformation, or mushrooming, at a rate depending on tip material and design, operating temperatures, rates of heating and cooling (thermal shock), and welding force.

Alloying between the electrode tip and the work metal can greatly increase the rate of deterioration of the electrode tip. Deterioration is especially rapid when copper alloy electrodes are used in welding work metal coated with tin, zinc, or aluminum, which alloy readily with the electrode metal.

Careful attention to electrode tip condition is needed to avoid such defects as weak or missed welds, irregularly shaped welds, erratic indentation, burning or discoloration of the work surface, surface melting, and electrode deposits on the work surface. Electrode tips should be

dressed and replaced at scheduled intervals. Preventive maintenance is particularly important when multiple electrode holders are used to ensure uniformity of resistance of each spot.

Materials for RSW electrodes should have sufficiently high thermal and electrical conductivities and sufficiently low contact resistance to prevent burning of the workpiece surface or alloying at the electrode face. In addition, the electrode should have adequate strength to resist deformation at operating pressures and temperatures. Because the part of the electrode that contacts the workpiece becomes heated to high temperatures during welding, hardness and annealing temperatures must also be considered. Electrode materials for RSW have been classified by the RWMA (Ref 2) and in International Standards Organization (ISO) standard ISO 5821 (Ref 3).

When welding two sheets of thickness up to 3 mm (1/8 in.) using truncated cone-type electrodes, the electrode tip diameter should be determined from:

$$d_2 = \sqrt{t} \quad (\text{Eq 1})$$

where d_2 is the initial tip diameter (in millimeters), and t is the thickness (in millimeters) of the sheet in contact with the electrode. When using truncated cone electrodes, the initial or set-up weld diameter should be equal to the diameter of the electrode tip:

$$d = d_2 = 5\sqrt{t} \quad (\text{Eq 2})$$

where d is the weld diameter (in millimeters). When welding two sheets of dissimilar thicknesses, the electrode dimensions and the required weld size should be specified appropriate to the thinner sheet thickness. In the case of three thicknesses, the second-thinnest sheet should be used.

When using domed or pointed electrodes, Eq 1 may not apply, and the electrode dimensions will depend on accessibility and flange width. In this case, the electrode tip dimensions and welding conditions should be chosen to give an initial weld diameter as specified in Eq 2. Where a pad or mandrel is used as the second electrode, its surface must be maintained to match the profile of the work.

During normal production, electrodes tend to mushroom, leading to an increase in electrode tip size. According to trends in automotive industry practice and international standards, the diameter of at least one of the electrode tips should not normally be allowed to increase above a value that results in a reduction greater than 30% from the starting weld diameter during a production run. This is equivalent to an increase in the electrode diameter to $1.3d$. When this diameter has been reached, the electrode should be replaced or redressed to its original size and contour. To maintain weld integrity, it is important to maintain weld shape and size and to prevent electrode mushrooming

(widening of the electrode face). A direct relationship exists between the weld size and the weld strength, with the strength increasing as the weld size is increased. Electrode mushrooming happens with use and is accelerated by the use of higher electrode forces required to successfully weld high-strength steels. To maintain weld size above the minimum required value (typically taken as four times the square root of the thickness of the sheets being welded), electrodes should be frequently dressed. It has become a common practice with many automotive companies to dress the electrodes after every 30 welds. Another practice for maintaining weld size is to use current steppers. The current steppers allow for a gradual increase in welding current, typically after every 200 welds, to maintain constant current density at the electrode-sheet interface. The drawback of the use of steppers is that this practice assumes a certain electrode tip life and preprograms current increase at regular intervals. The use of frequent electrode tip dressing is a more efficient way to maintain consistent weld size than the use of current steppers. Many fabricators, especially in automotive body fabrication, have resorted to the practice of frequent electrode tip dressing to improve weld quality and reliability of manufacturing practice.

Electrode shapes have been standardized by the RWMA. Figure 12 shows the six standard face or nose shapes, identified by letters "A" through "F" (Ref 2). Electrodes with type A (pointed) tips are used in applications for which full-diameter tips are too wide. Type D (eccentric, formerly called offset) face is used in corners or close to upturned flanges. Special tools are available for dressing the electrode faces, either in or out of the welding machine. It should be noted that electrode shape classification in accordance with ISO 5821 (Ref 3) is totally different from that in the RWMA classification. Due to the increased globalization of procurement by various companies, the use of the ISO standard for specifying electrode shapes is becoming popular.

The dome-shaped electrode (type B) and the truncated cone (type E) are commonly used in the automotive industry. The present trend is to use the dome-shaped electrodes. The reason for the popularity of dome-shaped electrodes is that they tend to stabilize quickly when welding coated steels and thus produce a consistent weld size soon after stabilization. To compensate for changes in weld size when making welds with new electrodes, especially when welding coated steels, a weld-size stabilization procedure is typically employed during laboratory evaluation of weldability of steels. The stabilization procedure conditions the electrode faces, thus stabilizing the weld size and promoting reproducible test results. The electrode stabilization procedure consists of adjusting the welding current as needed to maintain a specified or desired weld size.

Electrode Coolant Parameters. Generally, it is recommended that the water flow to the electrodes be a minimum of 4 L/min (1.1 gal/min) for welding two uncoated steel sheets of thickness up to and including 3.0 mm ($\frac{1}{8}$ in.). Higher flow rates are recommended when welding coated steels. The internal water cooling feed tube should be arranged to ensure that the water impinges onto the back working face of the electrode. The distance between the back and the working face of the electrode should not exceed the values given in the appropriate ISO or RWMA standard. The inlet water temperature should not exceed 20 °C (70 °F), and the outlet temperature should not exceed 30 °C (85 °F). To maintain these temperature levels, the electrode cooling water supply should be independent of transformer and thyristor water cooling circuits. Separate water circuits should be used for both top and bottom electrodes. Insufficient water cooling can cause degradation of the electrode, and copper from the electrode can melt and enter the steel substrate. The presence of molten copper in contact with the steel substrate can cause what is known as liquid metal embrittlement cracking. This type of cracking occurs along prior-austenite grain boundaries in steel and lowers the weld integrity.

Effect of Surface Condition on Welding

The workpieces to be welded or, at a minimum, the faying surfaces should be cleaned to ensure that the welds are free of inclusions. Dirt, scale, rust, and oxide film that may come in contact with the electrodes should be removed or reduced to ensure good surface appearance of the welds. Also, removal of foreign substances from workpiece surfaces reduces electrode pickup and consequently increases electrode life.

Effect of Oil Coatings. Thin coatings of oil on cold rolled or hot rolled pickled and oiled steel have little effect on the quality of spot welds. Excessive amounts of oil should be wiped off or removed in a degreasing operation. The oil itself may not be detrimental to the weld, but the dirt and other contaminants adhering to the oil may cause poor welds.

Effect of Rust, Scale, or Oxide. Steel coated with rust, scale, or thermally produced black or blue oxide finishes can be resistance spot welded in production, but the quality and consistency of welds is lower than on steel from which these coatings have been removed. Thin films that have low and uniform electrical resistance have the smallest effect on welding. Steel that is coated with extremely thick and nonuniform mill scale may not be weldable on a practical production basis without first removing the scale (Ref 4).

Steel on which uniform but heavy mill scale or oxide coatings are present can be welded in production by applying low-to-medium current in a series of pulsations at fairly high electrode pressure. The electrical conductivity of mill scale or oxide increases with temperature, and these coatings become fairly good conductors when red hot. Because of the variable time needed to break through the coating and establish current flow, manual timing gives more satisfactory results than automatic timing.

When metal having heavy scale or oxide coatings is welded, much or all of the scale or coating on the faying surfaces remains in the welds, regardless of current, surface resistance, or electrode pressure. These inclusions in the weld metal can cause voids, blowholes, and other internal defects that may sometimes be difficult to detect.

Surface Preparation. A film of dirt or oil can be removed from the surfaces of the workpieces by vapor degreasers and chemical baths; however, careful hand wiping of the surfaces to be spot welded may be sufficient. Oxide films can be removed by mechanical methods; the action must be severe enough to cut through the film but must not be so severe as to cause the formation of a rough or scratched surface.

Where it is impractical to use pickled or cold rolled steel, the surfaces to be welded can be machined, ground, or wire brushed far enough back from the edge of the workpiece to clear the electrodes, or for a distance equal to the overlap. Heating to elevated temperatures in a

Fig. 12 Standard electrode face and nose shapes. Type D was formerly called offset.

reducing atmosphere is also an acceptable cleaning method for some metals.

Abrasive blast cleaning methods using sand, coarse grit, or shot usually are not satisfactory because particles of sand or scale are left embedded in the surface. Fine, sharp steel grit is satisfactory in some applications.

Evaluation Methods

Several tests are generally used to characterize the RSW behavior of steels and the integrity of spot welds. These include the welding current range determination, metallographic characterization of the weld and heat-affected zone microstructures, and microhardness and weld tensile tests (Ref 5, 6). Metallographic characterization and tensile tests are destructive tests intended to evaluate weld integrity as well. Visual examination and ultrasonic examination are nondestructive methods to evaluate weld integrity.

This section is a brief review of test methods as they pertain to the RSW method. A more detailed description of weld integrity criteria and test methods is provided in the article [5C] in this Volume on weld quality and evaluation methods.

Welding Behavior Evaluation

Welding current range is a useful parameter to assess the weldability of materials, particularly of steels. The current range is useful because it provides a range of welding currents over which welds with buttons of acceptable size can be produced. Welding current is the difference between the welding current required to produce a minimum weld size (I_{\min}) and the current that causes expulsion of weld metal (I_{\max}). Typically, the minimum weld size is defined as:

$$4\sqrt{t}$$

where t is the nominal sheet thickness. This parameter for minimum weld size is generally used in the automotive and steel industries.

The procedure to determine current range is described in detail in Ref 7. Test coupons measuring 140 by 50 mm (5.5 by 2.0 in.) are used in the current range determination. The coupons are overlapped by 25 mm (1.0 in.), and a shunt or anchor weld is made on one side of each coupon pair. On the other side, 35 mm (1.4 in.) from the edge, test welds are made. The test welds are peeled open, and the weld sizes are determined using calipers.

Current ranges are obtained by first determining the lowest welding current that produced the minimum acceptable weld size. Then, the current is gradually increased at typically 100 A increments, until weld-metal expulsion results. The difference between the current at the minimum weld size and the current at the expulsion weld size gives the current range.

The broader the current range exhibited by a material, the more robust the useful welding current range for the material. Note that the occurrence of weld-metal expulsion results in a loss of weld metal and reduces the weld size. This, in turn, lowers the load-bearing capability of the weld. Therefore, weld-metal expulsion should be avoided to maintain weld integrity.

Figure 13 shows a plot between welding current and the weld sizes for three grades of dual-phase steels. Dual-phase steels are a class of new advanced high-strength steel (AHSS) grades that have been developed for automotive applications to help automakers improve occupant protection and fuel economy. Dual-phase steels are considered AHSS to distinguish them from the conventional high-strength steels (HSS) or high-strength, low-alloy (HSLA) steels. The HSS types include HSLA steels and carbon-manganese steels of tensile strength up to 440 MPa (65 ksi). While the use of AHSS was nonexistent until 2001, it is anticipated that AHSS use in automotive bodies will climb to 50% by 2015 (Ref 8).

A welding force of 4.2 kN (944 lbf) was used for 590 MPa (86 ksi) steel (refers to the minimum tensile strength of the steel), while 5.3 kN (1192 lbf) was used for the 780 and 980 MPa (113 and 142 ksi) steels. Figure 13 shows that a current range of 2.2 kA was obtained for the 590 and 780 MPa grades and 2.5 kA for the 980 MPa grade. These current ranges are considered broad and show that there is a wide current range to successfully weld these dual-phase steels.

Metallographic characterization of weld and heat-affected zone (HAZ) microstructures is performed to examine the microstructural constituents as well as to look for the presence of any imperfections, such as voids or cracks.

Voids can be caused by entrapped gases from the coatings or by shrinkage cavities from rapid solidification. Shrinkage voids generally tend to be small and innocuous. They are typically seen near the center area of the weld nugget, which is the last area to solidify. They are generally not believed to affect the service performance of welds as determined by tensile strength.

Microhardness traverses are done on weld cross sections to look for uniformity of properties and the type of microstructural constituents. For example, the presence of martensite in steels shows higher hardness in HSS compared to regions in the HAZ that may show softer ferrite and bainitic constituents. Microhardness traverses are generally intended for informational purposes and not for weld acceptance or rejection. A typical weld microhardness traverse is done across the weld to cover as many indentations in the weld and HAZ as possible (Fig. 14). Depending on the hardness of the weld and HAZ, indentations can be placed as close as 0.4 mm (0.016 in.) apart.

Weld Integrity

Two types of weld tension tests are typically done to assess the weld tensile strength (Ref 7). One is called the cross-tension test. In cross-tension tests, two test strips are positioned normal to each other, and a spot weld is made at the center of the overlapped region. In the cross-tension test, a tensile load is applied on the weld in a direction normal to the weld. The other weld tensile test is the shear-tension test (sometimes referred to as the lap-shear test). In this test, two sheet samples, typically measuring 140 mm (5.5 in.) long by 60 mm (2.4 in.) wide, are overlapped by 45 mm

(1.8 in.) and joined with a single spot weld located at the center of the overlapped region. Schematics showing the test coupon dimensions and layout are presented in Fig. 15. The sample is then pulled in tension.

The parameters monitored in weld shear- and cross-tension tests are the peak load to failure (termed the weld strength), energy absorbed at peak load, total energy absorbed, and failure mode. Spot weld strength (or the peak force required for the weld to fail) is influenced by the weld size, as can be seen in Fig. 16.

Figure 16 shows the relationship between weld size and weld strength for 780 MPa (113 ksi) dual-phase steel. It can be seen that as the weld size is increased, both the shear-tension strength (STS) and cross-tension strength (CTS) also increased. Thus, it is important to maintain as large a weld size as possible without achieving weld expulsion. Other factors that influence the STS are the sheet thickness and the base material strength. Generally, as the sheet thickness and base material strength increase, both the STS and CTS also increase. However, CTS is not

conclusively found to be influenced by the base material strength (Ref 9). From Fig. 16 it is also apparent that the STS is much higher than the CTS at any given weld size. This suggests that the method of loading the weld influences the load required to fail the weld.

Energy absorbed in failure can also be monitored during the weld tensile tests. The energy absorbed for failure is strongly influenced by the type of test. The total deformation of the sample prior to failure in the cross-tension test, for instance, is much greater than that in the shear-tension test. As a result, in samples having the same sheet thickness, weld diameter, and material properties, the energy absorbed is greater for the cross-tension than the shear-tension test. When welds fail by pullout mode, the energy absorbed is much higher than when the welds fail interfacially. This is because the total deformation that occurs in the sample is always greater when a pullout failure occurs compared to when an interfacial failure occurs. However, caution should be exercised in evaluating energy-absorbed data in STS tests because

tensile samples during the test undergo significant rotation when failure occurs by button pull-out, and they transfer part of the applied load onto the base material. Therefore, it is important to understand the limitation in interpreting the energy-absorbed-to-failure data in STS.

There are two different failure modes that are generally observed in weld tension and peel tests, namely, interfacial fractures and full button pullout (Fig. 17). In the interfacial fracture, the weld fails at the interface of the two sheets, leaving half of the weld nugget in one sheet and half in the other. In the full button pullout, fracture occurs in the base metal or in the weld HAZ at the perimeter of the weld. In this failure mode, the weld nugget is completely torn from one of the sheets, with the weld remaining intact. It is also possible to obtain a combination of the two failure modes in which a portion of the nugget is pulled out of one of the sheets and the rest of the weld nugget shears at the interface. All of the various fracture morphologies that can be seen in resistance spot welds are provided in Ref 9. Notice from Fig. 16 that the welds failed interfacially up to 6 mm (0.24 in.). Above 6 mm weld size, the failure mode in the shear-tension test was by button pullout. In the case of the cross-tension test, all weld sizes yielded button pullout fractures.

Visual examination can detect the acceptability of weld shape, electrode indentation into the base material surrounding the weld, weld location, weld appearance, expulsion of weld metal, and surface cracking. A resistance spot weld may be circular or oval in shape. In the case of oval-shaped welds, the aspect ratio (the ratio of major dimension to minor dimension) should be 2.0 or less. Note that surface appearance is not always a reliable indicator of spot weld quality, because shunting and other causes of insufficient heating or inadequate penetration usually leave no visible effects on the workpiece. Therefore, other methods of weld evaluation must be pursued.

Welds should be placed at proper locations in accordance with the applicable drawings. Overlapping or closely spaced welds are not acceptable. It is recommended that welds should have an electrode indentation depth of less than 30%. Indentation is measured as a ratio of the electrode indentation depth to the thickness of the base material (Fig. 18).

Criteria for Acceptable Weld Integrity. Acceptable weld integrity criteria generally vary significantly among manufacturers and industries. Therefore, each fabricator should establish its own weld acceptance criteria, frequency of testing, and methods to test spot welds in consultation with the end users of fabricated parts. Attributes such as minimum acceptable weld size, weld strength, and indentation should be discussed. Methods of weld testing should be agreed upon between fabricators and end users. It should be noted

that not all methods of weld testing need to be performed to judge weld integrity for acceptance. It is suggested that, at a minimum, visual inspection be performed to ensure that welds are of acceptable quality. However, as noted previously, visual inspection

has limitations in checking weld integrity and is not always a reliable indicator of weld quality. Generally, destructive tests such as metallographic testing and tensile testing are performed prior to establishing welding parameters that provide acceptable welds.

These tests can be repeated at some intervals for verification of weld integrity.

For RSW purposes, steel grades can be classified into four groups depending on their strength (Table 2). Groups 3 and 4 are considered AHSS.

Spot weld strength is higher for groups 3 and 4 HSS and AHSS than that of the low- and plain carbon steels (group 1) for a given weld size. In the evaluation of weld tension test results in spot welds, it is generally believed, especially in the automotive industry, that an interfacial shear failure is indicative of poor weld integrity. This has generally been true for low-strength steels (tensile strength equal to or less than 350 MPa, or 51 ksi—group 1 in Table 2) in which interfacial failure is normally associated with insufficient fusion or some sort of weld imperfection, such as gross porosity. However, recent work on interfacial fractures in shear-tension tests of AHSS indicated there is a critical sheet thickness above which the expected failure mode could transition from pullout fracture to interfacial fracture. In an analysis by Radakovic and Tumuluru (Ref 11), it was shown that as the strength of the steel increases, the fracture toughness of the weld required to avoid interfacial failure must also increase. Therefore, despite higher load-carrying capacity, due to their high hardness, the welds in HSS may exhibit interfacial fractures. Tensile testing showed that the load-carrying capacity of the samples that failed via interfacial fracture was found to be more than 90% of the load associated with a full button pullout. This indicated that the load-bearing capacity of the welds is not affected by the fracture mode. Therefore, the mode of failure should not be the only criterion used to judge the quality of spot welds. The load-bearing capacity of the weld should be the primary focus in the evaluation of the shear-tension test results in AHSS. With the increased use of these steels in automotive bodies, it is important to understand their fracture behavior in shear-tension tests so that welds, otherwise sound, are not rejected solely based on fracture appearance. It is important to note that partial buttons (plugs) or interfacial fractures do not necessarily characterize a failed spot weld in AHSS. Interfacial fractures may be typical of smaller weld sizes in low-strength (tensile strength less than 300 MPa, or 44 ksi) steels or in all weld sizes in AHSS.

In-Line Destructive Weld Testing. The use of pneumatic chisels to peel welded panels is generally practiced for checking the weld integrity of resistance spot welds during product testing. This is often done on production lines. However, in HSS, especially AHSS, this type of on-line product testing may produce fracture through the weld during destructive chisel testing. Fracture through the weld becomes more common as the sheet thickness and base material strength increase and can mislead inspecting personnel to classify the welds as

defective. Weld-metal fracture may accompany significant distortion of the metal immediately adjacent to the weld during destructive peel testing. Under these conditions, resultant weld fracture may not accurately predict service life of the joint. Therefore, proper judgment should be exercised when evaluating the results of in-line chisel tests.

Ultrasonic testing of spot welds has recently gained acceptance with some manufacturers. However, because the method relies heavily on operator judgment, proper interpretation of the results is essential for obtaining a reliable evaluation. This method still needs further development before it can replace destructive weld testing completely. Several on-line real-time systems to monitor resistance welds are

currently available and are being used in some weld fabrication shops.

Applications

The workpiece thickness and the weldability of the metals are key factors in determining whether two materials can be resistance spot welded. As noted in the article “Introduction to Resistance Welding” in this Volume, the thickness of mating parts in spot welding is crucial to the heat balance. Thicknesses differing by more than a factor of 4 to 1 become difficult to weld even in favorable material combinations. Spot welds are most easily made between matching materials of the same thickness,

Fig. 17 Photograph showing the two types of weld fracture commonly observed in weld shear-tension tests. Source: Ref 10 with permission

Fig. 18 Photograph of a weld cross section showing the method of measuring electrode indentation

because this matching allows the heating to be directed uniformly to both base materials.

Spot welding of specific alloys is described in the article “Procedure Development for Resistance Spot and Seam Welding” in this Volume. Many combinations of ductile metals and alloys can be spot welded. Table 1 lists some combinations that have been successfully welded. Many other combinations may also be satisfactorily welded. Copper and silver are difficult to weld, but they may be welded by the use of a low-conductivity electrode. Copper alloys are more commonly resistance brazed. In many applications, the weldability of copper is increased if it has a tinned surface.

Spot Welding of Uncoated Steels. Plain, low-carbon steels, which include interstitial-free steels with tensile strengths typically less than 300 MPa (44 ksi), can be satisfactorily welded using the RSW method over a wide range of time, current, and electrode force parameters. Practices recommended for spot welding SAW 1010 steel have been issued by the RWMA (Ref 2). These data can serve as starting points to establish suitable weld schedules. However, these data may require modification, depending on the type of welding machine, its dynamic properties, the pneumatic characteristics, the characteristics of the secondary circuit, the electrode shape, and the specific grade of steel being welded. Sufficient squeeze time should be chosen to enable the electrode force to build up to its preset value. This is particularly true for pneumatic guns that require time to build up the required electrode force. For lightweight gun welders with limited force

capability, the electrode force values are reduced up to 30% for sheet thicknesses greater than 1.6 mm (1/8 in.). The welding current must be adjusted accordingly. For welding sheets of dissimilar thickness, welding conditions may be based on the thinner sheet, or on the second-thinnest sheet when welding three sheets of different thicknesses.

Groups 1 and 2 are readily weldable using the RSW process, groups 3 and 4 require certain precautions to achieve acceptable welds. For welding of HSLA or AHSS grades (listed under groups 3 and 4 in Table 2), the following general guidelines are suggested as a starting point to develop specific weld schedules (Ref 12). Due to differences in steelmaking practices between various steel manufacturers, users should develop their own welding schedules (combinations of parameters) based on the specific composition of the steel grades being welded:

- Increase the electrode force by 20% or more than that used for similar-thickness low-strength steel.
- Increase the weld time, as appropriate.
- Try a multipulse welding schedule (several pulses of welding current and/or electrode pressure).
- Use a larger-diameter electrode tip than suggested for welding a similar-thickness low-strength, low-carbon steel.

The AHSS generally require less welding current and higher electrode force compared to low-strength plain carbon steels (group 1), because AHSS grades have higher electrical resistivity. This is due to the fact that these grades of steel contain higher amounts of alloying elements, such as manganese, chromium, and molybdenum, to develop the required strength. All of these elements increase the resistivity of steels. Therefore, welding current levels for AHSS are not increased and may even need to be reduced, depending on material chemical composition. The AHSS grades require higher electrode forces for equivalent thickness of low-carbon steels so as to decrease the resistivity at the sheet interface to control the heat generation.

An important precaution that should be followed when welding AHSS is that weld-metal expulsion should be avoided. Weld-metal expulsion is highly undesirable because it causes loss of weld metal, which, in turn, can lower the weld size, thereby reducing the weld strength. Expulsion is typically caused by the use of excessively high current or a misfit between parts to be welded, the latter being more common in industrial applications. Therefore, expulsion can be avoided by using welding current below the expulsion limit for the thickness and grade of steel being welded and ensuring that part fit-up is tight, without any gaps at the sheet interface.

Plain low-carbon steels with tensile strength up to 300 MPa (44 ksi) are readily weldable

using the RSW process. These steels can be obtained from a number of suppliers, with reasonable certainty of only minor variations in welding behavior. This is because these grades of steel contain only small amounts of carbon (generally less than 0.03%) and no other alloying elements as intentional additions. On the other hand, HSLA and AHSS grades of steels can have significant differences in composition between various steel suppliers, because these grades are typically specified by strength levels and total elongation, not composition. This is done to enable steelmakers to choose suitable compositions to produce the required strength and ductility levels based on their mill capabilities. Therefore, compositional variations between various steelmakers may require users to modify weld schedules to suit the specific composition being welded.

Spot Welding of Zinc-Coated Steels. The present trend in the automotive industry toward the use of larger amounts of zinc-coated steels in automotive assemblies required the users to know how these coatings affect the welding requirements. Coated steels offer additional resistance to the flow of current, on top of that offered by the substrates being welded, and therefore generally require lower welding current than uncoated steels. Caution should be exercised when welding coated steels because fumes containing zinc vapor are emitted. Provision should be made to extract the fumes safely. Welding of zinc-coated steels should be done in well-ventilated areas.

Two types of coatings are generally applied to steel sheets used in the automotive industry, namely, galvanized and galvanized coatings (Ref 13). Galvanized coatings contain essentially pure zinc with approximately 0.3 to 0.6 wt% Al. The term *galvanized* comes from the galvanic protection that zinc provides to steel substrate when exposed to a corroding medium. Two methods by which zinc coatings are applied to steel substrate are the hot dipping method and the electrodeposition method. The pure zinc coating is called the galvanized coating, and the zinc-iron alloy coating is called the galvanized coating. In the case of the hot dipping process of coating steels, a hot dipped galvanized (HDGA) coating is obtained by additional heating of the zinc-coated steel at 450 to 590 °C (840 to 1100 °F) immediately after the steel exits the molten zinc bath. This additional heating allows iron from the substrate to diffuse into the coating. Due to the diffusion of iron and the alloying with zinc, the final coating contains approximately 90% Zn and 10% Fe. Due to the alloying of zinc in the coating with diffused iron, there is no free zinc present in the galvanized coating. Galvanized coatings contain less aluminum, approximately 0.15 to 0.4 wt%, than the hot dipped galvanized (HDGI) coatings. These coatings can be applied by either a hot dipping process or electrodeposition. The coating thickness ranges from approximately 6 to 8 μm (0.24 to

0.32 mils) for galvanized coatings to approximately 12 to 14 μm (0.47 to 0.55 mils) for galvanized coatings.

Examination of the welding behavior of an AHSS grade of steel coated with 70/70 g/m² HDGI and 42/42 g/m² HDGA (steels coated on both sides)—“coating weights that are currently used in the automotive industry”—showed that the welding behavior was similar between the two coatings (Ref 13). One difference noted between the two coatings was that HDGA required lower welding current to form the minimum weld size. This may not be an advantage in the industry, given the current practice of frequent electrode tip dressing. Further, the type of coating had no effect on the weld shear-tension or cross-tension strength. The weld strength is controlled by the steel substrate.

Welding conditions can be easily optimized when using pedestal-type welding machines; however, this may not be the case in body-in-white assembly, where a combination of multiple spot welders and robotic cells are more commonly used. Such operations are susceptible to poor fit-up of parts, access problems, and electrode configurations that give rise to electrode skidding and expulsion. Consequently, the welding parameters may need to be adjusted to compensate for such situations. In many instances, one welding gun is used to weld a range of sheet thickness combinations or even a variety of material combinations in a particular part.

In these circumstances, the electrode life obtained may be lower than that derived using optimized welding conditions. For example, the electrode life obtained can depend greatly on the type of welding gun used (Fig. 19) or the angle of approach of the electrode. When multiple spot welding machines are used, it is essential that all welding machines are balanced electrically and that the same air pressure is supplied to each station. Electrode shape and configuration, water cooling arrangements, and electrode dressing schedules must be optimized. The last item is most important, because satisfactory weld quality can only be provided when the necessary electrode condition and shape are maintained over a production run. It is again stressed that frequent electrode tip dressing is highly recommended to maintain acceptable weld quality (hence integrity), especially when welding coated AHSS grades.

Water cooling is also a critical element of welding machine maintenance, because insufficient water cooling during welding can degrade the copper from the electrode and cause copper to melt and deposit onto the part surface. When this happens, molten copper can penetrate the steel substrate and cause liquid metal embrittlement cracking.

Weldability of Steels in Spot Welding. In HSS, several alloying elements are added to achieve the required strength levels. These alloying elements not only strengthen steels but affect other properties as well. Weldability

Fig. 19 Effect of resistance spot welding electrode gun type on electrode life for selected steels and alloys

is one important property of steels that is influenced by the addition of alloying elements. Weldability of a given grade of steel is generally described using the term *carbon equivalent* (C_{eq}). This term expresses the cumulative effect of various alloying elements on weldability. Most C_{eq} formulae contain such alloying elements as carbon, manganese, silicon, sulfur, and phosphorus that have significant influence on weldability (Ref 14). Most equations developed to predict the weldability behavior of steels in spot-welded applications are designed to provide an estimate of the weld zone hardness and shear- and cross-tension strengths of spot welds.

While there are several formulae for expressing C_{eq} of steels, there is no universally accepted, one single formula for expressing the weldability of steels in RSW applications. As a result, users must find a formula that best suits their application. It should be noted that C_{eq} should be used only as a general guide to assess weldability of steels. Assigning specific maximum values for accepting steels is not advisable.

Among all the elements used for alloying steels, carbon has the most effect on weldability of steels. Increases in base material carbon content increase the resultant weld hardness and weld shear-tension strength. However, increasing carbon content may reduce the useful welding current ranges of steels. A concern existed about the occurrence of weld interfacial fractures as the carbon content in steel is increased. This caused users to impose limits on maximum allowable carbon and C_{eq} . However, recent research has shown (Ref 11) that interfacial fractures are the expected mode of failure in AHSS, and that welds failing interfacially require more than 90% of the load necessary

to cause failure by button pullout. This means that occurrence of interfacial fractures should not cause concern about the load-bearing capability of spot welds in AHSS, and that fracture mode is not a good indicator of weld integrity, especially in AHSS grades.

Other alloying elements, such as manganese and silicon, do not have a significant effect on the welding behavior or welding current range in steels. However, increases in these two elements cause the resultant weld and HAZ hardness to increase. As mentioned earlier, an increase in weld and HAZ hardness causes the peak load in STS to also increase.

Weldability of Aluminum Alloys in Spot Welding. Most of the commercial aluminum alloys produced in sheet form can be spot welded, provided that suitable welding equipment is used. Because of the low electrical resistance of aluminum alloys, considerably higher welding currents are required relative to welding mild steel. In addition, the narrow plastic range between softening and melting means that welding forces, time, and current must be closely controlled. For consistent weld quality, it is essential that the tenacious surface oxide films are removed by mechanical or chemical techniques prior to welding.

To minimize the likelihood of cracking or porosity in the weld, careful control of the electrode force is necessary. If the force is applied too soon, the welding current may be insufficient due to a premature loss of contact resistance. Thus, correct initiation of the force relative to the current is essential. Dual force schedules are frequently used; therefore, a low-inertia welding head can be beneficial because it allows a more effective buildup of force to its final level.

Because of the higher secondary currents required when welding aluminum alloys, direct current secondary rectified or frequency converter welding machines are favored, particularly if high-quality welds are required (such as in aircraft applications).

Safety

As with any welding process, all necessary safety precautions should be followed to avoid injury to personnel and property and to prevent fires. Please consult Ref 15 and 16 for safety considerations required for welding operators. Safety considerations specific to RSW have been summarized in Ref 17. Some of the hazards in RSW are provided here for information purposes and include the following. Operators should be made aware of these and provided with adequate personal protective equipment to guard against injury and damage to equipment, building, and parts:

- Flying sparks from expulsion during welding can cause fire and explosion.
- Flying sparks can cause burn or injury to eyes and skin if operators are not protected properly.
- Because RSW is done primarily on sheet metal products that tend to have sharp edges, operators should be aware of cutting hazards. Cut-resistant gloves should be used when handling sheet metal.
- Electric shock can result from damaged cables and wiring.
- Equipment maintenance should only be done by authorized personnel after disconnecting all sources of energy, including electricity, compressed air, and water. Operators should be cognizant of potential energy in the system.
- Handling hot metal or welded parts can cause burns.
- Moving electrodes in RSW create pinch points. Extreme caution should be used when inserting or removing parts after welding.
- Fumes from spot welding on parts coated with paints or corrosion-resistant coatings can create fumes that cause inhalation hazards.

To avoid some of these hazards, operators should wear safety goggles or a face shield and not weld near flammable liquids or gases. Operators should wear dry insulating gloves (cut resistant when handling sharp objects) to prevent burns and cuts. Most important of all is to keep hands and fingers away from moving parts. Keep all protective guards in place. It is also important to ensure that there is adequate ventilation. Operators should familiarize themselves with the Material Safety Data Sheets for all materials, coatings, gases, and cleaners they handle.

DISCLAIMER

The material in this paper is intended for general information only. Any use of this material in relation to any specific application should be based on independent examination and verification of its unrestricted availability for such use and a determination of suitability for the application by professionally qualified personnel. No license under any patents or other proprietary interest is implied by the publication of this article. Projection Welding

Warren Peterson, Edison Welding Institute

PROJECTION WELDING is a variation of resistance welding in which current flow is concentrated at the point of contact with a local geometric extension of one (or both) of the parts being welded. These extensions, or projections, are used to concentrate heat generation. The process typically uses lower forces and shorter welding times than similar applications without projections. Typically, large, flat-faced electrodes (Fig. 1) are used against the projection.

Introduction

Projection welding is often used in the most difficult resistance welding applications; for instance, applications with significant thickness mismatches or those involving several close-spaced simultaneous welds can be projection welded. Compared to standard resistance welding applications, modification of the weld

schedule or welding equipment for projection welding may be needed to achieve optimal results.

Types of Projections

Projection welding applications are generally categorized as either embossed-projection welding or solid-projection welding. Variations of these are shown in Fig. 2 and 3. Joint configurations for embossed- and solid-projection types range from sheet-to-sheet joints, to cross-wire welds, to annular attachments, to nut welds, to weld screws, to ball-sheet joints, and so on.

Embossed-projection welding is generally a sheet-to-sheet joining process in which a projection is stamped onto one of the sheets to be joined. Then, resistance welding is conducted on a stack of sheets. Initially, weld current is

Fig. 2 Typical stacked configuration for embossed-projection welding of sheet

Fig. 3 Typical configuration for solid-projection welding

concentrated at the contact point and within the walls of the projection. Due to rapid joule heating of the projection, the projection collapses into the original sheet early in the process. However, during projection collapse, the contacting area breaks up the oxides on the surface, promoting continued current flow through the joint area. The increase in bulk resistivity promotes continued resistance heating at this location. In the traditional usage of the process, weld development proceeds as a conventional resistance weld, forming a fused weld nugget. In an alternate usage, the strain and heat developed during the preceding projection collapse develops a solid-state metallurgical bond at the faying interface, without producing a molten nugget between the sheets. These two approaches may require different projection geometries, welding parameters, or equipment. The advantages of each variant are addressed later.

The projection geometry for most embossed-projection welding applications typically involves discrete dimples stamped in the sheets. An annular-projection geometry is also common, forming a continuous circular dimple in the one of the sheets. This geometry increases the load required to mechanically collapse the projection. Consequently, annular projections are typically used for projection welding very thin-gage sheet.

Solid-projection welding requires that the projection be forged or machined onto one of the two components. Then, during resistance welding, the contact point and the projection itself experience preferential heating. In this case, the projection does not simply collapse, as in embossed-projection welding. Rather, the projection collapses by penetrating into the surface of the opposing material and by extrusion of metal to the periphery of the joint. Compared with embossed-projection welding, the traditional approach produces solid-state joints, rather than forming a fusion zone at the weld interface. The actual joints are caused by a combination of material forging and diffusion bonding, similar to resistance butt and flash butt welding.

Compared to embossed-projection welding, solid-projection welding involves a considerably

wider range of process variants used in production applications. Some of the common geometric variations of solid-projection welding are described as follows.

Annular-Projection Welds. One of the most common applications of solid-projection welding is to attach either tubular components or members with circular bases to flat substrates. This is commonly accomplished by annular-projection welding, in which a projection is machined onto the circular base or the end of the tubular section. Then, resistance welding is conducted to set the projection into the substrate. A typical weld geometry is shown in Fig. 4(g). Annular-projection welding generally provides high-integrity joints and can be used for leak-tight applications.

Cross-wire welding is a variation of solid-projection welding in which the projection is formed at the contact point of two crossing wires. The geometry for cross-wire welding is shown in Fig. 4(n). Upon resistance welding, heat is maximized at the location of the wire-wire contact, and the parts are subsequently forged together. Depending on the application, either highly localized joints (minimal forging) or heavily forged joints can be made in wire diameters commonly between 1.5 to 13.0 mm (0.06 to 0.51 in.). In some applications, cross-wire welding is conducted at rates up to 30 welds/second.

Projection Weld Nuts/Studs/Screws. Weld nuts represent an application of solid-projection welding in which the projections occur as extensions of material from the face of the nut, stud, or screw head. Typically, the weld faces contain three, four, or six projections, or feet, spaced around the nut, stud, or screw periphery. During welding, all of the projections are attached simultaneously. Examples of weld nut geometries are shown in Fig. 4(k and m).

Edge-to-sheet welds are typically a cross between embossed- and solid-projection welding. They are used to attach the end of a sheet to the flat face of an opposing component (Fig. 4f). The projections are generally stamped into the face of the attaching sheet. During welding, full local projection collapse occurs; however, bonding is strictly solid state (see the article “Fundamentals of Solid-State Resistance Welding” in this Volume).

Resistance mash welds (Fig. 5) create a narrow forge-type joint formed between two overlapping sheets. The sheet overlap distance is normally equal to between 0.5 to 2 times the thickness of the thinner sheet. Typically, flat bar-shaped electrodes cover the length of the overlapped joint. This is similar to mash seam welding which involves electrode wheels with flat or radiused profiles (see the article “Resistance Seam Welding” in this Volume). Substantial clamping force (at least twice the electrode force) is required to fixture the sheets against separation during welding. High clamping forces are required due to resistance to the wedgelike action created during the

forging process. Weld current is conducted through the narrow overlap, which causes the metal to heat and forge in the production of a solid-state bond.

Pin-and-Tenon Welds. Pin-and-tenon projection geometry (Fig. 4j) is a type of annular projection that produces a solid-state weld between a machined face (typically at 45°)

Fig. 4 Examples of embossed- and solid-projection welds

Fig. 5 Example of resistance mash weld. This application used flat-faced bar electrodes. Courtesy of Edison Welding Institutel

and the square corner of the opposing part. This is a common joint involving thick components where the wall of the pin does not deform inward during welding (approximately a 3.2 mm, or 0.125 in., minimum wall thickness is required).

Ball-to-Sheet Welds. The ball-to-sheet weld joint (Fig. 6) creates an annular solid-state weld between a hole placed in the sheet and the contacting circumference of a ball bearing. The diameters of the hole and the ball bearing should be selected to produce an approximate 90° included angle relative to the center of the ball bearing. Similar to the other forms of

Fig. 6 Example of ball-to-sheet weld. The ball bearing is larger than the hole it is being welded into. Courtesy of Edison Welding Institute

Fig. 7 Examples of coined embossed-projection designs. Source: American Welding Society and International Institute of Welding recommended projection designs, circa 1950s

annular-projection welding, the joint is generally air- and liquid-tight.

History

Embossed-Projection Welding. Projection welding was used prior to World War II; however, most of the systematic development work performed on embossed-projection welding occurred in the 1940s and 1950s on uncoated sheet. While there were many approaches to forming embossed projections described in the literature, eventually two basic types of projections were commonly investigated in the 1950s and 1960s: coined (American Welding Society, or AWS, and International Institute of Welding recommended practices) and formed (Harris and Riley, and Humpage) projection designs. Examples are shown in Fig. 7 and 8. The coined-projection styles were produced by coining between matching die sets, while the formed type projections were made by limited pushing of the sheet into an open die cavity using a punch. The formed type is subject to thinning and splitting during forming. The coined projection is thicker and stiffer. While the crush resistance of the two projection types differed, good welds could be produced with either, using optimized conditions.

Today (2011), the coined-projection designs are the most common in the United States. Originally, the primary use for projection

Fig. 8 Examples of formed embossed-projection designs. Source: Ref 1

welding was a means of enhancing the formation of conventional resistance weld nuggets between the sheets. Used in this way, the projection acted as a means of locating the molten weld nugget. As such, the weld times and electrode forces were somewhat similar to conventional spot welding parameters. Initial expulsion of metal during projection welding, caused by excessively rapid heating and collapse of the projection during welding, was commonly controlled through the use of weld current upslope and adjustments of electrode force.

Solid-Projection Welding. Many forms of solid-projection welding were also used prior to World War II. Due to the varied forms of solid-projection welding, there were fewer examples of systematic work defining standard projection geometries and welding parameters. Many of the solid-projection welding applications in the literature indicate the need for rapid electrode followup. This is necessary to maintain weld metal integrity and to reduce accelerated electrode wear caused by a transient loss or reduction in electrode contact during welding.

Modern Projection Welding. With continued advancements in technology and usage, the application of projection welding has widened over the years to recognize both fused weld nuggets and solid-state bond formation as legitimate modes of projection welding. A mix of fusion and solid-state welds is used in embossed-projection weld applications. However, most solid-projection weld applications are produced as solid state bonds, with a few exceptions. Some of the drivers toward the conversion from the fusion weld mode to the solid-state weld mode may be the reduced cycle time required for solid-state weld formation. Unfortunately, there is little distinction between weld schedules developed around fusion weld formation and those promoting solid-state bonding. Without clear delineations between these modes, wide variations regarding projection geometries, weld equipment requirements, and welding parameters for embossed- and solid-projection welding applications are observed in the literature.

Application Advantages and Limitations

The primary advantages of all resistance welding processes are the relatively low unit costs and the applicability to high-volume mass production environments. Typical production costs for projection welding include the additional expense of producing the projections and ensuring that the electrodes are properly located over the projections. These costs are offset by the relatively low capital and consumable costs and low maintenance requirements typical of most projection welding applications.

The advantages of projection welding are related to the ability of the process to create highly localized weld joints. This is manifested in a number of ways.

Projection welding allows multiple welds to be made simultaneously in the same station. For instance, in one application, 12 simultaneous welds are produced on a large automotive exhaust clamp. These are made in less time than required for the production of a single conventional spot weld. Similarly, embossed-projection welding is highly adaptable to the joining of multiple-sheet stacks.

Projection welding can be used in a wide range of hard-to-weld metal applications. For example, pure copper can be resistance mash welded with a narrow material overlap (IT) using a weld-and-forge technique. Other examples include welding of attachments to resulfurized free-machining components. If welded very quickly, solidification cracking can be avoided through the formation of a solid-state bond at the interface. Because no melting occurs and the forged joint generates little heat outside the contacting interface, sulfur generally does not form extensive compositionally-driven melting within the heat-affected zone (HAZ) of the welded component.

Projection welding can be used over a wide range of allowable thickness mismatches. Generally, traditional resistance welding is considered adaptable to sheet thickness variations of less than 3 to 1. However, with projection welding, there is no limit to the difference in component thicknesses.

Embossed-projection welding can be used to avoid external marking of sheet surfaces. For example, because flat electrodes are used and short weld times are used, the process is very effective at localizing heat at the faying interface and minimizing the residual heat produced on the outside surfaces.

Solid-projection welding can also be used to produce hermetic seals. Annular-projection welds are often used to seal the housing of glass-filled electrical connectors against an enclosure. Due to the very short heating cycle and moderately low electrode forces required, a projection welding can be successfully produced without significant thermal expansion of the housing and cracking of the glass.

Limitations. The limitations of the projection-welding process are largely related to the need for proper projection design and any modifications to existing resistance spot welding (RSW) equipment that may be required for optimal performance. Other limitations of projection welding include:

- Forming of one or more projections on one of the workpieces may require extra operations, unless the parts are press formed to design shape.
- When several welds are made at once with the same electrode, alignment of the work and dimensions (particularly height) of the

projections must be held to close tolerances to obtain consistent weld quality.

- When making simultaneous projection welds, the projection layout will be dictated by the shunt current paths, which may not coincide with the desired location.
- Because two parts are moving relative to each other during the welding process, proper gaging is difficult.

Material Property Effects

Solid-projection welds are essentially strain-assisted diffusion bonds (Ref 2). Because the projections typically collapse at very high temperatures (generally, within several hundred °C of the melting point), bonding can occur within the very limited available time (usually, less than 1 s).

Not surprisingly, some of the material-related factors that affect diffusion bonding also affect solid-projection welding. The most notable of these is the ability of the metal to dissolve its own oxide, such as titanium and copper. As a result, materials that do not energetically favor solid solubility of oxygen within the metal at forging temperatures, rather than the formation of the oxide at temperature, such as aluminum, will be relatively difficult to projection weld.

The strength-temperature relationship also affects projection weldability. Materials that maintain their strengths at relatively high temperatures permit substantial heating before projection collapse and a loss of strain localization. This heat then becomes available to promote diffusion after collapse of the projection. Conversely, metals exhibiting a rapid deterioration of strength at elevated temperatures cause premature projection collapse. This results in a rapid reduction in the current density, lowering welding temperatures, which slows diffusion and prohibits bonding.

Bulk resistivity also plays a role in projection welding, but to a lesser degree. Increased bulk resistivity can reduce the effectiveness of the projection as a current concentrator. Because the yield strength of most metals decreases with temperature, metals with high bulk resistivity develop heat within the projection quickly, which promotes premature collapse. This is seen as a tendency toward delocalized heating and general, rather than local, collapse of the projection. As a result, high-resistivity materials are more difficult to projection weld without appropriately altering the projection geometry.

Projection Welding of Steels. Uncoated and scale-free mild steels are usually easily projection welded. Uncoated mild steels have moderate levels of contact resistance and a moderate capacity to adsorb oxides, making them relatively easy to bond. However, metallic-coated mild steels (galvanized, aluminized, etc.) are more difficult to weld because the

coatings act as a barrier to bond formation and must be dispersed from the weld location during welding. Additionally, typical coatings have low resistivity that increases the current required to weld and promotes general yielding of the projection. Typical embossed-projection designs applied to coated sheet steels result in the direct shunting of current to the opposing sheet once the projection is nearly fully collapsed and contact between the respective coating interfaces occurs. Consequently, projection welds in galvanized steels generally require a customized projection, generally taller and narrower than standard projection designs. Sometimes, reduced electrode face diameters are also used to further concentrate current during resistance welding.

There are different concerns in projection welding high-strength steels. Projection welding, like other resistance welding processes, produces high cooling rates. Depending on the carbon content of the base metal, the hardness of the weld and the near HAZ can be very high. Additionally, these joints are often under high constraint. These conditions can lead to a loss of weld ductility and strength perpendicular to the sheet surface if postweld heat treatment is not used. Commonly, this is done by using an in situ tempering current pulse. The second current impulse is applied only after the weld and HAZ have cooled below the martensite finish temperature and without releasing the electrodes. Only proper adjustment of the magnitude of the temper current level will produce the desired improvement in weld toughness properties. Insufficient or excessive temper currents will not result in improved performance.

High-strength steels can also have relatively high electrical resistivities. This may lead to accelerated projection collapse and may require a customized projection design for best performance. Generally, a slight increase in projection height and a reduction in the base diameter are sufficient to accommodate the accelerated projection collapse compared to similar projections produced on mild steel.

Projection Welding of Aluminum and Aluminum Alloys. Aluminum and aluminum-base alloys can be very difficult to projection weld. The aluminum oxide is so tenacious that solid-projection welding, in particular, is nearly impossible by using traditional projection designs. The high initial electrical resistance of the aluminum oxide promotes surface expulsion at the projection tip. This expulsion may help remove the oxide at the initial contact location, but more extensive expulsion will harm weld quality.

In addition, it is very difficult to localize heat during the projection welding of aluminum alloys, because they soften at low temperatures. This is especially true for embossed projections. The characteristic rapid softening of the projection mandates the use of very short weld times, high currents, and low electrode force.

Rapid electrode followup head designs must be incorporated into the welding equipment. Special embossed-projection designs, with accompanying fast followup equipment, have been developed to accommodate the rapid softening and collapse characteristics of aluminum projections. Because the aluminum oxide is very stable, extensive deformation of the projection and the part surface is required to fracture and locally disperse the oxides prior to bond formation. However, weld consistency should be carefully evaluated.

Projection Welding of Copper and Copper Alloys. Projection welding is commonly applied to copper and copper-base alloys. In many applications, projections are virtually required for resistance welding, because of the generally high conductivity of these materials. In any case, projection welding must be performed very rapidly to localize heat at the faying interface. The projection should be designed to resist rapid collapse, similar to those made in aluminum.

Because electrical resistivity and strength at elevated temperatures are generally proportional, the ease of projection welding copper alloys can usually be ranked by their electrical conductivity. For alloys with relatively low electrical conductivity, heating of the contacting surfaces can be accomplished relatively easily while those of high conductivity may be very difficult. Similar to projection welding aluminum, the rapid softening of projections made in copper alloys requires very short weld times, high currents, low electrode force, and rapid electrode followup head designs incorporated into the welding equipment. However, different from welding aluminum, copper easily adsorbs its own oxide and therefore does not require the same extensive deformation to achieve bonding.

Electrodes for projection welding copper are often made of copper alloys. Some electrode sticking may occur, mandating frequent dressing. Water cooling is necessary to reduce sticking and maintain the electrode surface. In some cases, either pure or sintered refractory metals are used to avoid sticking issues. However, the refractory metal electrodes generate heat, which may promote rapid projection collapse and deterioration of weldability. Refractory electrodes are preferred in other cases, such as joining or consolidating the ends of stranded wires.

Copper alloys containing significant amounts of zinc can produce violent expulsion of metal due to the vaporization of zinc during welding. These alloys require weld schedules with short weld times and higher electrode forces. Custom projection designs may be required.

Other Metals. Low-alloy nickel-base alloys are ideal materials for projection welding, because they readily dissolve their own oxides and have adequate strength-temperature and resistivity properties. Stainless steels and higher-alloy nickel-base materials become slightly more difficult to weld because of the

formation of more-stable chromium oxide, increased high-temperature properties, and higher resistivities.

Conventional titanium alloys are relatively difficult to projection weld. Although titanium readily dissolves its own oxide, its high resistivity and low forging temperature generally cause premature collapse of the projection.

Specifications and Recommended Practices

Several recommended weld schedules and practices for the projection welding of various materials are given in the AWS publication C1.1M/C1.1:2000, "Recommended Practices for Resistance Welding." These schedules may be used as starting conditions for development of specific welding applications. This recommended practice also covers the shear and cross-tension testing method for resistance welds.

Other information sources include the current edition of the *Resistance Welding Manual*, published by the Resistance Welder Manufacturers Association, with recommended practices for projection welding and electrode materials. Several European specifications and recommended practices also can be used to define resistance projection welding applications (see the list at the end of this article along with other AWS specifications).

Automotive manufacturers have proprietary specifications and welding requirements for projection welding. These often follow other published guidelines. While not specifically called out, test methods and procedures for determining resistance spot weldability for automotive applications are defined in AWS D8.9:2002. Weld quality characteristics of individual welds may be defined by the applicable measures detailed in specification AWS D8.1M:2007. In 2007, AMS-W-6858A (2000)

and MIL-W-6858D (1992) were replaced by AWS D17.2.

Process Fundamentals

As previously mentioned, two modes (embossed and solid) of projection welding are often possible. When embossed-projection welding is used as a spot weld initiator, relatively long weld times are used to generate the bulk resistive heat at the joint interface necessary for melting to occur. Figure 9 shows the stages of projection collapse and weld nugget development in embossed projections. Early in the weld cycle, the projection serves to enhance the initial contact resistance and locate the weld at the faying interface (Fig. 9a). Unless conveyed away by thermal conduction, the initial heat generated through collapse of the projection is retained within the weld area (Fig. 9b). Further resistive heating of the bulk metal occurs with continued current flow (Fig. 9c). With sufficient energy input, a molten weld nugget will form (Fig. 9d). Generally, the weld nugget diameter will not exceed the base diameter of the projection. Used in this way, the projection acts as a heat balance technique to localize the molten weld nugget with respect to the faying interface location. Because of its similarity to the method of heating used in standard resistance welding applications, projection weld schedules that result in a molten weld nugget will often use somewhat similar values for weld time, electrode force, and so on compared to similar RSW applications. This mode is generally used only for embossed-projection welding.

Alternately, the projection can produce a solid-state bond at the faying interface, similar to the flash butt welding processes. In this case, little or no melting occurs throughout the weld cycle. The objective of this mode of welding is to produce a metallurgical bond through

Fig. 9 Stages of projection weld collapse and nugget formation. (a) Initial condition. (b) Solid-state weld formed after 20% of total weld time. (c) Region of incipient melting after 70% of weld time. (d) Complete weld nugget at 100% of weld time

heating and collapse of the projection. The weld is formed by the appropriate combination of strain, heat, pressure, and time developed at the faying interface (Fig. 9b). During heating of the projection, the surfaces of both the contacting portions of the projection and the workpiece soften and strain, resulting in a breakup of oxides at the faying interface. For some materials, the elevated temperatures allow adsorption of some of these metal oxide fragments, depending on the solubility of the oxides within the solid metal at elevated temperatures. Deformation of the metals at the faying interface exposes metallurgically clean surfaces under intimate contact at elevated temperature and pressure. In appropriate combinations, these conditions promote bonding, provided they exist for a sufficient length of time. In some cases, a very thin transient liquid film may form early in the heating cycle. If formed, this liquid is quickly expelled or squeezed from the joint, taking with it the metal oxides that act as barriers to bond formation. This mode of projection welding uses very short weld times and high weld currents and requires equipment with good mechanical followup of the electrode.

The extent of projection collapse is limited by the establishment of mechanical equilibrium at elevated temperature and is determined by the projection design and applied electrode force. The solid-state welding mode is used primarily for solid-projection and some embossed-projection welding applications. This is especially true of metals with good electrical conductivity or when producing a molten nugget would result in an adverse metallurgical condition or when the required weld cycle time is relatively short.

Equipment

Resistance projection welding equipment may require specific modifications compared to common RSW equipment, such as the use of low-mass (inertia) weld heads. The approach rate of the head should not cause damage to the projection tip beyond that provided by the applied electrode force. A “soft” approach rate can improve weld consistency. Because the nature of projection welding is to direct current flow to the desired weld locations, there is considerably more flexibility in tooling. Conventional spot welding practice requires electrodes of specific sizes and shapes in order to localize current for welding. Projection welding uses large, flat-faced electrodes.

Additionally, projection welding equipment uses straight-acting force systems on pedestal welders, weld guns, or similar welding machines. A typical pedestal welder suitable for general-purpose projection and spot welding is illustrated in Fig. 10. Rocker-arm-type welders are generally not used. The type of force system significantly affects the mechanical electrode followup characteristics of the machine, depending on the masses of the moving components. Examples of the force systems used on projection

welding machines include pneumatic, hydraulic, “air-over-oil,” and other forms of mechanical-driven systems, such as cam operations. Pneumatic systems can provide fast response to projection moment, depending on the size of the orifices, the masses involved, and an ample supply of air. An air accumulator may be necessary to stabilize the supply pressure. Generally, hydraulic and air-over-oil systems provide slow electrode followup response. However, these may be adequate for the fusion mode of projection welding. Alternately, a separate fast followup head can be placed in line with the electrodes. Mechanical systems can provide very fast electrode followup characteristics, depending on the cam design. Servo guns may not be appropriate for projection welding. The displacement or force feedback systems that are used may not respond fast enough to match the rapid collapse of the projection during welding.

Electrode Followup. Projection welding requires high compliance or the rapid response of the loading system. This is necessary because projection welding requires the collapse of a projection, which, in turn, requires some motion of the welding head. If the followup of the welding head is insufficient, then a local loss of force will occur, potentially causing catastrophic overheating of the contacting surfaces and expulsion of metal from the joint. This causes porosity, cracking, or accelerated electrode wear. Therefore, projection welding systems typically use “fast followup” heads (Fig. 11), which consist of relatively low-inertia (mass) head components and mechanisms to maintain a nominally constant force. The head shown in Fig. 12 uses a relatively low-volume diaphragm assembly and a spring to maintain

this force on the components. Most systems, however, use either these low-volume diaphragm assemblies or springs to accomplish fast followup.

Calculating the dynamic response of the welding machine depends on the sum of the masses of the electrode, holder, and other moving components of the welder, as well as the applied electrode force and friction in the moving components. Figure 13 can be used as a guide to determine the maximum moving mass for a given level of electrode force. Generally, the sum of the moving masses should be less than 1% of the applied electrode force.

Welder Stiffness and Electrode Parallelism. The welding machine should have sufficient stiffness so that the upper electrode can remain parallel to the welding surface throughout the weld cycle. A loss of parallelism will result in expulsion during welding or poor weld quality when multiple projections are welded simultaneously. The upper and lower portions of the welder frame are sometimes tied together to improve mechanical stiffness and maintain parallelism of the electrodes. Similarly, the welded component should have sufficient stiffness, and the weld surface should be sufficiently backed up to avoid flexure of the part during welding.

Power Supply Types. Several types of weld power supplies can be used for projection welding. Standard alternating current (ac) weld power supplies are often used. These can be used in full-cycle and half-cycle operation. Traditional resistance welding equipment controls on full cycles (both positive and negative “half-cycles”) of the ac current waveform. This type of current is best used for the fusion

Fig. 10 Typical general-purpose projection and spot welder

projection weld mode. The weld controller should be operated in constant voltage current mode rather than in constant secondary current mode. Constant current mode increases variability in weld quality for projection welding. This is because the dynamic resistance constantly changes during projection collapse, and adjustments to the weld current made

from feedback from the controller cannot be performed rapidly enough to maintain weld consistency, especially for the solid-state welding mode. Half-cycle ac weld power supplies are used in conjunction with high secondary voltage transformers to produce a very short-duration, single-impulse weld current. This effectively makes these welders a direct current

(dc)-type power supply. A stacked core transformer is recommended for these applications. These are usually used with the solid-state welding mode.

There are several types of dc power supplies. These include primary rectified dc, secondary rectified dc, midfrequency dc (MFDC), capacitive discharge, and other types of dc power sources. The dc-type power supplies do not usually exhibit the high peak currents associated with ac waveforms and therefore reduce the levels of expulsion observed during welding. As they have become more powerful, MFDC-type power supplies have rapidly replaced many types of traditional dc-type power supplies. The time to peak current is an important characteristic of dc-type power supplies. The solid-state mode of welding generally operates best with fast welding times, dictating a fast current rise time to peak current. The capacitive discharge type of dc power supplies produces a very fast rising current pulse. In some applications involving dissimilar metals, the polarity of the power should be checked to ensure that appropriate heat balance is maintained in the joint. The size and resistance of the secondary loop also influences current rise time.

Electrodes. Projection welding is typically done with large, flat electrodes. In most applications, tooling is simply shaped to match the contour of the part in the contacting location. The electrodes should be machined to produce flat parallel faces. Electrode parallelism should be checked when installed and prepared in the welding machine and when refractory-faced electrodes are used on only one side of the joint.

Personnel

Like all resistance welding processes, projection welding processes often use automated equipment, since the expertise level required to operate the equipment is relatively low. Generally, the skill levels and the health and safety issues are identical to those of conventional RSW. An area in which expertise is beneficial is the attention to detail by the operator. Resistance welding is subject to variations in setup conditions, and projection welding may be extraordinarily sensitive to setup variations in situations where the placement of projections is critical.

With limited expertise, operators or supervisory staff can visually inspect the characteristics of the process and the welds themselves to identify improper setups, as well as maintenance needs. These quality-assurance efforts, which fall under the auspices of total quality management or total quality joining, can be established with a minimum of on-line training and experience.

Process Requirements

The geometry of the projection is critical for many applications. The projection shape, base diameter, and height should be defined for optimal performance. A poorly designed projection may not be weldable in some applications. The projection should have appropriate symmetry and not be placed on the edge of the component face.

The projection shape should be selected to produce a controlled dynamic mechanical collapse, under the applied electrode force, such that the current density at the faying interface can be managed during heating and forging of the projection. Tall and slender projections tend to buckle during deformation, explode during welding, or are too stiff to promote the strain needed for bond formation. Short and wide projections tend to flatten rapidly at the contacting face and therefore provide insufficient current concentration during welding to heat or strain the faying interface for bonding.

Selecting a projection with the proper relationship between the projection height and base diameter will produce heat and strain at the faying interface, which encourages bond formation. Sometimes, an initial flat is placed on the top of the projection to avoid premature flashing during the initial surge of weld current. However, the width or diameter of this flat should be minimized because it reduces the strain developed at the projection tip.

The slope of the projection sides will govern the increase in contact area during projection collapse. The increase in conduction area should be proportional to the rate of the rising slope of the current impulse (dynamic current density), and the projection height should be sufficiently tall to develop the strain needed to

bond within the heating time allotted for the process. Similarly, if multiple projections are made simultaneously, then the projection heights should be tightly controlled. The projection geometry can be optimized for specific metals, coatings, or the mechanical performance of specific welding machines.

Tables of parameters for embossed-welding projection can be found for joining many types of metals. These should be examined in reference to the projection welding mode. This is most often indicated by weld time and electrode force specified. Weld times similar to those of RSW are used for the fusion weld mode of projection welding, but much shorter weld times are used for the solid-state mode. Weld current upslopes are usually not used for the solid-state mode of projection welding. Tabulated weld parameters for various materials are discussed as follows. Most of these are consistent with the fusion weld mode for the embossed projection designs.

Steel Embossed-Projection Welding

The embossed-projection welding of heavy-, intermediate-, and thin-gage sheet mild steel, as well as welds between dissimilar thickness joints, is described as follows.

Heavy-Gage Sheet Steels. The projection welding of heavy-gage steels, which involves an embossed-projection welding process, has many of the characteristics of solid-projection welding, particularly in its early stages, because of the thickness of the sheet.

In addition to defining the geometry of the projection, projection designs should provide an annular relief for projection material that is forged to the side during welding. Projection and die geometries for steels that range from 3.12 to 6.22 mm (0.123 to 0.245 in.) are shown in Table 1. The process requirements for forming these welds are given in Table 2. All welding schedules described in this article are single-pulse welding schedules.

Slope control is sometimes recommended to prevent preflashing of the projection upon initiation of the welding current or when the inertia of the welder is excessive. The application of a forge force is also recommended to alleviate weld porosity. Electrode or die wear may also be a concern, as it is in the spot welding of heavy-section steels. In such applications, pulsation welding schedules may be recommended.

Intermediate-Gage Sheet Steels. The projection welding of steels ranging in gage from 0.56 to 3.43 mm (0.022 to 0.135 in.), using single-point projections with single-impulse welding schedules, is well established. Projection-stamping die designs are given in Table 3, whereas process requirements are given in Table 4. Lower forces and shorter welding times are required, when compared with the conventional spot welding of these gages.

Thin-Gage Sheet. The projection welding of thin-gage steel sheet (<0.50 mm, or 0.020 in.) differs significantly from the projection welding of intermediate-gage sheet in that single-point projections become mechanically unstable. It also becomes increasingly difficult to use single-point projections to make adequate-sized welds. Therefore, annular projections are typically recommended for thin-gage steel. Table 5 provides the annular-projection weld geometry, as well as the required process conditions.

Dissimilar-Thickness Joints. As previously noted, the projection welding process is ideally suited for the joining of sheets of widely disparate thickness. When fabricating such joints, the best practice is to place the projection on the thicker sheet, where possible, using the projection design that is appropriate for the thinner sheet. This is done because the projection has the effect of concentrating the heat at the contact surface, regardless of the thicknesses of the sheets being joined. As a result, selecting conditions based on the thinner sheet has the effect of sizing the weld for that (attached) material.

Steel Solid-Projection Welding

Solid-projection welding of steels that are described as follows includes annular, nut, and cross-wire projection configurations.

Annular-Projection Welding. Neither specific projection designs nor process conditions for annular-projection welding are well established. There is a general consensus on the use of 90° included angle triangular cross section projections in sizes that are scaled to the thickness of the opposing sheet. Typical practice includes approximately 4.5 to 8.9 kN (1000 to 2000 lbf) of force per linear inch (or 25 mm) of projection, as shown in Table 6. Weld times for annular projections for diameters ranging from 6.4 to 25 mm (0.25 to 1.0 in.) usually range from a single cycle to approximately 10 cycles. Typically, shorter welding times result in more-robust processing conditions. Maximum welding times are often limited by concerns over thermal damage to the base metal.

The best annular-projection design will recess the base diameter of the projection from the outside diameter of the part. Reasons for this are shown in Fig. 14. Projection designs that extend to the outside diameter of the part have the potential for unstable projection collapse, which can result in the formation of an incipient notch at the outside diameter of the part and an increase in the incidence of weld-related failures.

Larger-diameter annular-projection welds cause a problem in attaining the proper heat balance around the periphery of the projection. Typically, the side of the projection that is toward the throat of the machine will heat preferentially for two reasons. First, the shortest conductive (and highest current flow) path is

Source: Ref 3

along the inside of the throat, including the inboard side of the projection. Second, there is an inductive “skin” effect associated with alternating-current machines, which tends to concentrate current along the inside of the welder throat. Intermediate-diameter projections have

been successfully welded using direct current, because it minimizes the skin effect and appears to allow better heat balance.

Larger-diameter projections may require dual-throat machines, which have dual transformers located on opposite sides of the

workpiece. Each has its own “throat.” The effect is to balance the resistive/inductive effects, allowing the welding of very large-diameter projections.

Nut Welding. Specific criteria for the design of weld nut projections, as well as appropriate

Source: Ref 3

processing conditions, are not well established. The weld current should be set to relatively high values, with weld times set to relatively short values. The weld current and time should be adjusted to achieve bonding while avoiding expulsion. Too high of an electrode force will produce inconsistent results, while too little force will promote expulsion.

There is a general consensus that the ideal number of projections on a weld nut is three, because it is assumed that all three will contact the opposing surface when the electrode force is applied, if the projections are of the same height and if the electrodes are aligned properly.

The actual design of the welding projections is not well established, although 90° included-angle square pyramidal, truncated cone, and hemispherical projections are common. When changing from one projection design to another, the height-to-base diameter ratio of the projection should roughly be maintained. Projection dimensions are nominally scaled according to the opposing sheet. Designs for embossed projections of the appropriate sheet size can be used as a guideline. The projections should be symmetric and not placed on the edges of the weld nut.

Cross-Wire Welding. The process conditions for the cross-wire welding of a range of wire thicknesses are given in Table 7. The conditions are usually specified in terms of requirements to achieve a certain level of compression set-down for the wires. Set-down is defined in Fig. 15. In general, joint strength increases as

the degree of set-down increases. The defined process conditions are for mild steels. Higher-strength materials, such as stainless steels or nickel-base alloys, will require higher forces and longer welding times to promote wire collapse and diffusion across the bond line.

Sources of Defects

The most common defects in projection welding include lack of bonding, cracking, holes, porosity, and cratering from metal expelled from the projection base. Lack of bonding (Fig. 16) is the result of insufficient heat to produce a fusion weld nugget or insufficient heat generated during projection collapse to produce bonding. Most often this is due to improper projection designs or imbalances in weld current levels, weld times, and electrode forces. Cracking, holes, and porosity (Fig. 17) can occur in projection welding from causes similar to RSW. This includes high hardness of the weld or HAZ, low-melting constituents in the weld metal, expulsion, and so on. Expulsion (Fig. 18) is often caused by excessive current, insufficient electrode force, inadequate electrode force followup, improper projection design, or excessive weld time.

Electrode wear can also deteriorate weld quality. Repeated welding operations can cause pitting, electrode contamination, or erosion of the electrode face. These can alter the heat generated at the electrode face or reduce the

effectiveness of projection collapse. Pitting or contamination can alter the heat generated at the electrode surface. For thermally conductive materials, increases in heat generated at the electrode interface can diffuse into the projection and soften it, causing premature collapse. Alternatively, electrode face contamination can reduce the heat generated at the faying interface or change the heat balance of the joint, resulting in a loss of weld quality. Locally deep erosion of the electrode face can reduce the available projection collapse distance during welding and reduce bond quality. Electrode wear can be reduced by improving the flow of coolant (water) through the electrodes and by electrode dressing. Accelerated electrode wear can also be caused by insufficient squeeze and hold times, electrode geometry, followup characteristics, and the quality of the refractory used on the electrode face.

Excessive weld current can produce a number of undesirable effects. Expulsion can also contaminate the threads on a weld nut application or make a fluid-carrying device unusable. It can cause surface marking on show surfaces. Incidental contact between the components (Fig. 19) during projection welding can shunt weld current and cause expulsion away from the intended weld location.

Quality Control and Inspection

There are many tests that can be used to validate projection weld quality. These tests

(a) Configuration designations are for the purposes of this table only. (b) Based on 60 Hz. (c) Electrode force contains no factor to further form poorly made parts. (d) Starting values shown are based on experience of Resistance Welder Manufacturers Association member companies. (e) Tensile-shear strength per projection depends on the joint design. (f) Schedule A is usable for welding more than one projection if current is decreased, but excessive weld expulsion may result and power demand will be greater than that for schedule B or C. (g) Schedule B is usable for welding more than three projections, but some weld expulsion may result, and power demand will be greater than that for schedule C. (h) Schedule C is usable for welding less than three projections with weld current increased approximately 15% and possible objectionable final sheet separation. Source: Ref 3

measure the strength, ductility, performance, or integrity of the bond.

Shear- or normal-type tensile tests (Fig. 20) can be performed, typical of other RSW applications. These tests can be applied to coupons or actual components in orientations representative of part performance. It provides a good measure of weld strength, but in some cases, it may not accurately describe weld ductility.

The peel test (Fig. 21) is frequently used on the shop floor to assess weld quality. It provides a qualitative assessment of weld ductility and strength.

The pushoff test (Fig. 22) is often the best test for defining weld quality of annular-projection or multiprojection welded components. It consists of pushing or pulling the welded component from the part in an orientation normal to the sample surface. The peak load and/or displacement is recorded. Interpretation of the fracture appearance also provides significant clues to weld performance or quality. Usually, the pushoff test is much more discriminating than the torque test.

The torque test (Fig. 23) is widely used on welded nut and similar configurations. Like the shear or tensile test, the torque test also places the weld under a shear-type load. However, the torque values commonly applied are representative of the part usage rather than its loading capacity. Additionally, this test does not assess the ductility of the weld. Because of the limited test torques often used and the orientation of the stresses, the torque test should be used as a proof test method. Other tests should be used to develop the production weld schedules.

Metallographic inspection is a common method to assess bond line quality. Other metallurgical features (hardness distribution, grain size, etc.) of the weld can also be assessed. While it does not provide numerical values or assess the whole weld, metallurgical inspections can be invaluable for interpreting other test results.

The current range test is actually a set of test results that measure weld quality over a range of weld currents. When used as a quality measure in conjunction with changes to projection geometry, an optimal projection geometry can be defined for a specific application.

Projection set-down (Fig. 24) can be a useful indicator of weld quality, when it has been correlated with weld performance using some other weld quality test method. It is nondestructive and often can be used in feedback control schemes.

Feedback controller systems are available that can monitor weld voltage and current to compute dynamic resistance. Displacement of the weld head can also be monitored. This measure can often be directly related to weld quality. To be effective, the monitored displacement must measure the projection set-down. Displacement measurements within the fast followup head can be used to characterize the dynamic force applied to single projections. Displacement of the upper ram can be used to identify stiction (dynamic friction) issues with the welder.

Safety

Safety concerns on projection welding are similar to those for other resistance welding processes. Concerns over pinching and crushing hazards, sharp metal edges, hazardous fumes, metal expulsion, hot work, electrical grounding and shock hazards, and other issues are identical because the welding equipment and base materials are very similar.

Personal safety equipment includes protective eyewear, gloves, wrist and arm guards, and so on. The welding machines can be further guarded in a number of ways. Some of these include two hand initiation switches, light curtains, barrier guards and locks, various other proximity sensors, electrical continuity monitoring, ground fault current relays, and so on. These are common to other forms of resistance welding.

Resistance Seam Welding

Robert Matteson, Taylor-Winfield Technologies

SEAM WELDING, as defined by the American Welding Society, is "A resistance welding process wherein coalescence is produced by the heat obtained from resistance to the flow of electric current through the work parts held together under pressure by circular electrodes. The resulting weld is a series of overlapping spot welds made progressively along a joint by rotating the electrodes."

Seam welding machines are capable of making two types of lap joint. A continuous, pressure-tight joint (Fig. 1a) is produced on the overlapped materials by continuously rotating electrodes with a welding current that is interrupted regularly to achieve the effect of overlapping spot welds. An interrupted current is not required on some thin materials. On these, a continuous welding current will produce a good-quality continuously fused seam weld.

A seam welder is also capable of producing a row of spot welds that do not overlap (Fig. 1b). While not actually seam welding, this roll spot welding operation can be accomplished on standard seam welder machines and is a useful production technique where a pressure-tight joint is not required. These lap seam welding techniques are the most simple and most readily accomplished in production. Where justified by final product appearance, another method is mash seam welding (Fig. 2), sometimes called narrow-lap welding. Mash seam welds are produced by overlapping two sheets, with work metal compressed at the joint.

Fig. 1 Types of lap joints. (a) Pressure-tight joint. (b) Nonpressure-tight joint

A variety of workpiece/wheel configurations are possible (Fig. 3). In mash seam welding, electrode shape may be flat or contoured (radiused), depending on the thickness of the sheet. Wide-faced wheels with flat cross-sectional shape should not be used in mash seam welding of materials thinner than 1.0 mm (0.04 in.), while wheels with a contoured edge (Fig. 2c) are used on materials thinner than 1.0 mm (0.04 in.) or on thicker sheet. The radius of the electrode contour is about 100

Fig. 2 (a) Lap seam weld, (b) mash seam weld with flat electrodes, and (c) mash seam weld with radiused (contoured) electrodes. Flat electrodes in mash seam welding should not be used when sheet thickness is less than 1mm (0.040 in.). Radiused electrodes can be used for sheet thicker than 1mm with the electrode radius of curvature about 100 times the sheet thickness.

times sheet thickness. Metal finish seam welding (Fig. 3c) uses a chamfered electrode wheel, and one side of the joint is mashed down while the other side of the joint has a smooth, flat finish. Overlap is greater than for mash seam welding, and higher current amperages and electrode forces are also required.

Two rotating circular electrode wheels are often used to apply current, force, and cooling to the work metal. When two electrode wheels are used, one or both wheels are driven, either by a direct drive of the wheel axles or by a knurl drive that contacts the peripheral surface of the electrode wheel (Fig. 4). For some applications, the electrode wheels idle while the workpiece is driven. Other electrode systems for seam welding may use one wheel and one flat bar-type electrode (Fig. 5), or a wire-feed system in which a copper wire is fed into a groove on the wheel.

Electrode wire seam welding (Fig. 6) is a patented process that requires an intermediate wire electrode between each wheel electrode and the workpiece. The electrode wire seam welding process is used almost exclusively for seam welding of tin mill products to fabricate cans. The copper wire travels around the wheel electrodes at the welding speed. The circular or flat cross-section of copper wire electrode provides a continuously renewed surface, but it is not consumed in the welding operation. This wire-feed process continuously provides a new copper surface for contact with the work metal and is often used on coated materials. In tin mill products, the tin build-up which would occur on a copper wheel electrode is thus avoided. The process requires specially designed welding systems. The seam welds may be made with two wheel electrodes, or one wheel electrode and a mandrel electrode.

In seam welding, a series of spot welds is made without retracting the electrode wheels or releasing the electrode force between spots. The electrode wheels may rotate either continuously or intermittently. Weld speed, current magnitude, current waveform, cooling system, and the electrode parameters of force, shape, and diameter are all related and must be carefully selected to optimize the process and produce the highest-quality weld.

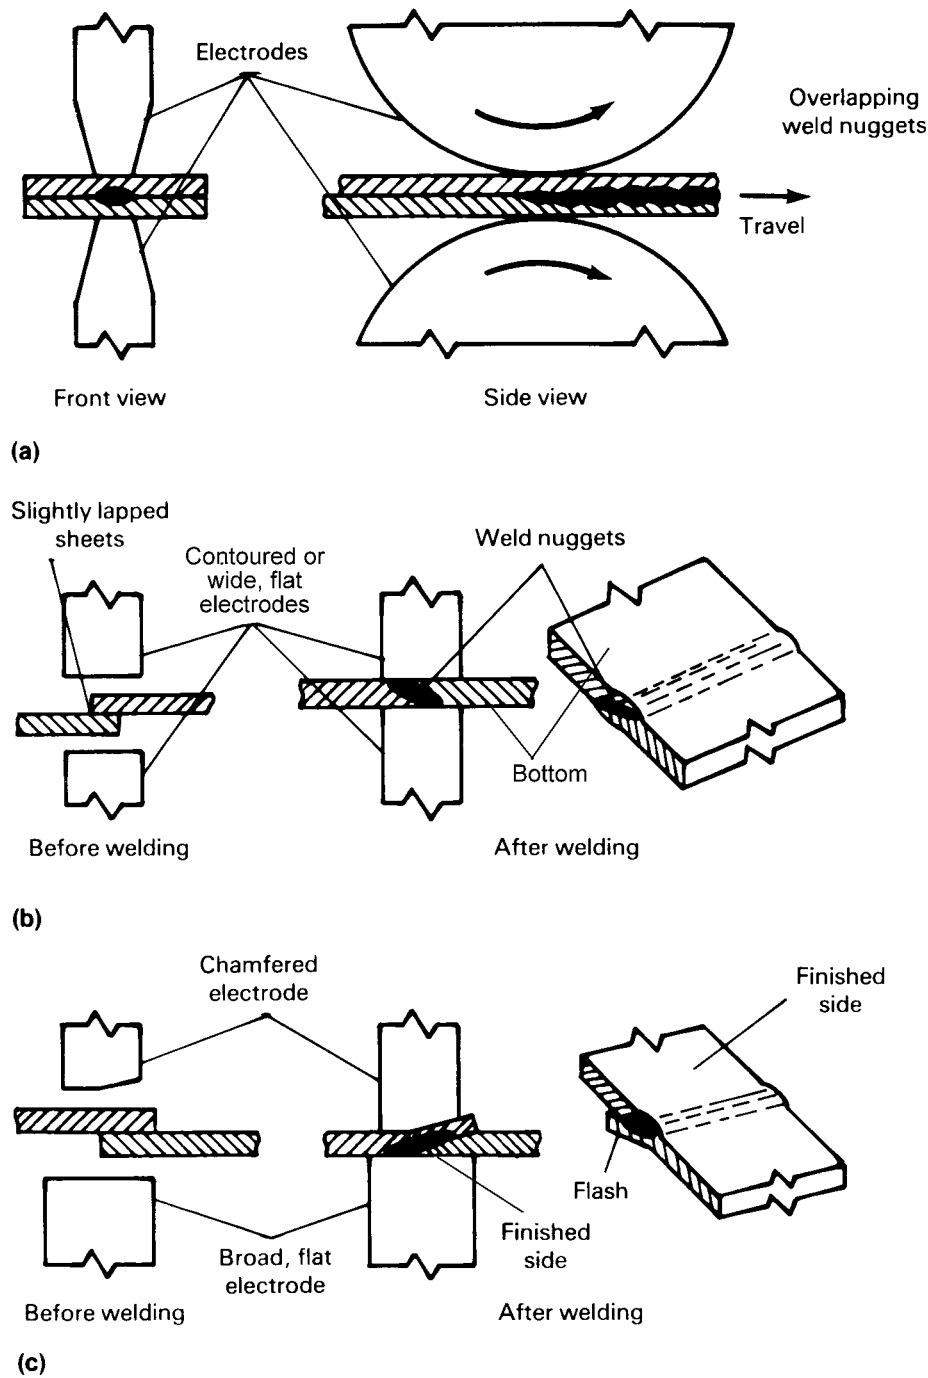

Fig. 3 Basic configuration of joints and resultant welds formed in resistance seam welding. (a) Lap seam welding. (b) Mash seam welding. (c) Finish seam with chamfered electrode. (d) Electrode wire seam welding.

Process Applications

Lap Seam Weld. Lap seams (Fig. 1a) are popular in automotive applications, such as automotive fuel tanks, catalytic converters, mufflers, and roof joints, as well as in nonautomotive applications, such as furnace heat exchangers, water tanks, and certain types of can making (Fig. 7c). Lap seam welding of multiple stackups and dissimilar thicknesses is also possible.

Mash Seam Weld. The process of mash seam welding is a variation of lap seam welding, where the overlap of the sheet is minimized to produce a weld that can be minimized in overthickness both by the welding process and by a subsequent planish (rolling) operation. This process is used in welding drums, barrels, and coils of steel in processing lines.

In a mash seam joint (Fig. 2b, 3b), the two sheets overlap by approximately one to two times

the sheet thickness. The weld area is forged or mashed down to an overthickness 5 to 25% greater than a single sheet thickness. Depending on the amount of overlap, much of the thickness reduction can occur during welding, and some occurs during planishing. With narrow overlap (in the range of $1 \times$ thickness of one of the sheets), it is possible to produce practically no “hump” in the as-welded condition.

It is necessary to have some amount of overthickness so the current path can be controlled, because the electrode wheels in mash seam welding can be wide and flat-edged. If flat (infinite radius) electrodes are used, especially on thin materials, wear grooves in the electrodes allow the electrodes to touch parent material outside the weld overlap, and current can flow that does not pass through the weld. Radiused (contoured) wheels are used to prevent current shunting when welding thin materials (materials less than 1.0 mm, or 0.04 in., thick, as previously noted).

Surface appearance and thickness can be improved through the use of hard steel planishing wheels to cold work the joint before or after welding. There always has been a need to minimize the overthickness of the welded seam in processing lines. One of the early ways to achieve this was to preplanish the edges of overlapped sheets, retract the overlap somewhat but not entirely, weld, and postplanish. The preplanish produced a taper on both edges of the overlap. Retraction then did two things:

- It meant welding thinner sheet edges together.
- It provided a region for the mashed materials to escape to.

This process was the basis of the Prep/Lap welder (Taylor-Winfield Technologies) provided in over 100 galvanizing lines from 1965 until 2000. Generally, this technique was used with commercial- and drawing-quality sheet steels that do not exhibit significant work hardening with the preplanish operation.

Typical applications of mash seam welding include drums, buckets, vacuum-jacketed bottles, aerosol cans, water tanks, and steel mill coil joining. Sheets of dissimilar thicknesses and/or coatings have been successfully mash seam welded. This development has created a whole new set of applications in tailored blank manufacturing, primarily for automotive use (see the *ASM Handbook* article “Forming of Steel Tailor-Welded Blanks” in Ref 1).

Advantages and Limitations

Advantages of seam welding, compared to resistance spot welding, projection welding, and laser welding, are:

- Gas-tight or liquid-tight joints can be produced (not possible with spot welding or projection welding).
- Seam width may be less than the diameter of spot welds, because the electrode contour

Fig. 4 Position of electrode wheels relative to throat on resistance seam welding machines

Fig. 5 Seam welding with single wheel and lower electrode

Fig. 6 Typical setup for an electrode wire seam welding process showing positions of wire relative to grooved wheel

- can be continuously dressed and is therefore of a stable shape.
- High-speed welding (especially on thin stock) is possible.
 - Coated steels are generally more weldable using seam welding than spot welding, because coating residue can be continuously removed from the electrode wheels if special provisions are made. Often, seam weld wheels that are used to weld coated materials are driven with another drive that simultaneously removes the buildup from the electrode. Also, large-diameter electrodes on coil-welding applications only rotate a few times per weld. This allows time between welds for electrode cleaning.
 - Coated steels are generally more weldable using seam welding than laser welding, because coating volatility is minimized by the intense pressure field in the weld zone.
 - Resistance seam welding is not particularly fitup-sensitive as compared to some other production-line methods, such as laser welding.

- The hardness of resistance seam welds made with air cooling is less than that of laser welds (120 HV versus 250 HV, respectively, for drawing-quality bare steel, and 170 HV versus 300 HV, respectively, for organic-coated drawing-quality steel).

Limitations of seam welding, apart from those it shares with spot welding and projection welding, are:

- Welds must ordinarily proceed in a single plane or on a uniformly curved surface. For special cases, multiplane welding has been achieved using a tilting welding head. The

radius of curvature connecting the planes must be sufficiently large.

- Obstructions along the path of the electrode wheel must be avoided or compensated for in the design of the wheel.
- Material handling must not induce extraneous forces into the fragile, molten weld zone during welding.
- Sharp corner radii or abrupt changes in contour along the path of the electrode wheel must be avoided (Table 1). Sharp corner radii or abrupt changes in contour will produce wheel wear and deposit copper on the weld surface, which is not desirable because it can lead to weld failure.

Fig. 7 Arrangement of electrode wheels relative to workpiece for selected flange-joint lap seam welds. (a) Single and double flange. (b) Two-member outward flange. (c) Two-member inward flange. (d) Small upper electrode wheel to avoid sidewall interference. (e) Canted large-diameter wheel to avoid sidewall interference

- Fatigue life of resistance seam welds is usually shorter than that of welds made by other seam welding methods.

The length of seams made in a longitudinal seam welding machine is limited by the throat depth of the machine (Fig. 4b). Current shunting through the weld, or a change in electrical impedance caused by the movement of the product inside the throat of the machine, can require current compensation (or constant current) as welding proceeds. Components using multiple crossing seam welds can be quality-sensitive at the weld intersections.

External water cooling of the electrodes and the weld zone may be required for high-speed welding. (Under high-speed conditions, the weld nuggets are still molten as they leave the pressure field of the wheels.) External cooling may add tooling cost for water containment and water removal from the parts after welding.

Materials requiring postweld heat and temper can be seam welded with special

considerations. Chromates and insulating lacquer coatings are not resistance seam weldable, because chrome-coated or lacquered materials are not readily weldable.

Fundamentals of Lap Seam Welding

The article "Resistance Spot Welding" in this Volume describes basic principles that are also generally applicable to seam welding. Certain concepts from resistance spot welding apply to resistance seam welding, because seam welding generally consists of a series of overlapping spot welds. The analog is that spot welding parameters depend on three key variables: current, the duration of current flow, and sheet thickness.

Likewise, there is a range of welding parameters for suitable seam welding—except that welding speed is a key parameter in seam welding (as opposed to the time of current flow in spot welding). For a given section thickness, the range of suitable current becomes more

narrow with higher welding speeds (Fig. 8). For example, the upper limit of current is defined by the onset of weld splash, while the minimum limit is the current necessary to develop a continuous seam weld.

The optimal weld speed may be identified experimentally as the speed with the widest current range for making good welds. Good welds are nominally free of typical metallurgical discontinuities (for example, surface cracks, gross lack of fusion at the weld interface, or surface melting eruptions). Additional discussion on developing the optimal welding lobe (such as in Fig. 8) for different thicknesses of sheet is included in the article "Procedure Development for Resistance Welding" in this Volume.

It is important to note that the current range of seam welding is widened by the judicious use of pulsed current to form distinct nuggets. Impulse profiles of 25 to 33% off-times are commonly used. Impulses contain off-time for the electrodes to draw heat away from the weld

Table 1 Recommended minimum radii of curvature for seam-welded aluminum and steel components

Base material	Minimum radius			
	Inside radius, R_1		Outside radius, R_2	
	mm	in.	mm	in.
Aluminum	250	10	75	3
Steel	150	6	50(a)	2(a)
			57(b)	2¼(b)
			64(c)	2½(c)
			75(d)	3(d)

(a) $0.8 \text{ mm} \leq t \leq 1.3 \text{ mm}$ ($0.031 \text{ in.} \leq t \leq 0.051 \text{ in.}$). (b) $t \leq 1.6 \text{ mm}$ ($t \leq 0.063 \text{ in.}$). (c) $t \leq 2.0 \text{ mm}$ ($t \leq 0.079 \text{ in.}$). (d) $t \leq 3.0 \text{ mm}$ ($t \leq 0.12 \text{ in.}$). Source: Ref 2

Fig. 8 Typical weldability lobe for seam welding of mild steel sheet (1.2 mm, or 0.05 in., thick) with alternating current. Source: Ref 3

surface. Therefore, the occurrence of surface discontinuities is lessened. In addition, off-time allows heat to redistribute itself within the weld, away from local hot spots.

Hot spots are places within the weld where thermal spikes may be occurring due to a relatively high local resistance, a nonuniform current density, a multiple stackup, or a stackup of unequal sheets. Hot spots are especially common along the weld interface when welding either thick plates or prepainted sheets. Hot spots on the outside surface of a weld occur naturally with unequal sheet thicknesses (on the thin side) or when welding is faster than permitted. On the other hand, hot spots can also occur within the sheet bulk, if due to erratic time distribution of current during on-time. Bulk hot spots begin to occur when welding near the maximum speed for a material, because current is actually not applied uniformly throughout the on-time, and time is required for the resulting nonuniform heat pattern to redistribute itself (Fig. 9).

The ideal impulse shape under high-speed conditions would seem to be a square wave (Fig. 10a). Because typical industrial power sources can only approximate this shape (Fig. 10b), it is worthwhile to accurately record the waveform of the actual secondary current in order to monitor its shape and stability during welding. Current range is greater in impulse mode than in nonimpulse (continuous-current) mode. The extra range seems to provide more robust penetration under difficult welding conditions, such as when intersecting other welds or turning corners with the seam.

One of the disadvantages of seam welding relative to spot welding is that solidification of the weld nugget occurs after the weld metal leaves the pressure field of the electrode wheels. Thus, if there is a large separating force on the weld before it freezes, it can come apart as it leaves the wheels. This postweld separation has been called “unzipping” or “alligatoring.” Impulses effectively cure this problem because the off-times create a modulating penetration profile (Fig. 11), providing cool tack joints between the molten spots.

It is desirable from a process control standpoint to select an impulse schedule that will produce nuggets of nearly equal length and width, in conjunction with the other parameters used (speed, wheel diameter, wheel width, and power source).

When welding dissimilar thicknesses, on-time must not be greater than the optimal weld time for the thinnest outer sheet (TOS). Mathematically:

$$t = 4(0.0292)(TOS)^2 \tag{Eq 1}$$

where TOS is in millimeters.

One way to satisfy the weld-time needs of both total stackup and TOS for thick-thin welding is to raise the number of nuggets (n) in the weld zone to 2 or 3. The goal here is to weld for the proper total time, but to do it with pulses of on-time no greater than dictated by Eq 1. To increase n , one must carefully consider the electrode wheels as well as the impulse schedule. Even when taking advantage of pulsation, it may become impossible to

Fig. 9 Schematic showing lengthwise sectional view of the weld centerline of a lap seam joint with irregular nugget shapes. The lack of uniformity in the shape of the nuggets is attributable to an irregular pulse shape that does not provide sufficient time for heat flow to blend together the doublets.

Fig. 10 Weld current profiles for seam welding. (a) Ideal impulse shape. On-time is 75% of impulse period, while off-time is 25% of impulse period. (b) Actual impulse shape is typically complex and nonideal. In this specific case, impulses are from an alternating current single-phase (3 on/1 off) current source.

Fig. 11 Schematic showing lengthwise sectional view of proper nugget development in the weld zone of a pulsed lap seam weld. The length of the contact head footprint, L , is sufficient to contain three nuggets under the wheel.

seam weld extremely dissimilar thicknesses without damaging the thinnest outer sheet. This difficulty should become pronounced for thickness ratios above approximately 3 to 1, which is the general limit for thickness ratios.

Wheel Geometry, Weld Force, and Wheel Maintenance

The primary role of wheel geometry and force in seam welding is to control the dimensions of the weld zone or the size of the footprint that the wheel makes on the workpiece while welding. The length of the footprint, L , is an important factor in determining weld time. The variable L is primarily controlled by wheel diameter, force, and current. (As either force or current is increased, the wheel will sink deeper into the work, and L will increase.)

It can be worthwhile to measure or estimate L . This has been done experimentally using special voltage probes on the electrodes and by an optical silhouette method (Ref 4). A less accurate (but simpler) method is to read the heat pattern at the beginning and end of the weld, to estimate the number of nuggets (n) under the wheel at any one time. For bare steel, n can be as low as 1. However, the weldability of coated materials and dissimilar thicknesses improves when n is as high as 2 or 3 (Fig. 11). Keep in mind that the contact length will decrease somewhat as the wheel wears to a smaller diameter. (Normally, this change should not be of concern, except possibly when welding beyond the theoretical top speed for a material combination.)

Footprint width is best matched with impulse length, d , to produce nearly round nuggets. Width, however, is of secondary importance to impulse length.

A transverse radius on the wheel generally improves the welding range, because under high current conditions, it automatically reduces current density by sinking further into the work.

Under given electrode conditions, increasing weld force improves the welding range for speed and helps control cracking.

It is generally true that the current range improves with higher wheel pressure, until longitudinal splits begin to occur at seam starts or stops. On the other hand, at low force, transverse surface cracks may result at the upper end of the current range, especially on coated steels. A good rule of thumb is to weld at 80% of the seam-splitting force, or less. In addition, it may be helpful to de-energize the weld force except while welding, so as not to cause undue wheel wear.

For the highest-quality joints, it may be necessary to lightly machine the wheels as they are used, to maintain a constant edge profile. The types of wheel dressing tools are:

- Scrapers to remove contamination when welding coated materials
- Width cutters to remove mushroomed copper and to control wheel width
- Knurlers (Fig. 4) to maintain the transverse profile on the wheel and drive the wheels as needed
- Conditioners, which are essentially rollers with a reverse mask shape to roll the electrode into its correct shape. The conditioners have the distinct advantage of hardening the copper alloy of the electrode, which improves the wheel life without changing the electrical properties.

If wheel maintenance on the machine is not feasible, the wheels can be removed and redressed off-line. Alternatively, the wire-electrode seam welding process provides a constant wheel condition (Fig. 6) and thus eliminates the need for continuous wheel dressing.

Cooling the Weld

The weld cooling system is very important for process control of seam welding. Its primary role is to minimize thermal damage to the outer

surfaces of the weld while the weld interface is being heated above the melting point. The key elements in the success of the weld cooling system are:

- Electrode material (thermal or electrical conductivity)
- Electrode transverse shape (radius profile is best)
- Electrode cleanliness (should be dressed free from pickup of nonconducting coatings)
- Electrode cooling system
- Cooling water applied directly to the weld (if applicable), termed flood cooling

Cooling water for seam welding wheels can be either internal or external. Internal cooling systems cool the wheel but not the weld. The key advantage of internal cooling is that the process is dry; the workpiece, the machine, and the operator stay dry. The cost of installing floor drains and water-containment facilities is avoided. Neither is it necessary to remove water from inside the workpiece (as in the case of automotive fuel tanks). However, internally cooled wheels may cost more due to additional machining costs. Thus, operating costs for internal cooling may be higher than for external cooling. Some internal systems do not directly cool the wheel but only the wheel shaft.

On the other hand, with external cooling, spray nozzles are aimed with some precision at the workpiece-wheel separation point. The benefits of external cooling include:

- Thermal damage to the weld surface and any coatings is reduced, so that weldability is improved.
- Weld distortion is reduced.
- Fume emission is reduced.
- Wheel cleanliness improves, because water is directly applied to the hottest point on the wheel, producing a quench/cleaning action on the wheel surface.
- Weld hardness will increase, adding strength to the weld under certain loading conditions, such as crush loading. (*Some quench-sensitive materials may not allow external cooling.*)

In welding bare steel, rust-preventive water solutions are sometimes used.

Metals Welded

Most low-carbon, high-carbon, low-alloy, and stainless steels and many coated steels above approximately 0.15% carbon equivalent (CE) tend to form areas of hard martensite upon cooling. For steel sheet products, the following CE formula is used:

$$CE = C + (Mn + Cu + Cr)/20 + Si/30 + Ni/60 + Mo/15 + V/10 + 5B$$

In critical applications, the welds may require postweld tempering to reduce the hardness and

brittleness. In some cases, this can be done in the welding machine. Tempering can also be done in a furnace or by induction heating.

Aluminum and aluminum alloys can be wide-lap seam welded but not mash seam welded, due to their narrow plastic range. Nickel and nickel alloys can also be seam welded, but seam welding is not recommended for copper and high-copper alloys. Compatible combinations of dissimilar metals and alloys can also be seam welded. For additional information on the seam welding of stainless steel, aluminum alloys, and copper alloys, see the article "Procedure Development for Resistance Welding" in this Volume.

Types of Seam Welds

Several types of resistance seam welds can be made:

- Lap seam welds joining overlapping flat sheets
- Flange-joint lap seam welds with at least one flange overlapping the mating piece (Fig. 7a)
- Foil lap seam welds, in which an alloy metal foil is placed at the weld interface
- Mash seam welds with work metal compressed at the joint to reduce joint thickness (Fig. 2b)

In addition, both low-frequency and high-frequency induction and resistance welding are used for butt welding strip stock into tubes and other shapes.

Lap Seam Welds

The most common type of seam weld is a simple lap seam in which the pieces to be welded are lapped sufficiently to prevent the sheet edges from becoming part of the weld (Fig. 2a). Applications include sealing of cans and tanks in which liquid-tight or gas-tight joints are needed.

Flange-joint lap seam welds are used in joining assemblies having one straight member and one outward-flanged member at the joint to be welded (for example, the duct in Fig. 7a) or assemblies with two outward-flanged members (for example, the automotive gasoline tanks in Fig. 7b). Common applications include containers with out-turned bottoms or tops, and ducts or structural parts with out-turned sides. Unless the workpiece length is less than the usable throat depth of a longitudinal machine, seam welds of this type are made on a circular machine.

Often, container ends are dished for added strength, and one or both electrode wheels must be mounted at an angle to clear the workpiece. Wheel diameter limitations may also necessitate setting a wheel at an angle (Fig. 7a, right view).

Flange-joint seam welds can also be used for welding assemblies in which the flanges face

inward at the joint (Fig. 7c). However, to reduce overhang of the arm supporting the lower electrode or to reduce the required throat depth of the machine, the length of the workpiece should be kept to a minimum. If the lower electrode support is small, too much overhang can result in excessive deflection of the support and thus cause inconsistent weld quality because of force variation.

Mash Seam Welds

Mash seam welds are produced by overlapping two sheets by an amount ranging from one to two times the sheet thickness and applying electrode force and current. The resulting overthickness is 5 to 25%.

The joint itself acts as a current localizer, as in projection welding, because the overlap is thicker than either sheet by itself. Because the wheels are wide, the transverse position of the joint on the wheels can be oscillated as needed to prevent a groove from forming on the wheels and to increase the period between wheel dressings.

Careful selection of an impulse weld schedule will result in higher penetration and greater joint strength, although the "bumpy" appearance of a weld made with pulsating current may not meet product requirements. Cosmetic mash seam welds can be made with nonpulsed (continuous) current.

Because sheet overlap is a critical parameter, workpieces must be rigidly and accurately clamped or tack welded to prevent lateral motion during welding. Clamp distance is highly important and is related to stock thickness. On continuously fed, moving-part setups and thin-metal processes (where clamp distance would be too small), clamps may not be feasible. In these cases, a Z-bar and nosedpiece tooling arrangement is used to help position the edges to be welded.

In applications in which the mashed surface must be as flat and burr-free as possible after welding to facilitate porcelain enameling and to present a good appearance, a bar-type electrode is used against the surface to be enameled, and an electrode wheel is used against the other surface. The bar-type electrode may require periodic dressing to avoid excessive grooving and subsequent loss of current density. When a premium-finish appearance is required, the weld can be ground or roll planished to remove surface imperfections.

In steel coil joining, it is sometimes desirable for the final thickness of the mash seam weld to be similar to the single sheet thickness. To minimize the thickness gain from welding, pre- and/or postweld planishing rolls are used. These rolls are hard steel wheels, typically 100 mm (4 in.) in diameter and 20 mm (0.75 in.) in width. Planishing rolls are typically loaded to 22 kN (5000 lbf) or to twice the weld wheel force, to cold work the weld. In this way the overthickness may be held to as little as 5% on low-carbon steels and as much as

25% on dual-phase and transformation-induced plasticity grades. Also, the overlap may be retracted slightly after the preweld planish to further limit overthickness.

The highest-quality mash seam welds are made in low-carbon steels and stainless steels. The process is widely used in the manufacture of refrigerators, stoves, laundry equipment, and other products that receive porcelain enamel coatings. Mash seams are gaining popularity in automotive applications for creating tailored blanks that reduce weight and material loss in certain large stampings (for example, body sides and doors), reduce manufacturing complexity, and reduce the number of components and welds required to make finished automotive subassemblies.

Because of their narrow plastic range, nonferrous metals generally cannot be mash seam welded.

Processing Equipment

A seam welding machine is similar in construction to a spot welding machine, except that one or two electrode wheels are substituted for the spot welding electrodes. Power sources used for seam welding are similar to those used for spot welding. They usually consist of a welding transformer, with a tap switch in the primary circuit, driven by a silicon-controlled rectifier switching system and a secondary circuit with electrodes for transferring the welding current to the work metal.

Controls for seam welding are generally similar to those for spot welding, except for differences related to the relative motion of the work and the electrodes. Most modern weld timers are capable of generating impulse weld schedules for seam welding. (Higher impulse frequencies for welding thin stock can be obtained using special high-frequency systems, although complete machine redesign may be necessary due to transformer and throat area limitations that are directed by the frequency.) Tap switches and a phase-shift heat control are used as in spot welding for changing the transformer output current. In theory, direct feedback current regulation would be a desirable feature in seam welding, and some work has been done to develop and improve this.

Seam Welding Machines

In general, seam welding is done in a press-type resistance welding machine. Most seam welding machines are powered by alternating current, either three phase or single phase; some are designed for use with direct current, which includes medium-frequency direct current. Stored-energy seam welding machines have been built, but this type finds little use. Direct current frequency converter power supplies are used to tailor custom pulsation schedules.

Equipment for seam welding must be capable of:

- Delivering low-voltage, high-amperage current
- Supporting the electrodes and workpiece and applying the electrode force
- Moving the workpiece and/or driving the electrodes
- Regulating, timing, and sequencing the application of the welding current, force, and cooling water (if applied)
- Careful part handling, such that extraneous forces are not imposed during welding
- Provide cooling for forced-cooling systems or electrode cooling for indirect-cooled seam welding

Electrode Force and Support. The upper electrode wheel is mounted to, and insulated from, the operating head. The head, which is actuated by a direct-acting air or hydraulic cylinder, applies the electrode force. The lower electrode is either a wheel, a platen, or a mandrel and is mounted on a supporting arm, table, or knee. This lower support can be made adjustable for applications in which the work metals must be maintained at a constant level above the floor.

Electrode or Workpiece Drives. Workpieces are moved by rotating the electrodes with knurl or friction drive, by direct drive of the wheel shaft, by a driven workpiece and idling wheels, or by clamping the workpieces to a bar electrode and moving the bar electrode (Fig. 5).

Weld travel tends to be continuous on thin steel sheets (less than 1.7 mm, or 0.067 in.), whereas it is intermittent on thick sheets (greater than 3.0 mm, or 0.118 in.). The need for intermittent weld travel arises from the longer weld-time requirements of thick steel.

Knurl Drive versus Friction Drive. In a knurl drive or friction drive, one or both of the electrodes are rotated by a knurl or friction wheel on the peripheral surface of the electrode wheel, to provide nearly constant linear speed regardless of the diameter of the electrode wheel. The knurl drive, which has ridges or beads on the drive wheel to aid in turning the electrode, minimizes slippage and is more positive than the friction drive, in which the turning surface of the drive wheel is smooth. The knurled wheel also removes some of the pickup from the electrode wheels. A knurl drive is used when welding coated metals, such as galvanized steel and terneplate, in any application in which the electrodes are likely to pick up material from the work metal, and for scaled stock that cannot be precleaned. A knurl drive usually is not employed if good cosmetic appearance of the weld is important. Knurl or friction drives can be used only with electrode wheels large enough in diameter to allow clearance.

Gear drive is used if small-diameter electrode wheels cannot be driven by the use of knurled or friction wheels because of interference, or if the application cannot tolerate an electrode wheel that has been roughened by a knurled drive roll. With gear drive, in which

the mounting shaft of the electrode wheel is driven, the speed of welding decreases as the wheel wears down.

In a standard seam welding machine, interference may exist at some minimum distance between electrode wheel centers. If one wheel must be small to clear the workpiece, the other must be correspondingly large. If the ratio of the electrode wheel diameters is greater than 2 to 1, the smaller wheel should be driven, to minimize slippage. Welding speed can be kept constant in spite of wheel wear by a variable-speed gear-driven mechanism.

Movable Carriages. When a mandrel or a platen is used as the lower electrode (Fig. 5), the operating head carrying the upper electrode may be mounted in a carriage. The carriage is moved by an air or hydraulic cylinder, or by a motor-driven screw, and thus the upper electrode is passed over both the workpiece and the lower electrode. The upper electrode is free-wheeling, but it may be equipped with an idling knurl or conditioner wheel for dressing. Sometimes it is necessary to use a high-slip drive to assist on thin materials, to prevent wrinkling. In some machines, the workpiece is clamped to a bar-type lower electrode and moved under an idling fixed-position upper electrode wheel.

Types of Machines. There are four basic types of resistance seam weld machines: circular, longitudinal, universal, and portable.

Circular. The axis of rotation of the electrode wheels is at right angles to the front of the machine (Fig. 4a). This type of machine is used for circular work, such as for welding the heads on containers and for flat work requiring long seams. Head pivot capability for welding on an inclined plane is optional.

Longitudinal. The axis of rotation of the electrode wheels is parallel to the front of the machine (Fig. 4b), and throat depth is typically 300 to 915 mm (12 to 36 in.). This type of machine is used for welding short longitudinal seams in containers, for attaching pieces to containers, for coil joining, and for similar work. Machines with traveling heads or traveling electrodes, in which a mandrel or a platen is used for the lower electrode, are normally of the longitudinal type.

Universal. A swivel-type head and interchangeable lower arms allow the axis of rotation of the electrode wheels to be set either at right angles or parallel to the front of the machine.

Portable. The workpiece is clamped in a fixture, and a portable welding head is moved over the seam, either manually or by using a robot. This type of machine is used when the workpiece is too bulky to be handled by a regular machine or when it is more efficient to move the welding head rather than the workpiece. This type of machine is sometimes used for joining the roof and body sides on automobiles. The portable welding head is moved by motor-driven wheels, and an air cylinder mechanism provides the electrode force.

Selection of Electrodes

Alloy type and wheel configuration are the primary factors that determine electrode selection.

Class 1 Copper. Electrode wheels made of Resistance Welder Manufacturers Association (RWMA) class 1 copper (RWMA No. 1.16200) have been used for seam welding of aluminum and magnesium alloys, galvanized steel, and tin-plated steel. The minimum electrical conductivity of class 1 copper is 80% International Annealed Copper Standard (IACS). Recently, this material has been replaced by hot-forged and heat treated RWMA class 2 copper in the overaged condition (RWMA No. 1.18200). With adequate cooling and proper parameters, the high electrical and thermal conductivities of this material keep the electrode-workpiece interface at a temperature below the point where metallurgical discontinuities are formed near the weld surface.

Class 2 Copper. Seam welding of low-carbon and low-alloy steel is usually done with electrodes made of hot-forged and heat treated RWMA class 2 copper (RWMA No. 2.18200). Minimum conductivity is 75% IACS. Minimum hardness is typically 65 HRB. Class 2 also works well with all types of coated steel, but the metallurgical optimization of weld parameters and provisions for wheel maintenance are critical to the success of welding coated steels. For longer electrode life, premium class 2 wheels are available in the 20% cold-worked form, where a minimum hardness of 75 HRB may be specified. Cold-worked wheels show no appreciable loss of conductivity over the forged class 2 material; however, because the wheel surface is heated above annealing temperature during welding, it is necessary to continuously condition the wheel to maintain the cold-worked hardness. This is usually done with a conditioning roll shaped to the reverse image of the wheel shape and pressed against the rotating electrode.

Class 20 copper (RWMA No. 20.15760) is also used for electrode wheels, with properties similar to those of class 2 premium wheels. Class 20 wheels are made using a powder metallurgy process that produces a pure copper product, dispersion-strengthened with alumina. The alumina adds hot strength and tends to reduce pickup during welding of coated steels.

Class 3 copper (RWMA No. 3.17510) is sometimes used for seam welding materials with lower electrical conductivities, such as stainless steel, Nichrome, and Monel alloys. However, class 3 is used with special ventilation only because of the health hazard of atmospheric beryllium when welding or machining with class 3 material. (Beryllium-free class 3 alloy RWMA 3.18000 is also available.) Class 3 wheels have lower electrical conductivity (45% IACS), so they tend to run hot.

Sizes and Shapes. Electrode wheels range in diameter from 50 to 610 mm (2 to 24 in.). Popular sizes range from 100 to 305 mm

(4 to 12 in.), with widths from 6 to 19 mm (¼ to ¾ in.). Edge contours may be flat, radiused, beveled flat, or angled. In lap seam welding, weld quality seems to be easiest to control with a radius edge, as discussed previously. The need for nonradius contours is usually a matter of cosmetic appearance, or due to a tool access limitation. Mash seam welders use a flat-edge or radiused wheel, depending on sheet thickness (Fig. 3b).

Weld Quality and Process Control

It is best to design the entire process around proven weld parameters that have been metalurgically validated on workpieces very similar to actual production parts. Sensitive parts of the weld typically are starts, stops, corners, adjacent shunt paths, intersecting seams, and areas of poor metal fit. On coated metal, parameters should be flexible enough to handle normal coating variations. General troubleshooting information is summarized in Table 2.

To select starting weld parameters, use the guidelines presented in the section “Fundamentals of Lap Seam Welding” in this article and a welding schedule similar to that in Table 3. See also the article “Procedure Development for Resistance Welding” in this Volume for additional coverage on welding parameters. Working values should be chosen that are not too near the extreme limits of the material, the weld tool, or the plant facilities. To make leak-tight seams, weld spots should have approximately equal length and width. Ideally, the same welding parameters should be used for the entire length of the weld. Also, establish production procedures for maintenance of electrode wheels and cooling sprays (if applicable). Check process parameters against required values frequently, and make adjustments and repairs as needed.

The quality of resulting welds can be verified using chisel tests, Olsen ball tests, metallographic sections, pressure tests, or fatigue tests, depending on product requirements. Record target values for speed, force, pulsation,

and water cooling (if applicable). Record tap setting and lower and upper root mean square secondary current limits for acceptable weld quality. Record the actual secondary current waveform to see that it is acceptable (as in Fig. 10) and consistent throughout the weld. Process changes should be made only on the basis of data.

Nondestructive testing (for example, resistivity, ultrasonic testing, dye penetrant, magnetic particle, or eddy current) may be useful in some low-volume testing applications. However, such techniques should come into use only after the optimal parameters are verified metallographically and the process is well understood. In many instances, much can be observed from the external appearance of a lap seam weld, provided the weld surface is not planished or scarfed after welding.

Coated Steels. For a process that has been properly set up and optimized as described previously in this article, the difference in parameters between coated and uncoated steel lies mainly in weld current. Steels with low-melting

Table 2 Troubleshooting in resistance seam welding

Trouble	Cause	Remedy
Hot metal “squirts” out between the parts being welded.....	Welding current is too high. Welding force is too low for current used. Overlap is too small. Welded parts do not fit properly. Sequence is incorrect, allowing welding current flow without electrode force.	Lower transformer tap switch one step, or decrease heat dial setting. Increase air pressure in operating cylinder. Redesign parts with proper overlap and correct forming operations. Correct sequence by adjustment of electrical controls, pressure switch, or speed-control air valves.
Heating is uneven.....	Overlap is too small. Welded parts do not fit properly.	Redesign parts with proper overlap and correct forming operations.
Parts burned and pitted, or steel adheres to electrodes	Electrode face width is too small or not correctly shaped. Welding electrode is made of copper alloy having too much electrical resistance. Surfaces of welded parts are covered with excessive scale, dirt, or foreign matter. Flow of cooling water is too weak or not directed at weld. Welding speed is too fast for thick-nesses of steel being welded.	Reshape electrode to proper face width. Substitute an electrode of higher conductivity. Degrease parts or pickle them to remove grease, scale, and dirt. Increase quantity of cooling water, and properly direct it. Decrease the revolutions per minute of the electrodes.
Work does not weld at all.....	Welder settings have not been changed from those for welding thinner sheets.	Reset welding variables for thicker sheets.
Heat decreases as weld progresses	Magnetic material is being fed into the welder throat and reducing the welding current.	Use additional current-regulating control, or weld one-half length of joint, reverse, and weld other half.

Table 3 Recommended practice for seam welding of 1010 low-carbon steel

Data are for material free of scale, oxide, paint, grease, and oil. Welding conditions determined by thickness of thinnest outside piece.

Thickness (t) of thinnest outside piece(a)		Electrode dimensions						Net electrode force		Welding speed				Minimum contacting overlap(c)

(a) Data for total thickness of pile-up not exceeding 4t. Maximum ratio between thicknesses, 3 to 1. (b) For RWMA class 2 electrode material (minimum conductivity, 75% IACS; maximum hardness, 75 HRB). Wheel width is overall width of a flat-faced wheel or of a wheel with a 75 mm (3 in.) radius face; face width is that of the contacting surface of flat-faced wheels. (c) For larger assemblies, minimum contacting overlap indicated should be increased 30%.

metallic coatings require more current than uncoated steels. Organic-coated steels require approximately the same current as uncoated steels (although the current range for making good welds will be smaller for the organic-coated steels). Some coatings (for example, zinc and aluminum) are particularly active at the electrode-workpiece interface. For these surface-active coatings, speed, force, and pulsation are selected to keep the surface temperature of the weld below the point where metallurgical discontinuities are developed. Diligent maintenance of the wheel condition and the cooling system cannot be overstated for sensitive applications.

Flash Welding and Upset Welding

R. (Bob) Matteson, Taylor-Winfield Technologies, Inc.

FLASH WELDING, also called flash butt welding, is a resistance welding process in which a butt joint weld is produced by a flashing action and by the application of pressure. In basic terms, it is a melting and a forging process. The pieces to be joined are suitably heated by many electrical arcs at the joining interface until the pieces are sufficiently hot to perform an upset, thereby forging the pieces together. The process is capable of producing welded joints with strengths equal to those of the parent materials. Flash welding is used to join metallic parts that have similar cross sections, in terms of size and shape. The process lends itself to joining nearly all grades of steel, aluminum, brass, and copper parts, in addition to selected dissimilar materials.

Introduction

Figure 1 is a schematic representation of a typical flash-welding operation. Flash butt welding has been in existence for 100 years or so, originally developed by Elihu Thompson. Generally, one of the metal pieces to be joined is held in a stationary clamp and the other is held in a movable clamp. Voltage is applied between the clamps during the flashing and often during the upset period as well. Clamping ensures good electrical contact between the current-carrying dies and the workpiece and prevents the parts from slipping during the upsetting action.

Flash welding is rapid and economical, and when properly executed, welds of uniform high quality are produced. Over the years, many improvements have been incorporated into the process, which have resulted in dimensional stability of the final assembly of pieces, removal of the external upset material, soundness of the final assembly, and other improvements. The process is used to join rails for railroads, coils of steel for processing in pickle and cold reduction lines, automotive parts, rings for aircraft engines, band-saw blades, and a wide variety of parts.

Flash welding can be used for joining many ferrous and nonferrous alloys and combinations of dissimilar metals. In addition to low-carbon steels, metals that are flash welded on a production basis include low-alloy steels, tool steels, stainless steels, aluminum alloys, magnesium

alloys, nickel alloys, and copper alloys. The joining process is fairly forgiving, which has produced a wide range of methods for the flashing rate that manufacturers of the equipment have argued is better than other flashing rate schemes.

Actually, on many materials, especially on low-carbon steels, the flashing rates may differ between different manufacturers and still produce satisfactory results. However, with the advent of advanced high-strength steels (AHSS), the heating rate during flashing and upsetting has a significant effect on the characteristics of the weld. These steels are referred to as AHSS materials and are classified into this category if the ultimate material strength exceeds 420 MPa (61 ksi). It is the introduction of AHSS materials that led to the current method of flash butt welding. Especially in the cases where the final product is repeatedly flexed, stressed, or bent, the current method imparts superior weld characteristics that cannot be achieved with other methods.

Upset welding (Fig. 1b) is a similar process to flash welding, because it uses much the same equipment and control features. However, in upset welding, the process does not produce flashing. The parts to be welded are held tightly together in clamps while voltage is applied. When the interface between the two parts is sufficiently heated to the correct temperature profile, upset occurs. Generally in upset welding, less material is lost as compared to flash welding. Upset welding is slightly less forgiving than flash welding because the loading of the parts must be more accurate. Both processes produce similar final results and are described in this article.

Flash Butt Welding

The four basic steps in flash welding are shown in Fig. 2. It is a variation of resistance welding, where arcing (flashing) is used to supply the major portion of the initial heat for the formation of a butt weld. The major difference between the temperature pattern developed in flash welding and that developed in resistance welding is that flash welding produces a much steeper thermal gradient. This steep thermal gradient, combined with the resulting

Fig. 1 Flash and upset welding process features (top) with typical profiles of resulting joints (bottom). (a) In flash welding, heating from an arc occurs before the upsetting operation is initiated. (b) In the upset welding process, electric current is applied while the pieces are pressed together.

characteristic upset pattern, enables flash welding to accommodate a much greater variety of materials and shapes than can be welded by resistance welding. Once the proper temperature-distribution pattern has been established, the abutting surfaces are rapidly forced together.

Three distinct peaks are characteristic of flash welds (Fig. 3). The two peaks on either side of the weld line represent the material displaced by the upsetting action; the center peak is the molten metal extruded out of the weld, including oxides or contaminants formed during heating. During the flashing action, craters are formed that contain molten metal and possibly oxides. If the energy input that produces the flashing is properly controlled, these oxides should be expelled with the flashing molten-metal particles that give the process its name. When the upsetting force is then applied, most of the impurities not expelled by the flashing are expelled with plastically deformed upset metal. Any nonmetallics that are not expelled usually remain at the fusion line, with little apparent depth back into the base metal on either side. Most static and fatigue failures that occur in flash welds originate at such discontinuities. These discontinuities normally have little effect on static strength but can measurably reduce fatigue life. Excessive energy input and insufficient upsetting force or travel speed are the most common causes of such inclusions.

Flash welding is commonly used to join sections of metals and alloys in production quantities. Materials with cross sections ranging from 65 to 13,000 mm² (0.1 to 20 in.²) are commonly flash welded. The process is also used to manufacture components of solid and tubular shape, in addition to strips and complex configurations. Flash welding is commonly used to weld rings that range in diameter from a few inches (Fig. 4)

to as much as 4.6 m (15 ft) (Fig. 5). The aircraft engine industry uses flash-welded rings made from heat-resistant materials in accordance with military specifications for jet aircraft.

Other flash-welding applications include:

- Chain links
- Transmission bands
- Automotive flywheel ring gears
- Strips that are joined for continuous processing lines
- Wire and bar drawing operations for continuous stamping press feed lines
- Roll form lines
- Aircraft landing gear
- Tube and rod eye clevises
- Band-saw blades (Fig. 6)
- Drill extensions using two different materials
- Miter joints for automotive and home window frames

Process Steps in Flash Welding

Preweld Preparation. Parts that are flash welded come in a variety of forms, including forgings; rolled or extruded bar; sheet, strip, or plate; ring preforms; and castings. As a minimum precaution, the ends of the workpiece that are clamped on the current-conducting die must be free from dirt, scale, surface oxidation, and grease. The ends of the workpiece that extend into the weld zone must be free from any contamination that could react with the base metal at the high temperatures developed during welding.

Preweld cleaning of the workpieces at the die contact area also is important to ensure proper current flow and prevent local overheating of the workpiece surface. Because of the high current densities, hot spots can develop between the current-conducting dies and the workpiece if insufficient electrical contact is made. These localized hot spots are called die burns. Surface coatings (plated metal, conversion coating, or anodized coating) should not be present before welding, because they result in weld-area contamination or die burns. Oxides and foreign particles also can cause small pits in the surface as they overheat and burn into the workpiece. Loose scale and grease also may cause the parts to slip during upsetting.

Common cleaning techniques include abrading the surfaces by grinding, grit blasting, or wire brushing; pickling or chemical descaling; and vapor degreasing. In some cases, the ends of the workpiece must be machined or ground to fit the dies, particularly in welding of rough forgings or castings. Also, a chamfer may be required on the ends of the workpiece to initiate flashing action. Die burns, upset slippage, and inferior welds may be caused by poor fit-up between the current-conducting dies and the workpiece.

Burnoff. After the parts are clamped in the welding machine and the welding power is activated, the abutting surfaces are brought together for a brief period of violent flashing. This phase of the welding sequence is called burnoff. It serves the function of squaring off the abutting surfaces and compensates for inconsistencies in end preparation.

Preheating is a resistive heating phase of the welding process in which the heat is generated by the electrical resistance of the workpieces. It is accomplished by bringing the workpieces together under light pressure, creating a short circuit. The pressure must be great enough to prevent flashing but not so great that workpieces are prematurely welded.

In practice, preheating is performed in a cyclic manner; workpieces are brought together briefly, then separated for a brief period to allow the heat generated to diffuse into them. This sequence is repeated several times. Fully automatic machines perform this function, thus eliminating operator variables.

Flashing Stage. The primary purpose of flashing is to generate enough heat to produce a plastic zone that permits adequate upsetting. The rate of energy input must be in proper

proportion to the travel of the platen or movable die, so that constant flashing is maintained until the appropriate amount of metal is flashed off and the required plastic zone is obtained.

When the ends of the workpiece are brought together under light pressure, an electrical short circuit is established through the material. Because the abutting surfaces are not perfectly matched, the short-circuit current flows across the joint only at a few small contact areas. The large amount of current flowing through a relatively small area causes very rapid heating to the melting point. Heating is so rapid and intense that molten metal is expelled (flashed off) from the joint area. Following this expulsion, a brief period of arcing occurs. Arcing is not sustained due to the low voltages employed. Studies have shown that stable flashing can be maintained with as low as 2½ to 3 V, but typically the flashing voltage for alternating-current machines is from 5 to 10 V.

After the expulsion of molten metal and subsequent arcing, small craters are formed on the ends of the abutting surfaces. The pieces are steadily advanced toward one another, and other short circuits are formed and additional molten metal is expelled. This process continues as random melting, arcing, and expulsion occur over the entire cross-sectional surface. During flashing, many active areas are in various stages of this sequence (Fig. 7). Flashing surfaces act as heat sources, and the steep thermal profile is established primarily from these heat sources. Temperatures of the flashes are at or above the melting point of the material and are progressively lower as distance progresses from the flashing surface toward the clamp.

In general, the flashing rate in flash butt welding has been achieved by using motor-driven cams, analog computers, or digital computers to create position-versus-time profiles. Each of these systems either advances the movable platen and clamp directly or through the use of hydraulic systems. The hydraulic systems can incorporate proportional valves, servo valves, or indirect control of follow valves. Regardless of the method used to advance the movable plate during flashing, the process achieves similar final results. The analog and digital systems have allowed platen position to be determined by such controls as constant input power (kVA), constant acceleration, elliptical acceleration, or natural log acceleration. These schemes are adjusted to prevent deleterious effects such as freezing (solid interface mating) during the flash weld interval.

Upsetting (Forging) Stage. Bonding takes place during the upsetting action. Table 1 gives typical upsetting pressures for numerous classes of alloys. During upsetting, some metal must be extruded from the weld zone to remove slag and other inclusions not expelled during flashing. The extruded metal should extend beyond the cross-sectional boundaries of the workpiece to ensure that maximum amounts of slag and inclusions are removed when the weld upset is removed during subsequent trimming.

When the weld upset is removed, no evidence of the weld should remain. Porosity near the outer surface on an etched section of the weld, or a crevice around the workpiece after the weld upset has been removed, indicates incomplete bonding because of either insufficient upsetting force or insufficient plasticity during upsetting.

A large upset produced by an excessive upsetting force can be detrimental to weld quality, can waste metal, and indicates that most of the plastic metal has been extruded, requiring bonding to take place in metal where plasticity may not have been sufficient to ensure a good weld.

Postweld Heat Treatment. When welding materials with high carbon equivalents, it may be important to heat the weld to the austenitizing temperature and slow-cool to prevent the formation of martensite. This can be done by unclamping the part, opening the dies to the full-open position, reclamping with the weld in the center between the clamps, and applying short bursts of current to reheat the area.

Processing Equipment

Flash-welding machines are a horizontal press-transformer combination, which consists of a low-impedance welding transformer, a stationary platen, and a movable platen with clamping dies to position and hold the workpieces. The seven major components include:

- A machine bed that has a fixed platen attached to it, as well as a set of electrically insulated ways that support a movable platen

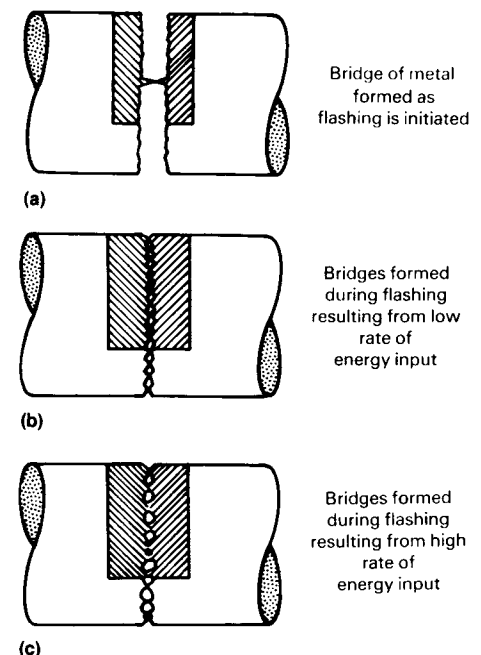

Fig. 7 Growth of contact points produced by energy input during flash welding

- A movable platen, which is generally mounted on the electrically insulated ways that are attached to the machine bed
- Two clamping assemblies, one of which is rigidly attached to each platen to both align and hold the parts to be welded in place
- Equipment for controlling the motion of the movable platen
- A welding transformer with adjustable taps
- Controls and monitors for machine functions
- A vent/flash catcher, which is incorporated to collect any fumes and excess flash materials to ensure operator comfort and safety and to maintain the cleanliness of the work area

Flash-welding machines may be manual, semi-automatic, or fully automatic. With manual operation, the operator controls the speed of the platen from the time flashing is initiated until the upset is completed. In semiautomatic operation, the

operator manually initiates flashing and then actuates an automatic cycle that completes the weld. In fully automatic operation, after the operator initiates the welding sequence, a fully automatic cycle can be used through the use of position-indicating devices and timers. Values for the various welding parameters are preselected by the operator. Automatic feedback control is used in some applications. These fully adaptive circuits vary from current to voltage feedback circuits, and data are obtained to control the welding sequences.

Various types of electrical, air, or hydraulic systems may be used for controls during flashing and upsetting. An example is illustrated in Fig. 8. The movable platen of a flash welder can be driven by a number of different methods. The simplest type often uses a cam that is motor driven through a gear box. Flashing time is then controlled by the speed of the motor. The cam is machined to produce the desired flashing cam curve profile, including the:

Table 1 Recommended upsetting pressures for flash welding of selected alloys

Strength classification	Upset pressure		Alloys	
	MPa	ksi	SAE designation	Others
Low forging	69	10	1020, 1112, 1315	High-strength low-alloy steels
Medium forging	103	15	1045, 1065, 1335, 3135, 4130, 4140, 8620, 8630	...
High forging	172	25	4340, 4640, 300M	Tool steels, titanium, aluminum
Extra-high forging	241	35	A-286, 19-9 DL	Nickel-base alloys(a)

(a) Materials exhibiting extra-high compressive strength at elevated temperatures

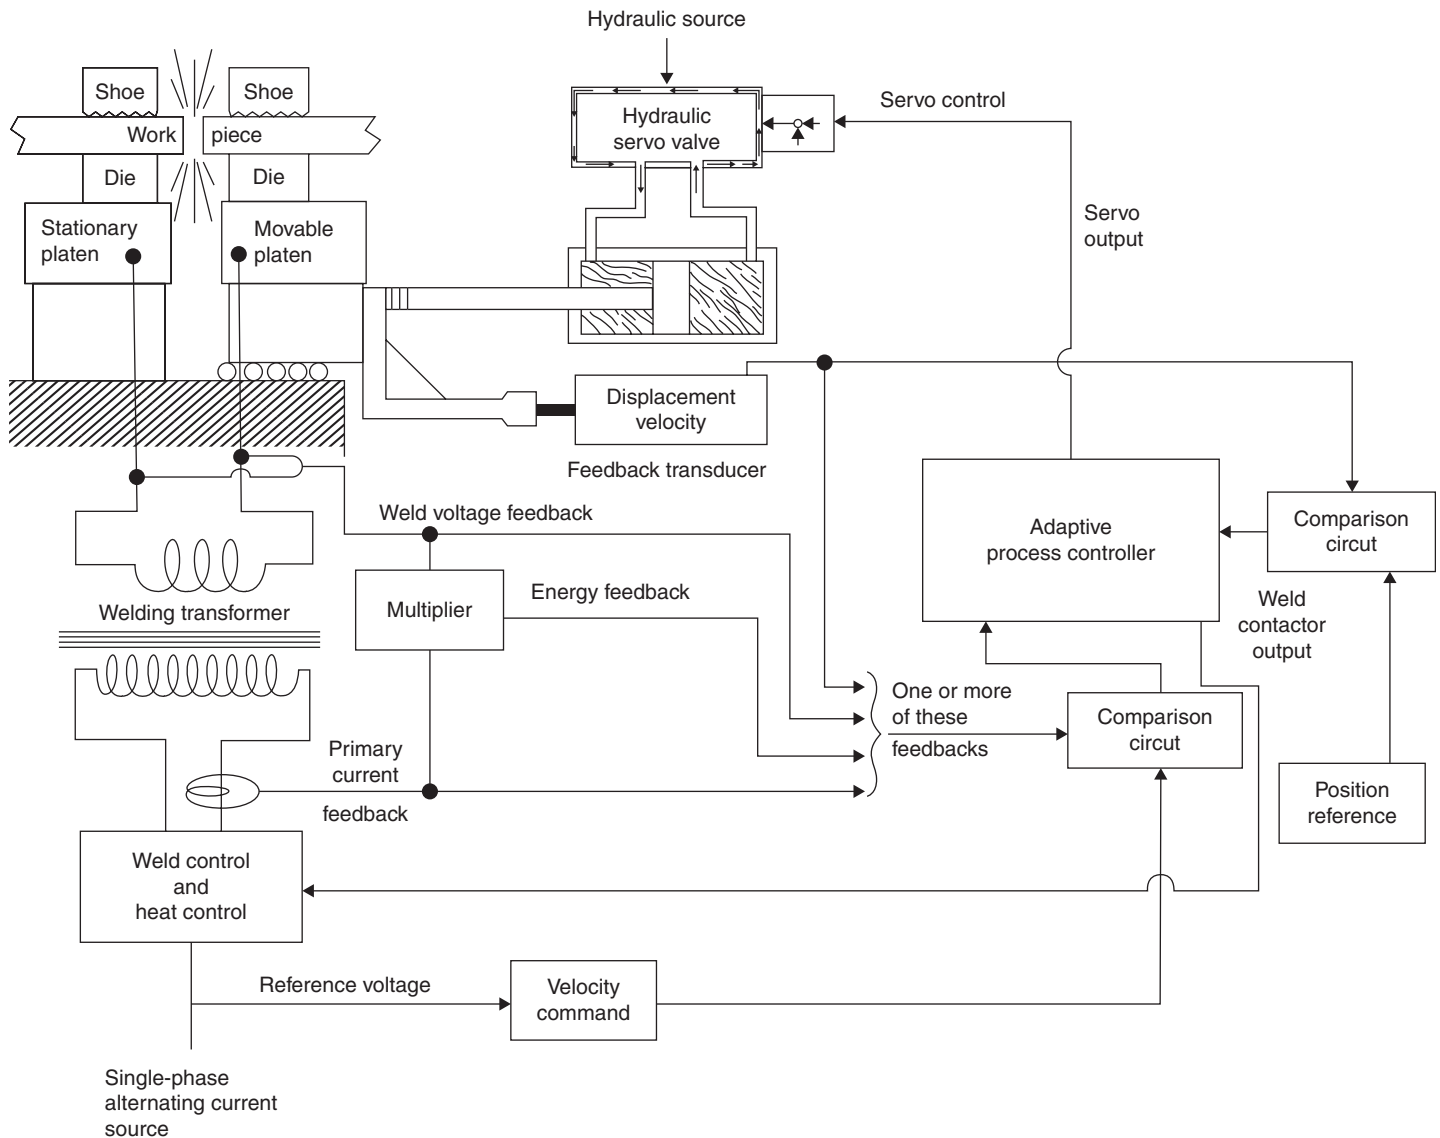

Fig. 8 Flow diagram showing adaptive controls used to control and monitor flash-welding process

- Initial burnoff region of linear flash
- Accelerating curve for the actual flashing profile (Fig. 9)
- Upset portion that causes the parts to be forged together after flashing

Machines that are either larger or more complex use hydraulic cylinders to drive the movable platen and to incorporate hydraulic servo systems. Although it is possible to use a servo valve to directly control the position of the platen via a hydraulic cylinder, this is not the preferred method, because contamination by the oil is extremely difficult to prevent. The better approach is to use a hydraulic servo actuator, in which the servo valve operates on its own refined oil system and the oil that circulates through the platen cylinder is derived from another hydraulic source. This approach has been shown to be more reliable and more accurate and to vastly improve servo valve life.

Controls and Auxiliary Equipment. Electrical controls on flash-welding equipment are designed to sequence the machine, control the weld current, and precisely control the platen position during flashing and upsetting. These controls often comprise programmable controllers, welding current controllers, and either motor or servo valve controllers. Silicon-controlled rectifier (SCR) contactors (solid-state switches) are used as the devices to control the flow of welding current from the power lines to the welding transformer. Older machines used ignitrons for this purpose, but SCRs have fully replaced them in recent years. Preheat and post-heat cycles are often required procedures in

flash-welding operations; timers with phase-shift heat control are used to accomplish these important functions.

Power Sources. The most common source of power for flash welders is single-phase alternating current (ac) power. Flash-welding transformers are kVA rated at 50% duty cycle. If an extremely large demand current is required and an adequate single-phase ac source is not available, then ac to direct current conversion is employed using a three-phase transformer/rectifier. The most frequently used rectifier systems are the three-phase half-wave and three-phase full-wave types, often supplied as a six-phase star configuration. In actual practice, no discernible differences in the weld produced by these two rectifier systems can be detected.

State-of-the Art Welding Unit Components. Devices that monitor and control selected process parameters are commonly incorporated into the latest flash-welding units.

A *linear ramp preflashing approach rate* is usually built into the flashing cam and minimizes any tendency of the weld to freeze at the beginning of flashing. The term *flashing cam* is used regardless of whether the cam is a motor-driven machined cam or if the position curve is generated electronically.

Natural Log Flashing Curves. Numerous technical articles have been published on what constitutes the best flashing curve. Although engineers are divided on this issue, it has been shown that the use of natural log curves results in significantly better welds than are produced using any other curve. The natural log system conforms to the natural heat-transfer

characteristics of the metal being welded, thereby creating a flashing progression that parallels the development of heat at the interface with a natural log gradient toward the clamp.

Natural log flashing curves are shown in Fig. 9. In this illustration, four values of natural log curves are shown, with exponent numbers of one to four. The curves with low exponent numbers are typically used on low-carbon materials because the starting travel rate is fairly fast and the final travel rate is slightly accelerated. The curves with high exponent numbers, three or four, are used for welding high-strength, low-alloy and AHSS materials because they require a slower starting rate and a higher final rate to develop flashing and to achieve the correct temperature profile for upsetting all of the material.

Ramp Turn-On of SCRs. Not to be confused with the linear approach ramp, this control device slowly and progressively turns on the SCRs at the beginning of the flashing cycle. Because the magnetic condition of a weld transformer may be unknown at the end of a previous weld, the ramp turn-on device is used to restore the transformer to a known condition. This greatly extends the life of the transformer itself, in addition to the SCR contactor, because it avoids the high inrush of current that would have occurred when the next weld was initiated.

No Phase Shift during Flashing. This control feature ensures that full voltage will be applied to the dies whenever flashing conditions are present, except during the ramp turn-on interval. A phase shift can reduce the average voltage but does not reduce the peak voltage. During the phase-delay period of the voltage waveform, the platen continues to travel forward until a peak voltage is suddenly applied, causing violent flashing and deep cratering. Although the pyrotechnics of a phase-shift flashing action can be quite impressive, the resulting weld will be a disaster. The best flashing action is relatively subdued and produces flash particles of significantly lower intensity and size.

The oxygen-depletion system used in this process is a patented method of combusting the oxygen that would otherwise exist in the weld interface region. In actual use, the oxygen-depletion system does more than remove oxygen. By heating the gases in the interface region, the ionization voltage is reduced, and higher flashing currents can be sustained at relatively low flashing voltages.

Clamping Dies and Fixtures. The materials commonly used for clamping dies are Resistance Welder Manufacturers Association (RWMA) class 3 and hardened tool steels such as H11, L6, and O1. Bronze and other copper-base electrode materials can be used in some applications. The die half (upper or lower) that conducts the current usually is made of a copper-base material. The other half is made of the same copper-base material or of hardened steel.

Fig. 9 Exponential flashing curves with related current

Generally, the shape of the clamping-die surface is such that the die encompasses almost the entire workpiece surface. The required area of clamping-die contact depends on the current needed for heating the workpiece and the pressure needed for holding it. Semicircular dies are used where the line contact provided by V-shaped dies gives insufficient surface for the current to flow without burning the workpiece, or for holding the workpiece without marking it. Table 2 gives the minimum lengths of clamping dies for welding rounds, tubing, and other sections of various diameters or minimum dimensions; these data are for welding steels of low or medium forging strength.

Failure Origins in Flash Welds

Porosity. Insufficient upsetting force or travel may leave porous areas of cast metal in the weld. Excessive electrical energy input can also lead to porosity by the formation of large craters by the expulsion of molten metal. Where large-diameter pieces are to be joined, one end face should be slightly chamfered so as to start the flashing at the center of the cross section. This helps to avoid trapping of particles in the weld.

Incomplete Fusion. Inadequate heating results in incomplete fusion, but it may also result from an upsetting travel that is so slow that the metal does not become sufficiently plastic to forge properly during upsetting. Another cause of inadequate heating can be the shunting of electrical current around the closed side of a ring to be flash welded; sufficient current may be bypassed to make flashing difficult, even resulting in a melt-through of the closed side of the ring.

Poor Weld Contours. Whenever heating is not uniform over the intended joint, an unfavorable temperature gradient is established that contributes to misalignment after welding. If parts are not properly aligned by the dies, they may slip past each other during upsetting, creating a lap instead of a proper weld. Workpieces of different cross sections that have not been adjusted in design to achieve a good heat balance, such as tubes of different diameters or wall thicknesses, may slide (telescope) over each other and create a poor-quality weld.

The internal flash and upset metal formed in flash welding of tubes or pipe are normally not removed (often, they cannot be), which leaves a reinforcement with two sharp notches adjacent to the fusion line. These notches act as stress raisers that, under cyclic loading, reduce the fatigue strength. They also restrict fluid flow and can serve as barriers to streamline fluid movement concentration-cell sites for corrosion.

Hot Cracks. Alloys that possess low ductility over a temperature range below the melting point may be susceptible to hot cracking. Such alloys are more difficult to flash weld but can usually be welded if the most favorable welding conditions are selected. Tension obviously should be avoided, and because the rim of the upset metal is in circumferential tension as upsetting progresses, it may be necessary to keep the upsetting force to the minimum acceptable. In such an operation, some cracks are likely to form that are shallow enough to allow complete removal when the upset metal is machined away. Precise coordination of current cessation and upsetting travel are important, and the joint should be under moderate compression during cooling.

Cold Cracks. Insufficient heat during upsetting or excessive upsetting travel causes colder metal to be forced into the weld zone. The metal cracks transversely to the weld line in the upset zone. This effect is also encountered in the flash welding of hardenable steels, because of the mass quench provided by the remainder of the workpiece. The use of a slow cooling rate, as well as heat treatment following welding, alleviates transformation stresses that could cause cracking under service loads.

Upset Welding*

Upset welding is a resistance welding process using both heat and deformation to form a weld. Pressure is applied before heating is started and is maintained throughout the heating period (Fig. 1b). As noted, the equipment used for upset welding is very similar to that used for flash welding. Upset welding differs from flash welding in that the parts are clamped in the welding machine, and force is applied to

bring the parts tightly together. High-amperage current is then passed through the joint, which heats the abutting surfaces. When they have been heated to a suitable forging temperature, an upsetting force is applied and the current is stopped.

The high temperature of the work at the abutting surfaces, plus the high pressure, causes coalescence to take place. After cooling, the force is released and the weld is completed. There is no arc or flash in upset welding. The area at the joint is usually enlarged over its original dimension. It can be used only if the parts to be welded are equal in cross-sectional area. For upset welding of large parts, the peak power drawn from the electrical supply may be a disadvantage.

Upset welding typically results in solid-state welds (no melting at the joint). The deformation at the weld joint provides intimate contact between clean adjoining surfaces, allowing formation of strong metallurgical bonds. If any melting does occur during upset welding, the molten metal is typically extruded out of the weld joint area.

A wide variety of shapes and materials can be joined using upset welding in either a single-pulse or continuous mode. Wire, bar, strip, and tubing can be joined end to end with a single pulse of welding current. Seams on pipe or tubing can be joined using continuous upset welding by feeding a coiled strip into a set of forming rolls, resistance heating the edges with wheel electrodes, and applying a force to upset the edges together.

Upset welds have similar characteristics to inertia friction welds, which are also solid-state welds. The amount of deformation is usually less for upset welds, and the deformation can be more precisely controlled using upset welding. For example, a pipe butt weld made using inertia friction welding will have a large upset on both the inside and outside, whereas an

upset weld can be controlled, through joint design and welding parameters, to have essentially no internal upset (Fig. 10).

The metallurgical structure of the weld area is that of a hot-worked material with a good diffusion bond across the weld interface, as can be seen in Fig. 10. This microstructure results in higher strength in the weld area than can be achieved for fusion welds (Fig. 11). With solid-state welds, there is difficulty in good nondestructive testing techniques to determine the quality of solid-state bonds. Normally, control of process variables is sufficient to ensure quality. Nondestructive methods, such as ultrasonics, are being applied to solid-state welds for determination of bond quality (see the article “Nondestructive Evaluation for Solid-State Welding” in this Volume).

Solid-state upset welding has advantages compared to typical fusion welding processes. These advantages are due to the simplicity of the welding process and the resulting solid-state weld microstructure. These advantages include:

- *Speed:* The upset welding process is fast (usually less than 1 s).
- *Ease of control:* The process has only three primary variables (current, force, and time).
- *Fewer defects:* Typical fusion welding defects, such as porosity, missed joints, incomplete fusion, spatter, and solidification cracking, do not occur in upset welds.
- *Enhanced weld properties:* The metallurgical properties of the weld metal and heat-affected zone in upset welds are those of hot-worked material. In other words, the strength of the weld zone is not reduced to that of an annealed structure, as in fusion welds.
- *Simplicity of equipment:* Upset welding equipment is not complex, involves no

rotating parts, and requires minimal maintenance.

- *Less-strict composition requirements:* Minor alloying elements do not affect upset weld quality, and thus, attention to alloy composition for weldability can be eliminated.
- *Ability to join difficult-to-weld materials:* Alloys normally considered unweldable can be joined by upset welding. For example, a variety of stainless steels (including A-286), superalloys (including thoria-dispersed nickel), refractory metals (including

tungsten), grade 2 titanium, and aluminum alloys (including 2024) have been successfully upset welded.

The effect of welding conditions, other than the basic parameters of force, current, and time, is generally minimal. Surface roughness usually has little effect, because it is overshadowed by the deformation that takes place during welding. Surface cleanliness and welding atmosphere may or may not be important, depending on the amount of deformation that

Fig. 11 Hardness across upset welds and in materials of various strengths compared to fusion weld hardness. Note that the weld area hardness (and therefore strength) is greater for the upset welds than for the fusion weld.

Fig. 10 Upset weld configurations in butt welds of pipe with an outside diameter of 25 mm (1 in.) and a wall of 3 mm (0.1 in.). Upset has been machined from the outside surface (on left). occurs to break up any oxide present before, or formed during, welding.

Plug welds are a type of upset weld that requires little fixturing. Plug welds up to 125 mm (5 in.) in diameter are used to seal the fill holes of canisters employed in the long-term disposal of high-activity nuclear waste. The canisters, which are made from 304L stainless steel, are 610 mm (24 in.) in diameter and 3 m (118 in.) in height. The plug configuration is shown in Fig. 12 relative to the hole of the canister being plugged. The considerable upsetting that occurs during the welding process results in a solid-state weld. Typically, these welds are made using pressure of 300 kN (75,000 lbf) with 230,000 A current applied for 1.5 s. The resulting welds have the high reliability required for long-term containment of radioactive material.

High-Frequency Welding*

Revised by Menachem Kimchi, Edison Welding Institute

HIGH-FREQUENCY RESISTANCE WELDING (HFRW) is a resistance welding process that uses high-frequency currents to concentrate the welding heat at the desired location. The heat generated by the electrical resistance of the workpiece to high-frequency currents produces the coalescence of metals, and an upsetting force usually is applied to produce a forged weld. High-frequency resistance welding is an automated process and is not adaptable to manual welding.

High-frequency resistance welding was developed during the late 1940s and early 1950s to fill the need for high-integrity butt joints and seam welds in pipe and tubing. The progressive development of this technology (Table 1) has served as the basis for the modern high-speed pipe and tube welding systems in current use. In this continuous process, high-frequency current is concentrated in the formed strip edges and generates rapid heating in a small volume of metal at the weld interface. Pressure rolls are then used to force the edges together to produce a solid-state weld (Fig. 1).

The principal application of high-frequency welding continues to be in the manufacture of seam-welded pipe and tube. The process is also used in the manufacture of products such as spiral-fin boiler tubes, closed roll form shapes, and welded structural beams. Other examples of manufacturing applications are the welding of the metal shielding layer that surrounds high-frequency coaxial cable, the manufacture of butt joints in strip material and for solar panels, and for the butt joints in pipe and tube production. In the production of welded tube and pipe, HFRW mills operate at very high speeds, generally ranging from 15 to 152 m/min (50 to 500 ft/min), depending on material diameter and thickness. Application sizes range from hypodermic needles to pipelines.

The tubemaking incorporates the simplest method of controlling high-frequency currents, that is, the generation of an edge “V.” High-frequency currents can be supplied to the welding process or workpiece by using either an induction coil (known as high-frequency induction welding) or electrical contacts (known as high-frequency resistance welding). The edge “V” is a series component of the circuit (Fig. 2).

Because of proximity and skin effects, current flow is concentrated across the full face width of the strip edges, resulting in controlled surface heating and subsequent welding. In this process, a coil of strip material is first formed into a longi-

tudinal hollow on a forming mill. The two edges of the strip are then high-frequency welded and squeezed together to form a continuous welded seam. As a result of squeezing or upsetting, some of the material from the butting faces

Table 1 Historical overview of high-frequency welding of pipe and tubing

1940 to 1950—Butt joints

Welds in butt joints were made with 10 kHz motor-generator power sources equipped with induction coils that could be opened for removal from the pipe or tube after the weld was formed. A municipal utility was the first to use mobile high-frequency welding equipment in the streets of New York City for the welding of butt joints in pipe. Pipes as large as 305 mm (12 in.) in diameter with wall thicknesses up to 8 mm (5/16 in.) were welded. The pipe ends were fitted and pressed together, then were induction heated to the forge-welding temperature in approximately 60s.

1949—Forge welding of continuous seams

The first high-frequency induction welding system was introduced for the continuous forge welding of the longitudinal seam in small steel tubes. The system used a 10 kHz motor generator equipped with a split-return induction coil suspended over the seam, similar to those used for continuously normalizing the weld seam in pipe welding. These systems were operated for many years but had the disadvantage of heating a large portion of the pipe.

1952—Induction welding of continuous seams

Thomas Crawford tested the continuous induction welding of longitudinal seams in various metal tubes, including some with electrical cable inside, using the induction welding process. Tests were made at an electrical frequency of 400 kHz and used an induction coil surrounding the tube. This technique for the seam welding of pipe and tube was highly successful and continues to be employed for pipe with outside diameters up to 406 mm (16 in.).

1952—Butt, lap, and T-joints

Wallace Rudd and Robert Stanton invented a high-frequency contact welding process for welding a large variety of continuous joints. The Rudd and Stanton system operated at 400 kHz and introduced the high-frequency welding current directly into the workpiece by means of sliding contacts. The sliding contacts permitted the production of butt joints, lap joints, and T-joints in pipe, strip, and structural products.

1954—Continuous seam welding

Successful tests were made for welding the longitudinal seam in aluminum tubing, leading to the introduction of the first commercial welding of aluminum irrigation tubing. This high-frequency welding equipment used motor-generator sets with a maximum output frequency of approximately 10 kHz. By the early 1960s, these systems had been superseded by high-frequency vacuum tube oscillators that typically operated at approximately 400 kHz.

1986—Solid-state induction welding

The first solid-state induction welding machine was installed and operated at the Société Meusienne in France. This equipment operated at a welding frequency of approximately 100 kHz.

1990—Solid-state inverter power sources

Solid-state inverters replaced vacuum-tube oscillators in many new equipment installations during the 1990s. These units were more easily configured to operate at a variety of welding frequencies between 80 and 800 kHz. Experience, supported by mathematical theory, showed that selecting the correct welding frequency could greatly improve weld quality, improve mill yield for difficult-to-weld metals, and adapt the properties of the weld to the specific application. Seams in pipes up to 660 mm (26 in.) in diameter were welded using solid-state inverter power sources operating between 80 and 150 kHz with power outputs of up to 1800 kW.

2000s—Selectable-parameter power sources

High-frequency welding power sources with selectable parameters became available that allowed the continuous adjustment of the parameters of this process. This increased the range of pipe and tube products that could be produced by a single tube mill.

flows outward both at the outer and the inner diameters of a pipe or tube. This material, sometimes called flash or an upset, is usually trimmed by skiving knives. This is a good practice, but sometimes the flash on the inner diameter is rolled back into the material, instead of trimming.

Fundamentals

High-frequency current has certain characteristics that make it useful for welding. Unlike direct current or low-frequency alternating current, high-frequency current tends to flow at high densities along surfaces (skin effect) and seeks adjacent parallel surfaces for its return path (proximity effect). This means that the heating can be efficiently concentrated and focused to the surfaces where it is needed.

As noted, nearly all high-frequency welding processes involve surface bonding by some mechanical force that squeezes the materials together. This procedure helps produce a high-quality weld by squeezing out residual oxides and molten metal, which are detrimental to weld integrity. The removal of any molten metal from the weld zone is beneficial because it eliminates

the potentially harmful effects associated with cast structures, such as lower fracture toughness and poorer corrosion resistance.

There are two basic process variations of HFRW: contact resistance welding and induction welding. Both variations use high-frequency current to produce the heat for welding. In HFRW, the electrical contacts physically touch the workpiece when current is conducted through the workpiece. During induction welding, the current is induced in the workpiece by magnetic coupling with an external induction coil. There is no physical contact with the workpiece. Both methods rely on the properties of high-frequency electricity and thermal conduction, which determine the distribution of heat in the workpieces.

High-frequency contact welding and high-frequency induction welding are used to weld products made from coil, flat, or tubular stock with a constant joint symmetry throughout the length of the weld. Table 2 lists typical welding parameters for high-frequency seam welds and butt joints by induction and contact welding. Recommendations are shown for various metals and product forms.

Figure 3 illustrates basic joint designs used in high-frequency welding. Figures 3(a) and (b) are butt seam welds; Fig. 3(c) is a mash seam weld produced with a mandrel, or backside/inside bar. Figure 3(d) is a butt joint design in strip metal, and Fig. 3(e) shows a T-joint. Figures 3(f) and (g) are examples of helical pipe and spiral-fin tube joint designs. Figure 3(h) is an example of a seam weld in a closed roll shape; Fig. 3(j) illustrates a butt joint in pipe, showing the placement of the coil. Figure 3(k) shows a butt joint in bar stock.

High-frequency current in metal conductors tends to flow at the surface of the metal at a relatively shallow depth that becomes shallower as the electrical frequency of the power source is increased. This commonly is called the skin effect. The depth of electrical current penetration into the surface of the conductor is a function of electrical resistivity and magnetic permeability, the values of which depend on temperature. Thus, the depth of penetration also is a function of the temperature of the material. In most metals, the electrical resistivity increases with temperature; as the temperature of the weld area increases, so does the depth of penetration.

Metals that are magnetic at room temperature lose the magnetic properties above the Curie temperature. When this happens, the depth of penetration increases drastically in the portion of metal that is above the Curie temperature while remaining much shallower in the metal that is below the Curie temperature. When these effects are combined in steel heated at a frequency of 400 kHz, the depth of current penetration is 0.05 mm (0.002 in.) at room temperature, while it is 0.8 mm (0.03 in.) at 800 °C (1470 °F). The depth of current penetration for several metals as a function of frequency is shown in Fig. 4.

The second important physical effect governing the high-frequency welding process is thermal conduction of the heat generated by the electric currents in the workpiece. Control of

the thermal conduction and the penetration depth provides control of the depth of heating in the metal. Because thermal conduction is a time-dependent process, the depth to which the heat will conduct depends on the welding speed and the length of the electrical current path in the workpiece. If the current path is shortened or the welding speed is increased, the heat generated by the electric current in the workpiece will be more concentrated and intense. However, if the current path is lengthened or the welding speed is reduced, the heat generated by the electric current will be dispersed and less intense. The effect of thermal conduction is especially important when welding metals with high thermal conductivity, such as copper or aluminum. It is not possible to weld these materials if the current path is too long or the welding speed is too slow. Changing the electrical frequency of the high-frequency current can compensate for changes in welding speed or the length of the weld path, and the choice of frequency, welding speed, and path length can adapt the shape of the heat-affected zone (HAZ) to optimize the properties of the weld metal for a particular application.

It should be noted that the high-frequency current path at the surface of the workpiece is controlled by how close it is, or its proximity to its own return path. This phenomenon, called the proximity effect, is illustrated in Fig. 5. The proximity effect becomes more pronounced as the frequency is increased. Increased frequency reduces the penetration depth by confining the current to a shallower and narrower path. This property is illustrated in Fig. 6(a) and (b), where current patterns are shown for workpieces with the same geometry when the frequency of the electric current is 60 Hz and 10 kHz.

Referring to Fig. 6, a 60 Hz current in the steel plate flows in the opposite direction of the current flowing in the adjacent proximity conductor. In this case, the size and shape of the proximity conductor have negligible effect on the distribution of current in the steel plate. This example also shows that penetration at 60 Hz is deep compared to the thickness of the plate. As a result, the current flows fairly uniformly throughout the cross section of the plate. When the 10 kHz current is applied to the same system, the current flowing in the steel plate is confined to a relatively narrow band immediately beneath the proximity conductor. This narrow band is the path of lowest inductive reactance for the current in the plate. The shape and magnetic surroundings of the proximity conductor have a considerable effect on the distribution of the current in the steel plate but have no effect on the depth of penetration.

Controlling the concentration of current in a workpiece can achieve extremely high heating rates and high temperatures in a localized area, thereby heating only the region of the workpiece to be welded. By controlling the relative position of the surfaces to be welded, the heat can be positioned at the weld interface where it is needed without excessively heating the rest of the metal. The effect of changing the spacing and geometry

Table 2 Typical high-frequency welding parameters

Process and application	Metal	Principal workpiece dimension		Thickness		Welding speed		Welding power source range, kW	Welding frequency, kHz
		mm	in.	mm	in.	m/min	ft/min		
Induction seam welding: pipe and tube	Low-carbon steel (can be aluminum or zinc coated)	Outside diameter: 10–75	Outside diameter: 0.4–3	Wall thickness: 0.6–2	Wall thickness: 0.025–0.080	25–300	80–1000	50–500	300–400

Induction welding: spiral-fin boiler tubes	Low-carbon steel, stainless steel, or in combination	Outside diameter: 25–75	Outside diameter: 1–3	Wall thickness: To 10	Wall thickness: To 0.374	10–40	30–120	100–350	300–400

Source: Ref 1

of the conductors is shown in Fig. 6(c). The closer proximity conductor develops a more confined current path. A rectangular proximity conductor with the narrow edge at the same distance from the steel plate as the close round conductor exhibits a broader current distribution in the plate. If a magnetic core were placed around the proximity conductor, the current would be further concentrated and heating would take place directly below the proximity conductor, as shown in the figure.

If the two conductors, with currents flowing in opposite directions, are metal sheets placed edge to edge in a plane with a small gap between them, the proximity effect will cause the current to concentrate at the two adjacent edges, thus causing them to heat. The skin effect will confine the currents to a shallow depth at those edges. This is the situation that characterizes all high-frequency welding applications.

Advantages and Limitations

The advantages of high-frequency welding are that it is well suited for high-speed welding and can weld a large range of product sizes

and materials. Weld quality is not particularly sensitive to the presence of air, and special atmospheres are usually not needed. Weld quality is relatively (but not completely) tolerant of surface oxides and contamination. The disadvantages of high-frequency welding are that it is not well suited for low welding speeds and small-scale operations where welding is done by hand. High-frequency welding must be done continuously; continuous welds cannot be made in stop/start operations because a discontinuity in the weld will usually occur.

Because the concentrated high-frequency current heats only a small volume of metal at the weld interface, the process can produce welds at very high welding speeds and with high energy efficiency. High-frequency resistance welding can be accomplished with a much lower current and less power than is required for low-frequency or direct-current resistance welding. Welds are produced with a very narrow and controllable HAZ and with superfluid cast structures. This often eliminates the need for postweld heat treatment in tube production.

Oxidation and discoloration of the metal and distortion of the workpiece are minimal.

Discoloration may be further reduced by the choice of welding frequency.

Maximum speeds normally are limited by mechanical considerations of material handling, forming, and cutting. Minimum speeds are limited by material properties, excessive thermal conduction such that the heat dissipates from the weld area before bringing it to sufficient temperature, and weld quality requirements.

The fit-up of the surfaces to be joined and the manner in which they are brought together are important if high-quality welds are to be produced. However, high-frequency welding is far more tolerant in this regard than some other processes.

Flux or shielding gas are almost never used but can be introduced into the weld area for joining highly reactive metals such as titanium or for certain grades of stainless steel.

Applications

A wide range of commonly used metals can be joined by high-frequency welding. Materials that can be successfully high-frequency welded

Fig. 3 Basic joint designs for high-frequency welds in pipe, tube, sheet, and bar stock. Source: Ref 1

into tube and pipe include carbon steels, stainless steels, aluminum, copper, brass, and titanium. Exceptions are materials that are unstable at welding temperatures, have a negligible hot-work capability, or experience property deterioration that cannot be subsequently recovered. Where necessary, a gas shield can be provided for reactive metals. Tube or pipe sizes fabricated by high-frequency welding range in size from 13 to 1220 mm (½ to 48 in.) in diameter.

High-frequency welding is most suitable in applications that involve the continuous edge, or butt, joining of metals. The largest single use of high-frequency welding is in the manufacture of tube and pipe. High-frequency welding is useful in the manufacture of certain types of heat-exchanger tube, where the edge of a rectangular strip is continuously welded onto the outside diameter of a tube to form a cooling fin. The fin can be welded around the tube in a spiral configuration (Fig. 7), or it can be straight

and parallel to the pipe axis. The greatest volume of heat-exchanger tube is made with low-carbon steel for both the tube and fins. However, other alloy combinations are growing in use, such as low-carbon steel fins on both stainless steel and chromium/molybdenum alloy steel tubes, stainless steel fins on low-carbon steel and stainless steel tubes, and aluminum fins on cupronickel tube.

High-frequency welding can also be used for the production of structural shapes, such as T-sections and I- and H-beams. The specific shape is constructed by welding rectangular strips together to produce the desired configuration. A heating "V" is established as the strip materials are brought together.

The end, or butt, welding of metal strip is another application in which high-frequency welding can be used. Single lengths of strip are welded to form a hoop that is subsequently formed into products such as wheel rims. High-frequency butt welding is also used to make long, continuous lengths of strip by butt welding together a series of shorter lengths. This is done for certain manufacturing processes that require strip material longer than that which is commercially available.

Equipment

Units for producing power for high-frequency welding include solid-state inverters (and perhaps some vacuum-tube oscillators still in operation). Depending on the application, frequency requirements can vary from 100 to 700 kHz, whereas power requirements vary from 30 to 1000 kW. Solid-state inverters produce frequencies ranging from 100 to 400 kHz. Vacuum-tube oscillators are available in frequencies up to 700 kHz. Because of their improved efficiency, solid-state units are replacing vacuum-tube units when frequency requirements permit.

Water-cooled copper conductors are used to carry the power to the coil or contacts. These conductors must be of minimum length and closely spaced to minimize impedance losses. The use of induction coils or electrical contacts to deliver high-frequency power to the workpiece has specific advantages and disadvantages.

Induction coils are commonly used in applications where the geometry of the workpiece can act as a closed circuit to pick up the induced power (for example, the welding of tube). The advantages of an induction coil are that it is generally more convenient to use and requires less maintenance than contacts. Because the coils do not contact the workpiece, they leave no marks or scratches. Induction coils are usually made from a water-cooled copper conductor that has one to three turns.

The delivery of high-frequency power through electrical contacts is more efficient than that through the use of coils because the power can be more directly and efficiently distributed to the weld area. The disadvantages of contacts are

Fig. 4 Effect of frequency on depth of penetration. Source: Ref 1

Fig. 5 Restriction of flow path of high-frequency current by proximity effect of the return conductor

Fig. 6 Depth and distribution of current adjacent to various conductors

that they wear out, require periodic replacement, and can scratch, mar, or leave deposits on the surface of a workpiece, which can be objectionable in some cases. The presence of surface scale on base material can affect the current transfer from the contacts to the substrate.

In the production of tube and pipe, induction coils are usually used to make the smaller diameters (<305 mm, or 12 in.) because their advantages outweigh the loss of efficiency. Contacts are generally used for larger diameters because of their greater efficiency. Contacts are also used in structural shapes and fin heat-exchanger tubes, as well as for end welding, because induction coils cannot induce the current densities necessary for welding.

Impeders are used to improve welding efficiency in tube and pipe production. Impeders that consist of one or more water-cooled cores of ferrite material are placed inside the tube parallel to and under the weld area. The reason for this is the existence of a power-dissipating circuit loop consisting of the inside surface of the tube being welded. The impeder increases the inductive impedance of this path, which bypasses the weld zone. The positioning may vary for a given application based on experience. The impeder is generally positioned so that it extends approximately 1.5 to 3 mm (1/16 to 1/8 in.) beyond the apex of the "V" and the equivalent of one to two workpiece diameters upstream of the induction coil or contacts (Ref 2). Impeders are particularly important when a mandrel must be run through the workpiece in the weld area to perform an inside weld bead treatment (such as inside bead scarfing or bead rolling). Impeders are generally not required when welding a large-diameter workpiece with a high-frequency contact welding process (Ref 2).

Fig. 7 Manufacturing a spiral-fin tube using high-frequency welding

During operation, impeders efficiency is affected by temperature and degrades over time during welding. This reduction in efficiency during operation causes a drop in weld temperature and thus may affect quality by increasing the likelihood of producing cold welds. Corrections include either some periodic replacement of impeders and/or adjustment of the input power level to maintain a sufficient weld temperature.

Personnel

A considerable amount of on-the-job training is required for new operators of high-frequency welding equipment, as would be the case in any other mill process. High-frequency welding is a high-speed and, usually, high-volume process that often operates in conjunction with precision forming and handling equipment. The operating speed of tube mills ranges from 30 to 240 m/min (100 to 800 ft/min). A tube must be precisely formed prior to welding. Therefore, an operator must be familiar with both the operation of the welding equipment and the associated mechanical equipment for the forming or handling of the metal. Troubleshooting and repair of the welding equipment generally require specially trained personnel and are often conducted by the manufacturer. Improved and simplified systems for speed and/or power and weld temperature control are reducing the operator dependence of the process.

Safety

Serious consideration must be given to the health and safety of welding operators, maintenance personnel, and other workers in the area of the welding operations. Good engineering practice must be followed in the design, construction, installation, operation, and maintenance of equipment, controls, power

supplies, and tooling to conform to federal, state, and local safety regulations and industry standards.

Because high-frequency welding power sources are electrical devices, they require all the usual precautions in handling and repairing such equipment. Voltages, which range from 400 to 30,000 V, can be either low or high frequency and may be lethal. To prevent injury, proper care and safety precautions should be taken while working on high-frequency systems and generators. Modern units are equipped with safety interlocks on access doors, as well as automatic safety grounding devices that prevent unsafe operation of the equipment. The equipment should not be operated when panels or high-voltage covers have been removed or when interlocks and grounding devices have been blocked.

High-frequency, high-voltage leads must be encased in grounded metal ductwork to ensure safety and to minimize electromagnetic radiation. Induction coils and contact systems should always be properly grounded for operator protection. Grounding lines should be kept short to minimize inductive reactance. Injuries from high-frequency power, especially at the upper range of welding frequencies, tend to produce severe, local, surface tissue damage. Care should be taken that the magnetic field from the output system, particularly the output transformer, does not heat adjacent metallic sections by induction.

The high-frequency power source must also conform to the requirements of the Federal Communications Commission (FCC) as stated in Title 47, Part 15 concerning the radio-frequency emissions from industrial, scientific, and medical sources. Responsibility for complying with FCC standards is undertaken by the power-source manufacturer and does not pose a problem for the end user of the equipment, if the power source is installed following the manufacturer's recommendations. Information manuals provided by the manufacturers of equipment must be consulted, and

recommendations for safe practices must be strictly followed.

High-frequency currents are more difficult to ground than low-frequency currents, and ground lines should be as short as possible to minimize inductive reactance. All leads between the power source and the contacts or induction coil should be totally enclosed in an insulated or grounded structure and constructed in a way that minimizes electromagnetic interference. Also, care should be taken to prevent the high-frequency magnetic field around the coil and leads from induction heating of the adjacent metal mill components.

The weld area should be protected so that operating personnel cannot come in contact with any exposed contacts or induction coils while these devices are energized. Injuries to personnel from direct contact with high-frequency voltages, especially at the upper range of welding frequencies, may produce severe local tissue damage. The design, construction, installation, operation, and maintenance of the equipment, controls, power sources, and tooling should conform to the requirements of the United States Department of Labor in Occupational Safety and Health Standards for General Industry, (29) CFR Part 1910, Subpart Q. The American Welding Society document "Safety in Welding, Cutting, and Allied Processes," ANSI Z49.1: 2005, covers safe practices specifically for the welding industry.

Inspection and Quality Control

Although the quality of the weld can be very high with the HFRW process, a few weld-related quality problems exist. Modern nondestructive evaluation (NDE) techniques, such as eddy current and ultrasonic inspection, are commonly used to detect open-seam conditions such as cracks. However, the major problem that remains undetected is a condition referred

Fig. 8 Cross sections from welds of type 409 stainless steel tubes after high-frequency (HF) welding at different temperatures. (a) Excessive weld temperature results in melting and a fusion zone. (b) and (c) Good welds with sufficient heating and formation of a sound solid-state weld. (d) Insufficient heating results in a cold weld without a complete solid-state bond.

to as cold weld (also called paste or stuck weld) that is the result of improper welding parameters. Today's inspection and NDE techniques cannot always detect the cold-weld condition. This condition is difficult to detect because it visually appears to be a good weld. It is also difficult to detect by ultrasonic test methods if the defect is thin, filled with oxide scale, and short in length. A cold weld is usually welding-process-related and is typically revealed during mechanical testing or in service as a fracture or splitting along the weld seam.

New quality-control methodologies and monitoring techniques are being applied to HFRW mills, resulting in significant reduction and elimination of weld quality problems related to premature weld seam failures due to a cold-weld condition. Full-scale testing is done to generate production mill process windows for a range of critical welding variables, such

as temperature, squeeze force, displacement, and mill speed. Monitoring the welding parameters is done with traditional data-acquisition sensors and systems.

Monitoring of the resultant weld seam shape, size, and characteristics is also performed using a noncontact (laser) optical technology to make measurements of the surface profile of the prewelded and just-welded tube surface. These profile images are compiled from three-dimensional surface topography data that can be analyzed, enabling precise measurement of surface conditions and defects. Optimum welding parameters for a specific mill are correlated to laser-based profile images of the weld bead (upset geometry). The laser profile images can then be used to determine the quality of the welds as they are being made. A final step is to use the laser monitoring technique for feedback to control and maintain the optimum welding parameters

during welding, ensuring robust, high-quality tube and pipe.

Weld cross sections in Fig. 8 are from 409 stainless steel tubing welded at different temperatures. The welds shown in Fig. 8(b) and (c) are sound solid-state welds. An excessively high welding temperature (Fig. 8a) results in a fusion zone, while insufficient heating (Fig. 8d) results in a cold weld.

Procedure Development and Practice Considerations for Resistance Welding

Murali D. Tumuluru, United States Steel Corporation
Hongyang Zhang, University of Toledo
R. (Bob) Matteson, Taylor Winfield Technologies

A GOOD WELDING PROCEDURE is essential to achieve acceptable-quality welds. To develop such a procedure, users must have a clear understanding of the effect of welding variables on the welding process. In resistance welding, the three key variables that affect the weld quality are the welding current, the electrode force, and the welding time (Ref 1, 2). An understanding of their role in weld formation will help in choosing the appropriate welding parameter combination. The effect of each of these variables is described subsequently. Much of the discussion is applicable to both spot and seam welding. In the first half of this article, variables, as they relate to spot welding, are presented. The second part of this article covers seam welding procedure development.

Spot Welding Variables

This section describes the significance of the three variables (welding current, electrode force, and welding time) that affect the resistance spot welding process. In addition, the effects of weld spacing as well as the effect of surface preparation on weld quality are presented. The process fundamentals of resistance spot welding are described in the article "Resistance Spot Welding" in this Volume.

Welding Current

Welding current is perhaps the most influential welding parameter that controls the heating at the sheet-to-sheet interface and hence the weld nugget (melted and solidified region) development and formation. Both alternating current (ac) and direct current (dc) are used in resistance spot welding. The ac and dc currents possess distinctive characteristics in both the total heating and the heat input rate, and their effects on weld formation and weld quality are different.

The common electric current waveforms are shown in Fig. 1. The single-phase ac current waveform is strongly affected by the resistance and reactance of the welding loop. As seen in Fig. 1(a), the electric current does not reach the designated value immediately after it is switched on. Rather, it is delayed by the impedance for approximately three cycles. Such a delay is also observed in single-phase dc (Fig. 1b), three-phase dc (Fig. 1c), and midfrequency direct current (MFDC) (Fig. 1d) current waveforms for the same reason. In addition, there are moments of time in which the electric current ceases flowing in Fig. 1(a), resulting in cooling in the weld stack-up. Because of the alternating nature of a single-phase ac current, the heating rate fluctuates between zero and its peak, and the heat provided may be insufficient for welding metals with high thermal conductivities, such as aluminum alloys. In spite of this shortcoming of ac transformers, they are widely used in the sheet metal industry because of their simplicity and low cost. Satisfactory results have been achieved in steel welding using such transformers.

To supply continuous heating, direct current has been used in various forms. The simplest one is a single-phase dc, as shown in Fig. 1(b). The moments when the current ceases flowing are significantly reduced, yet large current ripples still exist, meaning a fluctuating heating rate. An improvement to this is the three-phase dc, which fluctuates in a very narrow range (Fig. 1c). The MFDC transformers, which are gaining their market share, eliminate the rippling effect (Fig. 1d) and provide the necessary continuous heating needed for welding metals of high electrical and thermal conductivities. Even for steel welding, the advantages of MFDC are obvious. Shown in Fig. 2, the welds made on an interstitial-free steel using an MFDC and a single-phase ac have different shape and volume (Ref 4). More fusion is observed in the MFDC welds at both welding stages than in the ac welds. In addition, the

annular shape of the welds made using the ac in the figure could be the result of "skin effect," which is the phenomenon that an alternating electric current tends to flow on the outer part of a conductor. The concentration of electric current on the outer portion of the electric contact at the faying interface generates more heat at the periphery than the center of a weld. More discussion on the influence of skin effect on welding can be found in Ref 3. In ac welds, the current distribution can also be affected by the "throat effect," where the current tends to travel along the inside path, or throat, of the circuit. While generally not harmful, this effect can be observed in the weld nugget shape.

In resistance welding, the heat developed is proportional to the resistance in the electric circuit, which, in turn, is inversely proportional to the contact area. During welding, the contact area between the sheets is not constant, because it is enlarged as electrodes deteriorate through metallurgical alloying and mechanical deformation at the electrode-sheet interfaces. Weld quality is compromised if the electric current density drops due to electrode enlargement (or mushrooming) to a lower level than is originally set. Frequent electrode dressing is a very effective method to eliminate electrode tip size changes, thereby maintaining a constant current density. Another practical approach to address electrode tip face changes is the use of current steppers, which is common in production environments. The basic idea in current stepping is to maintain the level of current density so that sufficient heat is generated. The stepping algorithm can be derived both experimentally and analytically. The changes needed in electric current as a function of the increase in electrode face area are plotted in Fig. 3 (Ref 3). Because a larger weld is formed with a stepped-up current, more electrode force is needed to contain the liquid nugget. The changes in electrode force to maintain the pressure level are exactly the same as those for the current, as shown in the figure. The use of frequent electrode tip

Fig. 2 Cross sections of interstitial-free steel welds made using midfrequency direct current (left) and alternating current (right) at different welding stages. Source: Ref 4

dressing is a much more efficient way to maintain constant current density than the use of current steppers. More automotive manufacturers have switched to the use of frequent electrode tip dressing to maintain consistent weld quality.

Welding or Electrode Force

Welding force, or electrode force, is the force applied to the workpieces by the electrodes during the welding cycle. Electrode force, usually measured and expressed as a static value, is a dynamic force in operation and is affected by the friction and inertia of the moving parts of the welding machine.

The workpieces to be spot welded must be held tightly together at the indented location of the weld to allow passage of current. Because increasing the electrode force decreases the contact resistance of the workpieces and therefore decreases the total heat generated between the faying surfaces of the workpieces by the welding current, electrode force should not be excessive.

The electrode force must be compatible with a welding current that is within the capacity of

the equipment and must permit the use of a welding time long enough to be reproducible. Also, the workpieces must be in reasonably intimate contact at the weld area without excessive electrode force. If the workpieces are deformed so that contact is not intimate in the weld zone, an excessively high force may be needed to overcome the deformation. Variations in weld strength and quality often result from the variations in electrode force required to bring the workpieces into proper contact, especially in the spot welding of stampings, formed workpieces, or thick sections of work metal. This is especially true when welding high-strength, low-alloy steels. Because of the high strength of these materials, they have considerably higher springback and thus require higher electrode forces than plain carbon steel. Sometimes, a squeeze time longer than that normally used is needed to force the

workpieces together. Also, because of the possibility of springback, hold time must be sufficiently long to permit solidification of the weld metal when the workpieces are still held together by the electrodes.

Because variations in electrode force cause changes in interfacial resistance and therefore heating, variations in electrode force can cause changes in the size and location of the lobe curves and current level, as seen in Fig. 4. Increased electrode force shifts the curves to higher current levels. This shift in the lobe curve indicates that weld current and weld time combinations which produce acceptable weld nuggets at one electrode force may no longer produce acceptable weld nuggets at the new electrode force. Thus, care should be taken when making electrode force changes, especially in alloys that have a limited acceptable weld current range, such as some of the

more difficult HSLA steels with yield strengths above 690 MPa (100 ksi).

Pound-force (lbf) and kilo-Newton (kN = 10^3 N) are the commonly used units for electrode force in resistance welding. Occasionally, deca-Newton or deka-Newton (daN = 10^1 N) are also used. The electrode force is a strong function of the drive mechanism. A pneumatic-cylinder-driven welding machine may produce a fluctuating electrode force during the application of electric current, resulting from the expansion/contraction of the weldment stack-up. Depending on the cylinder size, compressed air supply, and lubrication/alignment of the moving part of the welder, the electrodes may or may not respond to and follow the contraction of the weld, to provide a forging force. In addition, combined pneumatic and hydraulic cylinders have been used to supply a forging force to the weld. Servo-motor-driven welders have been developed that provide the opportunity of adjusting the electrode force during welding, in coordination with electric current. For instance, a sequential profiling of electric current and forging force has been realized on an electric servo welding gun (Ref 6). In the study by Grimes (Ref 5), the effect of forging force on weld quality was demonstrated. In Fig. 5, the electrode force was ramped up during welding by as much as twice the original force level, to suppress internal void/porosity formation. Satisfactory results were obtained.

Electrode force is also critical in controlling expulsion, an important process affecting weld quality. In a study on suppressing expulsion in welding an aluminum alloy AA5754, the critical level of electrode force was derived based on considering the interaction among the mechanical, thermal, and metallurgical processes during welding, as shown in Fig. 6 (Ref 7). The predicted electrode force levels were verified by experiments, and good agreement was achieved.

Fig. 3 Changes needed in electric current and electrode force as a function of the change in electrode face diameter

Fig. 4 Weld diameter vs. electrode force in welding an aluminum alloy. Source: Ref 5

Weld Time

Weld time (the duration of passing the welding current) is generally divided into several parts.

Squeeze time is an interval of delay between closing of the initiating switch and application of the welding current. It provides time for the solenoid-actuated head cylinder valve to operate and for the welding head to bring the upper electrode in contact with the workpiece and to develop full electrode force. This time must be sufficient to ensure that the parts have maintained intimate contact. On a 228 mm (9 in.) diameter cylinder, operated at 276 kPa (40 psi), it can take 120 cycles to develop full electrode force.

Weld time is the interval during which the welding current flows through the circuit. On many HSLA steels, a slightly longer weld time than normally applied for plain carbon steel has been noted to broaden the lobe curve and thus increase acceptable weld current ranges.

Fig. 5 Electrode force profile during welding with a forging force provided by an electric-servo motor. Adapted from Ref 5

Fig. 6 Electrode force needed to suppress expulsion in welding AA5754. Source: Ref 7

Upslope time is a period of time when the weld current is deliberately ramped up from an initial value to the weld current value. This function is used often on multiple projections to reduce the possibility of destroying the projections that first make contact.

Hold time is the interval during which, after the welding current is off, the electrode force is held on the workpiece until the metal of the spot weld has solidified. Some HSLA materials

are hold-time sensitive. With hold times as great as 30 to 60 cycles ($\frac{1}{2}$ to 1 s), these materials tend to experience interfacial tearing when peel tested.

Off time is the interval from the end of the hold time until the beginning of the squeeze time for the next cycle. In an automatic cycle, off time is the time needed to retract the electrodes and to index, remove, or reposition the work. In manual operation, it is not fixed as a

maximum period by the control equipment but depends on time taken by the operator to start a new cycle. Upslope time permits the welding current to be increased over several cycles from a low value to that needed for welding, instead of having the full welding current applied instantly. A low initial or welding current reduces or prevents expulsion of metal, or spitting, when the current is first applied. Upslope control is used for welding at high current values and for welding scaly stock as well as most kinds of plated metals.

Downslope time permits the welding current to decay gradually to a low value instead of ending suddenly, and it helps to produce good welds in some types of heat treatable metals by lengthening the cooling time gradient. It is rarely needed in welding low-carbon steel, particularly if the carbon content does not exceed 0.15%, but is used when cooling rate must be limited, as in welding hardenable steels. Downslope can also be used to reset the core flux in the welding transformer to obtain uniform magnetic conditions of the transformer.

Effect of Surface Finish

In spot welding of assemblies that are to be porcelain enameled or painted, or are to receive other decorative surface finishes, the surface condition and close fit of parts after welding are as important as weld strength. Excessive indentation, overheating of the outside surfaces, spatter, and crevices interfere with the finishing operations and must be avoided.

Welding schedules and conditions must be selected that produce a weld of adequate strength with a minimum of indentation and minimum evidence of heating. This requires a uniform welding procedure that is best obtained with automatic control of current, time, and force. Electrode faces should be dressed at regular intervals, before they have worn so much that unsatisfactory spot welds are produced. Workpieces should be cleaned thoroughly before welding.

Effect of Weld Spacing on Heating

Shunting occurs when a second spot weld is made so close to the first one that the welding current can flow either through the metal at the first weld or through the metal between the electrodes at the point of the second weld. The welding current flows in inverse proportion to the resistance of the two paths. Division of current depends chiefly on the ratio of resistance of the base metal to interface resistance at the point of the second weld.

When making a second and following spot welds, the metal between the electrodes becomes a divided circuit; part of the current travels through the metal to the previously made spot weld, while the remainder travels through the metal between the electrode faces at the point of the second weld. If the distance

to the first spot weld is great enough, the resistance of the path through the first spot weld, compared to that directly through the metal, is high, and the shunting effect can be neglected. If the distance to the first spot weld is short, a significant fraction of the current is shunted through the first spot weld.

As the temperature of the metal between the electrode tips rises, the resistance at that point increases, thus adding to the shunting effect. Metals having high electrical resistivity are less influenced by the shunting effect than are low-resistivity metals.

The minimum spacing of spot welds in low-carbon steel workpieces depends on stock thickness, diameter of the fused zone, and cleanliness of the faying surfaces. The minimum recommended weld spacing for low-carbon, medium-carbon, and low-alloy steels is given in Tables 1 to 3. Welds can be made at less-than-recommended minimum spacing without significant shunting by using higher current and electrode force, shorter weld time, and fast follow-up.

If spot welds are made too close to the edge of a sheet or flange, there is an insufficient volume of base metal to withstand electrode pressure and heating. This results in a reduction in the effective force along the edge and uneven heating, causing the hot metal to be expelled from the

weld. When spot welds are made too close to an upright flange or sidewall, arcing may occur between the electrode and workpiece, or there may be a poor fit at the faying surface because of the bend radius. If large-diameter electrodes are needed because of the metal thickness, eccentric, or offset, faces may be used.

The minimum contacting overlap between two pieces of metal depends somewhat on the metal thickness, which, in turn, governs the electrode diameter and diameter of the fused zone. The minimum overlaps for low-carbon, medium-carbon, and low-alloy steels are given in Tables 1 to 4.

Development of Welding Schedules

A typical sequence of steps for determining the satisfactory conditions for spot welding is described as follows. The usual criteria for satisfactory welds in steps 1 to 4 are penetration, nugget diameter and indentation suitable for the application, and the absence of porosity, cracks, excessive expulsion, and gross imperfections:

1. *Make a preliminary selection of electrode force:* This is completed for the work to be welded and the electrodes to be used. Tables of recommended practices, such as Tables 4

to 7, provide starting points for this selection, as well as guidance in choosing preliminary values of current, weld time, and hold time for making trial welds to verify or correct this preliminary selection of electrode force.

2. *Establish the weld time and hold time:* This is done by evaluating trial welds made at several levels of current for each of a number of combinations of weld time and hold time. Squeeze time is not critical in welding trials and is usually set at a convenient value that is long enough to allow for a wide range of test conditions.
3. *Select electrode force:* Using the established combination of weld time and hold time, make welds at several different current levels, using a number of values of electrode force to cover a wide range of force.
4. *Select the welding current:* Using the established weld time, hold time, and electrode force, make test welds at current levels that cover a wide range of amperage.
5. *Verify selection of conditions:* Make trial runs under the welding conditions established by steps 1 to 4, to verify these selections as well as to establish reference data on weld quality and reliability for use in process control. A more complete evaluation than for steps 1 to 4 is performed at this stage.

Source: Recommended Practices for Resistance Welding, AWS C1.1

These five steps not only determine optimum values for each of the welding variables but also establish ranges of satisfactory values for them and the criticality of each variable. The sequence of steps followed in setting up a resistance spot welding schedule may vary, depending on special aspects of the equipment or the work, the extent of experience with similar types of work, and requirements imposed by the purchaser or applicable specifications. When adjustment of welding conditions is needed at the start of or during production runs, the adjustment is usually made on weld time, hold time, or current, whichever is most convenient and effective.

Welding Machine

Many of the electrical and mechanical characteristics of a welding machine have a significant influence on the welding process and weld quality. Limited research has been conducted in this regard, primarily because of the difficulties in altering a welding machine mechanical and electrical features, especially in a systematic manner. The electrical characteristics of a welding machine are determined by the transformer, the

electrical cables, and the secondary loop. The mechanical aspects of a welding machine usually refer to the machine stiffness, friction, and moving mass. They interact with a welding process through affecting the electrode force and electrode follow-up characteristics (Ref 3), and their effects can be summarized in the following.

Machine Stiffness. The direct reflection of the effect of machine stiffness is the electrode force characteristics. In general it was found that high machine stiffness is beneficial to expulsion prevention and tensile-shear strength of the welds (Ref 8). As shown in Fig. 7, a higher stiffness results in a higher electrode force during welding than a lower stiffness, given the preset values of the electrode force being equal. A stiff welder also reduces electrode misalignment, resulting in less electrode wear and improved weld quality.

Friction primarily affects the follow-up behavior of the electrodes of a welder during welding. A well-lubricated and aligned guide-way of a welding machine allows the electrodes to move in when the weld contracts during cooling. This is critical in suppressing solidification cracks/voids by providing the necessary

forging force. Figure 8 clearly shows the effect of machine friction on the microstructure of welds. Without additional friction, the forging force provided by the electrodes created a dense structure (Fig. 8a), while the weld made with additional friction shows a large solidification void due to a lack of forging force. The welds made without additional friction also show slightly higher strength than those with additional friction.

Moving mass affects the touching behavior of a welder, and a weld stack-up tends to vibrate more if the moving mass is small than a welder with more moving mass. This in general does not affect the welding process or the weld quality, if the electric current is switched on after vibration stops. The dynamic force imposed by a moving mass on the weldment during welding is generally too low to make a noticeable impact.

In addition to these factors, the responses of the mechanical system to the welder control should also be understood. For instance, the actual squeeze time of electrodes can be significantly different from the input (Ref 3), which may have certain implications on weld quality, especially with short welding cycle time.

Table 7 Conditions for resistance spot welding of 1010 steel, with and without zinc coating(a)

Use of Weld Lobe Diagrams

The welding parameters, that is, welding current, time, and electrode force, all affect the weld formation and weld quality, as discussed previously. However, the values of these welding parameters must be decided together, not individually. Weld lobe diagrams are an efficient and most common means of dealing with both individual and interaction effects of various welding parameters in resistance welding.

Fig. 8 Cross sections of welds made using machines with different frictions on a 1.7 mm (0.067 in.) steel. Source: Ref 8

A typical lobe diagram demonstrates how, together, the electric current and welding time affect the formation of minimum-sized welds and the occurrence of expulsion. These two limits divide the current-time domain into three regions, as shown in a schematic of a lobe diagram in Fig. 9. When the time is too short or the welding current too low, the heat generated is not sufficient to form an acceptable-sized weld. Another extreme case is when the heat is excessive, produced either by long welding time or high current; then expulsion or even electrode sticking could occur. In the middle is the region in which the current-weld time combinations produce acceptable welds without expulsion. The width of this region defines the

Fig. 9 Schematic of a lobe diagram

window of operation. A large or wide operation window is obviously preferred, because small fluctuations in welding parameters will not affect the welding process, or create an undesirable weld.

There are standard procedures, such as that recommended by the American Welding Society (AWS/SAE D8.9M, Ref 9), which can be followed to develop weld lobes. The weld lobes are material (in chemistry and thickness) dependent. Other process variables, such as electrode force, may have a significant influence on the shape and location of a lobe. For example, Fig. 10 is a three-dimensional lobe diagram for low-carbon steel showing the effect of electrode force. There are three classes of weldability lobes: A, B, and C. The class A lobe has a wider current-time window for suitable welds than class B or C lobes.

Figure 11 is the current-time plot for the class A, B, and C weldability lobes in Fig. 10. Note that the Resistance Welder Manufacturers Association (RWMA) chart schedule is outside the lobe boundaries. This is occurring more frequently, because current steelmaking practices of low-carbon steel are different than when the original RWMA schedules were developed. Current steelmaking practices, with electric arc melting and ladle metallurgy treatment, offer better composition control than in the past.

Influence of Process Variables on Weld Lobes. A weld lobe is defined by the boundaries of minimum and maximum currents at

specific welding times. The shape, size, and location of the boundaries and therefore the lobe are affected by a number of process-related variables.

Electrode Size and Condition. The electrode size determines the current density and pressure distribution at the interfaces and therefore the weld formation and expulsion. Large-sized electrodes require large welding current to produce sufficient heat or heating rate, which raises the minimum limit in a lobe diagram. For a fixed electrode force, a large electrode means low pressure, which is favored by expulsion and lowers the maximum current. Other electrode conditions, such as electrode wear and the face geometry of electrode caps, may also change the mechanical and electrical aspects of welding and the lobe diagrams.

Electrode Alignment. A weld lobe shift caused by electrode misalignment was reported by Karagoulis (Ref 10). The alignment of electrodes, either axially or angularly, affects the contact area for electrical current and mechanical pressure at the interfaces. The current density may be raised because of electrode misalignment, which promotes weld nugget formation and lowers the minimum current limit. On the other hand, the concentrated heating due to high electric current density and the reduced containment on the liquid nugget from the electrode make expulsion easier to occur. Therefore, the maximum current limit is reduced as well, resulting in a shift to the left of a lobe.

Fig. 10 Three-dimensional lobe diagram showing the effect of electrode force on suitable range of welding current and time in spot welding low-carbon steel

Fig. 11 Class A, B, and C weldability lobes for spot welding 16-gauge (1.6 mm, or 0.062 in.) low-carbon steel (Fig. 10). See text for discussion on Resistance Welder Manufacturers Association (RWMA) chart values outside the weldability lobes.

Part Fit-Up. The sheet fit-up condition affects the weld formation and expulsion in the same way as electrodes and electrode alignment. A poor fit-up condition may promote weld formation as well as expulsion and moves the weld lobe to the left. In addition, the electrode force needed to overcome the gap between the sheets with an abnormal fit-up condition is larger than in a normal situation, and therefore, the dependence of a weld lobe on electrode force is affected by part fit-up.

Electrical Impedance. The electrical characteristics, such as resistance and reactance of a welding setup, affect the heat input and therefore the weld formation and expulsion. Such an influence is complicated, especially when other process variables are involved. It was reported that the weld lobes become narrower and the boundaries steeper when adhesives were used in weld bonding (Ref 11). The changes in the shape and size of weld lobes are a result of the changes in the resistance of the weld stack-up because of the use of adhesives.

Electric Current Waveform. The effect of welding current profile on a weld lobe diagram is obvious. Welding that uses a steady, not a rippling, current supply is preferred, because the heating process is easier to control. The weld formation starts at an earlier stage when using an MFDC than an ac, which lowers the minimum current in a lobe diagram. In a comparative study of zinc-coated steels, it was found that expulsion is delayed when switching from a single-phase ac to an MFDC (Ref 4).

Electrode Force. It has been concluded by many researchers that varying an electrode force could lead to changes in the position, size, and shape of a lobe, as reported in the work by Kaiser et al. (Ref 12), for instance. In general, increasing electrode force often means a wider process window (Ref 13). More discussion is needed on the influence of electrode force on weld lobe diagrams.

The process abnormalities affect the weld lobes as well as the weld quality. In a statistical analysis by Li (Ref 14), several process variables were altered to create abnormal welding conditions. The weld lobes, characterized by the weld window location (the center of the current window, $\frac{1}{2}(I_{min} + I_{max})$), and the window width ($I_{max} - I_{min}$), were found to be a strong function of electrode size and welding time and a weak function of electrode force, fit-up, and axial and angular misalignment. In general, abnormal process conditions significantly reduce the current range, while the electrode force increases the window size. The experiment was conducted on 0.8 mm (0.03 in.) hot-dipped galvanized drawing steel, using a single-phase ac welder. Some of the conclusions of this study could be different for welding with different setups.

Effect of Electrode Force. The electrode force is usually fixed at a certain level when developing a lobe diagram. Therefore, the role of electrode force in a lobe diagram is often overlooked. In fact, the electrode force directly determines the mechanical and electrical

contact at the faying interface, which, in turn, affects the weld formation and expulsion processes. The electrical contact resistance at the faying interface is inversely proportional to the pressure and size of the contact area created by the electrode force. Therefore, increasing electrode force often delays weld nugget formation as the result of less Joule heating. Because the electrode force plays a major role in suppressing expulsion, large electrode force is beneficial for preventing expulsion. In general, both the current of minimum weld and the expulsion current are pushed up with an increased electrode, and, in most cases, the current range for making welds of a desired size without expulsion, or the operation window, is also enlarged. In welding a DP600 steel, it was found that increasing electrode force both widens the current range and moves the lobe to the right, as shown in Fig. 12 (Ref 15).

In addition to the magnitude of electrode force, the lobe diagrams are also strongly affected by the profile of electrode force. In a study comparing the influence of two different electrode driving mechanisms, Grimes (Ref 5) studied the difference in weld formation when welding with a pneumatic cylinder-driven and an electric servo-motor-driven pedestal welder. The servo motor welder was able to supply a forging force during welding, and experiments have shown that such a forging force not only helps reduce porosity in a weldment but also lowers the welding current required for forming a weld. Figure 13 shows a significant reduction in welding current when welding aluminum alloy sheets using a servo welder, compared to that using a welder with a pneumatic cylinder. The nominal electrode force is 300 daN (675 lbf) in both cases, while the servo welder supplies a 600 daN (1350 lbf) forging force at the end of welding. Therefore, welding with a forging force helps lower the minimum current in a lobe diagram. An electrode force with a forging component is also expected to raise the expulsion current, because electrode force is largely responsible for containing the liquid

metal in the nugget from being ejected. The effect of forging force on expulsion may diminish when expulsion occurs in the early stage of welding, as often observed in aluminum welding (Ref 16). In conclusion, welding with a forging action may lower the minimum welding current and raise the expulsion limit, as well as enlarge the current range or operation window.

Probabilistic Boundaries in Lobe Diagrams. In lobe diagrams, both the minimum weld current and the expulsion limit are usually expressed as lines with definite values. However, such limits are rarely used in practical welding directly. These boundaries, in fact, are affected by a number of uncontrollable random variables, and they are more of a probabilistic than deterministic nature. Many process variables, such as electrode condition, surface condition, sheet fit-up, and so on, have effects on weld formation

and expulsion. Therefore, a lobe diagram should be derived considering the uncertainty in obtaining a weld of specific size, or the occurrence of expulsion, through a standard statistical process. In the work by Zhang, et al. (Ref 17), the expulsion boundary was presented as a current range with limits corresponding to the chances of expulsion, for example, 0 and 100%.

In Fig. 14, the probabilities of expulsion of 0.05 and 0.95 are presented as the maximum current limit for a drawing steel. Such a limit, or a range for the expulsion boundary, is a strong function of welding time and electrode force. It is also clear from this figure that treating the expulsion boundary as a definitive line does not reflect the probabilistic nature of expulsion. Ideally, both the maximum and the minimum current boundaries should be determined, in terms of probabilities, through a

Fig. 13 Weld formation of 1.1 to 1.5 mm (0.04 to 0.06 in.) aluminum sheet stack-ups using a pneumatic and a servo pedestal welder. Source: Ref 5

Fig. 12 Lobe diagrams for welding a DP600 steel. Source: Ref 15

Fig. 14 Expulsion probabilities in welding a drawing steel under various levels of electrode force. Source: Ref 17

systematic statistical procedure. However, this may be difficult in practice because of the large amount of experiments involved in developing these boundaries.

Three-Dimensional (3-D) Lobe Diagrams. The boundaries of minimum-sized weld and expulsion of a lobe diagram are commonly expressed in terms of the combinations of welding time and current only, at a fixed electrode force. Three-dimensional lobe diagrams, such as the one in Fig. 10, can be used to show the effects of electrode force on the current-time weldability lobes. A higher force increases the range of welding current and time window for suitable welds (e.g., class A in Fig. 11).

The electrode force can be set high with low-carbon steels, so that the welding process may not be very sensitive to electrode force. However, lightweight materials such as aluminum or magnesium alloys are more sensitive to electrode force. Aluminum and magnesium usually experience large thermal expansion during heating and melting, and welding such materials depends strongly on the electrode force applied. When the electrode force is not treated as a variable, very limited information can be obtained on the interaction between the electrode force and other process variables. It is also difficult to optimize welding schedules without knowing the role the electrode force plays over a certain range, in weld formation and expulsion suppression. Therefore, it is of practical interest to consider the welding current, time, and electrode force together in developing welding schedules, that is, to construct 3-D lobe diagrams.

Most of the lobe diagrams incorporate the effect of electrode force by overlaying the lobes corresponding to different levels of electrode force in the same diagram. For instance, Fig. 12 shows the limits of minimum weld and expulsion under two electrode forces: 2.0 and 3.34 kN (Ref 15). Because only very limited levels of electrode force can be used in one lobe diagram, the electrode force is not treated in the same way as the other two, and its effect cannot be fully accounted for. A true 3-D lobe diagram presents the boundaries of minimum weld and expulsion as surfaces in a 3-D space of welding current, time, and electrode force. Using analytical expressions of expulsion probabilities developed through experiments for a drawing steel and two aluminum alloys (AA5754 and AA6111), Zhang (Ref 16) presented the surfaces of expulsion with the probabilities of 0.05 as the functions of all three welding process parameters in Fig. 15 to 17.

A probability of 0.05 represents a very small chance of expulsion, and therefore, the surfaces in the figures can be used as the limits of maximum-sized welds with a low risk of expulsion. As seen in the figures, different alloys have distinctive expulsion surfaces or characteristics. In general, low heat input, represented by low current and short time, has a low chance of expulsion when supplemented by a high electrode force. Expulsion in steel welding is contained if the combinations of current, time, and electrode force are located under the surface in Fig. 15. The risk of expulsion dramatically increases if the limit is

exceeded that is, when a combination of parameters located on the surface moves outward. Reducing welding current level and welding time and raising electrode force is efficient in avoiding expulsion in welding this steel. The difference between welding steels and welding aluminum alloys is evident by the drastically different expulsion surfaces in the 3-D lobe diagrams. The expulsion surface for AA6111 welding (Fig. 16) is less curved than that for welding the steel. The electrode force and welding current still affect the chance of expulsion, although to a smaller extent. Welding time is influential only when the electrode force is low, and it is virtually irrelevant under high electrode force. Similar observations are made on welding AA5754 (Fig. 17). In addition to the fact that the welding time has little effect on expulsion at both high and low electrode force levels, the expulsion exhibits very limited dependence on electrode force. The expulsion surface is very flat, and expulsion occurs once a critical value of welding current is reached.

Three-dimensional lobe diagrams present an opportunity for choosing all three welding parameters together, which is desirable in practice, especially when welding new materials on which not much practical experience is available. They also provide important information on the intrinsic nature of the sheet materials. For instance, the virtual independence of expulsion on welding time and electrode force exhibited in Fig. 17 for welding AA5754 implies that the liquid metal is ejected at a very early stage of welding (so varying welding time has little effect), and the volume of liquid metal may grow quickly to a level where expulsion cannot be effectively contained by electrode force. The difficulties and high cost associated with preparing the models of minimum-sized weld and expulsion for the limits in a 3-D lobe diagram, generated through a large experiment matrix, prohibit the use of 3-D lobe diagrams. Taking the probabilistic nature of the limits into consideration will make them more expensive to implement in practical welding.

Seam Welding Procedure Development

Seam welding produces coalescence by the heat obtained from resistance to the flow of electric current through the work parts held together under pressure by circular electrodes. Seam welding machines are capable of making two types of lap joint:

- continuous seam joint of overlapping materials from a series of overlapping spot welds made progressively along a joint by rotating the electrodes
- row of spot welds that do not overlap

Unless otherwise specified or required, the first method achieves a continuous, pressure-tight seam joint on fully overlapped sheet materials. The latter method, known as roll spot welding,

is not actually seam welding but is discussed at the end of this section, because it can be accomplished on standard seam welding machines.

During seam welding (Fig. 18), the electrodes continuously rotate while the welding current is interrupted regularly to achieve the effect of overlapping spot welds. On some thin materials, interrupted current is not required

Fig. 15 Surface of expulsion with a probability of 0.5 for a drawing steel. Source: Ref 16

Fig. 17 Surface of expulsion with a probability of 0.5 for AA5754. Source: Ref 16

to produce a good-quality continuously fused seam. Another process variation is mash seam welding (see the article “Resistance Seam Welding” in this Volume). This process uses wide-faced welding wheels and a small, accurately gaged overlap of the sheet materials to be mash seam welded.

Seam welding is a proven production process, and its benefits are most readily achieved when product designers are aware of its characteristics and limitations. It is obviously impractical to set up charts that would cover all welding jobs and conditions, but this section provides some data tables for making

high-quality welds consistently, at maximum speed, and with the least maintenance of welding electrodes. However, it may be necessary to use other setups, because some applications may not require highest-quality welds, such as in difficult-to-reach places that need to be welded. The welding data tables are given as a good starting point, but other setups may be more suited for certain applications.

Seam Welding of Low-Carbon and Stainless Steels

Some of the general guidelines described earlier for spot welding are also applicable to seam welding and are highlighted for various typical low-carbon steels, such as SAE 1005, SAE 1010, SAE 1015, and so on, and for a group of chromium-nickel (austenitic) stainless steels classified as types 301, 302, 303, 304, 308, 309, 310, 316, 317, 321, 347, and 349. Applications involving ferritic and martensitic stainless steels must have special consideration, because the exact chemical composition and thickness of stock determine the practicability of seam welding.

Examples of seam welding parameters are summarized in Tables 8 to 10 for

Notes:

- Low-carbon steel is hot rolled, pickled, and lightly oiled, with an ultimate tensile strength similar to steel (SAE 1005–SAE 1010) (42–45 ksi).
- Electrode material is RWMA class 2 alloy.
- Surface of steel is lightly oiled but free from grease, scale, or dirt.
-

- Heat and cool times are indicated in cycles of 60-cycle frequency.
- Electrode force does not provide for force to press ill-fitting parts together.
- For large assemblies, minimum contacting overlap should be increased by 30% for ease of guiding.

Source: Ref 18

- Large assemblies should be welded at the slower speeds for ease of handling and guiding.
- Electrode face may be flat or crowned (for best weld appearance), as shown:

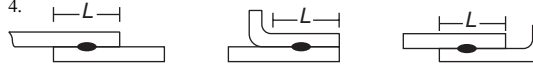

- Welding current is about 10% higher than shown for pressure-tight joint at same weld speed.
- Adjust the cool time to give desired spot spacing.

5. Frequency of welding current is 60 cycles/s.
6. Electrode force does not provide for force to press ill-fitting parts together.
7. For large assemblies, minimum contacting over-lap should be increased by 30% for ease of guiding.

Source: Ref 18

8. Large assemblies should be welded at the slower speeds for ease of handling and guiding.
9. Electrode face may be flat or crowned (for best weld appearance), as shown:

10. Phase-shift heat control range is recommended to attain the best weld quality and appearance.
11. Since welder used on thicker materials must operate at "phased-back" current output, maximum full-wave current, output of welder must be approximately twice that of the welding current shown.

low-carbon steel and austenitic stainless steels. Further discussion is given in the section "Seam Welding Parameters" in this article. As noted, the welding data tables represent welding setups to make not only the highest-quality welds but also to make them most consistently, at maximum speed, and with the least maintenance of welding electrodes. It is these combinations of variables that are listed in the welding data tables. However, all factors must be given consideration before actual values are selected from the charts, because other setups may be needed for specific applications.

Surface Preparation. Low-carbon steel should be free from rust, mill scale, paint, heavy grease or oil to achieve high-quality seam welds. Steels with zinc, tin, or lead-coated surfaces are weldable. However, the electrodes need more frequent cleaning to maintain weld quality.

Steel grit blasting, grinding, or pickling are preferred methods for removing heavy scale or rust. A light film of thin oil to prevent the steel from rusting usually has no adverse effects on the weld, provided that dust has not been allowed to accumulate on the sheet surfaces during storage. If dirt has accumulated, it should be wiped off before welding.

As with carbon steels, stainless steels should be free from rust, scale, dirt, paint, heavy grease or oil for seam welding. Any satisfactory degreasing solution will remove grease and oil and thereby minimize the possibility of surface burning. Stainless steel sheet seldom has any surface scale on it. If scale is present, it can be removed by a 50% (by volume) solution of muriatic (hydrochloric) acid and water, heated to 60 to 65 °C (140 to 150 °F). Wash thoroughly in clean running water. The resulting dark "smutty" surface is cleaned by immersing in a solution of 20% (by volume) nitric acid. After the surface is clean, wash in hot water.

In some applications where the highest degree of weld quality and consistency is essential, it may be necessary to "immunize" or passivate the stainless steel before welding on a freshly machined, polished, or pickled article. A thin oxide film can be made to form rapidly and uniformly by dipping the stainless steel in a cold 20% nitric acid solution for approximately 30 min or warm (approximately 65 °C, or 150 °F) 20% nitric acid solution for approximately 10 min. This passivating treatment forms a thin protective coating of oxide. It also dissolves small particles of foreign material that may

have become lodged in the surface as a result of contact with forming tools or polishing wheels. These particles of common steel will rust and mar the stainless surface if not removed. While the aforementioned procedure allows very good welding results, it is not usually necessary before welding. By sending the welded assemblies through a similar treatment after welding, any discoloration will be removed and the appearance of the finished parts will be improved.

Part Fit-Up. Parts that are to be overlapped, or flanged and welded, should have enough overlap or flange width to prevent excessive burning of the edges of the parts by the welding heat or too much "spitting out" of hot metal. The welding data tables indicate the minimum width of overlap and flanges to make the best welds. For the welding of low-carbon steel with interrupted current timing, two sets of overlap dimensions are shown. With interrupted current timing, the larger dimension is preferred and should be used whenever the application permits. The smaller dimension will give reasonably good results, but it is imperative that guiding fixtures be used to make certain that the center of the electrode face rides over the center of the flange

Notes:

- Types of steel—301, 302, 303, 304, 308, 309, 310, 316, 317, 321, 347, and 349.
- Electrode material is RWMA class 3 alloy.
- Surface of steel is free from grease, scale, or dirt.
- 
- Heat and cool times are indicated in cycles of 60-cycle frequency.
- Electrode force does not provide for force to press ill-fitting parts together.
- Use maximum electrode force at maximum speed and when welding cold-worked material of 150 ksi or above ultimate tensile strength.
- For large assemblies, minimum contacting overlap should be increased by 30% for ease of guiding.

Source: Ref 18

- Large assemblies should be welded at the slower speeds for ease of handling and guiding.
- Welding current is about 10% higher than shown for pressure-tight joint at same weld speed.
- Adjust the cool time to give desired spot spacing.
- For best appearance, use radius-faced electrodes. Average application can be welded with flat-faced electrodes.

or overlap at all times. Slight runouts will cause pronounced spitting and deformation of the overlapped metal.

The amount of overlap dimension is associated with the electrode face width. If the smaller dimension of overlap is used, the smaller dimension of electrode face width should also be used, but the material thickness always determines the minimum electrode face and therefore the minimum overlap.

The range of welding speeds used with continuous current makes it inadvisable to reduce the overlap dimension from the indicated values, because of difficulty in guiding the work at such speeds. While smaller overlap dimensions would result in equally good welds, the design and operation of suitable guiding fixtures become difficult.

The overlap in seam welding is of great importance in making a satisfactory product.

If the application is such that the shape of the parts being welded makes it difficult for the operator to control the overlap in the seam welder, the overlap should be fixed by spot tacking. In this operation, the overlap is first established and held in some suitable manner until several spot welds are made along the line of the future seam weld. The spot welds fix the overlap so it will not change in seam welding because of warping, skidding, creeping, and so on.

While spot tacking can be done on the seam welder, with the welding electrodes preferably not rotating, it is better done on a spot welder assigned to the purpose. It is not unusual to have one spot welder in operation, spot tacking parts to be welded on several seam welding machines.

Parts should lie flat against each other where welds are to be made so that no force is required

from the electrodes to make the parts touch each other. The welder is not a forging machine, and improperly fitting parts will result in inconsistent and inferior welding, greater power demand, as well as excessive maintenance and replacement of the welding electrodes.

Seam welds in circular work require adequate inspection and close supervision to obtain the required conditions of good fit. Press fits or other types of assembly permitting intimate metal-to-metal contact around the entire circumference at the zone to be welded should be used if at all possible; otherwise, less than best-quality welds will result.

In many applications, it is necessary to weld along a continuous curve such as a flanged bottom to a cylindrical container. It is advisable to limit the minimum diameter to 100 mm (4 in.) to allow a suitable diameter of electrode and adequate working life. Smaller

diameters can be seam welded but require special consideration in selection of welding equipment electrode shapes and in welding technique.

The minimum advisable radius of seam welds around contoured corners (such as a gasoline tank) are:

- 50 mm (2 in.) radius for sheet steel gages of 22 through 18
- 60 mm (2¼ in.) radius for 16-gage steel
- 75 mm (3 in.) radius for sheet steel gages of 13 through 11

Electrode Drives. The best type of circular electrode drive for a specific application depends on the shape of the parts to be welded, the degree of surface marking that can be tolerated, and the surface condition of the steel.

Seam welding machines employ three types of electrode drive mechanisms: Knurl or friction roll drive, gear drive, and traveling head (or traveling fixture) drive, which uses idling weld wheels.

The knurl (or friction)-type drive has either the upper or lower (or both) rotating electrodes driven by a hardened steel contact wheel at the periphery of the electrode. The power-driven steel wheel usually has knurling on the engaging surfaces that cut into the face of the wheel or the sides of the wheel adjacent to the face. This type of drive has an advantage in that the peripheral speed of the electrode is independent of the electrode diameter. Hence, the speed remains constant as the electrode diameter changes. Also, both upper and lower wheels may be driven, and they will have the same peripheral speed, regardless of changes in electrode diameter during their useful life.

In the gear-driven type of machine, one electrode is usually driven by means of its gearing and the connected drive shaft. The other welding electrode idles and is turned by friction with the welded product between the electrodes. This drive is desirable in cases where the electrode face must be kept smooth to minimize marking of the product. Also, where space is limited in some welding products and small electrode diameters are required, the gear-driven design is mechanically more practical.

In the travel head type of welder, the head of the welder (with idling electrode wheel) is pushed or pulled over the work, which is clamped on a stationary fixture. A traveling fixture type of machine moves the work under or between stationary, idling electrodes. Traveling head seam welding machines are preferable when the welded product is large or difficult to manipulate through the welder. Traveling fixture type of machines are useful where the product must be accurately located or firmly clamped during the weld.

Gear drive is preferable for any required small electrode diameters and to minimize surface

marking on the welded product. Knurl drive is best to drive both electrodes, to automatically maintain the contour of the welding electrode, or to continuously knurl the electrode face. Knurl drive is desirable when welding coated materials such as template, galvanized, aluminized, or tin-plated steel.

Welding Machine Operation. The sequence most generally used is as follows:

1. Rotating electrodes set down on work
2. Force (pressure) on
3. Current on (current timing pattern starts)
4. Current off (end of weld, current flow is stopped)
5. Force (pressure) off
6. Rotating electrodes separate from work

Seam welding machines are usually built with control circuits to assure the proper sequence of operation, if all adjustments are properly made. The operation should be carefully checked to make sure that the proper sequence is obtained before turning on the welding current.

Seam Welding Electrodes

The welding electrodes must be of the proper material and shape and should be adequately water cooled. For welding low-carbon steel (Table 8), electrodes made of RWMA class 2 alloy usually give the best performance and life, while RWMA class 3 is recommended for welding of stainless steels.

The size and shape of the electrode is usually determined by the shape of the parts to be welded, the location of the welds, and the needs of the driving mechanism to keep the electrodes rotating. If welds are to be made on flanges, one edge of the electrode face is often made practically flush with the side of the electrode, allowing the face to weld the flange with the minimum degree of clearance.

From Table 10, it can be seen that radius-crowned electrodes are recommended when welding stainless steel. This selection is preferred for the best surface appearance, because the marking and indentation from the electrodes will be minimized. If electrode indentation is not objectionable, flat-faced electrodes of the same shape as those used for welding low-carbon steel are usable and will give good results.

The contour of the electrode will change in welding, and the contacting electrode face becomes wider and will eventually reach a point where the reduced unit welding current and unit force will not cause fusion. The faces should be redressed as often as necessary, and the best method of redressing is to put them in a lathe and machine them. Several sets should be available so that the redressing time does not reduce the production time of the welder. If radius-crowned faces are used, a

radius gage may be used for properly checking the contour to see that the correct radius is maintained.

When the parts to be welded are of approximately equal thickness and it is desired to have as little surface marking as possible on one workpiece, the electrode in contact with the part to have a minimum of marking should have its face width at least 50% greater than the widths given in the welding data tables. The diameter of electrodes used in seam welding is determined principally by the application. Provide an adequate mass of copper alloy to prevent excessive temperature rise. Provide sufficient clearance to prevent the arms holding the welder bearings from interfering with the workpieces.

If the working conditions permit, the following sizes of electrodes are used:

- For light work (electrode forces up to 445 daN, or 1000 lbf), electrodes are usually 9.5 mm (¾ in.) wide and 178 mm (7 in.) in diameter.
- For medium work (electrode forces up to 890 daN, or 2000 lbf), electrodes are usually 13 mm (½ in.) wide and 203 mm (8 in.) in diameter.
- For heavy work (electrode forces up to 1335 daN, or 3000 lbf), electrodes are usually 19 mm (¾ in.) wide and 254 mm (10 in.) in diameter.

Some applications will necessitate using electrodes of different diameters. One electrode may be a small diameter to fit into the part being welded, and the other may be a large diameter to provide clearance between the horns of the welding machine carrying the bearings. As an example, select the case of a flange circular disc being welded into a cylindrical container of small diameter (Fig. 19). The electrode must pass into the bottom of the container, and, for the interests of adequate electrode life, it is made as large in diameter as possible. The outside electrode must be large in diameter to provide adequate work clearance. When the parts are assembled for welding, it will be noted that more metal is in contact with the smaller-diameter electrode. This metal will be cooled rapidly and will not reach welding temperature at the same time as the small area of metal in contact with the larger-diameter electrode, if the electrode face widths are equal. Consequently, to create a heat balance and prevent excessive surface marking of the metal in contact with the top electrode, the wheel face widths are varied (Fig. 19). The W_3 on the outside wheel is greater than the W_2 on the inside.

Seam welding machine electrodes can be internally water cooled if necessary, but this method is much less effective than the usual system of flooding water directly on the electrode and work. The cooling water is normally directed from four tubes to the point where the weld is being made. Continuously moving

Thickness of each workpiece	D_1 , in. min.	D_2 , in. min.	D_3 , in.	W_2 , in.	W_3 , in.

Fig. 19 Setup for seam welding a circular flange disc into a cylindrical container of small diameter

cold water thus cools the hottest part of the electrode and work on both the upper and lower surfaces of the weld. Water cooling promotes longer electrode life. Water cooling has other desirable effects. It quickly quenches the weld metal while considerable force is on the workpiece, thus making high rates of welding speed possible.

When welding coated materials such as galvanized or terne-coated steels, it is quite necessary to minimize pickup of the coating on the electrodes. The quenching action is also desirable when welding stainless steel in order to

minimize possible future corrosion of the steel due to the welding heat. In stainless steels of the chromium-nickel type (and not stabilized), there is a zone of temperature between 4425 and 815 °C (8000 and 1500 °F) in which carbide precipitation occurs. A proper application of cooling water keeps the time in this critical temperature range sufficiently short.

By having suitable water cooling, the warpage of the workpieces is minimized. It also allows easier handling of the parts, because the welding heat flows into the cooling water rather than into the parts themselves.

When welding two unequal thicknesses, the weld nugget will usually penetrate deeper into the thicker piece. By adjusting the flow of cooling water so that the thicker piece is cooled more thoroughly, the penetration into the thicker piece can be decreased while penetration into the thinner piece is increased. In other words, the flow of cooling water is adjusted to assist in compensating for the uneven heat balance condition created by the two unequal sheet thicknesses. The recommended welding technique is shown in Table 11.

A 5% (by volume) solution of borax in the cooling water will minimize the rusting of low-carbon steels. This solution should not be used as a cooling fluid in the welder transformer or internal cooling passages, because it may eventually clog such passages.

Seam Welding Parameters

Like spot welding, the formation and quality of seam welds depends on welding current, electrode force, and welding time. One key difference is that welding time is expressed as the speed of seam welding, based on the travel speed of the rotating electrodes. Like spot welding, these welding parameters must be decided together, because the quality of seam welds depends on the combined effects of welding current, electrode force, and welding speed.

Electrode force should be as high as is practical and will depend on the material thickness, the hardness of the material, the type of electrode material, size, and shape, as well as the mechanical and electrical capacity of the machine used. The welding force is usually applied by an air cylinder.

Table 8 gives recommended values to be used in the listed setups. It will be noted that two ranges are given for low-carbon steel seam welding using interrupted current timing. The lower range should be used with the minimum electrode face width. This combination should be selected only when the other combination cannot be used because of geometry of the parts, machine capacity, and so on. To weld under these conditions necessitates careful guidance of the workpieces and close control of welding variables. There must be no electrode force required to force the parts together before welding, and the work dragging load (tending to stop rotation of the electrodes) should be small.

The higher welding force range should always be used when the parts have been previously cold worked. Higher force should also be used when welding takes place at the maximum recommended speed. The effect of electrode force on maximum welding speed is shown in Table 12 for mild steel. A 3-D lobe diagram is shown in Fig. 20.

Most modern welding machines are supplied with gages, charts, or tables to show the different welding forces for the various machine settings. Where such calibrations are not available, force gages can be used to

Table 11 Seam welding dissimilar thickness of low-carbon steel with interrupted current

- Notes:
1. Low-carbon steel is hot rolled, pickled, and lightly oiled with an ultimate tensile strength of similar to steel (SAE 1005 – SAE 1010) (42 – 45 ksi).
 2. Electrode material is RWMA class 2 alloy.
 3. Surface of steel is lightly oiled but free from grease, scale, or dirt.
 4. 
 5. Heat and cool times are indicated in cycles of 60-cycle frequency.
 6. Electrode force does not provide for force to press ill-fitting parts together.
 7. For large assemblies, minimum contacting overlap should be increased by 30% for ease of guiding.
 8. Large assemblies should be welded at the slower speeds for ease of handling and guiding.
 9. Electrode material—RWMA class 2 having shape of:

It is impossible to list all combinations of thicknesses—variables can be estimated as follows:
If thickness ratio is greater than 2 to 1, use variables indicated in Table 9 (for thinner sheet) except:

1. Increase electrode force by 15%.
2. Increase current by 30%.

If thickness ratio is less than 1.8 to 1, use variables indicated in Table 9 (for thinner sheet) except:

1. Use average of electrode force (normal).
2. Use average of welding current for the same approximate speed and timing pattern.

measure such welding forces (under static conditions).

Welding Speed and Time. As noted, welding time during seam welding is controlled through the travel speed of the electrodes. Like spot welding, lobe diagrams are a common means of evaluating suitable parameters, except that welding speed (instead of welding time) is a variable in lobe diagrams for seam welding. Examples of lobes diagrams are shown for narrow seam weld (Fig. 21) and wide seam weld (Fig. 22) of low-carbon steel. Higher welding speeds narrow the processing window for suitable welds, as indicated in Fig. 21 and 22.

The time of heating during seam welding depends on whether continuous current or interrupted current (timed periodic impulses of current) is used. When continuous current is used, the welding current flows all or part of each half-cycle. An electronic or magnetic contactor permits the continuous current to flow during the complete time of each half-cycle, and transformer taps control the amount of current. Such current flow is designated as full-wave continuous current.

With the use of electronic contactors and phase-shifting heat control circuits, the continuous current can be made to flow only a portion of each half-cycle, and its magnitude

can be readily adjusted from 100 to 40% for a 220 V welding machine or from 100 to 20% for a 440 V welding machine. Such current flow is designated as phased-back continuous current.

Welding by the use of full-wave continuous current (supplied from a 60-cycle system) may be used if the stock thickness is 20 gage or less and the geometry of the work is such that welding speeds as indicated in Table 9 can be used. If the speeds must be much lower, phased-back continuous current is recommended.

With thicknesses of sheet above 1 mm (0.040 in.), welding with full-wave continuous current becomes less satisfactory. The surface appearance is poor, with deep ridges and occasional burned areas. Phased-back continuous current should be used to a material maximum of 0.2 mm (0.0075 in.) and is satisfactory under normal circumstances.

Variations in sheet surface cleanliness due to rust spots, and so on cause more trouble when continuous current is used than when the current is interrupted. Either full-wave continuous current or partial-wave continuous current may be used when making mash seam welds, depending on the thickness of the material.

Interrupted (periodic impulse) current is obtained by using an electronic current interrupter or timer. This interrupter allows current to flow for several cycles (heat time) and to stop flowing for several cycles (cool time) and thus repeats this heat-cool pattern as long as the control circuit is actuated and force is on the work. In commercial models of seam welding machine timers, the timing pattern of heat-cool is adjustable for a range of welding conditions.

The current flow or heat time is indicated in cycles (60 cycles per second, because this is the frequency of most power systems). If the heat time is 6 cycles, it means the current flows for exactly 6/60 or 1/10 of a second. The current cool time is indicated in a similar manner.

A pressure-tight joint will require a number of spots per inch to continuous fusion. The range is approximately 15 for 0.25 mm (0.010 in.) thick steel to 5 for 3.2 mm (0.125 in.) thick steel. In most cases, good welds result when the heat time is nearly equal to the cool time. Excessive welding speed will require a welding current so great that surface melting or burning of the material will result. Also, the excessive speed will cause the electrode to roll from the weld metal before it cools. This action results in erratic and inconsistent welding.

Electrode pickup occurs because the semi-molten material tends to adhere to the electrode. Increasing the kVA capacity of the welding transformer does not necessarily enable higher welding speeds.

If slow welding speeds are necessary (usually because of the shape of the work), the cool time should be increased to achieve proper weld spacing.

The number of welds per inch (or per centimeter) are calculated as follows:

$$N = \frac{60T}{(H + C)L} \text{ (for 60 cps frequency)}$$

where:

N is the number of impulses or spots per inch,

L is the length of the weld in inches (or centimeters),
 T is the time in seconds (to weld L),
 H is the heat time in cycles (current flow period), and
 C is the cool time in cycles between successive heat times. This equation may be transposed to:

$$H + C = (60T)/(NL)$$

Seam Welding Current. The welding current is the current that goes through the work and is measured in amperes. It is not usually practical to measure the welding current directly, so the current drawn by the welding machine from the shop power supply is measured and then multiplied by the welder transformer turns-ratio to obtain the welding current.

The turns-ratio for the various welder tap switch settings, if not in the manufacturer's instruction book, can be calculated by measuring the input (primary) voltage and dividing it by the measured output (secondary) voltage. It can also be obtained from the machine manufacturer.

With continuous timing, a standard ammeter can be used for measurement of primary current. With interrupted timing, the heat time is so short that accurate primary current readings cannot be measured with standard ammeters. The use of pointer-stop meters will accurately measure short-time welding currents of 3 cycles duration or longer.

As a general rule, the current is set as high as possible at the start of the weld to ensure, if possible, having enough current at the end of the weld. The degree of reduction of the welding current depends on the analysis of the material, the material thickness and shape of the parts, the area and shape of the welder throat opening, and the location of the work in the throat. Minimum current requirements for narrow and wide seam welds are compared in Table 13 for mild steel. Currents for mild steel are compared with high-strength steel in Table 14 and with coated steels in Table 15.

Many applications of seam welding are such that more magnetic material enters the throat of the welder as the weld progresses. This additional magnetic material in the welder secondary circuit reduces the welding current available. In longitudinal welding, this condition always exists. If it is not possible to obtain sufficient current at the end of the weld without excessive burning at the start of the weld, it is necessary to apply some form of current compensation. Suitable compensation controls can be incorporated in welding machines for magnetic materials. These controls are equipped with constant current, so they are not affected by magnetic circuit changes in the machine.

Seam Weld Testing

There are several methods of testing seam welds. The selection should depend on the final use of the welded product. The first rough check of a weld is easily performed by trying to tear the sheets apart by driving a chisel through the welded area. If the weld cannot be chiseled apart without tearing through the sheets, further tests may be made.

Fig. 20 Effect of electrode force on weldability lobes in seam welding of 1.2 mm (0.05 in.) thick mild steel (wide seam with alternating current). Source: Ref 19

Fig. 21 Weldability lobes for narrow seam welding of a mild steel (alternating current). Source: Ref 19

A cross-sectional etch test to show the percent overlap of the fused nuggets, which should be approximately 20%, and the penetration of the fused zone into the sheets, which should be between 35 and 70% of the sheet thickness, is the normal metallurgical inspection test. The width of the weld depends primarily on the electrode face width and should be from 1½ to 3 times the stock thickness. If the weld width is too narrow and penetration is inadequate, physical strength will be sacrificed. If the weld width is too wide and penetration is

excessive, the weld center will be overheated. This causes excessive buckling, warpage, and poor appearance.

One of the more reliable tests is the pillow test, in which two sheets of convenient size, say 150 by 150 mm (6 by 6 in.), one of which has a pipe nipple welded to it, are seam welded completely around the edges and then subjected to hydrostatic pressure until failure takes place. Failure will usually occur on an inside edge of the seam, where the buckling due to expansion of the test sample is greatest.

After the welding schedule has been determined by the various types of test, production tests on containers can be satisfactorily made by subjecting each piece to air or gas pressure while submerged in water. A safe value of air pressure will disclose any leaks as rapidly as a much greater hydraulic pressure.

It is impractical to make seam welds without some indentation on one or both sides of the stock. Consequently, the stock thickness is reduced by the amount of indentation, causing some slight loss in strength. If the indentation is properly controlled, the welded joint will have a tensile strength of 80 to 100% of the parent metal.

Bearing Maintenance

A resistance seam welding machine bearing mechanism must transmit thousands of amperes from a stationary housing to a rotating shaft, on which is mounted the circular welding electrode. This bearing must also withstand heavy force and maintain proper electrode alignment.

Although journal-type bearings are more common, current collector types and needle bearing designs are frequently employed to achieve improved bearing alignment and to decrease maintenance requirements.

To ensure proper operation and reasonable life, adequate lubrication is necessary. Different bearing designs will require a particular type of lubricant and frequency of lubrication. Lubricant must be of a type to permit electrical current to flow freely. It is therefore important to precisely follow the maintenance recommendations of the welder manufacturer. Many bearing designs have built-in water cooling. In operation, water flow must be maintained to avoid excessive heating.

	Maximum	11.75	11.0	10.3	9.6
	Range	2.5 (2.75)	2.3 (2.7)	0.4 (0.9)	0.6 (1.6)

Note: Minimum current refers to current for continuous weld plug; values in parentheses refer to current for stuck weld. Maximum current refers to current giving weld splash. Source: Ref 19

Other Methods

Mash Seam Welding. When the thickness through the finished weld must be a minimum, mash seam welding is used. A slight overlap of 1 to 1½ times the thickness of one workpiece is held by rigid external clamps or by tacking spot welds. Tacking spots should be close enough together to prevent the seam from opening up ahead of the electrodes, and the spot spacing will vary from 40 mm (1½ in.) on 0.5 mm (0.020 in.) material to approximately 75 mm (3 in.) on 2 mm (0.075 in.) material. The assembly is placed between two broad-faced flat electrodes, which forge the sheets together while welding them. The resulting thickness in the weld area is approximately 50% greater than one original sheet thickness. The process variables listed in Table 16 apply.

Mash seam welding is limited to low-carbon and coated steels of 13 gage (2.2 mm, or 0.090 in.) or less for most applications. Its use requires higher electrode maintenance than lap seam welding. It should not be used if lap seam welding is practical. Mash seam welding of stainless steel is not recommended, because the narrow plastic range of the material causes excessive burning and spitting, and the high hot-forging strength of the stainless steel causes excessive electrode wear, making the process impractical.

Roll Spot Welding. Seam welding machines are used for roll spot welding—making a series of spot welds with a gap between them. Roll spot welding is a useful production technique where a pressure-tight joint is not required.

Interrupted current timing must be used, and the spot spacing is determined by selecting the proper current cool time with relation to the welding speed. Tables 9 and 10 indicate a range of speeds for roll spot welding. This range is very flexible. Normally, the geometry of the work will allow selection of one of the three indicated ranges.

If a slower speed is desired, the minimum speed indicated for a pressure-tight joint can be used. No currents are indicated because they should be similar to the three ranges indicated

for pressure-tight joints. For example, if the welding speed is 100 in./min and spots are desired every 50 mm (2 in.) in 0.75 mm (0.030 in.) thick stock, the welding data table indicates the current heat time (H , in number of cycles) should be 3 cycles.

Proper cool time may be calculated by the formula:

$$H + C = (60T)/(NL) \text{ (at 60 cps)}$$

For example, with spot spacing of 50 mm (2 in.), N is ½. With a welding speed of 100 in./min, then L is 100 in. and T is 60 s. Heat time is 3 cycles, so calculating for cool time (C) to achieve proper spot spacing is as follows:

$$3 + C = (60 \times 60)/(1/2 \times 100) = 3600/50 = 72$$

$$C = 72 - 3 = 69 \text{ cycles}$$

Long cool times for intermittent seam welding may require the modification of standard seam weld timer ranges to obtain such times.

Nonferrous Alloys

Resistance spot, seam, projection, and upset welding are used to weld nonferrous sheet products. Suitability may vary depending on the work metal. For example, some of the coppers and copper alloys can be spot welded but not seam welded because of high conductivity, and not projection welded because of low compressive strength of the projections at elevated temperature.

Resistance welding of aluminum and copper alloys is common and discussed further. Titanium, nickel, and magnesium alloy sheets with thicknesses up to approximately 6 mm (¼ in.) are also welded by spot, seam, and projection resistance processes.

Aluminum and Its Alloys

Aluminum alloys, both of the non-heat-treatable and heat-treatable types, either wrought or

cast, can be resistance welded. Some of these alloys are welded more readily than others. Gas shielding may be required to maximize joint quality. Characteristics of aluminum alloys include comparatively high thermal and electrical conductivity, a relatively narrow plastic range (approximately 95 to 205 °C, or 200 to 400 °F, temperature differential between softening and melting), considerable shrinkage during cooling, a troublesome surface oxide, and an affinity for copper electrode materials.

Although aluminum alloys can be resistance spot and seam welded, some alloys or combinations of alloys have higher as-welded properties than others. Table 17 gives melting ranges, electrical and thermal conductivities, and resistance weldability of some wrought alloys and casting alloys.

Resistance welding is also done on Alclad products made by roll cladding some of the alloys listed in Table 17 with a thin layer of aluminum or aluminum alloy. Because this layer is anodic to the core alloy, it provides electrochemical protection for exposed areas of the core. Alclad alloys 2219, 3003, 3004, 6061, and 7075 have a cladding of alloy 7072, which contains 1% Zn; Alclad alloy 2014 has a cladding of alloy 6003 or sometimes alloy 6053, both of which contain approximately 1.2% Mg; and Alclad alloy 2024 has a cladding of alloy 1230, which contains a minimum of 99.3% Al.

The hardness of an alloy is one variable influencing weldability. Any alloy in the annealed condition (O temper) is more difficult to weld than the same alloy in a harder temper. In general, alloys in the softer tempers are much more susceptible to excessive indentation and sheet separation and to low or inconsistent weld strength. Greater deformation under the welding force causes an increase in the contact area and variations in the distribution of current and pressure. Therefore, welding of aluminum alloys in the annealed condition or in the softer tempers is not recommended without special electromechanical or electronic controls.

High-strength alloys such as 2024 and 7075 are easy to resistance weld but may require

Table 15 Comparison of minimum alternating current requirement for mild steel and coated steels

Welding speed, m/min	Minimum current for continuous weld plug(a)

0.090	13	3100	0.118	47	20,700	45–60

- Notes:
 1. Low-carbon steel is hot rolled, pickled, and lightly oiled. Ultimate strength is similar to steel (SAE 1005–1010) (42.5–45 ksi).
 2. Electrode material is RWMA class III. Electrode diameter from 8 to 12 in.

3. Surface of steel free from grease, scale, or dirt.
 4. Initial overlap must be closely controlled either by spot tacking prior to seam welding or by rigid clamping during seam welding.
 5. The final joint thickness will be about 150% of one sheet thickness.
 6. Degree of mashdown is equal on both sides.
 7. Phase-shift heat control range is recommended to attain the best weld quality and appearance.
 8. Since welder used on thicker materials must operate at phased-back current output, maximum full-wave current output of welder must be approximately twice that of the welding current shown.

applications of a forge pressure, because they are more susceptible to cracking and porosity than the lower-strength alloys.

Equipment. Best results in resistance welding of aluminum and its alloys are obtained by using a machine that has these features:

- Ability to handle high welding currents for short weld times
- Synchronous electronic controls for weld time and welding current
- Low-inertia welding head for rapid follow-up of electrode force
- Slope control (for single-phase welding machines)
- Multiple-electrode-force system to permit proper forging of the weld nugget and redressing of electrodes

Electrodes. Selection of electrode material and face shape, maintenance of the face, and cooling of the electrode are important in producing consistent spot and seam welds in aluminum alloys. The RWMA classes 1, 2, and 3 are used for welding aluminum alloys. These electrode materials have high electrical and thermal conductivities, which, combined with adequate cooling, help keep the temperature of the electrode below the temperature at which aluminum will alloy with copper and cause electrode pickup. Design of spot welding electrodes suitable for spot welding of aluminum includes both straight and offset electrodes. Straight electrodes should be used whenever possible, because deflection and skidding may occur with offset electrodes under

similar welding conditions. If offset electrodes are used, the amount of offset should be the minimum permitted by the shape of the assembly being welded. Electrodes should have the cooling-water hole within 9.5 mm (3/8 in.) of the face surface.

Copper and Its Alloys

Resistance spot welding is widely used for joining copper and copper alloys. Principal applications include welding sections up to approximately 1.50 mm (0.060 in.) thick, particularly those alloys with low electrical conductivities.

Many copper alloys with low conductivities can be seam welded easily. Coppers with a low weldability factor are difficult to seam weld. Projection welding is not recommended for copper or for most brasses. Bronzes can be projection welded with satisfactory results in many applications.

The resistance weldability of any copper alloy is inversely proportional to its electrical and thermal conductivities. Generally, alloys with lower conductivities are easier to weld. Compared with steel, most copper alloys require shorter weld time, lower electrode force, higher current, and different electrode materials that are compatible with the alloy being welded.

Welding Equipment. Single-phase and three-phase direct-energy and electrostatic stored-energy (capacitor-discharge) welding machines are used for resistance welding of copper and copper alloys. The addition of slope control to single-phase direct-energy welding

machines is not necessary for spot welding most copper alloys. In welding high-zinc brasses, the use of upslope can result in an increase of as much as 20% in weld strength. Downslope is not recommended for welding of any of the copper alloys.

Copper alloys are particularly sensitive to variations in welding conditions, and therefore, all direct-energy machines used for welding these alloys should be equipped with synchronous electronic controls, especially in applications requiring short weld times. These devices are capable of controlling weld time and welding current for repeated operations with extreme accuracy.

Electrodes. The current used for resistance welding of copper alloys is much higher than that used for welding low-carbon steel, and therefore, the electrode must have high electrical conductivity to minimize heat buildup. The RWMA class 1 electrode materials (typically tungsten or molybdenum alloys), containing copper and cadmium, are sometimes used for welding copper and high-conductivity brass and bronze. Class 2 materials, containing copper and chromium, are used on low-conductivity brass and bronze and the copper-nickel alloys. Class 3 materials are used in electrodes for seam welding.

Electrodes must be sufficiently water cooled to minimize sticking to the work metal and to prolong their life. Face contours must be carefully prepared, and the electrodes must be properly aligned for welding.

Coppers and copper alloys having electrical conductivity higher than approximately 30% IACS are the least well suited for resistance spot, projection, or seam welding, mainly because of severe electrode pickup.

Thin copper stock can be welded using electrodes faced with RWMA class 13 (tungsten) or class 14 (molybdenum), but surface appearance is poor and frequent electrode maintenance is required. A tinned coating on wire or sheet is helpful in welding copper.

Beryllium copper alloys can be resistance welded most successfully in thin gages. Spot welding produces satisfactory welds; seam welding is less successful. Projection welding is satisfactory, provided that the projections can be formed with the work metal in the annealed condition and without cracking the work metal around the projection. Close control of welding conditions is required for consistent weld size and joint strength.

Oxide films produced by heat treating must be removed to ensure low and consistent contact resistance. Work metals that have not been heated after rolling frequently need only degreasing before welding.

Low electrical conductivity (22% IACS for alloys C17000 and C17200) contributes to the weldability of beryllium copper alloys. However, they are more difficult to resistance weld than low-carbon steel. Alloy

(a) International Annealed Copper Standard, volume basis at 20 °C (68 °F). For comparison, copper alloy 102 (oxygen-free copper) is 101% and low-carbon (1010) steel approximately 14%. (b) Based on copper alloy 102 as 100%, which has a thermal conductivity of 391 W/m · K (226 Btu/ft · h · °F) at 20 °C (68 °F). Low-carbon steel has a thermal conductivity of approximately 13% on this relative scale. (c) RW, readily weldable; ST, weldable in most applications but may require special techniques for specific applications; LW, limited weldability and usually requires special techniques; NR, welding not recommended

C17500 has an electrical conductivity of 45% IACS and is more difficult to resistance weld than higher-strength, lower-conductivity beryllium copper.

Low- and High-Zinc Brasses. The low-zinc brasses are difficult to weld, although easier than copper, and are subject to electrode pickup. Welds made in these brasses may lack strength, principally because of comparatively high electrical conductivity (32 to 56% IACS).

The high-zinc brasses have an electrical conductivity of 27 to 28% IACS and can be both spot and projection welded over a wide range of conditions. Electrode pickup can be a problem unless weld time, welding current, and electrode force are properly selected.

Excessive electrode pickup and blowthrough of the weld may occur when long weld times, high energy input, and low electrode forces are used. Yellow brasses (alloys C26800 and C27000) are less susceptible to electrode pickup than cartridge brass, except when long weld times and high energy input are used. Electrode force should be sufficient to prevent

arcng or expulsion of molten metal, to which these alloys are subject because of their 30 to 40% Zn content, which boils at approximately 905 °C (1665 °F). As shown in Table 18, the recommended electrode force, when using electrodes having a face diameter of 4.8 mm ($\frac{3}{16}$ in.), is approximately 1.8 kN (400 lbf).

Copper Nickels. The copper-nickel alloys have electrical conductivities of 4.5 to 11% IACS, are readily spot and seam welded with relatively low welding current, and generally do not alloy with the electrode material and cause electrode pickup.

Bronzes. The phosphor bronzes, except alloy C50500, which is not recommended for resistance spot and seam welding because of its high electrical conductivity (48% IACS), have relatively low electrical conductivity (11 to 20% IACS) and are readily spot and seam welded using low welding currents. Electrode pickup can be reduced by use of a type F (radius) electrode face and frequent redressing to keep the face clean and smooth. Hot shortness can be minimized by supporting the workpieces to prevent strain

during welding and by using a greater minimum overlap than recommended by the data in Table 19.

Evaluation and Quality Control of Resistance-Welded Joints

Hongyan Zhang, University of Toledo

EVALUATING THE QUALITY of resistance welds is unique in several aspects. Unlike in fusion welding, where the joint is exposed and therefore can be visually inspected, a resistance weld is formed between two sheets. In the case of resistance spot welds, the geometric characteristic annular notch makes it a natural stress raiser in the edge of the weld nugget at the faying interfaces. Under loading, the stress concentration due to the geometry can promote cracking near the nugget, either in the heat-affected zone, which often results in a weld pullout, or along the original faying interface for an interfacial failure. The load-bearing capability of a resistance weld depends on the material, including the chemistry, strength, and sheet thickness, and the loading mode. In addition to the strength, other features of a weld, such as indentation depth, surface quality, and so on, are also considered as the quality attributes of a weld. The multifaceted nature of weld quality results in a large variety of quality definitions of spot welds, based on various aspects of the manufacturers' needs by the sheet metal industry and professional organizations.

The commonly used quality attributes, testing methods, and quality-control strategies in resistance spot welding are discussed in this article. First, some structural attributes of spot welds are presented. Commonly performed destructive and nondestructive evaluation methods also are presented in this article. Destructive evaluation is commonly conducted for both welding schedule development and quality assurance, where a certain percentage of the assembled parts are destructively tested in a manufacturing process. It has the advantages of being reliable and simple to perform, but the destroyed components generally cannot be reused, which represents a manufacturing cost. Nondestructive evaluation, on the other hand, can overcome the shortcomings of destructive evaluation methods, but the complexity and high cost of the testing devices and the skills required to perform such tests make it less attractive than it should be.

The quality of resistance welds also can be evaluated either during a welding process or after a weld is made. The in-process evaluation involves collecting process signals, and it has certain advantages, such as being nondestructive in general. The process signals, once they are correlated with weld quality, can be used to monitor a welding process. The controllable welding parameters, such as electric current, electrode force, and welding time, can be adjusted in a welding cycle to produce a quality weld. The off-line approach, on the other hand, is relatively easier to implement and therefore is more prevalent in practice, typically by destructive testing of the weld.

Quality Attributes of Resistance Welds

In this section, the structural attributes of spot welds are presented first. Some of them are purely cosmetic, and others have implications on the weld strength and hence its performance. The weld strength is measured through destructive testing, and the strengths of spot welds gathered from published works are compared for selected materials and tests. It is also attempted to correlate easily measurable weld geometric attributes with weld strength to form

the basis of using such attributes for weld quality. The industrial requirements for weld quality are presented at the end of this section.

Structural Attributes

A weld's quality is often described by its structural characteristic. Some of the structural attributes of a weld can be measured externally, and others can be revealed through destructive testing only.

Spot Welds. A spot weld contains a number of distinctive regions, as shown in Fig. 1.

Weld Nugget. In this region, the metal melts during heating and solidifies when the electric current is shut off. The microstructure of the nugget is more like that of a casting than of a rolled sheet, because it does not experience any cold work.

Heat-Affected Zone (HAZ). This region is adjacent to the weld nugget, in which the highest temperature during welding is below the melting temperature of the metallic grains, so they stay as a solid in the course of welding. However, certain solid-phase reactions may occur in this region, which may alter the structure and strength of this region. In addition, the region of the HAZ adjacent to the fusion line may experience grain-boundary melting, and it is termed the partial-melting zone.

Fig. 1 Schematic of a spot weld. HAZ, heat-affected zone

Partial-Melting Zone. Although the temperature in the HAZ does not reach the melting temperature of the crystals of the metal, certain low-melting compounds at the grain boundaries may melt during welding. This region may exist in some metals and affect the structural integrity, such as in welding many aluminum and magnesium alloys. It may have minimal effect in welding most steels, if it even exists.

Base metal is the portion of a weld that does not experience metallurgical changes. The base metal adjacent to the HAZ is also influenced by the plastic deformation in the nugget and HAZ, and the base metal could be distorted. Such a distortion may affect the loading mode, and it also indicates the level of residual stresses in the weld.

Indentation Width and Depth. Because a weld indentation is directly related to the heating process and therefore the nugget formation, it is the most indicative index of weld quality that can be obtained without sectioning the weld or using nondestructive devices. As a matter of fact, many industrial companies have specific requirements for indentation in both width and depth. The indentation width is related to the area of heating or weld size, and its depth is a strong function of weld penetration. Because the indentation is a result of joule heating, its volume, approximated as a (hollow) cylinder, is related to total heat input and is used to measure the dimensions of the weld nugget. In certain cases, indentation has been successfully correlated with nugget size and weld strength. However, the correlation is strongly affected by material and processing factors, such as electrode cap size and shape. Therefore, it is still considered a qualitative measure of weld quality, and experience plays an important role in its use for quality measurement.

Typical Imperfections in Resistance Welds. Certain weld imperfections can be revealed directly by inspecting a weld externally. The commonly inspected imperfections are listed as follows, based on the observations of welding practitioners and researchers and on many resistance-welding-related standards and recommendations, such as AWS D8.7 (Ref 1):

1. Surface defects, including holes, cracks, and craters
2. Surface expulsion
3. Surface colorization
4. Excessive indentation
5. Excessive sheet separation and distortion
6. Edge weld
7. Insufficient weld spacing
8. Mislocated weld
9. Overlapped welds
10. Edge tears (only in seam welds)

Note that some of the listed imperfections are pertinent only to resistance spot welds and not seam welds. Seam welds, in most cases, tend to be continuous welds. For example, items 4, 7, and 9 are some of the attributes that generally pertain to spot welds.

A surface free of visible defects is always a requirement. Surface defects include cracks, burning holes, craters, and others abnormalities such as excessive indentation and so on. If the extent of these defects is limited to the surface only, they may have negligible effect on the strength. However, these defects very often are associated with internal defects and inferior weld nugget. For instance, the burning hole and the debris or whiskers shown in Fig. 2 are the result of localized overheating of the electrode-sheet contact interface, possibly due to the large contact resistance resulting from electrode deterioration. The adverse effects of these defects on weld quality are unquestionable. However, the influence of some surface defects may not be as obvious. The weld shown in Fig. 3(a) has fine surface cracks, and they appear to be insignificant. A cross section of the same weld, however, shows cracks extending through the thickness of the weld (Fig. 3b). In general, surface defects should be treated with care, understanding the possible existence of associated internal defects.

When the contact resistance at the electrode-sheet interface is high, excessive heating at the interface may melt the metal, which may be ejected under the electrode pressure. One example is shown in Fig. 4 (Ref 2). Similar to other surface defects, if such expulsion is limited to the surface, it may have little or no effect on weld strength. However, such an expulsion may be linked to other defects, for instance, a burning hole, as shown in the figure. Overheating related to surface expulsion is also the primary reason for electrode deterioration. Another sign of surface overheating is colorization of the weld surface. The temperature at the electrode-sheet interface is so high that the electrode surface is melted, leaving a trace of copper alloy on the surface of a weld. Because this is the result of melting of the electrode surface, rapid electrode wear may follow.

A weld can be severely distorted when the workpieces are improperly stacked and/or excessive heating or electrode force is applied. If a large gap exists between the sheets before welding, the sheets must be deformed by the electrodes to create the necessary contact at the faying interface for welding. Such a deformation is often aided by softening of the sheet material during heating. Even without poor fit-up of the sheets, a large electrode force or overheating may press the metal between the electrodes and force it to flow to the edges of the nugget around the faying interface. The distortion of spot welds is not a major concern from a cosmetic point of view if the weld is not located on the outer panel of a product such as an automobile. However, it has a quality implication in weld strength and overall dimensional stability. It may alter the loading mode of the weld and create a stress concentration that may not be anticipated. A severely distorted weld may significantly reduce the thickness of the metal that links the weld and the base metal and compromise the load-bearing

Fig. 4 Surface expulsion of an AA5754 weld. Source: Ref 2

capacity of the weld. In addition, the local distortions of individual welds may be accumulated and result in an out-of-specification structural component. There are significant efforts to reduce or control spot weld distortion to maintain dimensional stability of welded structures (Ref 3–5).

There are a number of quality attributes mainly related to design, maintenance, and execution of welding. If a weld is made too close to the edge of sheets, such as in the case of insufficient flange width, an edge weld may result (Fig. 5) in which the liquid metal is squeezed out to the edge of the sheets. Figure 6 shows welds made with insufficient spacing between the welds. The weld on the right was made after that on the left, using the same welding parameters, but its indentation is clearly smaller and shallower than that of the first weld. When making the second weld, part of the electric current is diverted by the first weld through a process called shunting, which effectively reduces the heat input in the second weld (Ref 6). Special attention is needed when performing weld repair in which insufficient weld spacing may be unavoidable. Higher electric current should be applied when adding a

Fig. 5 Edge weld. Source: Ref 1

Fig. 6 Welds with insufficient spacing. Source: Ref 1

weld close to an existing weld. Welds may also be made at locations different from their designated places, and a malfunctioning welding robot may put two welds on top of each other, resulting in dislocated welds and overlapped welds.

Internal Characteristics. The internal characteristics of spot welds are usually revealed through metallographic examination of the weld cross section. The geometry and dimensions of various zones of spot welds are schematically shown in Fig. 1. The fusion zone is characterized by the nugget width and penetration. The nugget width may be different from the weld diameter, depending on the weld quality and testing method. The HAZ can be divided into two parts: a zone of solid-phase transformation near the base metal, and a partial-melting zone. It is beneficial to separate the partial-melting zone from the rest of the HAZ, because the metallurgical reactions in this zone are usually significantly different from those in the rest of the HAZ, and the implication for structure as well as weld quality should not be ignored. For instance, in welding aluminum alloy AA5754, it was found that liquation cracking may initiate from the molten grain boundaries in the HAZ next to the fusion zone, as seen in Fig. 7 (Ref 7).

In general, the following information can be obtained through metallographic examination of a spot-welded joint:

- Dimensions of various zones of a spot weld. These include the nugget width and height (penetration), width of the HAZ, and the extent of a possible partial-melting zone in the HAZ.
- Microstructures and phases of the regions. Because of the drastically different processing conditions of the base metal, the HAZ, and the nugget, their structures as well as properties can be significantly different.

Fig. 7 Cracking in the heat-affected zone of an AA5754 weld near the fusion line. Source: Ref 7

- Discontinuities or imperfections. Solidification cracks and voids/pores may form in the nugget, and liquation cracking may occur in the partial-melting zone in the HAZ.
- Interfacial expulsion

The nugget, depicted as the fusion zone in Fig. 1, is clearly the most important part of a weld. Its geometry is usually described by the nugget width and penetration. Because a spot weld nugget is the joint that links the sheets, a large nugget width is preferred for load bearing. In addition, the height of the nugget, or penetration, is a direct indicator of the amount of heating, and therefore, a certain amount of penetration is required by most manufacturers. In most research on the strength of spot welds, the nugget size, or weld size, is linked to the load-bearing capability and other strength attributes, such as ductility. Because the formation of a weld nugget involves melting and solidification, defects such as liquation cracking and voids/pores may form in the nugget, in addition to significantly different microstructures from the HAZ and the base metal. In Fig. 8 (Ref 8), metallographic examination of a 590 MPa (85 ksi) dual-phase steel weld reveals a sizeable void as well as pores in the weld nugget. These are the direct result of a volume deficit caused by irreversible expansion and contraction during melting and solidification of the weld, due to expulsion, as evidenced by the remnants of the ejected and solidified metal at the faying interface near the nugget. There are also surface cracks, and one of them extends into and is connected with a pore in the nugget, through the HAZ along the grain boundaries. The structures of the weld nugget and the HAZ are significantly different from that of the base metal, as shown in the figure, and result from solidification and solid-phase transformations in the weld. The two typical phases, ferrite (body-centered cubic) and martensite (body-centered tetragonal), are observed in all of the regions. However, their morphologies, amounts, and distributions are drastically different. In the base metal, martensite is evenly distributed in a matrix of ferrite. The HAZ has more martensite, with its volume fraction increasing rapidly from the base metal to the fusion line, and the fusion zone is filled with martensite. Finer martensite and ferrite are observed in the HAZ, resulting from the repeated rapid heating-cooling cycles and the restricted grain growth in the region, as explained by the authors of Ref 8. Retained austenite and lower bainite are also observed in the region. In addition to the favorable chemistry for martensite formation in 590 dual-phase steel, the rapid cooling during resistance spot welding, estimated at a few thousands of degrees Celsius per second, plays an important role.

In addition to the structural difference in the HAZ from the base metal or the nugget, the unique location of the HAZ makes it an

influential factor in determining weld strength. Due to the characteristic geometry of a sharp notch near the nugget at the faying interfaces, a stress concentration may occur in the HAZ when a weld is loaded. The different material properties, such as yield strength and so on, in the HAZ from those in the nugget and base metal may enhance the stress concentration. As analyzed by Zhang and Senkara through finite-element modeling (Ref 6), the mechanical properties of the HAZ determine the performance of a weld. By varying the size, yield strength, ultimate tensile strength, and ductility of the nugget and HAZ of a weld, it was found that both the peak load and elongation of a weld increase with the nugget size, while changing the ductility and strength of the nugget has little effect. This can be primarily attributed to the fact that when loaded, the interior of a nugget is little stressed. On the other hand, the performance of a weld is very sensitive to the changes in the HAZ. Significant increases in peak load and elongation of a weld result from increases in the HAZ width, strength, and ductility.

Imperfections may also appear in the HAZ of a spot weld. Figure 9 (Ref 9) shows liquation cracking in the HAZ of a magnesium alloy AZ31D weld. The intergranular characteristics of the crack are the result of melting of intermetallic compounds such as $Mg_{17}Al_{12}$ at the grain boundaries. When the volume fraction of such low-melting compounds is sufficiently high, a network of liquid phases may exist in the HAZ surrounding the solid grains. Under thermal stresses during heating and cooling, the HAZ may be torn apart along such liquid grain boundaries. This has been observed in a number

of material systems, such as AA5754, AA6111 (Ref 10), AZ31B, and AZ91D (Ref 11).

Welding with expulsion is common on many production lines, because it is often used as an indicator of sufficient heating during welding. However, the loss of liquid metal during expulsion may create internal imperfections such as voids and cracks. In Fig. 10, large voids resulted from heavy expulsion in an AA5754 weld. There are several theories for the mechanisms of expulsion, and they are discussed in the book by Zhang and Senkara (Ref 12). The root cause of expulsion is the loss of containment of the liquid metal in the nugget, which imposes a large pressure onto its solid surrounding, that is, the HAZ. Because the pressure results from melting and thermal expansion of liquid metal, different materials have different tendencies for expulsion, due to their different thermal characteristics. Welding of aluminum and magnesium alloys is more prone to expulsion because of their higher volume expansion during melting than steels. As discussed by Zhang and others (Ref 2, 12), expulsion has an adverse effect on weld strength and should be avoided. Increasing the electrode force and lowering the welding current are two methods of suppressing expulsion.

Quality Requirements

Because the quality of spot welds is evaluated by their structural attributes and/or strengths in various tests, the requirements for weld quality are generally based on these two aspects as well. Almost all quality requirements, either by industrial companies or

professional organizations, contain certain provisions for weld size. An obvious advantage of using weld size as a required quantity is the close relationship between weld size and strength. Other geometric characteristics, such as penetration and so on, also appear as required weld attributes in various standards and recommendations. Because a weld is made for joining sheets together, a more meaningful weld-quality index is weld strength. However, the complexity in testing a welded joint and the large variance often associated with the testing results prevent the frequent performance of most types of tests, and only the peak load measured in a tensile-shear test is required for certain materials. In general, the measured strength of a weld, such as the peak load, is a function of the testing method and testing specimen geometry, in addition to the type of loading.

Destructive Testing

The quality of the weld is assessed by several quantitative and qualitative metrics from mechanical testing and/or by metallographic examination. Both techniques are destructive. In metallography, the weldment is sectioned for examination with a microscope. In mechanical testing, the weldment is loaded until the specimen fails.

Mechanical testing may be done manually or by mechanical loading with an instrumented device. In a manual test, the weld features, such as the weld shape and size, failure mode, and so on, are recorded. An instrumented test also

Fig. 8 Cross section and microstructures of a DP600 spot weld. Source: Ref 8

Fig. 9 Cracking in the heat-affected zone of an AZ31D spot weld. Source: Ref 9

Fig. 10 AA5754 weld with expulsion. Source: Ref 2

creates quantitative measures of weld strength, in addition to the observations from a manual test. Instrumented testing is necessary to quantitatively characterize weld strength.

Instrumented mechanical tests also can be classified into two groups: quasi-static tests and dynamic tests. In a quasi-static test, the load is applied slowly to minimize the influence of the load rate. In a dynamic test, the load rate is a process variable that is reported with the testing results. The load and displacement signals are commonly recorded for an instrumented test.

Manual Testing

Because weld size, shape, and failure mode revealed through a manual test are closely related to weld strength, manual testing is prevalent in both the production environment and laboratories. The commonly performed tests are:

- Chisel test
- Peel (roller) test
- Bend test
- Temperature monitoring of a seam weld

As illustrated in Fig. 11 for a chisel test, a chisel is forced into the gap at the faying interface between two adjacent welds until the weld fractures, which results in either a weld button or interfacial failure. This type of test is commonly performed on welded components when a peel test is impractical. Because of the constraint imposed by the neighboring welds, the load exerted by a chisel favors interfacial fracture rather than weld pullout. Therefore, an interfacial fracture obtained in a chisel test does not necessarily imply a substandard weld. An operator must be able to distinguish a

Fig. 11 Chisel test. Source: Ref 1

reasonable weld from a cold weld when an interfacial fracture mode is observed. Occasionally, a mechanized rather than a manual chisel test is performed in the production environment, especially when heavy-gage sheet welding is involved.

Another shop floor test is the peel test. It is usually performed using a hand tool, as shown in Fig. 12, and therefore, it is generally not applied to testing welds made on heavy-gage sheets. With one of the separated sheets gripped firmly, the other is rolled up to break the joint, either along the faying interfaces for a brittle weld, or leaving a weld button, usually on the gripped sheet. The fracture is recorded for the weld size, fracture mode, and so on. Certain experience is also required in performing a peel test, especially for the consistency of testing. Because the sheet must be rolled in the test, thick-gage or hard metals cannot be tested due to their high bending resistance.

A not-so-common manual test is the bend test. It is used to estimate the ductility of spot welds and to detect weld flaws, especially cracks. In the test, a section of three welds on a weld coupon is made by cutting from the center of the coupon along the longitudinal direction (Fig. 13). The specimen is bent to a certain angle and examined for cracks and other defects. The bend test is unique because the stress states in the weldment cannot be produced in other tests. Because the specimen is not uniform and the preparation process may not be consistent, a bend test is usually performed for visual inspection of weld quality only.

In the case of seam welds, an optical pyrometer is used to measure the temperature of the solidifying weld behind the welding electrode. A relationship between weld quality and measured temperature is established with trials. Generally, a temperature lower than an established optimal temperature is indicative of a cold weld, which results in poor fusion.

Generally, in all the tests, a load exerts certain crack-promoting stresses, either shear or tensile, on the nugget and HAZ of a spot weldment. The initiation and propagation of cracking depend on the stress level at a specific location and the material strength at the same location. The possible failure modes commonly observed in peel testing, along with the

Fig. 12 Peel test. Source: Ref 1

evaluation procedure, are summarized in a chart in Fig. 14 (Ref 13). Although the failure modes are obtained in peel testing of spot welds, they are representative and contain all the typical observations for destructive evaluations. The quality interpretation of an interfacial fracture is often confusing. Certain tests and materials, such as impact testing and thick/stiff sheets, tend to produce interfacial failure even on a sound weld. As outlined in the figure, welds that fail with interfacial (including partial interfacial) fracture should be considered acceptable if there is fusion in the fractured weld area, with a size meeting the minimum weld requirements.

Quasi-Static Mechanical Tests

It is often desirable to generate uniform pure tensile or pure shear loading in material testing. In testing a spot-welded joint, however, such mode of loading is difficult to achieve because of the geometric characteristics of a spot-welded joint and the deformation/rotation of the specimens during testing. Various tests have been performed to measure the tensile, shear, or combined tensile and shear load-bearing capacity of spot welds. A more detailed description of the weld tensile tests is provided in the article "Resistance Spot Welding" in this Volume.

Cross-Tension Test. This test is intended to exert a normal tensile load to a weld. The specimen geometry and a typical mounting fixture are shown in Fig. 15 (Ref 14). Slippage of the specimen in the holding fixture may occur, and it changes the loading on the joint. Caution is also needed to minimize sheet distortion during testing. In addition, it may be difficult to prepare such a specimen with the weld properly

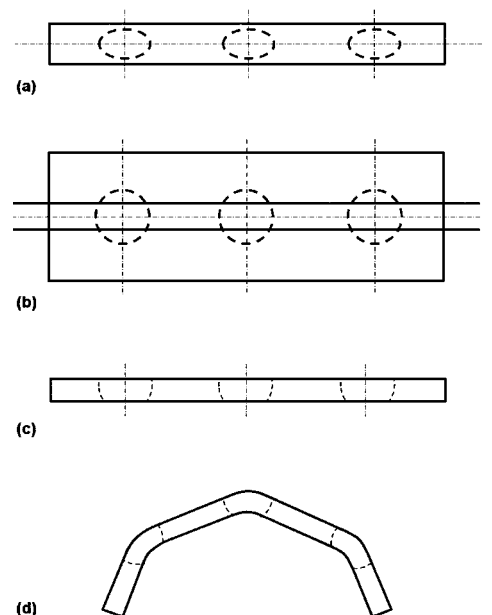

Fig. 13 Bend test. Source: Ref 12

**Resistance Spot Welding
peel test assessment flowchart**
Step 1. Perform peel test
Step 2. Measure fusion/button size.

Notes:

- (a) Weld size is greater than or equal to the minimum values specified.
- (b) Aspect ratio of the maximum dimension to the minimum dimension is less than 2 to one.
- (c) Measured in accordance with AWS D8.9
- (d) Measured dimension of fused area is greater than or equal to the minimum weld size specified.
- (e) Evidence of metal deformation due to the existence of a weld
- (f) Average diameter of through-sheet button plus partial thickness fracture is greater than or equal to the minimum weld size specified.

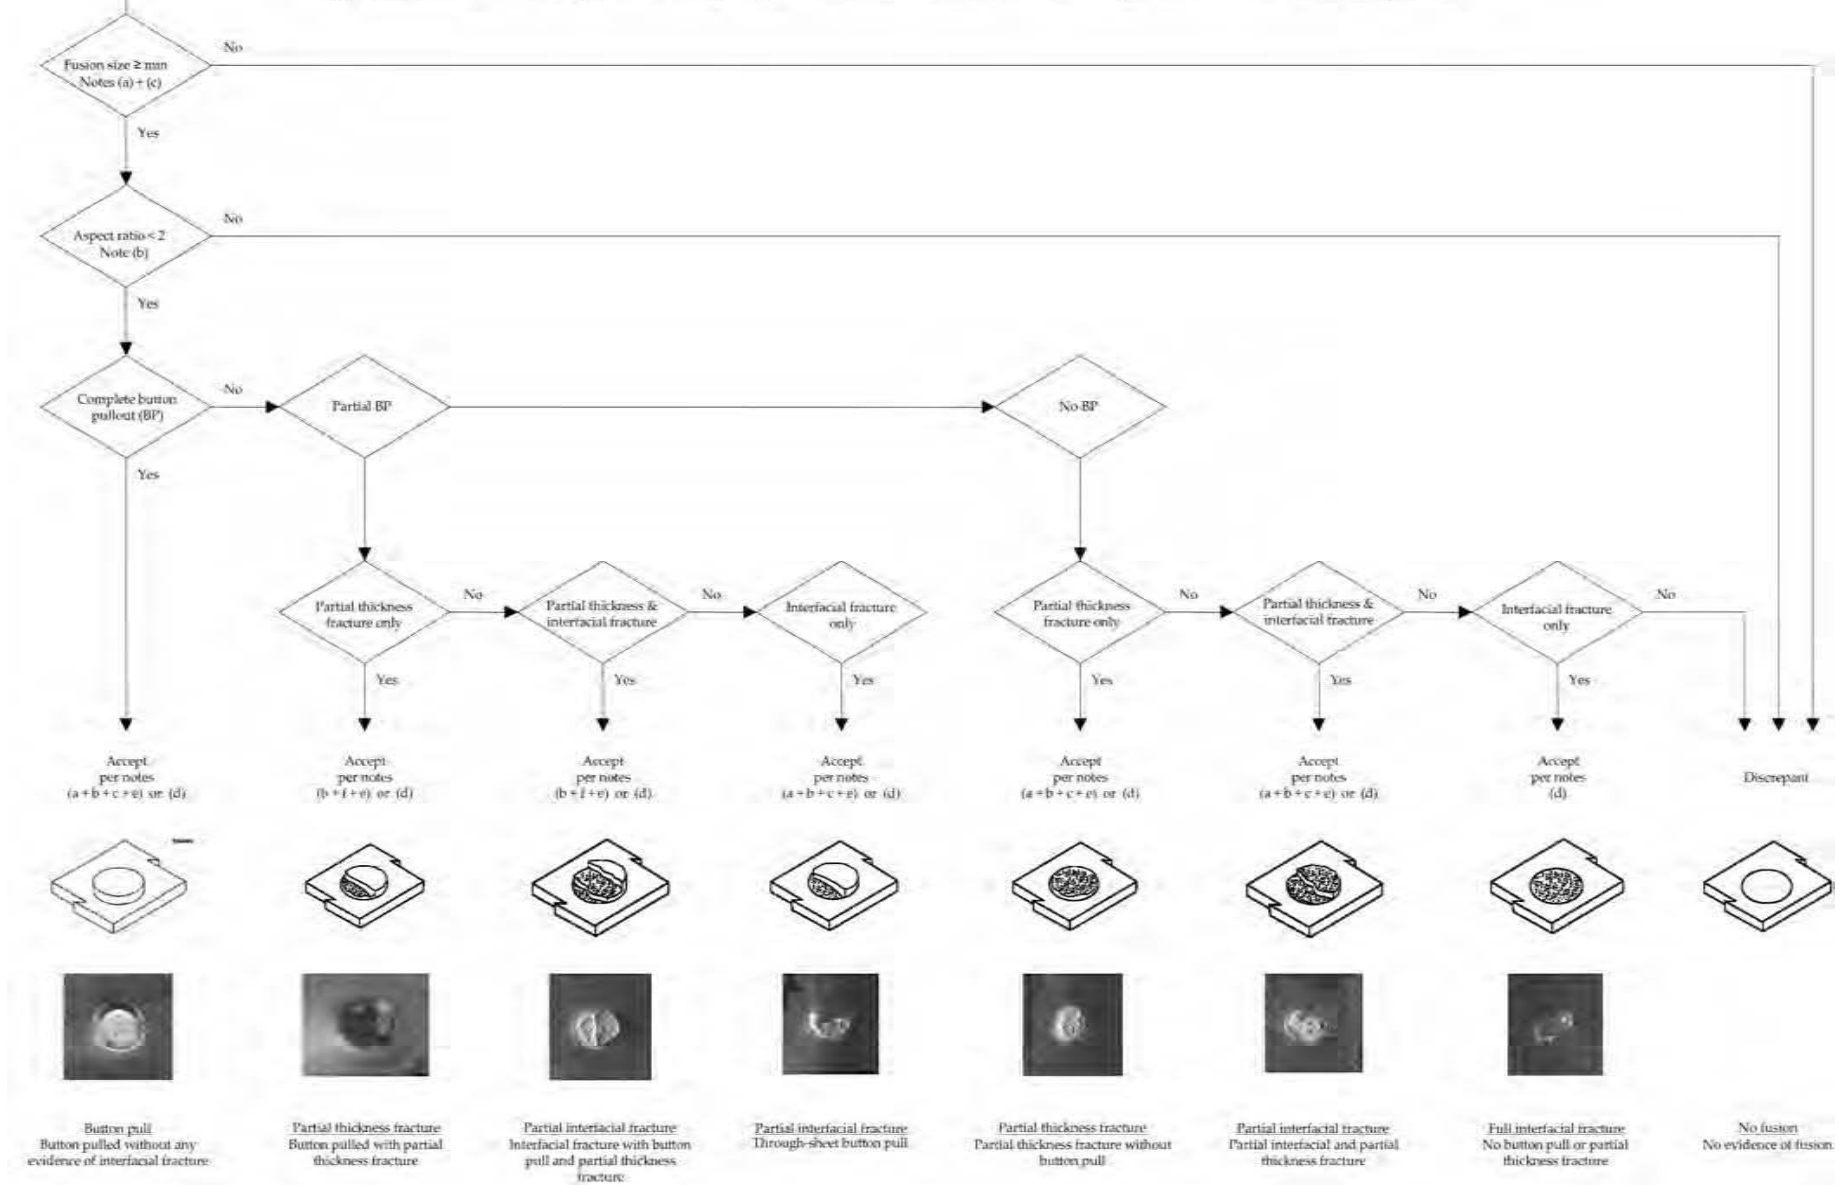

Fig. 14 Weld-quality assessment flow chart. Source: Ref 13

centered. The loading mode is altered if welds are not located at their designated locations, and the testing consistency may suffer as well.

U-Tension Test. A tensile load may be applied using a U-shaped specimen (Fig. 16). Such a specimen may create less deformation or distortion than that in a cross-tension test. Mounting a U-tension test specimen requires alignment of the hole/bolt, and spacers are generally needed to restrain a specimen. Certain formability is needed on the sheet material for it to be bent to the required radius without fracture.

In both cross-tension and U-tension tests, the specimen experiences unavoidable bending in the base metal during loading, which makes an accurate measurement of the weld tensile strength difficult. The low testing consistency, difficult mounting, and tedious specimen preparation make these tensile tests less popular than others, such as the tensile-shear test.

Tensile-Shear Test. Also commonly referred to as a tension-shear test, a tensile-shear test is the most commonly conducted test in weldability study. Compared with cross-tension and U-tension, the tensile-shear test has several advantages in specimen preparation and testing. A simple lap joint of two metal strips by a

single spot weld (Fig. 17), or occasionally by two or more welds, can be tested using standard tensile testing machines and grips. Because of the asymmetric nature of the testing specimens, bending of the base metal at the grips and rotation of the joint cannot be avoided during a tensile-shear test. This significantly affects the loading on the joint. An increasing portion of pulling load, and therefore a smaller portion of shear load, corresponds to the rotation of the joint. For specimens made of thick sheets, shimming is needed to avoid excessive bending of the base metal and the weld. Numerous studies, such as the one by Zhou et al. (Ref 15), have concluded that sufficiently wide specimens are required to minimize the influence from weld rotation. Their study also proved that a weld coupon length of 150 mm (6 in.) is sufficient for thin-sheet specimens.

In tensile-shear testing, the peak load is commonly monitored and used as the strength of the weld. A more complete description of weld quality needs information on the ductility of the joint, which can be described by the maximum displacement or the energy.

Combined Tension and Shear Test. Although the tensile and shear tests are intended to create tensile and shear loading modes, respectively, the actual loading is almost always a mixture of these two types of loads, in an uncontrollable manner. Efforts by Lee et al. have been made to purposely create a combined tensile and shear loading mode (Ref 16). In their study, simultaneous tensile and shear loadings can be applied, with control of the ratio of the two by varying the loading angle to the weld plane, as shown in Fig. 18 (Ref 16). There are pairs of holes on the lock plates that can be used to adjust the loading angles and create various mixtures of tensile and shear loadings. Similar to other tests, the weld should be centered with respect to the

mounting fixture to achieve the desirable loading mode. The testing mechanism shown in Fig. 18 has the flexibility of adjusting the location of the weld in the fixture by adding shimming plates of necessary thickness in the grips. By using this testing rig, it was found that the peak load a spot weld can withstand decreases with increase of the tensile component in a mixed tensile and shear loading, and the lowest strength was obtained when cross-tension loading was applied.

A less commonly conducted test on spot welds is the torsion test. Two types of torsional loading can be applied to a spot weldment. One is twisting a standard tension test specimen in which the angle of twist at failure is measured for the strength, in addition to the weld diameter and failure mode. Another so-called torsional shear test measures both strength and ductility through the ultimate torque required and the angle to destruction. In both tests, the weld diameter can be measured on separated sheets. The main drawback of a torsion test is the mounting of a specimen. To avoid excessive distortion, which is highly possible in a torsion test, a specimen must be tightly constrained. More details can be found in Ref 12.

Dynamic Mechanical Tests

Spot-welded joints in structures such as automobiles are generally under dynamic loading in service. Similar to that observed in testing of uniform specimens without a welded joint, the static strength of spot welds has certain implications for their dynamic performance, but there is no one-to-one correspondence, and extrapolation from static performance to dynamic behavior of spot welds could be erroneous and misleading. Dynamic testing of spot welds generally refers to fatigue tests in practice. Impact testing, which has significant implication for the crash-worthiness of automobiles, is rarely conducted on spot welds because of the complexity and low repeatability involved in the test. It has occasionally been conducted on welded structures (Ref 17).

Fatigue Tests. Vibration in welded structures, such as automobiles, imposes repetitive loading to the welded joints, and the process is called fatigue. The notchlike shape of a spot-welded joint makes it a stress raiser, which is undesirable for any mechanical loading, especially fatigue. The fatigue behavior of a spot-welded joint has several unique characteristics compared with other tests:

- Under small loading, failure may occur only after a large number of loading cycles.

Fig. 15 Specimen and mounting fixture for a cross-tension test. Source: Ref 14

Fig. 16 U-tension test specimen. Source: Ref 1

Fig. 17 Tensile-shear test

- The failure loads are significantly lower than the static loading limits, which should be fully accounted for in structural design.
- A fracture surface usually has a brittle appearance; even static testing of the same weld renders a ductile appearance.

In practice, fatigue tests are usually conducted under constant loading ranges for simplicity. A number of factors must be taken into consideration, and certain precautions must be made in fatigue testing of spot welds. Standards and recommendations, such as the ISO standard for fatigue tests (Ref 18), which outlines the steps for fatigue testing of spot-welded joints, can be followed in testing. A common practice is to follow the ASTM International standards for fatigue testing of welded specimens (Ref 19). There are several issues that may affect the interpretation of fatigue testing and results, and they are discussed in the following.

Stress Concentration. Both the notchlike geometry around the edge of a weld nugget and the distributed strength in a weldment contribute to the stress concentration at a spot-welded joint. When loaded, the stress level at the notch can be several orders higher than at locations of a certain distance from the weld. A stress concentration, or even a singularity, exists at the vicinity of the weld. Stress distribution is also a strong function of material strength, which varies (often drastically) from the base metal to the nugget, as exhibited by the microhardness profiles in a weldment. Because a softer material would deform more than a harder one, given all conditions being equal, the stress level rises at the junction between these two parts. Similar phenomena are observed in a weldment.

Residual stresses are inevitable in a resistance spot weldment because of irreversible thermomechanical deformation during welding. There are three important aspects of residual stresses in characterizing stress distribution and understanding the effect of such stresses. The effect of residual stresses on the fatigue behavior of a spot weldment must be understood by considering the nature, amplitude, and location of the stresses. As in other types of loading, the nugget edge and the HAZ have the highest stress concentration, and the tensile residual stresses at these locations promote crack initiation and propagation, as observed by many researchers in fatigue testing. The residual stresses in a spot weldment are affected by many welding process-related factors. For instance, excessive heating induces large distortion and therefore high stresses. A properly constrained welding process, as discussed in Ref 10 and 12, can effectively minimize the distortion as well as residual stresses.

Specimen Preparation. Because of its simplicity, lap joint specimens are usually used in fatigue tests. However, a lap joint specimen can take very little compression without buckling. Care must be taken in selecting fatigue loading in accordance with the testing specimens. The ASTM International standards for fatigue testing of welded specimens (Ref 19) should be followed in preparing the specimens. Different-sized specimens impose different degrees of constraint onto the spot weld and affect deformation under loading. Therefore, the fatigue failure mode is a function of the specimen dimensions, similar to that observed in quasi-static tensile testing.

Loading. In fatigue testing of spot-welded joints, the loading can be force or moment.

There are a number of variables to be selected for a fatigue test: amplitude and range of loading, nature of loading, rate of loading, and number of cycles or repetitions. The types of loading commonly applied in fatigue testing of spot-welded joints include:

- Fluctuating tensile loading
- Fluctuating compressive loading
- Fluctuating loading, with maximum load tensile and minimum load compressive
- Completely reversed loading

Data Presentation. In fatigue testing a spot weldment, the fatigue life is usually expressed in terms of load versus cycles, or $L-N$ curves, instead of stress versus cycles. Similar to the information collected in fatigue testing a uniform specimen, the $L-N$ curve, range of loading, endurance limit, load ratio, cycling frequency, and criterion for termination of a test are usually reported.

Fracture Surface. A general fatigue fracture has a unique, characteristic appearance. Cracking usually starts from discontinuities, such as internal voids or inclusions, or locations of high stress concentration. Most fracture surfaces have a smooth appearance, even when the material is ductile, and it should not be confused with brittle fracture. Certain fatigue fracture characteristics, such as clamshell markings, may not be observed on spot-welded sheet specimens.

In a study by Ma et al. (Ref 8), the fatigue performance of spot welds of various sizes showed that weld size does not have much effect on fatigue life. The welds with expulsion appear to have a slightly lower fatigue limit.

Impact Test. The importance of impact performance of spot welds and spot-welded structures is obvious. However, because of the complexity, the relatively low reliability and repeatability, and the high cost, impact testing of spot welds is performed in very limited cases, and mostly on welded structures such as beams rather than single welds.

When properly instrumented, both tension and shear can be imposed during an impact test. There are several kinds of impact tests based on different mechanisms. Some of these tests, together with the testing specimens, can be found in AWS C1.1-66 (Ref 20), AWS D8.9-97 (Ref 13), or Ref 12. They are briefly discussed in the following.

Shear Impact Test. A modified pendulum-type impact testing machine is used for this type of loading. A simple conversion from potential energy to kinetic energy provides the impact loading by using a modified single-pendulum impact tester. It has the advantages of being simple to instrument, easy to prepare test specimens, and straightforward to interpret test results. The disadvantages are associated with the testing mechanism. For instance, the unrestrained specimen may experience large deformation, which can take a significant proportion of the measured impact energy. In

Fig. 18 Fixture for testing spot welds under simultaneous tension and shear loading. Source: Ref 16

general, it has fairly low accuracy and repeatability.

Drop Impact Test. By using test specimens as illustrated in Fig. 19, an impact tensile loading can be applied to a weld when the fixture is attached to a testing machine that provides rapid loading. Because bending of the plates and slippage of a specimen in the mounting fixture are difficult to avoid, and the energy absorbed by these two processes cannot be fully accounted for, the impact energy needed to fracture the spot weld is not accurately determined. Efforts have been made to stiffen the testing specimens to reduce bending, or minimize slippage by using serrated clamps.

Shear Impact Loading Test. This test, which is similar to the shear impact test, uses a pendulum-type impact tester. The fixturing mechanism and the U-shaped specimen (Fig. 20) make the spot weld under shear loading during impact. Although the U-shaped sections make it difficult for the sheet metal to deform, preparing such a specimen can be tedious, and specimen consistency as well as testing accuracy could be unsatisfactory.

Tension Impact Loading Test. This test uses the same type of U-section specimens and the same testing mechanism as a shear impact loading test. The only difference is that the impact loading is in tension. In addition to the difficulties in preparing the test specimens, the inevitable bending of the specimen when the spot weld is loaded in tension is a major source of inaccuracy in measurement.

Fig. 19 Testing specimen for drop impact tests

Double-Pendulum Impact Test. All the aforementioned impact tests, except for the shear impact test, are complicated in specimen preparation and fixturing. The shear impact test, on the other hand, is simple in specimen and test preparation. The disadvantages of the shear impact test are also obvious, and efforts have been made to improve various aspects of specimen preparation, specimen mounting, and testing. A brief discussion of this test can be found in Ref 21 and 22. A novel impact testing mechanism has been developed using two pendulums for testing the impact strength of various joints, including resistance spot welds, loaded in either tension or shear. The basic working mechanism, specimens, and testing of this impact test are presented in this section.

As shown in Fig. 21, there are two pendulums on this device instead of one, as in a shear impact tester. A Z-shaped welded specimen (Fig. 22c) is mounted on one pendulum at one end and fixed to the machine base at the other end. The weld is placed at the center joining the two pieces of bent coupons. In the test, the impact energy input is defined by the initial position of the pendulum on the right side, adjustable by the weight and the angle θ_0 . The potential energy in this pendulum is converted into kinetic energy at the bottom when it hits the other pendulum to which the testing specimen is attached. The specimen, under the impact load, may or may not break. Its impact strength is measured by the impact energy absorbed by the specimen, through the maximum angles (θ_A and θ_B) of the pendulums after impact. A welded joint may not fracture if the predefined impact energy input is not sufficient, resulting in only a least estimate of its impact strength. The tester provides two types of loading to a joint: peeling and tensile-shear, and the specimens are shown in Fig. 22. In tensile-shear testing with this device, the specimen is restrained between the head of the pendulum on the left and the base of the tester. Little rotation is allowed in the sheets to minimize the impact energy consumed by sheet deformation and to maximize the proportion of the shear component in impact loading.

Force and displacement sensors can be installed on the tester to understand the detailed behavior of a welded joint under impact, in addition to the impact energy measured directly from the dial meters. Figure 23 shows the force and displacement profiles when a weld fails by

Fig. 20 One type of testing specimen for shear impact loading test

a weld pull-out. In general, the profiles can provide a more detailed account of weld impact strength than the impact energy from measurement of the angle read-outs. This is especially important when base-metal tearing is involved during testing. Good testing consistency has been observed using the tester on mild steels, high-strength steels under room and low temperatures (down to -60 °C, or -76 °F), and on self-piercing riveted aluminum joints.

Metallographic Examination

Some of the weld characteristics can only be revealed through metallographic examination. For instance, the weld size measured on a fractured weld may be drastically different from the actual size of the weld nugget, and it is influenced by the loading, property of the weldment, and others. A metallographic examination directly exposes the internal structure of a weld, such as the nugget size and shape, microstructures of various zones, internal defects, and so on.

A metallographic examination is usually performed on a specimen cut through a weld along one of the three planes shown in Fig. 24. For convenience, sectioning is usually done perpendicular to the coupon length (i.e., transverse direction), or plane A in Fig. 24. Because of the different constraint in electrical, thermal, and mechanical conditions in different orientations, the development of a weld nugget is not identical along planes A, B, and C in the figure. An example of the cross section of an AA5754

Fig. 21 Double-pendulum impact tester

Fig. 22 Schematic diagram of testing procedure and specimen configuration for the double-pendulum impact test

weld along plane A is shown in Fig. 25(a). The weld nugget and some pores close to the center of the weld are clearly seen. When another weld, made under an identical condition as that of Fig. 25(a), is sectioned along the longitudinal direction, or plane B in Fig. 24, a weld of different shape and size appears, as in Fig. 25(b). In addition to the voids in the nugget, this cross section also reveals several liquation cracks in the HAZ. Such cracking is not visible in the transverse section of the weld, except a fine trace of crack in Fig. 25(a), which can be easily overlooked. The difference in cracking in these two sections is the result of different constraining conditions during welding, as discussed in detail in Ref 10. Occasionally, sectioning is done along the original faying interface, or plane C in Fig. 24. One advantage of such sectioning is that interfacial expulsion can be clearly observed, for instance, in a magnesium weld (Fig. 26). A large amount of ejected metal is visible outside of the weld area, through the liquid network of metals in the HAZ during welding (Ref 11).

Another common use of metallographic sectioning is for microhardness testing. The hardness value is usually measured along a diagonal direction across the base metal, the HAZ, and the nugget, with a constant spacing. In Fig. 27 (Ref 23), the indents, shown as dots in the figure, are the marks left from microhardness testing on a transverse cross section of a DP780 steel weld, with a distance of 0.38 mm (0.015 in.) between the indents (Ref 23). The measured microhardness values on welds of various material combinations are shown in Fig. 28 (Ref 14).

Nondestructive Testing

The advantages of nondestructive testing of spot welds are obvious. Such testing can be performed during welding, or on-line, through monitoring the process signals, or after a weld is made (off-line). Ultrasonic testing is the most common test in off-line evaluation of welds. Both on-line and off-line nondestructive evaluation methods of spot weld quality are discussed in this section.

Weld-Quality Monitoring Using Process Signals

Electric tip voltage, current, electrode force, and electrode displacement are commonly measured during resistance welding, and they generally correlate well with the welding process and weld quality. A typical data-acquisition system is shown in Fig. 29 (Ref 24).

Process Signals. Typical profiles of voltage, current, electrode force, and electrode displacement monitored in alternating current (ac) welding are shown in Fig. 30. When using high-magnitude ac welding, the strong induced magnetic field may corrupt the signals, and

certain treatment of the collected data, such as adaptive signal processing techniques, is needed (Ref 25).

The signals can be roughly classified as input variables and responses. The electric voltage

Fig. 27 Cross section of a DP780 steel weld with indentations from microhardness testing. Source: Ref 23

and current are obviously input to a welding process. However, they are affected, in general, by the welding process and possess the characteristics of response variables as well. For instance, the electric voltage, monitored during a normal welding process, as seen in Fig. 30(a), fluctuates as the electric resistance varies during welding and the electric current is controlled to be constant. Therefore, electric voltage is not a “pure” input. The dual characteristic of both input and response is more

evident for electrode force. As an input variable, its value is selected by the operator, but it is heavily influenced by thermal expansion and contraction, as seen in Fig. 30(c). Therefore, these input variables are responses as well, and clearly distinguishing inputs from responses may not be possible or necessary during resistance spot welding.

Electric Voltage. Depending on the welding control mechanisms, electric voltage for resistance welding can be either constant or variable. When the electric current is kept constant, the voltage varies with the dynamic resistance during welding. The voltage can be easily measured, because its level for resistance welding is fairly low. However, the collected signals are usually corrupted by the induced alternating magnetic field during ac welding, as shown in Fig. 30(a). The area of the wire loop of the voltage sensor should be minimized to reduce such an influence. Using a compensating loop is an effective means to approach this issue.

Electric Current. A very high electric current is usually needed in resistance spot welding, which demands an indirect measurement of its value. An induced voltage by the welding current, rather than the current itself, is measured, and as a result, the measurement may be polluted by process noises. For a direct current (dc) or a low-amperage ac, a resistive shunt method can be applied, in which the voltage across a known resistor is measured, and the current passing through the welding circuit can be derived. Because of inductance and resistance in the secondary loop, a welding current, either ac or mid-frequency dc, does not reach the designated value immediately after the current is switched on. Rather, it ramps up during the first few cycles of welding. As a result, the amount of heat may be less than calculated. This may not have much effect on the process or weld quality in steel welding, but it should be accounted for in welding aluminum or magnesium, because the welding time is usually very short for these alloys.

Dynamic resistance during resistance welding provides important information for both welding process and weld quality. It is generally measured through the electric voltage and current. This is a straightforward process when dc is used. However, care must be taken during ac welding because of the inductance in the secondary loop.

Because dynamic resistance is a strong function of the geometric and physical characteristics of a weldment, their changes during welding are directly reflected in the signals of the dynamic resistance measurement. As seen in Fig. 31, the dynamic resistance in welding a DP600 steel (Ref 24) shows initial melting of the faying interface (zone 2 in the figure), continued heating of the stack-up, more melting, and solidification. Expulsion, when it occurs, reduces weld thickness and increases the contact area in a short period of time. Therefore, it is usually revealed by a sudden drop in dynamic resistance.

Fig. 28 Microhardness profiles of various material combinations. HSLA, high-strength, low-alloy; DP, dual phase. Source: Ref 14

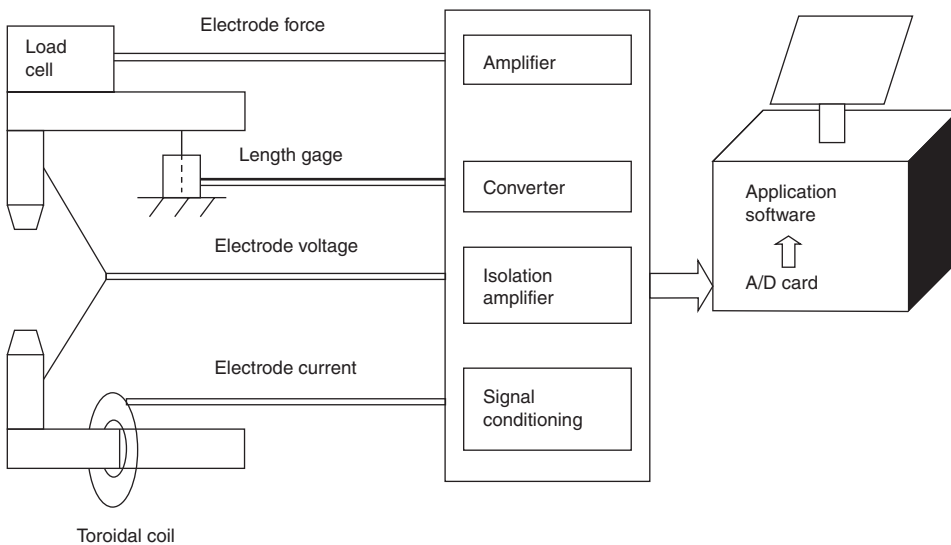

Fig. 29 Schematic of a typical data-acquisition system. A/D, analog/digital. Source: Ref 24

Electrode displacement is the result of expansion and contraction of a weldment along the electrode axis. They are the result of heating, melting, solidification, and cooling. However, electrode displacement can only serve as a qualitative, not quantitative, indicator of the welding process or weld quality, because the motion of an electrode is affected by more than one type of deformation in the weldment.

For instance, heating makes the weldment expand, yet it softens the solid material and makes it easier for the electrode to protrude into the weldment under the applied electrode force. The varying and nonuniform temperature and strength distributions in the weldment, the heating/cooling of the solid, the melting/solidification, along with constraint from the sides of the weld, make it difficult, if not

impossible, to quantitatively correlate the electrode displacement with the processes in the weldment.

Linear variable differential transformers and fiber-optic sensors are commonly used for displacement measurement in welding. The electrode displacement profile, measured using a fiber-optic sensor, is shown in Fig. 32. The increased distance between the electrodes corresponds to growth of the weldment thickness due to solid expansion and melting under heating. The measured electrode displacement is the result of two competing processes: an increasing electrode displacement corresponding to thermal expansion due to heating, and a decreasing electrode displacement due to softening of the weldment. The fluctuation in the displacement curve is the result of alternating cycles of heating (peaks in the displacement curve) and cooling (valleys in the curve). Other physical changes may also be revealed by the electrode displacement measurement. In Fig. 32, a large drop in displacement indicates expulsion, when a sudden loss of liquid metal reduces the distance between the electrodes. The magnitude of displacement drop may be used to describe the severity of expulsion.

Electrode Force. As an important input variable, electrode force creates necessary electric contact at the faying interface, contains the liquid metal to suppress expulsion, and provides a forging force to prevent porosity formation and cracking. Electrode force is usually applied in three stages in a typical welding cycle: touching, welding, and hold. Because it is measured by the reaction of the weldment to the electrodes, electrode force directly reflects the welding process and can be used to measure weld quality in a way similar to electrode displacement.

Figure 33 shows electrode force as a function of time in a welding cycle. When the electrodes touch the sheets, the electrode force may increase steadily or fluctuate, depending on the stiffness and damping properties of the sheet stack-up, the stiffness of the electrodes and welder, and so on. Such vibration may not affect weld formation if an electric current is applied after the electrodes are stabilized. However, an electric arc may be generated if the current is applied while the electrodes vibrate, and it may adversely influence weld quality. Controlling electrode force is an efficient way to suppress void formation and expulsion, and a large force is needed to create a large weld to balance the force from the liquid nugget (Ref 2).

Pneumatic cylinders are commonly used to drive electrodes. Therefore, electrode force is closely associated with the pressure change and follow-up characteristics of a cylinder. Other driving mechanisms, such as combined pneumatic and hydraulic systems, have been developed to control the electrode force in resistance welding. Electric servo-motor-based welders also provide the

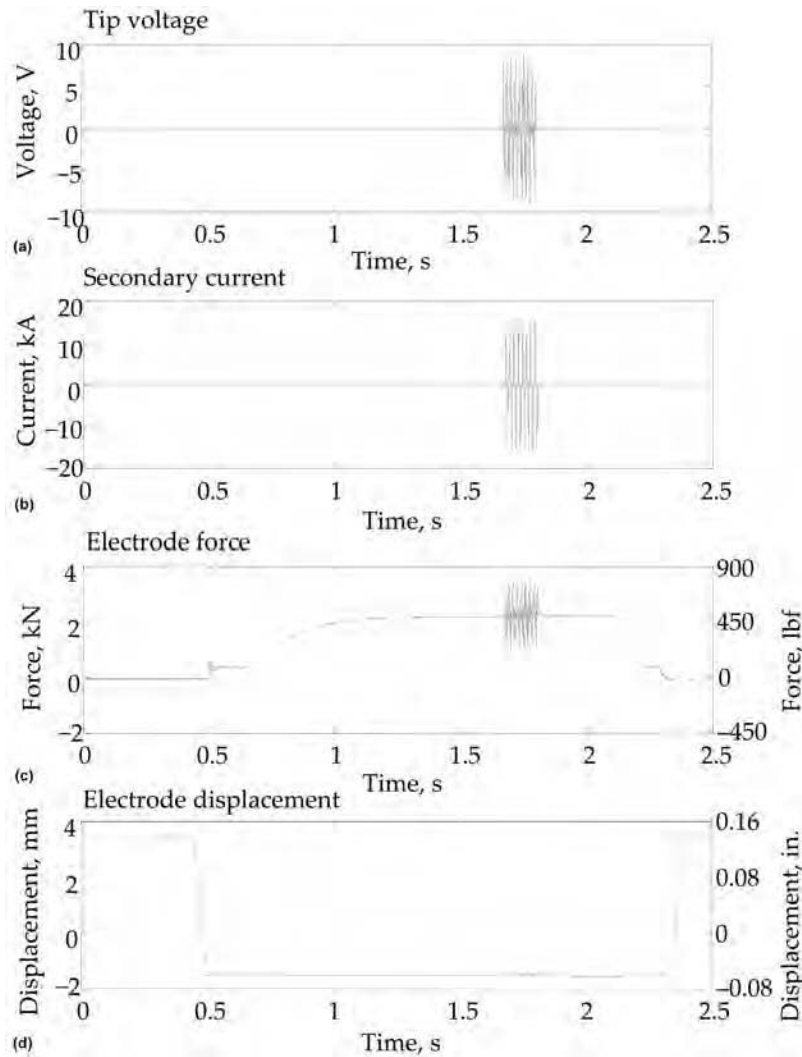

Fig. 30 Typical profiles of voltage, current, electrode force, and electrode displacement monitored in an alternating current welding

opportunity to alter electrode force during a welding cycle. Electrode force is usually measured using a strain-gage-based force sensor or a piezoelectric force sensor. It is important to realize that, as in measuring other signals during ac welding, the force signals could also be heavily corrupted by the induced voltage.

Ultrasonic Evaluation

The process signals discussed in the previous sections are important for on-line monitoring of the welding process and weld quality. However, they are generally of an indirect nature, and there is a lack of one-to-one correspondence between a monitored signal and the welding process. Therefore, the ability to use process signals for weld-quality monitoring is limited.

Ultrasonic inspection, on the other hand, has been quite mature in examining the internal structure of components. It has been applied to quality inspection of resistance spot welds as well, by providing a direct measurement of the structural characteristics of a weldment. Various ultrasonic inspection techniques currently used in resistance welding are briefly reviewed in this section.

The ultrasonic A-scan technique is also known as a ring-down technique. It is basically a plot of wave amplitude versus time (Fig. 34). When applied to a spot weldment, the ultrasound is reflected when it encounters an interface, back to the transducer. As a result, a series of echoes is formed. The location of a reflecting interface, determined by the echo positions on the time scale, is associated with the characteristics of a weldment.

Fig. 31 Dynamic resistance profile in welding a DP600 steel. Source: Ref 24

Fig. 32 Electrode displacement measured with a fiber-optic sensor during alternating current welding with a heavy expulsion. Source: Ref 6

The typically observed waveforms in using the ultrasonic A-scan technique for evaluating a resistance spot weld are illustrated in Fig. 34 (Ref 26).

The quality of a weld can be assessed by examining the features of the echo sequence in an ultrasonic A-scan. For a large weld of sufficient fusion at the faying interface, the ultrasonic wave passes through the faying interface and is reflected from the back surface of the stack-up. Figure 34(a) is the ultrasonic echo waveform for a good weld. In addition to the time intervals between the peaks corresponding to the time of flight of the reflected waves, a rapid attenuation is observed, resulting from the coarse microstructure in the fused part of the weld area. An acoustic beam onto a small weld is split into two parts, and the portion that is reflected by the unfused faying interfaces creates small, intermediate echoes, adding to those passing through the fused area (Fig. 34b).

Fig. 33 Electrode force profile during welding

Therefore, the echoes obtained are influenced by the nugget size, relative to the probe diameter, and the position of the probe.

For a weld of insufficient fusion or a cold weld, the acoustic wave can pass through the faying interface if there is certain adhesion created by melting of the metals, such as the zinc coating in a hot-dipped galvanized steel or a small amount of base metal. The insufficient heating creates surface melting or a shallow weld with a fine microstructure, and therefore, little attenuation to the reflected beam results. Therefore, the echoes measured on a cold weld (Fig. 34c) have a lower attenuation than those in Fig. 34(a). When there is no adhesion at the faying interfaces, reflection occurs only within the upper plate, meaning no weld. Because there is no melting and therefore no structural changes, very slow attenuation is observed in such a weld (Fig. 34d).

In practice, the use of ultrasonic A-scan depends heavily on the operator's experience, as analyzed in a repeatability and reproducibility study (Ref 27). The large number of possibilities of welds in shape, size, microstructure, internal defect, surface topology of the top and bottom surfaces, and so on may affect the correct interpretation of the ultrasonic waveforms.

Ultrasonic B-Scan Technique. Although an A-scan image provides useful information based on the thickness and microstructure of a weldment through the distance between peaks, decay in the echo magnitude, and overall pattern of the acoustic waveform, the interpretation is generally operator-dependent. Many factors, such as probe size, axial and angular alignment of the probe with respect to the weld, and irregularities of a weld, affect the operator's interpretation of weld quality.

As a significant improvement to A-scan, ultrasonic B-scan overcomes many of the shortcomings of A-scan for weld-quality inspection. An ultrasonic B-scan image is a plot of elapsed pulse time (from reflections) versus the position

of the transducer along a line on the surface of the testpiece (Fig. 35). Echo intensity is not presented directly, as it is in A-scan inspection, but is often indicated semiquantitatively by the relative brightness and/or color of echo indications. An ultrasonic B-scan display can be likened to an imaginary cross section through the testpiece, where both front and back surfaces are shown in profile.

Unlike in A-scanning, in which the signals are collected with a stationary probe positioned on the top of the weld, the probe is moved across the weld surface in B-scanning. At each location, echoes are generated, as in an A-scan, from the interfaces between the top and back surfaces. A sequence of such echoes created when the probe slides along a line through the weld center on the top surface forms a B-scan image. A correctly constructed B-scan image is able to reveal the location and size of various geometric features of a weldment, including the indentation, nugget, voids and cracks, and degree of adhesion for distinguishing cold welds. A schematic B-scanner is shown in Fig. 36.

Various welds were generated and examined (Ref 28) by using a B-scan inspection system developed by Applied Metrics. The image of a good weld is shown in Fig. 37. On the top plate, the surfaces of the base metal are clearly distinguishable from that of the indentation from the rupture of continuous echoes of the top surface at the indentation walls. There is an undefined zone at the junction between the surfaces of the base metal and the indentation, resulting from a loss of signals at the inclined indentation wall on which the reflected acoustic beam does not directly reach the receiver. Such a region widens as echoes decay.

The echoes of the top plate can be used to accurately measure the thickness of the plate, which can also be used to calibrate the measurement of other thicknesses of the weldment, for example, weld thickness. The top surfaces of a weldment, that is, the surface of the base

metal and that of the indentation, are differentiated by B-scan. The difference is amplified by the different travel speeds of the ultrasonic beam in different media. The indentation area appears deeper than it is, relative to the top surface of the base metal, because it takes a longer time for the acoustic beam to travel through water. The indented surface also reflects the topology of the electrode and can be used as an indicator of the electrode condition. The echoes under the electrode impression (in the range of the indentation) provide information on the nugget width, weld thickness, and internal defects.

From an ultrasonic B-scan image, weld geometric attributes can be derived, and they usually comprise of the indentation width and depth, nugget width, weld thickness, projection of an internal discontinuity, trace of expulsion, degree of fusion, and the difference in grain structures between the fused area and other parts. Some examples of evaluating spot welds of various characteristics are shown in the following. A more complete discussion can be found in Ref 28.

Figure 38 shows the B-scan of a weld with an internal crack created by welding with electrodes of annular tips. The crack, which is parallel to the faying interface, is clearly visible at the center of the fused area in the ultrasonic image. It is noticeable that the relative width of the crack appears bigger than that observed in the corresponding metallographic sectional view (on the right). The reason for this is that when the probe moves toward the crack in the nugget, assumed from left to right, an echo from the crack is registered once the crack tip is encompassed by the ultrasound beam diameter at the depth of the crack, even when the crack tip is not yet at the center of the ultrasound beam, which is used as the location of the echoes. As a result, the crack appears earlier in the B-scan image than its actual physical location. Care should be exercised when quantitatively measuring the width of the crack.

A cold weld results when there is insufficient fusion at the faying interface. This is illustrated by very similar echoes from the weld area to those from the original faying interface, accompanied by a slight bending of the base metal due to thermomechanical deformation in an ultrasonic image of a cold weld (Fig. 39). Although all cold welds are the result of insufficient heating, the amount of fusion could be drastically different among them. In other words, they may have different degrees of "coldness." Some cold welds may have considerable strength, and others may behave like a "no-weld." The degree of coldness can be evaluated by ultrasonic B-scan through the color (strength) and thickness of the echoes of the faying interface in the image.

As seen in Fig. 39 for a cold weld, the B-scan image shows little difference in the weld area from the back surface of the top plate. The sectioning through plane C in Fig. 24 of the weldment reveals melting of the zinc coating as well

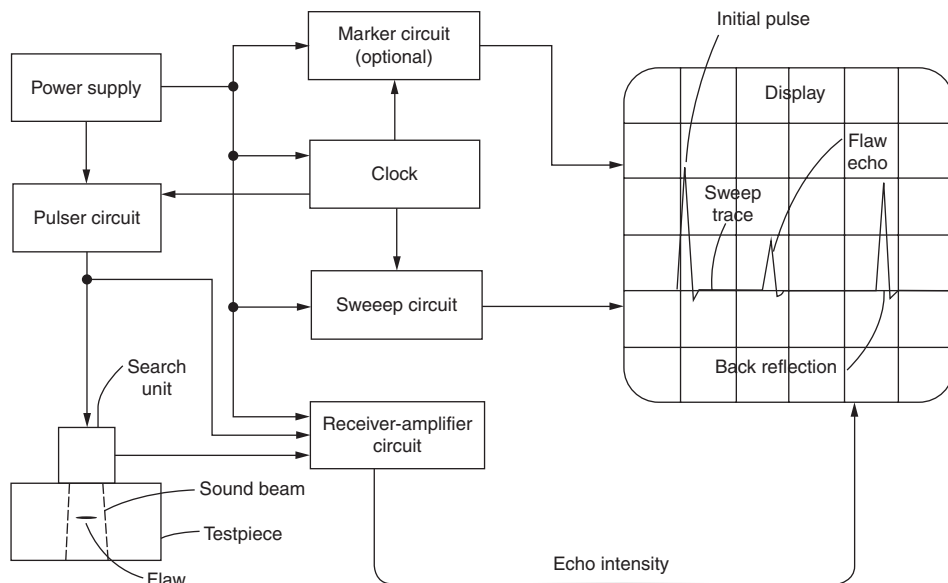

Fig. 34 Schematic of A-scan ultrasound and waveforms from A-scan ultrasounds of typical welds. See text for more information. (a) Good weld. (b) Reflection with unfused faying interfaces. (c) Cold weld. (d) No adhesion at the faying interfaces. Source: Ref 26

as some base metal at the center of the weld. In a B-scan image, the degree of fusion is reflected by the color, brightness, and thickness of the echoes. Increasing heat input, as observed in Ref 28, results in more base-metal melting and less degree of coldness. The corresponding changes in a B-scan image are that the colors of the echoes of the weld start to differ from those of the back surface of the top plate, and the echoes become thinner. For instance, the weld in Fig. 40 was made with 1000 A more current than that in Fig. 39, with more base-metal melting. The first echoes of the B-scan image of the weld are darker in color and thinner in thickness compared with that of less heat, because of less reflection from the original faying interface as more acoustic beam penetrates the interface, resulting from more fusion. The intensity of the echoes from the back surface of the weld, on the other hand, increases with brighter color. The difference between welds of different amounts of fusion is amplified by the attenuation of the signals, that is, the attenuated echoes. The attenuation rate of the hotter weld is higher, due to the coarse structure in the fused area.

In addition to ultrasonic A-scan and B-scan, arrays of ultrasonic probes are also used to obtain information on the in-plane attributes of a weld along the faying interface. These probes are currently in the development stage at a number of universities and industrial research laboratories.

In-Line Ultrasonic Test Monitoring. Besides off-line measurement of weld quality, attempts have also been made to use ultrasonic waves for on-line quality control. Generally, there are two different approaches for this purpose: the pulse-echo method and the through-transmission method. The former relies on analyzing the reflected echoes of ultrasound in a way similar to an A-scan (Ref 29). Difficulties may arise in interpreting the echoes, because the amplitude of the reflection and the time of flight are both strongly temperature dependent. The multiple interfaces, including the electrode-sheet interfaces, may complicate the interpretation. In the through-transmission method, the ultrasound signals are beamed from one side of the welding stack-up and received on the other side, as shown in Fig. 41 in the work by Kocimski et al. (Ref 30). The time of flight through a resistance spot welding setup was used to monitor weld quality at the moment the electric current was turned off. Because the transmission of the ultrasound through the weld stack-up is affected by the changes in the sheet metals, the difference in time of flight between two stages of welding, for example, before and after applying the welding current, can be used to evaluate the weld formed. The changes between the original and the welded stack-up due to welding, which are reflected in the ultrasound characteristics, include microstructure, adhesion at the faying interface, indentation, and temperature rise in the various media, including the cooling water, electrode, and weldment. Such changes are

reflected in the transmitted ultrasonic waves, and they are used to predict weld quality through a correlation between the quality and the changes in ultrasonic signals.

Because the received signals contain the contributions of all components in the path of ultrasonic wave propagation, it is necessary to isolate the portion resulting from fusion of the sheets. This requires an understanding of the temperature distribution in the setup. Finite-element modeling was used in the work by Kocimski et al. (Ref 30), and a good agreement with experimental results was obtained.

Introduction to High Energy Density Electron and Laser Beam Welding

J.W. Elmer, P.W. Hochanadel, K. Lachenberg, and T. Webber

HIGH ENERGY DENSITY BEAM WELDING refers to electron or laser processes where a beam of electrons or photons, respectively, can be focused to power densities high enough to melt and vaporize the metals being joined. The high power densities and associated metal vaporization can be used to produce welds with high depth-to-width aspect ratios, small heat-affected zones, and reduced distortion. In certain applications, high energy density beam welds can offer both high quality and cost-effectiveness when compared to other welding methods. Although there are many similarities between electron and laser welding techniques, there are also many significant differences. This article provides a brief history of electron and laser beam welding, discusses the properties of electrons and photons used for welding, and contrasts electron and laser beam welding by way of an introduction to the sections that follow, where each process is described separately. In addition, a section is included on the growing field of microjoining with electron and laser beams, which is becoming more important as miniaturization of components continues in the areas of microelectronics, implantable medical devices, sensors, optoelectronics, and micromechanical systems. Although many of the principles are the same between macro- and microjoining, when weld dimensions become less than a millimeter, spot size, beam control, and part manipulation become more challenging, joint preparation and cleanliness become more important, and not all of the material properties scale at the same rates. These factors bring new challenges to both the technological and metallurgical aspects of microjoints made by electron and laser beams.

History of Electron Beams and Laser Beams

The development of electron beams used for welding began in Europe in the mid- to late-1950s. In Germany around 1958, scientist

Karl-Heinz Steigerwald was conducting experiments on a transmission electron microscope and observed melting of the small samples as the beam current was increased (Ref 1, 2). About the same time in France, Dr. Jacques-Andre Stohr was looking to weld reactive materials with x-ray tube systems and began to develop electron beam welding through work carried out by the Commissariat Energie Atomique (CEA) (Ref 3–5). At the time, the science behind the production, acceleration, and focusing of electron beams in vacuum was well understood, so it was a relatively straightforward process to design and build systems large enough for welding practical materials once these initial ideas had germinated. The introduction of electron beam welding to manufacturing technology is important enough that one of the earliest electron beam welding machines from Steigerwald has been preserved and is on public display at the Deutsches Museum of Technology in Munich, Germany. By the early 1960s, high-voltage (125 to 150 kV) electron beam welding systems were being fabricated and sold by the Carl Zeiss Company in cooperation with Hamilton Standard, a division of United Technologies Corporation, and low-voltage (15 to 60 kV) systems by Sciaky SA through license agreement with CEA, which extended to Sciaky Brothers in the United States (Ref 3). These early machines were fabricated mostly for laboratory and limited commercial use. By the 1970s, electron beams became the welding method of choice for high-quality precision welds. The driving force for new developments during this time came mainly from the nuclear and aerospace industries, where 5 to 100 kW (7 to 130 hp) systems were developed for deep-penetration welding (Ref 2, 6). High-voltage systems, 150 to 200 kV, were developed to operate at less than 100 mA of beam current, while low-voltage systems, 30 to 60 kV, were developed to operate at higher beam currents of up to 1 A, with powers exceeding 50 kW (67 hp). The largest and most powerful electron beam welder to date was developed in Japan, reaching 300

kW (400 hp) at 600 kV, and was able to penetrate up to 305 mm (12 in.) of steel (Ref 7, 8).

Both high- and low-voltage electron beam welding systems were later integrated with computer numerical control systems using both fixed- and movable-head electron beam welding guns in the 1970s and 1980s to access greater commercial applications. Other advances in electron beam welding technology included out-of-vacuum welding systems, seam tracking, and beam rastering, which spurred new applications for heat treating, drilling, cutting, and cladding. Today (2011), electron beam welding is the method of choice for larger components that require welds to be made in vacuum, such as with reactive materials and hermetic vacuum sealing, and for welds with penetrations greater than approximately 12 mm (0.5 in.). Electron beam welding continues to evolve through the development of new applications, such as free-form fabrication with wire or powder filler metals (Ref 9), and rapid deflection optics to scan the beam in a way to allow a part to be simultaneously heat treated and welded with one beam, or allow multiple welds to be made using one beam (Ref 10, 11). In addition, electron beam diagnostics are being continually improved to provide a greater measure of quality control for electron beams that was not available in the past (Ref 12–14). These diagnostics are on par with diagnostics used for measuring power density distributions in continuous-wave laser beams and allow the two processes to be quantitatively compared. The number of electron beam welders appears to be approaching a steady-state value, where a rough estimated number of installed electron beam welders in the world is on the order of 2000 (Ref 3), which is approximately one-half the number of installed kilowatt-level high-power lasers used for welding (Ref 15).

While electron beam welding was being developed in the late 1950s and early 1960s for commercial applications, lasers were being invented and discovered in research laboratories in the United States. Many good articles exist on the early development of *lasers*, the

term first given to represent light amplification by stimulated emission of radiation by Gould in 1959 (Ref 16), so only a short introduction is provided here. The invention of the laser can be traced to the pioneering work performed in microwave electronics by A.L. Schawlow and C.H. Townes at Bell Laboratories for their work on infrared masers in 1958 (Ref 17). The first working laser, which was a solid-state flash-lamp-pumped synthetic ruby crystal laser that operated in a pulsed mode at $0.694 \mu\text{m}$ ($27 \mu\text{in.}$) wavelength, was developed in 1960 by Theodore Maiman at Hughes Research Laboratories (Ref 16). Shortly afterward, gas lasers based on helium and neon were developed at Bell Labs and were capable of being scaled to high powers due to easier heat management of the gas lasing medium (Ref 16). In 1962, semiconducting laser diodes were also developed at Bell Labs, further demonstrating the wide range of media capable of generating laser light (Ref 16).

Early lasers were not much more than laboratory curiosities, and it took more than a decade for their real commercial potential to be developed in consumer products, such as barcode scanners, compact disc players, laser pointers, laser printers, and materials processing applications. The majority of lasers used for welding today (2011) are either yttrium-aluminum-garnet (YAG) crystal solid-state lasers doped with neodymium or ytterbium, or CO_2 gas lasers. However, direct-diode lasers are now commercially available with high enough beam quality at high powers to be used for welding and other materials applications (Ref 18). The Nd:YAG and CO_2 lasers were both developed at Bell Laboratories in 1964, and although both operate in the infrared wavelength range, they have wavelengths that are an order of magnitude apart: 1060 nm ($42 \mu\text{in.}$) for Nd:YAG and $10,600 \text{ nm}$ ($420 \mu\text{in.}$) for CO_2 . This difference in wavelength results in different interactions with materials and requires different types of optics and laser delivery systems to be used for each. These differences, and the ease at which gas lasers were scaled up in the early years, led to CO_2 laser dominance of high-power laser applications, oftentimes competing with electron beams, while solid-state YAG lasers were used primarily for precision and low-power applications. By the early 1970s, CO_2 lasers had reached the 20 kW (27 hp) level, while flash-lamp-pumped Nd:YAG lasers were limited to only 400 W (0.5 hp) (Ref 19, 20). Today (2011), diode-pumped Nd:YAG lasers are available with powers up to 4 kW (5 hp), and direct-diode lasers are available with powers up to 10 kW (13 hp). The CO_2 lasers dominate the gas laser market and are commonly used for welding and cutting, with powers as high as 45 kW (60 hp) (Ref 21).

New-generation high-brightness lasers are being developed with ever-increasing powers. Disc lasers are now commercially available with powers up to 16 kW (21 hp), and fiber

lasers are available with powers up to 50 kW (67 hp) for military and commercial applications, with 200 kW (270 hp) powers planned for the near future (Ref 22). Note that the term *brightness* is used in this article as a descriptive term to refer to the quality of the laser beam, where higher brightness refers to higher-quality beams. These new-generation lasers use lasing media that are thin in at least one dimension so that heat can be removed from them efficiently. With less heating of the lasing media, higher-quality, higher-brightness beams are produced. In the case of disc lasers, the lasing crystal is a thin disk measuring only approximately 10 mm (0.4 in.) diameter and less than 1 mm (0.04 in.) thick. In the case of fiber lasers, the active lasing medium is a long, thin fiber only $10 \mu\text{m}$ (0.0004 in.) diameter.

High laser powers are now available from many suppliers, and after the overall power level for an application is established, the quality of the beam becomes the next important consideration. The quality of the beam affects how well the laser can be focused and delivered, and there are different ways to measure beam quality. One common measure of laser beam quality is the beam parameter product (BPP), which represents how tightly the beam can be focused under a limited divergence condition. The BPP is discussed in more detail later but is used in Fig. 1 to compare the beam quality of different types of lasers as a function of beam power up to their respective maximum

powers. Lower BPPs refer to more tightly focused and less divergent beams and are desired for precise cutting, deep keyhole welding, and long focal-length conditions. Diode lasers have the largest BPPs, which makes them most attractive for lower power density applications, where larger beam diameters and lower power densities are desired. Their high powers combined with large BPPs make them also very useful for nonwelding applications, such as large-area heat treating and cladding. Diode and flash-lamp-pumped Nd:YAG rod lasers are available from many sources with BPPs between 10 and 20 mm-mrad at the 4 kW (5 hp) level. These lasers, along with CO_2 lasers, have lower BPPs than diode lasers and dominated the laser welding and cutting market until solid-state disc and fiber lasers became commercially available. Disc lasers currently have BPPs on the order of 8 mm-mrad at the 8 kW (11 hp) level, while single-mode fiber lasers are now available with powers up to 10 kW (13 hp) and BPPs at the limit of diffraction for 1060 nm ($42 \mu\text{in.}$) beams of 0.37 mm-mrad . The CO_2 lasers below 10 kW can have similar diffraction-limited beam quality but have BPPs approximately 10 times as large as fiber lasers due to their longer wavelength. At power levels higher than 10 kW in CO_2 (up to 45 kW , or 60 hp) and fiber (up to 50 kW , or 67 hp), the BPP increases to the 6 to 8 mm-mrad range, because less-perfect multimode beams are required to generate these powers.

Fig. 1 Beam parameter product (BPP) plotted versus laser power up to the highest commercially available power levels for six different types of lasers. SM and MM refer to single-mode and multimode fiber lasers, respectively; Nd:YAG refers to neodymium: yttrium-aluminum-garnet laser. The estimated BPP range for electron beams is shown for comparison.

While the quality of laser beams is typically measured using the BPP, electron beam technology has not traditionally used the same convention, making it difficult to compare the two processes directly. However, estimates of electron beam quality can be made using diagnostic measurements of the beam power density distribution (Ref 23) and approximations of the beam divergence. Recent measurements of electron beams have been performed to determine the BPP of kilowatt-level electron beams, showing BPP values between 0.75 and 1.3 mm·mrad (Ref 11, 24, 25). This range is plotted in Fig. 1 for comparison with lasers, indicating that an equivalent BPP for electron beams is smaller than that of CO₂ lasers but larger than that of solid-state single-mode lasers. Additional work needs to be done to characterize electron beam quality using advanced diagnostics to determine the influence of operating voltage, cathode size and shape, and electron gun design on beam quality. However, it is clear that the recent increase in the quality and power of solid-state lasers has resulted in a large overlap of welding capabilities between CO₂ lasers, solid-state lasers, and electron beams, providing users with many options when selecting high energy density beam welding processes.

Properties of Electron and Laser Beams

Electron Beams

Electron beams are composed of electrons that are charged particles having a rest mass of 9.1×10^{-31} kg and can be accelerated in electron guns to relativistic velocities, giving them high kinetic energies. At 10 kV (13 hp), electrons travel at approximately 20% of the speed of light, while at 200 kV (270 hp) they travel at approximately 70% the speed of light (Ref 2, 26). The kinetic energy is the source of heat used for welding as the electrons in the beam rapidly slow down and deposit their energy into the substrate. The depth that the electrons penetrate into a substrate depends on the energy of the electron and the properties of material being welded and most importantly, is inversely related to the atomic number, Z . The penetration depth is often calculated using Carlo methods to account for multiple atomic collisions as the electrons continuously slow down (Ref 27). These calculations indicate that 150 kV (200 hp) electrons penetrate 10 to 100 μm (400 to 4000 $\mu\text{in.}$) in metals (Ref 26); thus, the majority of the electron energy is deposited in a rather thin surface layer. Electrons, being charged particles, interact with all types of matter, which places restrictions on how they are focused and delivered to the parts being welded. Unlike lasers, electron beam focusing is performed using magnetic lenses that do not function to the same degree of precision as optics for lasers. However, this magnetic lens

property does allow for dynamic adjustments of beam deflection and focus through computer control. Caution should also be used when working with magnetic and ferromagnetic materials and weld tooling so that the beam does not inappropriately deflect from the intended target. In addition, electron beams interact with gas molecules to the extent that a 100 kV (134 hp) beam will lose 90% of its energy after propagating through only 46 cm (18 in.) of air (Ref 26). Electron beam welding is therefore most typically performed under medium-to-high vacuum conditions of 13 to 0.13 mPa (10^{-4} to 10^{-6} torr) in large vacuum chambers to accommodate the welding of large structures (Ref 2, 6, 7). This vacuum environment is advantageous for welding materials that are reactive or refractory or require low levels of atmospheric contaminants. On occasion, electron beam welding is performed under non-vacuum conditions, but the beam must be kept very close to the surface of the part. Although the depth of the weld is significantly reduced compared to vacuum welding, numerous applications, particularly in the automotive industry, are found for out-of-vacuum electron beam welding (Ref 6, 28).

After electrons strike the substrate, they primarily lose their energy through elastic and inelastic scattering with atoms, causing the electrons to slow down as they deposit their energy into the material being welded (Ref 26, 27). In the process of slowing down, the electrons produce a spectrum of electromagnetic waves, particularly x-rays, which present a health and safety hazard that requires adequate shielding to protect the operator. Some of the electrons are backscattered from the surface, resulting in energy that is not deposited into the substrate. The fraction of backscattered electrons increases with atomic number, from approximately 0.1 for low- Z materials such as aluminum to nearly 0.5 for high- Z materials such as tantalum (Ref 2). Electrons can also be treated as waves instead of charged particles, according to the de Broglie equation $\lambda = h/p$, where λ is the wavelength of the electron, h is Planck's constant, and p is the electron momentum (mV) (Ref 29). Using this relationship and the relativistic velocity of the electrons to account for their increased mass at these speeds (Ref 29), the wavelength of electrons used for welding is smaller than atomic dimensions, ranging between $\lambda = 0.0123$ nm (0.0005 $\mu\text{in.}$) at 10 kV and $\lambda = 0.0025$ nm (0.0001 $\mu\text{in.}$) at 200 kV (Ref 29). These wavelengths are significantly less than photons used for laser welding, and this difference represents a fundamental difference between how electron and laser beams interact with materials.

Laser Beams

Lasers are devices that emit light (photons), typically in a narrow wavelength range (monochromatic) that is spatially coherent (in phase).

These properties allow lasers to be focused to much higher power densities than would be possible from incoherent multispectral light sources, giving lasers the ability to be used for a wide variety of materials processing applications, such as welding, cutting, drilling, and micromachining. Laser beams can be transported through air or inert gases and thus do not require the large vacuum chambers used for electron beam welding, which opens up a host of possibilities not readily accessible to electron beams. One of the most fundamental properties of laser beams is wavelength, which can vary from the ultraviolet to the visible and the near- and far-infrared regions of the electromagnetic spectrum. However, the majority of lasers used for welding have wavelengths close to either $\lambda = 1060$ nm (42 $\mu\text{in.}$) (solid-state lasers) or $\lambda = 10,600$ nm (420 $\mu\text{in.}$) (CO₂ lasers), representing a factor of 10^5 to 10^6 longer wavelengths than electron beams used for welding.

The minimum spot size of focused laser beams, and electron beams, operating under ideal conditions is ultimately limited by diffraction (Ref 29, 30). The minimum or diffraction-limited spot size for an ideal beam is given by $d_{\text{min}} = 2.44\lambda(f/x_c)$, where d_{min} is the smallest spot size of the laser beam, f is the focal length of the lens, and x_c is the coherence length of the beam taken to be the collimated beam diameter (Ref 30). Because the smallest-diameter spot is directly related to the wavelength of the beam, λ , smaller-wavelength electron beams can, in principle, be focused to many orders of magnitude smaller spot sizes than laser beams. However, the combination of the large size of the cathodes that emit the electrons, the comparatively poor quality of electron optics used for welding, and the mutual repulsion of electrons (space charge effect) prevents high-power electron beams used in welding from being focused to their diffraction limit. In fact, the sharpest focus conditions for most electron beam welders produce spot diameters on the order of 200 μm (0.008 in.) (Ref 12–14). On the other hand, high-power laser beams can be focused to diameters less than 100 μm (0.004 in.) for solid-state lasers with small f -number (ratio of focal length of lens to collimated beam diameter) optics (Ref 30). High-power CO₂ lasers, because of their longer wavelength, are at a disadvantage compared to solid-state lasers. However, their ability to produce Gaussian-like TEM₀₀ modes with low M^2 values (discussed later) at powers approaching 10 kW (13 hp) enables CO₂ lasers to maintain low BPPs and produce smaller spot sizes at high powers than Nd:YAG lasers, and similar spot sizes to fiber lasers at the 10 kW level.

Characterization and definition of laser beam propagation is important in order to compare different lasers and different optical configurations. This subject is discussed in many references and is detailed in ISO standard 11146 (Ref 31). A schematic drawing of the propagation of a laser beam is shown in Fig. 2, which

illustrates several important beam characteristics. As the beam is focused, the circular cross section, defined by either the second moment or 86% width (Ref 31), decreases in size as it converges to the waist of the beam where the sharpest spot occurs. The beam radius as a function of Z-axis position, $R(Z)$, reaches a minimum radius, R_o , at the beam waist. The Rayleigh length, Z_{RL} , is the Z-axis distance above or below the minimum beam radius, where the radius at that point, R_{RL} , increases by a factor of square root of 2, and the area of the beam is doubled. The beam diverges at a half-angle of θ in the far field, with the full beam angle of $\Theta = 2\theta$. The BPP is defined as the product of the half-width (beam radius) at the beam cross-over location and the beam divergence angle (BPP = θR_o) and has units of mm-mrad (Ref 31, 32). Note that the half-divergence angle, θ , is used and not the full-divergence angle for this calculation. The BPP is often used as a measure for comparing the quality of different laser beams and is a fundamental property of the beam and is not affected by the configuration of the output optics. Another common measure of the beam quality is M^2 , which is a dimensionless number defined as the ratio of the true BPP to the ideal BPP for a perfect Gaussian beam. It indicates how far the beam is from an ideal, diffraction-limited beam. Alternatively, K , which is defined as the reciprocal of M^2 ($K = 1/M^2$), is used as yet one more measure of beam quality, as a

matter of convenience. These definitions, and more details of beam quality, can be found in standard laser beam texts or beam-quality references (Ref 31).

Solid-state lasers operating at or near 1 μm (40 $\mu\text{in.}$) wavelength have rapidly evolved over the past decade from flash-lamp-pumped and diode-pumped rods to disk, fiber, and direct-diode lasers used for materials processing. These advances in technology have created commercial products with a wide variety of beam qualities and power levels, which are finding applications from low-brightness applications for welding of plastics, soldering, and brazing to high-brightness applications such as keyhole welding. Figure 3 plots these different regions on coordinates of BPP versus laser power, as redrawn and modified from Ref 18 to include keyhole welding, cutting, and drilling. Because the BPP is defined as the product of the beam radius at the beam waist with the far-field beam divergence, smaller numbers correspond to brighter beams that can be focused to higher power densities. More than 3 orders of magnitude of BPP are plotted in this figure, which cover a wide range of materials processing applications from large-area heat treating of metals at high powers without melting the substrate, to intense beams used for keyhole welding, cutting, and drilling. Although the regions of interest are only approximate and may vary by application, the overall plot is a useful starting point when considering the type

of laser and optical configurations required for a given job. Even though high-brightness lasers can be defocused to low-beam intensities, the higher cost of these systems may make less-expensive, lower-brightness lasers more cost-effective for selected applications.

Just as electron beams can be described in terms of either energy or wavelength using the de Broglie equation, so can laser beams. Because photons have no mass and travel at the speed of light, the relationship is simplified to $E = 1.240/\lambda$, where λ is in nm and E is in keV. Thus, the energy of a 1060 nm Nd:YAG laser beam is only 1.16 eV, and that for a 10,600 nm CO₂ laser is 0.116 eV, both being considerably smaller in energy than their electron beam counterparts. The lower energy and longer wavelengths of laser beams compared to electron beams results in significantly different beam/material interactions, particularly the fraction of energy that is absorbed by the substrate, which strongly depends on both the laser wavelength and the material properties (Ref 33). In addition, other factors, such as temperature, beam intensity, polarization, angle of incidence, alloy composition, surface roughness, oxide layers, and contamination, contribute to the absorption of laser beams (Ref 33).

Laser absorption increases as the wavelength decreases, and this factor is important when selecting the type of laser to use for a given application. The absorption for CO₂ lasers operating at 10,600 nm is 1/5 to 1/10 that of

Fig. 2 Illustration of the propagation of a focused laser beam as the beam radius, $R(z)$, varies along the Z-axis. The beam parameter product (BPP) is a fundamental property of the beam and is a useful way to compare different laser beams.

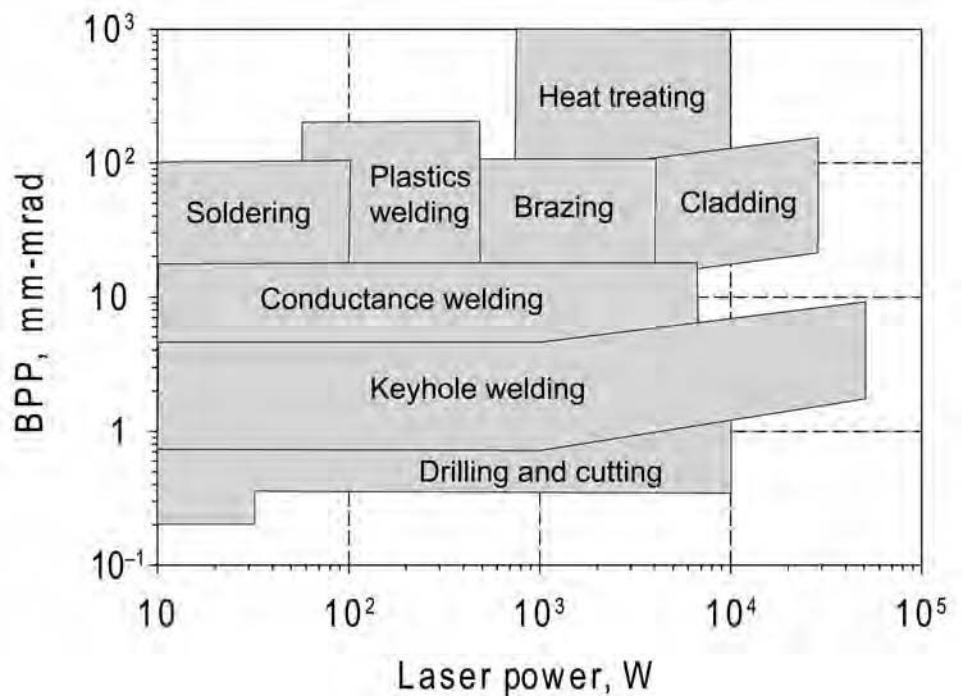

Fig. 3 Beam parameter product (BPP) plotted versus laser power, showing typical regions used for low- and high-brightness laser applications

solid-state lasers operating at 1060 nm on metal surfaces. Even for solid-state lasers with wavelengths of 1060 nm, the absorption is rather low. For example, absorption at 1060 nm is less than 0.5 for the highest-absorbing metals, such as titanium, and less than 0.05 for highly reflective materials, such as silver and gold, at room temperature (Ref 33). Significantly higher laser absorption on highly reflective metals such as gold and copper can be achieved by decreasing the wavelength into the green at 532 nm (21 μm) (Ref 34) or even lower wavelengths. These lasers are just now becoming commercially available in small packages with 10 W (0.01 hp)-level powers that are ideal for micro-electronic and small-component applications.

For material/laser combinations where the absorption is low, the fraction of energy not absorbed by the substrate is reflected and may or may not contribute to further heating of the material, depending on the weld geometry. The beam energy is absorbed in a very narrow surface layer because the photons interact only with electrons at these energy levels. This depth of penetration of the photons, or attenuation length, is inversely related to the material absorption coefficient, α . The penetration depth of the photons is on the order of 10^{-1} to 10^{-2} μm (4 to 0.4 μm) in metals, which is less than the wavelength of the laser beams. This shallow penetration is considerably smaller than that of electrons used for welding, which allows lasers to vaporize materials more easily, and is one reason why lasers are preferred over electron beams for precision cutting, drilling, scribing, marking, and micromachining.

Comparison between Electron and Laser Beam Welding

Beam quality measurements such as BPP are a good way to compare the brightness and focusing ability of different laser and electron beams. However, the power density, which is defined as the ratio of the absorbed power to the area of the beam, is the important parameter for determining how the beam will interact with a given material. High power density beam welding requires beams with power densities that exceed approximately 10^5 W/cm^2 (1.55×10^4 W/in^2), which is the level at which most metals will begin to vaporize rapidly beneath the beam (Ref 35). As the power density increases above this level, the rate of vaporization increases, producing deeper welds with little increase in the weld width. At a power density of 10^6 W/cm^2 (1.55×10^5 W/in^2), the depth-to width ratio of the weld can exceed 10 to 1. Further increases in power density above 10^7 W/cm^2 (1.55×10^6 W/in^2) can create such intense vaporization that metal is ejected from the keyhole, and the beam begins to enter a cutting rather than welding mode.

The power density is primarily controlled by the focal spot diameter and the beam power.

Figure 4 plots this relationship, showing the power required to achieve a given power density as a function of beam diameter. For example, to achieve a power density of 10^6 W/cm^2 (1.55×10^5 W/in^2), a 200 μm (0.008 in.) diameter beam only requires approximately 300 W (0.4 hp) of power, whereas a 1 mm (0.04 in.) diameter beam requires approximately 8 kW (11 hp) of power. Both laser and electron beams easily achieve the power density required for rapid vaporization and keyhole welding. To reach the higher power density limit of keyhole welding of 10^7 W/cm^2 (1.55×10^6 W/in^2), continuous beams of 5 kW (7 hp) would need to be focused to a diameter of approximately 250 μm (0.01 in.). This diameter and power combination has been easily achieved by electron beams for decades and is now being equaled, and surpassed, by solid-state lasers that can deliver these power levels through 100 μm (0.004 in.) diameter fibers with similar or smaller focused spot sizes, depending on the optics. These tightly focused laser beams now have the ability to produce power densities too high for welding and may need to be lowered in intensity by stepping up to larger-diameter fibers, using longer focal-length lenses, and/or defocusing the beam to produce acceptable welds.

When a beam interacts with a surface, not all of the beam power is absorbed by the substrate,

and one of the largest differences between laser and electron beams is the difference in absorption characteristics for lasers of different wavelengths and electron beams. Absorption of the beam is typically less for photons than electrons under most circumstances, and the differences can be large. Because the material must first absorb enough energy to melt before it can vaporize to form a keyhole, there is a power density level below which welding will not occur. This power level is highly dependent on the absorption as well as the thermophysical properties of the metal. While electrons instantly begin to penetrate the substrate and form a keyhole at 10^5 W/cm^2 (1.55×10^4 W/in^2), lasers may not if the reflectance is high enough to prevent a substantial portion of the beam from being absorbed. For electrons, where absorption is high, calculations show that materials with low thermal diffusivity, such as stainless steel and titanium alloys, will begin to melt at 5 to 10 times lower power densities than high-thermal-diffusivity metals such as copper and gold (Ref 7). For lasers, though, this threshold value may be as large as 2 orders of magnitude between high-reflectivity and high-conductivity metals or between low-conductivity and low-reflectivity metals (Ref 7). Pulsed lasers minimize the absorption problems at low powers by producing higher peak power densities than their

Fig. 4 Constant power density boundaries showing the relationship between the focused beam diameter and the absorbed beam power for approximate regions of keyhole-mode welding, conduction-mode welding, cutting, and drilling

continuous-wave counterparts, while maintaining the same average power. Electron beams can be pulse modulated for hole drilling, which is occasionally used for keyhole stability. However, pulse modulation does not increase the peak power density of electron beams and is not a technique used for initiating a keyhole in welds.

Travel speed plays the other major role in how the beam interacts with the substrate, because the energy density, rather than power density, is the parameter that ultimately controls the response of the material to the beam. The faster the beam moves, the less energy is deposited per unit length of weld, and the penetration decreases. The energy deposited per unit length of weld (J/mm) is defined by the beam power (W) divided by the travel speed of the weld (mm/s) and is one measure of how the travel speed influences weld behavior. Analytical solutions to heat-flow relationships in high power density welding (Ref 20, 36, 37) can be used to estimate the influence of welding speed on the threshold for surface melting and vaporization that leads to deep-penetration conditions, while more advanced models are continually evolving to predict the complicated relationships between welding variables and keyhole weld shape. These advanced numerical models use a coupled thermal-fluids approach to solve the equations of conservation of mass, momentum, and energy in three dimensions and must calculate the temperature distribution on the inside surface of the keyhole wall. In the case of lasers, multiple reflections of the beam off of the keyhole wall must be considered in how the keyhole is established and maintained (Ref 38). In the case of electron beams, the presence of welding in vacuum must be considered (Ref 39). More details about the numerical modeling of high power density beam welding can be found elsewhere in this Handbook.

A number of articles that compare laser and electron beam welding processes have been written. However, many of these comparisons are more than a decade old and have not kept pace with the recent advances in these technologies (Ref 40–45). Nevertheless, much of the reasoning behind the comparisons is still valid. For example, electrons require a vacuum to propagate the beam, and they generate large amounts of x-rays. Lasers, on the other hand, may require shielding gases, have higher reflectance, and present hazards in other ways. Concerning capital equipment and operating costs listed in some of these comparisons, it is important to note that the price per kilowatt of power has decreased significantly for lasers because higher average power lasers are being produced in more compact systems with smaller footprints and lower utility costs. Factoring in all the types of lasers used for welding and all the types of electron beam configurations creates too many variables to compare and contrast in this article. However, it is safe to say that either method will work well for many applications, but certain applications still

tend toward one method or the other. For deep-penetration welds over 12 mm (0.5 in.), for highly reflective metals, for welds on highly reactive materials that require vacuum conditions, and/or for welds that require hermetic sealing in vacuum, electron beams are most often the preferred method. Lasers, on the other hand, have more flexible delivery options and superior versatility that allow them to be directed into areas that are difficult to access with electron beams. This versatility allows lasers to be more easily configured and integrated into multiple-use workstations with associated potential cost-savings. Because lasers do not require vacuum operation, tooling is oftentimes simpler to fabricate and use, and production rates are oftentimes higher. In addition, lasers can be used to heat and melt non-electrically conductive materials, and they are not affected by magnetic or ferromagnetic base materials and tooling that tend to deflect and/or interfere with electron beams.

ELECTRON BEAM WELDING (EBW) is a high energy density beam welding process that is accomplished by bombarding the joint to be welded with an intense beam of electrons that have been accelerated up to velocities 0.3 to 0.7 times the speed of light at 30 to 200 kV, respectively. Some of the details were given in the article "Introduction to High-Energy Beam Welding" in this Volume. The instantaneous conversion of the kinetic energy of these electrons into thermal energy as they impact and penetrate into the workpiece on which they are impinging causes the workpiece surface(s) to melt and produces the weld-joint coalescence desired. Electron beam welding is used to weld any electrically conductive material that can be arc welded. Typically, the weld quality in most electron beam welded materials is equal to or superior to that produced by other welding processes.

Because the total kinetic energy of the electrons can be concentrated onto a small area on the workpiece, power densities as high as 10^8 W/cm² (10^7 W/in.²) can be obtained (Ref 1, 2). The high power density plus the extremely small intrinsic penetration of electrons in a solid workpiece causes an almost instantaneous local melting and vaporization of the workpiece material. This high power density characteristic can lead to keyhole formation. Keyhole-mode welding distinguishes EBW (and other high energy density processes) from other welding methods.

Principles of Operation

To illustrate the nature of an electron beam, Fig. 1 shows an electron beam weld being performed at a weld chamber pressure of approximately 13 mPa (1×10^{-4} torr). This figure illustrates that the electron beam has a small diameter, and the small beam diameter is retained over significant distances. The "beam" produces a visible glow that results from the

residual gas molecules that are excited by the electrons in the actual electron beam. This effect is reduced at lower pressures, where the glow is restricted to regions closer to the weld seam as vaporized metal atoms become ionized by the beam.

The electron beam is most often formed by a triode-style electron gun under high vacuum conditions, and a schematic of this is shown in Fig. 2. The triode assembly consists of a cathode, a heated source (emitter) of electrons that is maintained at some high negative potential; a grid cup, a specially shaped electrode that can be negatively biased with respect to the hot cathode emitter (filament); and an anode, a ground potential electrode through which the electron flow passes in the form of a collimated beam. The hot cathode emitter (filament) is made from a high-emission material, usually tungsten or tantalum, which is usually available in wire, ribbon, or sheet form. This emitter material is fabricated into the desired shape for being either directly or indirectly heated to the required emitting temperature of approximately 2500 °C (4500 °F). Other materials, such as lanthanum hexaboride (LaB₆), have also been used as filament material.

Diode-style electron guns have also been employed historically. In a diode gun, the specially shaped electrode (grid cup) is maintained at the same voltage as the emitter, thus making the diode gun a two-element (cathode and anode) device (Fig. 2). With this gun design, the flow of electrons cannot be adjusted by simply varying a grid voltage, as is done with triode guns, and beam current adjustments are usually accomplished by varying the operating temperature of the cathode emitter instead.

Electrons emitted from the surface of the filament are accelerated to a high velocity and shaped into a collimated beam by the electrostatic field geometry generated from the cathode/grid/anode configuration employed, thus producing a steady stream of electrons that

flows through an aperture in the ground plane anode. By varying the negative potential difference between the grid and cathode, this flow of electrons can be altered easily (i.e., the beam current control can also include gating "on/off" and ramping up/down to different levels), rapidly, and in a precisely controlled manner.

Once the electrons exit the anode, they receive the maximum energy input allowable from the operating voltage being applied to

Fig. 1 Photograph of an electron beam operating in an enclosed chamber maintained at a pressure of approximately 13 mPa (1×10^{-4} torr)

* Revised and updated from Electron-Beam Welding, *Welding, Brazing, and Soldering*, Vol 6, *ASM Handbook*, ASM International, 1993, p 254-261

Fig. 2 Schematic drawing showing primary components of an electron beam welding head with a triode-style gun assembly

the gun. Electrons then pass down through the electron beam column assembly and into the field of an electromagnetic focusing coil (a magnetic lens). This focusing lens reduces the diameter of the electron beam as it continues in its passage and focuses the stream of electrons down to a much smaller beam cross section in the plane of the workpiece. This reduction in beam diameter increases the energy density, producing a very small, high-intensity beam spot. The size of the beam spot is one of the most important variables in EBW and is influenced by the EBW conditions, as is discussed later. In addition, an electromagnetic deflection coil (positioned below the magnetic lens) can be employed to "bend" the beam, thus providing the flexibility to move the focused beam spot. Figure 2 illustrates the main elements of the EBW head. As described previously and shown in Fig. 2, electrons are emitted from the cathode and are accelerated to high speed by the voltage between cathode and anode, thereafter maintaining a constant speed until they strike the workpiece.

The "gun" portion of an electron gun/column assembly generally is isolated from the welding chamber through the use of valves when desired, or by using vacuum dividers when employing medium or nonvacuum systems. The gun may be maintained in a vacuum on the order of 13 mPa (1×10^{-4} torr) when the welding chamber is vented to atmosphere (for access reasons). This level of vacuum in the gun region is needed to maintain gun component cleanliness, prevent filament oxidation, and impede high-pressure short circuiting between the cathode and the anode or the filament and the grid cup, known as gun arcing. Generally, electron guns are operated with applied voltages that vary from 30 to 200 kV, and they employ beam currents that range from 0.5 to 1500 mA. Electron beam welding equipment with power levels up to 30 kW is common. In addition, several units with power levels of up to 200 kW are commercially available for specialized applications (Ref 3). However, Osaka University developed a 300 kW system that used an electron gun with 600 kV (Ref 4).

Typically, high-vacuum EBW beams can be focused to spot sizes of approximately 0.25 mm (0.010 in.) in diameter, with a power density of about 10^7 to 10^8 W/cm² (10^6 to 10^7 W/in.²) (Ref 1, 2). This high level of beam spot intensity generates temperatures sufficient to vaporize almost any material, forming a vapor hole that penetrates deep into the workpiece. When this vapor hole is advanced along a weld joint, the weld is produced by three effects that occur simultaneously:

- The material at the leading edge of the vapor hole melts.
- This molten material flows around the sides of the vapor hole to the trailing edge.
- This continuous flow of molten material fills in the trailing edge of the advancing vapor hole and solidifies as the vapor hole moves forward to produce a continuous weld.

Originally, EBW was performed only under high-vacuum (≤ 13 mPa, or 1×10^{-4} torr, or lower pressure/higher vacuum) conditions; because an ambient vacuum environment was required to generate the beam, welding the part within the same clean atmosphere was considered beneficial. However, as the demand for greater part production increased, it was determined that the weld chamber vacuum level need not be as high as that needed for the gun region; ultimately, the need for any type of vacuum surrounding the workpiece was completely eliminated for some applications. Currently, three distinct modes of EBW are employed:

- High-vacuum (EBW-HV), where the workpiece is in an ambient pressure ranging from 0.13 to 133 mPa (10^{-6} to 10^{-3} torr)
- Medium-vacuum (EBW-MV), where the workpiece may be in a "soft" or "partial" vacuum ranging from 133 to 3.3×10^6 mPa (10^{-3} to 25 torr)
- Nonvacuum (EBW-NV), which is also referred to as atmospheric EBW, where the workpiece is at atmospheric pressure in air or protective gas

In EBW-MV and EBW-NV, the electron beam broadens more rapidly or scatters by excitation collisions of the electrons with gas molecules. In these applications, the electron beam gun region is maintained at a pressure of 13 mPa (10^{-4} torr) or lower through differential pumping.

Advantages

One of the prime advantages of EBW is the ability to make welds that are deeper and narrower than arc welds, with a total heat input that is much lower than that required in arc welding. This ability to achieve a high weld depth-to-width ratio eliminates the need for multiple-pass welds, as is required in arc welding. The lower heat input results in a narrow workpiece heat-affected zone and noticeably fewer thermal effects on the workpiece.

Another distinct advantage of EBW is the ability to produce very shallow penetration welds and deep penetration welds with the same equipment by simply manipulating the weld parameters. By manipulating the EBW parameters such as beam current and focusing current, the power density is easily changed from very low to very high power densities, which allows for such a wide range of weld penetrations in EBW. For example, when using lower power densities, the beam does not produce a deep vapor cavity and can act similar to an arc weld.

In EBW, a high-purity vacuum environment is generally used for welding, which results in freedom from impurities such as oxides and nitrides resulting from the welding process. In addition, this high-purity vacuum environment is particularly beneficial when welding refractory metals, because these materials are prone to embrittlement by interstitial atoms from the atmosphere, such as nitrogen and oxygen.

The process (or energy transfer) efficiency, which is defined as the power into the workpiece divided by the source power (or the proportion of the beam energy that is actually transferred to the workpiece) is well understood and relatively high for EBW processes. In EBW-HV, the process efficiency is expected to be quite high, because only a small fraction of the beam power is lost. The process efficiency of EBW has been reported as being at least 90% over a wide range of welding conditions and materials for EBW-HV (Ref 5, 6). In EBW-NV, the process efficiency has been reported to be between 60 and 80% at various welding conditions (Ref 6), which is explained by beam energy losses due to atmospheric scattering. For comparison, the energy transfer efficiency of CO₂ laser beam welding has been shown to vary from 20% to approximately 90%, depending on welding parameters, surface condition, plume control, and so on (Ref 7), while the energy transfer efficiency for neodymium: yttrium-aluminum-garnet laser spot welding was shown to be 40 to 80% for key-hole-mode spot welds and less than 50% for conduction spot welds (Ref 8).

The characteristics of EBW allow for the following:

- Minimizing distortion and shrinkage during welding
- Facilitating welding of most hardened or work-strengthened metals, frequently without significant deterioration of mechanical properties in the weld joint
- Facilitating welding in close proximity to heat-sensitive components or attachments
- Allowing for hermetic seal welding of evacuated enclosures while retaining a vacuum inside the component
- Permitting welding of refractory metals, reactive metals, and combinations of many dissimilar metals that are not easily joinable by arc welding processes

- Producing very shallow to very deep penetrations. Electron beam welds with penetrations of more than 250 mm (10 in.) in high-vacuum conditions have been reported (Ref 9, 10).
- Projecting the electron beam long distances, which allows otherwise inaccessible welds to be completed.

To demonstrate the flexibility of EBW in terms of welding depths, Fig. 3 shows both a shallow- and a deep-penetration weld cross section.

Limitations

The capital equipment costs for EBW generally are higher than those for conventional welding processes. The cost of joint preparation and tooling is also more than that encountered in arc welding processes, because the relatively small electron beam spot size that is used requires precise joint gap and position and the use of nonmagnetic tooling materials.

Fig. 3 Cross sections of electron beam welding using high-voltage welding equipment. Palmer, Applied Research Laboratory of Pennsylvania State University, State College, PA. (b) Deeper-penetration weld on superalloy 718 with weld parameters of 120 kV, 83 mA, and a travel speed of 8.5 mm/s (0.3 in./s). Courtesy of G. LaFlamme, PTR-Precision Technologies, Enfield, CT

For EBW-HV and EBW-MV, the vacuum chamber and related evacuation is a limitation as well. The available vacuum chamber capacities are limited; workpiece size is limited, to some degree, by the size of the vacuum chamber employed. Consequently, the production rate (as well as unit cost) is affected by the need to evacuate the chamber for each production load. Recent advances by EBW manufacturers have been in the area of throughput, and, as such, index tooling has allowed for greater throughput. In addition, the employment of medium vacuum and cryogenic refrigeration (Meissner coils) is used to decrease the vacuum evacuation time cycle and thus increase the throughput.

Although most of the aforementioned advantages and disadvantages generally are applicable to all modes of EBW, several do not specifically apply to EBW-NV. Nonvacuum EBW does not offer the advantage of a high-purity environment (unless some form of inert gas shielding is provided), and it is not subject to vacuum chamber limitations. Because welding is not done within the confines of a vacuum environment, the maximum practical “stand-off,” the working distance between the bottom of the electron beam column and the top of the workpiece, currently used on EBW-NV systems is limited to approximately 35 mm (1 3/8 in.). The maximum attainable penetration is currently limited to approximately 25 to 32 mm (1 to 1.25 in.) for 60 kW, 165 kV machines. These limitations, however, are offset by higher production rates.

Finally, although covered further in the “Safety” section later in this article, the generation of x-radiation, inherent in EBW, is also a consideration of this process because of the additional safety requirements required for workers’ safety.

Process Control

Basic variables employed for controlling the results of an electron beam weld include accelerating voltage, beam current, welding speed, focusing current (or “increments” of defocus), and standoff (cathode design, gun column assembly-to-workpiece) distance. The final beam spot size that is produced in the plane of the workpiece is determined by:

- Accelerating voltage
- Beam current
- Focusing current, which controls the focal length of the lens and resulting beam focus location
- Gun column assembly-to-workpiece distance
- Characteristics of the electron beam gun/column assembly (gun and electron optics)
- Vacuum level
- Filament design and peaking

Each of these variables, separately and jointly, affects final beam spot size. With the advent of electron beam characterization/profiling, the

output of power density has provided useful information to welding personnel who are interested in understanding the welding reproducibility and beam/material interactions (Ref 11, 12). This subject is covered in some detail in the article “Quality Control of Electron Beams and Welds” in this Volume.

Increasing the accelerating voltage or beam current increases the depth of penetration; the product of these two variables—the beam power—influences the amount of metal melted for a given exposure time. Increasing the welding speed—relative travel motion between beam spot and workpiece—without changing any other process variable reduces depth of penetration and correspondingly reduces weld width. Changing any of the other basic control variables to increase beam spot size, thereby lowering the beam spot intensity (e.g., reducing the power density), reduces depth of penetration and increases weld width, if welding speed is left unchanged.

Beam deflection can be used to change the impact angle of the beam (slightly) or to produce controlled patterns of beam oscillation to create greater beam spot size or other special effects. The beam may be oscillated in circular, elliptical, and linear oscillation patterns. The beam can also be pulsed to vary the average amount of power input per unit of time. Workpiece speed and, in certain instances, standoff distance are generally preset to a desired value. However, it is possible to vary these parameters during welding with the use of computerized numerical control (CNC) types of systems. The CNC electron beam welding systems allow for the beam current, standoff distance, and welding speed to be varied simultaneously, as required, throughout the welding process.

Finally, weld process modeling is an efficient means of understanding how changes in EBW parameters will potentially change resulting weld morphologies. Weld process modeling is an effective means of investigating potential changes in weld morphologies without actually welding several test pieces. However, this topic is out of the scope of this introductory article.

Operation Sequence and Preparation

Tooling and welding procedures for each EBW application are typically developed first on experimental workpieces. Details of the welding sequence vary somewhat, depending on equipment differences and application requirements. A typical sequence of steps required to make an electron beam weld is as follows:

1. Assemble and prepare work and fixtures for welding. This includes cleaning and may include demagnetizing, preheating, and tack welding.
2. Load fixtured work onto worktable or workholding mechanism in welding chamber (except for EBW-NV).

3. Start chamber evacuation (except for EBW-NV).
4. For EBW-HV and EBW-MV, after chamber pressure has been reduced to 13 to 1.3×10^4 mPa (10^{-4} to 10^{-1} torr), focus on a target block and set beam parameters. It is recommended that the beam diagnostics tool(s) are used here to characterize the electron beam. An example of beam diagnostics used is found in the literature (Ref 11, 12). A weld or scanning program may be called up.
5. Align joint to the beam position, using optical or electron-optical methods or through the use of a beam scanning program.
6. Set the travel speed.
7. Begin the welding sequence (ramp up/down); this usually is performed automatically but can be performed manually.
8. Terminate the welding cycle.
9. Allow work to cool sufficiently if made of reactive material, then admit air to the chamber and remove fixtured work.

Alignment of the joint with beam position for nonvacuum welding is slightly less critical than for vacuum EBW, because the beam spot size and weld width are slightly larger in nonvacuum welding.

Joint Preparation. A joint for EBW ordinarily has close-fitted, abutting, square-groove faces such as a butt or step joint (self-aligning butt joint) configuration, and filler metal is not typically used. Filler metal can be used if desired, as in EBW of dissimilar metals and alloys or alloys that have low weldability when welded autogenously, such as 6061 aluminum. Generally, the faces of the joint are machined to a surface roughness of 3.20 μm (125 $\mu\text{in.}$) or less.

Surface finish on the weld groove faces may not be critical, depending on part and joint design and the requirements for weld properties. Provided the surfaces can be properly cleaned to remove all contaminants, the roughness of the faying weld joint surfaces is not generally critical. If the surface roughness is such that contaminants such as machining fluids remain even after cleaning, then the resulting weld quality will suffer.

Joint Fit-Up. Unlike arc welding, where a gap is employed to accommodate filler material, in autogenously welded components in EBW, joint fit-up requires closely fitted, nearly parallel surfaces to enable the narrow electron beam to fuse base metal on both sides of the joint. The members of a joint to be melt-through welded also are closely fitted. Fit-up tolerance depends on work-metal thickness and joint design but is usually 0.13 mm (0.005 in.) or less. Joint gap is usually smaller for thin work metal and unbacked joints and may be only 0.05 mm (0.002 in.) maximum. Interference fits may be used where shrinkage can cause cracking, as in circular joints on hardenable metals. In some instances, the use of beam oscillation to increase the effective beam size can be used to accommodate larger gap sizes

or poorly fitting joints. More information is given in the subsequent article, "Design of Electron Beam Welds," in this Volume.

Cleaning. Workpiece surfaces must be properly cleaned for EBW. Inadequate surface cleaning of the workpiece can cause weld flaws such as cracking, porosity, blowouts, and so on and a deterioration of mechanical properties (as it would in other fusion welding processes). In EBW-HV and EBW-MV, inadequate cleaning of weld surfaces also adversely affects evacuation time and gun operational stability, as well as contributing to the rapid degradation of the oil used in the vacuum pumps.

Generally, workpiece material and quality requirements define the need for cleanliness and should be addressed during the manufacturing quality reviews.

Wire brushing generally is not recommended, because contaminants may become embedded in the metal surface. Solvent cleaning is preferred for cleaning electron gun components and workpiece parts. If workpieces are cleaned in chlorine or other halogen-containing compounds, residue from these compounds must be removed by another cleaning method (usually thorough washing in a solvent) before welding. Cleaning methods have been outlined in the AWS C7.1 document, "Recommended Practices for Electron Beam Welding" (Ref 13).

Fixturing Methods. Methods used for fixturing workpieces in EBW are similar to those used for gas tungsten arc welding of precision parts without the use of filler metal, except that clamping force is usually lower and all fixturing and tooling materials should be made of non-magnetic materials.

Because total heat input to the weld is much less in EBW than for arc welding for a given depth, and because the heat is highly localized, heavy fixturing, massive heat sinks, or water cooling is generally not needed. However, if welding near a particularly heat-sensitive material, then some method for heat removal may be necessary. C-clamps are sufficient for many parts. In some applications, clamping may be supplemented or replaced by small tack welds or by a shallow weld pass (sealing pass) over the joint; the penetration weld is completed later at full power.

For EBW-NV, general-purpose welding positioners are satisfactory. Locating and aligning mechanisms are of simpler design than for welding in a vacuum; accessibility and beam widths for nonvacuum welding do not require as much accuracy in tracking of the joint. Maintenance of work-handling equipment for EBW-NV is simplified because of its out-of-chamber location.

Demagnetization. Workpieces and welding fixtures should be made of nonmagnetic materials such as austenitic stainless steel, copper, magnesium, aluminum, and so on. If the fixturing is made of magnetic materials, then the fixtures should be demagnetized before welding. Residual magnetism may result from magnetic

particle testing, magnetic chucks, or electrochemical machining. Even a small amount of residual magnetism can cause beam deflection. Workpieces are usually demagnetized by placing them in a 60-cycle inductive field and then slowly removing them. Before welding, workpieces should be checked with a gaussmeter (or magnetometer). Acceptable gaussmeter readings vary from 5×10^{-5} T (0.5 G) for very narrow (highly critical) welds up to as much as 2×10^{-4} to 4×10^{-4} T (2 to 4 G) for relatively wide welds.

Evacuation. The time required to evacuate the work chamber of an in-vacuum EBW unit down to the desired ambient pressure depends on the chamber size used, type of pump employed, and level of vacuum required. In any production application, the actual evacuation time is also affected by a number of factors, including the cleanliness of the work chamber, the amount of water vapor (humidity) in the ambient air, and the workpiece assembly (material and shape of both weldment and fixturing). Electron beam welding equipment currently employs either computer or program logic controls, normally providing automatic vacuum valve sequencing.

For EBW-HV, the required vacuum is generally provided by a mechanical pump operating in conjunction with an oil-diffusion pump. Other pumps may be used, such as cryopumps or turbomechanical pumps, depending on machine requirements. Evacuation times of approximately 5 to 15 min are generally achievable in EBW-HV.

For partial-vacuum EBW, diffusion pumps are not needed for the weld chamber, and weld chamber pumping is accomplished strictly by mechanical pumping. For high-production EBW of small parts in a partial vacuum, evacuation times of less than a minute are achievable. Again, the actual evacuation time is affected by a number of factors and can vary considerably, depending on the particular production application.

Electron beam welding equipment manufacturers are able to provide details on evacuation requirements and typical evacuation times.

Preheat and Postheat. Most commonly welded metals can be processed with EBW methods, even in thick sections without preheating, because of the extremely narrow width of the fusion and heat-affected zones. Hardenable and difficult-to-weld metals may need to be preheated, especially for thick sections and in applications when the weld is restrained.

High-strength alloy steels and tool steels thicker than approximately 9.5 mm (0.375 in.) ordinarily must be preheated before EBW to prevent cracking. Deep circular welds, especially partial-penetration welds, in thick sections of carbon steel containing more than approximately 0.35% C usually require preheating. However, welds subject to less restraint, such as circumferential welds on cylindrical shapes, can be made on 13 mm (0.5 in.) thick 0.50% C steel without preheating.

Preheating, when required, can be done before the work is placed in the work chamber, provided the evacuation time is sufficiently short, thus allowing the work to remain at the sufficient preheat temperature. Selection of heating method depends on the size and shape of the work and the preheat temperature; a combination of methods can be used. Torch and furnace heating are widely used; induction and infrared-radiation heating are also used. On small parts or where distortion from localized heating is not a problem and where increased cycle time can be tolerated, heating is sometimes done with a defocused electron beam; this method can also be used to supplement other methods of heating. Preheating can also be performed in the chamber for crack-sensitive materials using high-intensity heat lamps. One of the most recent developments in EBW is rapid beam manipulation (usually in the megahertz range). The concept is to rapidly manipulate beam movement such that the beam is "time-shared" in multiple locations. This allows for the beam to preheat the workpiece, weld, and postweld heat treat the workpiece concurrently (in the same weld pass). These modern EBW systems, when using fast beam manipulation (or rapid deflection), may provide an in situ pre- or postweld heat treatment (Ref 14). Postheating used on EBW parts is most often accomplished by conventional means (i.e., stress relieving or tempering) after removing the work from the welding chamber.

Operating Conditions. Starting and stopping the weld usually require special consideration to avoid discontinuities in the weld at these points and possible melt-through and loss of metal.

One technique that is used to avoid these difficulties is to start the weld at full beam power on a starting tab of the work metal that is tightly fitted against one end of the joint, and to conclude the weld on a runoff tab at the other end of the joint. The use of starting and runoff tabs prevents underfill at the ends of the joint, which is caused by the introduction or exit of the beam. Workpieces can also be made oversized to provide extra material for starting and stopping. The tabs or the extra material can be machined off after welding. Starting and runoff tabs are used mainly in low-production operations.

Another technique is to start and stop the weld on the work, raising the current gradually (upslope) at the beginning of the weld and reducing it gradually (downslope) at the end of the weld. Upslope and downslope power may be used at controlled rates and time intervals, as established for a specific application, and can be programmed into the welding procedure. The use of upslope and downslope is of special value where the weld is a closed path, as in welding circular and circumferential joints.

The use of CNC and computer beam control allows the programming of the motion and upslope/downslope, which helps in the starting

and stopping of the welding sequence, especially in areas of the workpiece that contain corners. This type of controller is also capable of coordinating focus, beam current, and travel conditions to tailor welds with changing conditions such as geometry (thickness or changing joint configuration).

In many applications of closed-path welds, the weld can be started at full power, with downslope at the end providing a sufficiently gradual termination and a suitable distance of overlap. Downslope of current after overlapping the beginning of the weld on circular welds in thick sections of high-hardenability steels is critical to avoid porosity and cracking. Other parameters may also be adjusted to avoid these defects. Upslope is usually rapid; downslope is from a few degrees to a major portion of a revolution.

A "cosmetic pass" is made when needed to smooth or flatten the reinforcement of a weld that is irregular or too high. Such a pass is used to correct undercut or underfill. The beam is usually defocused, reduced in power, and/or manipulated using circle/elliptical beam deflection to reduce the intensity of the beam (or a combination of these three). Filler metal may also be added in making a cosmetic pass intended to correct undercut or underfill.

Weld Geometry

The shape of the parts to be welded and the corresponding joint designs are critical to the successful application of EBW in vacuum or at atmospheric pressures (nonvacuum). While minimum heat input and low thermal distortions are important advantages of EBW, the molten metal still shrinks as it solidifies. Shrinkage stresses may lead to microcracks if parts, due to design restrictions, are unable to shrink at corresponding rates and the joint volume is completely constrained. Additional information is available in the article "Design of Electron Beam Welds plus Codes" in this Volume.

Joint Design

Butt, step, corner, T-, lap, and edge joints can be made by the EBW process using square-groove or seam welds. Fillet welds, which are difficult to make with vacuum EBW, are readily made using EBW-NV. Square-groove welds require fixturing to maintain fit-up and alignment of the joint. They can, however, be self-aligning if a rabbeted joint design is used. Self-alignment is particularly important in batch loading the vacuum chamber for efficient work manipulation. The weld-metal area can be increased using a scarf joint, but fit-up and alignment of the joint are more difficult than with a square-groove weld. Most joints are designed to be welded in a single pass with full penetration or penetration to a specified depth.

The article "Design of Electron Beam Welds plus Codes" has further details on joint design.

Electron Beam Welding Machines

This brief review is aimed at introducing the potential user to some of the EBW equipment currently available. Further advances in the control and programming of these systems can be expected because of the likelihood of uninterrupted progress in the technology and intelligent process control.

As discussed earlier in this article, the EBW process is accomplished in three pressure-dependent zones, referred to as the three modes of EBW. The original mode is the "hard" or high-vacuum mode, in which welding is carried out in the pressure range of 0.13 to 130 mPa (10^{-6} to 10^{-3} torr). In the second mode, medium vacuum, welding is carried out in the pressure range of 130 to 3.3×10^6 mPa (10^{-3} to 25 torr). This mode is also referred to as "soft" or partial-vacuum EBW. The third mode is called nonvacuum or atmospheric, with welding carried out at atmospheric pressure.

All three modes employ an electron beam gun/column, a power supply with controls, one or more vacuum pumping systems, and work-handling equipment. In nonvacuum welding, while the workpiece is not placed in an evacuated work chamber, the electron beam gun/column must be in a vacuum environment. The electron gun in all three modes is held at a pressure of 13 mPa (10^{-4} torr) or less; otherwise, the high voltage required for the acceleration of the electrons could not be sustained, and the heated filament/cathode would be subject to high rates of oxidation.

Electron beam welding equipment comes in two basic designs: the low-voltage system, which uses accelerating voltages in the 30 to 60 kV range, and the high-voltage system, with accelerating voltages in the 100 to 200 kV range. Beam powers up to 100 kW are available with both high- and low-voltage equipment.

The lower-voltage machines operate at a higher current. Typically, 30 to 60 kV machines operate at a maximum beam current of 700 mA. The high-voltage machines of 150 kV typically operate at a maximum of approximately 170 mA. The higher-voltage machines produce a greater depth-to-width ratio of the weld nugget, with values up to 50 to 1. The higher-voltage machines can use a longer standoff distance than the low-voltage machines; however, low-voltage machines can employ articulated gun movement for greater weld joint access.

High- and low-voltage equipment is suitable for high- and medium-vacuum operations, while nonvacuum welding is carried out at higher voltages (150 to 200 kV) only. The nonvacuum, high-voltage systems generally are used for welding materials less than 25 mm (1 in.) thick. With low-voltage systems, the gun may be fixed in position on the chamber or may be mobile inside the chamber. With

high-voltage equipment, the gun is generally fixed in position on the chamber.

Figure 4 shows an available high-vacuum internal, movable gun system configuration. The boom arrangement is shown with a chamber size of 3.8 by 3.8 by 2.8 m (150 by 150 by 110 in.). This installation has a movable gun. Low-voltage, high-vacuum systems with movable guns are available with power ratings of 7.5 kW (60 kV, 125 mA) 15 kW (60 kV, 250 mA), 30 kW (60 kV, 500 mA), and 42 kW (60 kV, 700 mA).

Medium-vacuum machines are frequently special-purpose units tooled for particular assemblies. The medium-vacuum mode of EBW was initially employed to increase the production capacity of the process. This mode of application typically involves the use of a chamber custom-designed to provide a minimum of weld-zone volume that has to be evacuated during each part cycle (that is, a chamber envelope that is not much bigger in size than the particular workpiece to be welded plus any fixturing it may require). Recall that only a small volume needs to be evacuated (evacuation times of less than a minute). This, coupled with the fact that EBW-MV is normally performed in an ambient vacuum level of nominally 6.5×10^3 mPa (5×10^{-2} torr), allows for much higher throughput. To capitalize on the shorter processing times, further improvements in throughput may be realized by rapidly transporting parts into or out of the weld area on EBW-MV systems. One of the major applications of EBW-MV and EBW-NV is for automotive applications (Ref 15, 16).

With a smaller footprint becoming more of a necessity in some plants, newer machines are becoming "palletized." An example of a palletized machine is shown in Fig. 5. All of the components of the equipment are available on a movable pallet, such that the system is more of a "plug-and-play" system that can easily be

Fig. 4 Internal, movable gun configuration in a low-voltage, high-vacuum electron beam (EB) welding system with a boom manipulator. The photograph shows different motion configurations. Courtesy of Sciaky, Inc.

installed, leveled, and moved to new locations in a much more rapid fashion.

Large-chamber systems are available in both low- and high-voltage configurations. Figures 6 to 8 show large-chamber systems, and Fig. 9 shows a very large-chamber EBW system.

Computer control systems are currently available in many modern EBW systems, allowing for more complex configurations of components to be processed. Control of welding operations can be expanded to include joint locators, five-axis programmable contouring, and several digitizing provisions that can be actuated on the basis of information generated by the seam locator. Many EBW systems can also be adapted for electron beam heat treating applications.

Finally, most of the EBW system manufacturers will build custom systems to meet the needs of the customer. The equipment variations and configurations are nearly limitless, and, as such, are not covered in detail in this article.

Safety

Protection must be provided by equipment design and arrangement, and by safety precautions in EBW and related operations, against the usual hazards of welding and the special hazards of exposure to the high voltages involved in generating the electron beam, the beam itself (direct viewing of intense radiation emitted by molten weld metal can be harmful to eyesight and thus the beam operation should be viewed only through a filtered lens commonly used for arc welding), and radiation of x-rays produced by impingement of the beam on the work or other materials. From a safety standpoint, an accelerating voltage of less than

20 kV produces soft x-rays, while an accelerating voltage of more than 20 kV produces hard x-rays (Ref 1). Shielding against radiation is more demanding as the acceleration voltage increases. Suitable precautionary measures and safety issues are described and addressed in several documents (Ref 13, 17–19).

Design Considerations for Electron Beam Welding*

Kenn Lachenberg, Sciaky, Inc.

Patrick Hochanadel, Los Alamos National Laboratory

John Elmer, Lawrence Livermore National Laboratory

ELECTRON BEAM WELDING (EBW) can produce deep, narrow, and almost parallel-sided welds with low total heat input and relatively narrow heat-affected zones in a wide variety of common and exotic metals. In many applications, a single pass is sufficient to weld the components. When initially used for industrial applications in the 1950s, EBW had to be performed totally in vacuum. In this form, EBW was primarily used because of its ability to reliably produce very high-quality welds in materials normally considered extremely difficult to join (for example, refractory metals, oxidizable metals, stainless steels, and superalloys). This made it ideally suited for use in aerospace, nuclear, and other similar (high-technology) manufacturing industries.

During the 1960s, the ability to employ the EBW process for medium-vacuum and nonvacuum welding tasks was developed. This increased production capacity helped make EBW more attractive to other businesses, such as the automotive and off-highway equipment industries, desiring to take advantage of the numerous joining benefits it provided. However, the use of EBW in these industries required that the applications be performed in a fairly high-volume production.

EBW is used to join not only difficult-to-weld materials but also common materials such as steel (≤ 150 mm, or 6 in., thick), aluminum (≤ 305 mm, or 12 in., thick), and copper (≤ 100 mm, or 4 in., thick) (Ref 1). These and other metals (in thicknesses ranging from foil to plate dimensions) can be welded by EBW. In addition, EBW can be used to join numerous combinations of dissimilar metals. See the Section "Electron Beam Welding" in this Handbook for a description of EBW systems and equipment.

Weld Geometry

The shape of the parts to be welded and the corresponding joint designs are critical to the successful application of EBW in vacuum or at atmospheric pressures (nonvacuum). Although minimum heat input and low thermal distortions are important advantages of EBW, the molten metal still shrinks as it solidifies. Shrinkage stresses may lead to microcracks if parts, due to design restrictions, are unable to shrink at corresponding rates and the joint volume is completely constrained.

Part Configuration

Whether a component is welded in a vacuum or at atmospheric pressure (nonvacuum), part configuration and the corresponding joint designs used are critical parameters in the successful application of EBW. A circular weld in the axial direction, for example, that joins a disk-shaped member (gear or cup) to a shaft (Fig. 1) may experience severe constraint. Such joints are practical in easily welded metals—those that are soft, have low yield points, and exhibit low shrinkage—but not in difficult-to-weld steels that have high strength and hardenability.

The difficulties encountered in welding shapes such as those shown in Fig. 1 are aggravated if the weld zone is broadened by defocusing the electron beam. This is a frequent problem if exact beam position cannot be controlled, either because of beam instability, magnetism of the parts, or excessive tolerances in tool fixtures.

Shrinkage stresses are better managed in radial welds, as shown in Fig. 2. The volume

Fig. 1 Cutaway view showing location and penetration of a circular electron beam weld joining a disk-shaped component to a shaft

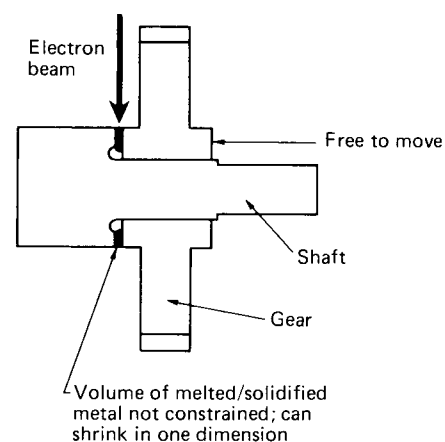

Fig. 2 Shrinkage stress in a radial weld

* Adapted from the article Procedure Development and Practice Considerations for Electron-Beam Welding, *Welding, Brazing, and Soldering*, Vol 6, *ASM Handbook*, ASM International, 1993, p 851-873

of molten metal is less constrained by the axial direction if the gear hub is allowed to move by using push fit and no restraints. The weld must also have root clearances—the weld zone must not extend into the shaft. Stresses are lower if the melt zone has parallel side boundaries. Triangular weld zones that are caused by broadened beams, uneven beam power distribution, or incomplete penetration have more complex stresses that may result in cracking.

The same principles of joint design discussed previously for joints between shafts and unlike members apply equally to T-joints and corner joints between plates. Figure 3 shows recommended and nonrecommended weld configurations. It is important in all welding methods, and essential in EBW (which is usually performed in a single pass), that constraints on the volume of the melt be avoided by self-aligning interlocking steps in the joint. In multilayer arc welds, the individual weld bead is less constrained in volume and shrinks from its surface downward. Functionally, it is not useful to make the cross section of the joint any less thick than the plates that are being joined. If two welds are made in succession, the second weld may be constrained by the first (Fig. 3), which may lead to solidification cracking. It is thus advisable to direct the beam at the joint parallel to the faying surfaces and to cause melting over the whole contact area.

Surface Geometry

Usually, EBW does not use or need filler wire. Therefore, V-grooves or large joint gaps are not required; in fact, too much of a gap could be detrimental to the process. Surface tension pulls some of the molten metal up the V-shaped or large gap surfaces so that it is no longer available to fill the space created by the keyhole that is generated by the moving beam. Voids remain in the actual joint plane (Fig. 4).

A step in the surfaces at the joint line is also undesirable. Any small lateral shift of the beam from the low to the high side, or vice versa, changes the penetration to some extent. In the extreme case, this shift may be equal to the height of the step, as shown in Fig. 5. On circular welds, with joint configurations similar to Fig. 5(a), a noncircular weld profile may develop with irregularities that can lead to uneven applied stresses. By contrast, a mere shift in the melt zone, as shown in Fig. 5(b), does not affect weld quality, as long as the entire joint line is consumed.

Configurations for Wide Welds

The high speed and autogenous nature of an electron beam weld can be advantageous when a wide weld (6.5 to 13 mm, or ¼ to ½ in.) is needed without great depth-to-width ratio. The electron beam can be deflected in a raster pattern and/or defocused to provide a wider beam energy distribution to facilitate a wider weld.

Fig. 3 Optimum versus least desirable weld configurations. (a) Not recommended—maximum confinement of molten metal, minimum joining cross section (arrows); wastes beam energy for melting, nonfunctional metal. (b) Most favorable—volume of melt not confined; maximum joining cross section (arrows). (c) Not recommended—maximum confinement of melt (unless gap is provided); joining cross section less than plate cross section. (d) Most favorable—minimum constraint and confinement of melt; minimum internal stresses; warpage can be offset by bending prior to welding; tilt can be offset by location of T-arm at less than 90° to base prior to welding. Fillet obtained by placing wire in right corner and melting it with the beam. (e) Not recommended—two successive welds; second weld is fully constrained by the first weld and shows strong tendency to crack.

Fig. 4 Gap in joint plane created by surface tension

Fig. 5 Effect of beam and melt zone position on weld penetration. (a) Inclined electron beam. (b) Vertical electron beam

Fig. 6 Edge-flange weld typically used to join thin panels

A wider beam may need to be employed on some edge weld applications, as illustrated by the edge-flange weld in Fig. 6. For edge welds, changes in energy input per unit length and changes in power density affect only the amount of molten metal. Offset and gaps up to the thickness of the sheet to be joined can often be tolerated (Ref 2). In making an edge-flange

weld (Fig. 6), the same advantages exist, provided the flange is high enough. For joining thinner sheet that is tightly clamped, edge welds also can be made with the electron beam in the horizontal position.

The EBW process can tolerate and fill large gaps if sufficient sacrificial metal or wire feed is available to be melted by the beam (Fig. 7). If not, surface tension may pull whatever metal is melted to either side of the weld joint.

Melt-Zone Configuration

Welds with parallel sides are preferred over welds that are more triangular shaped (Fig. 8a). The parallel sided weld (Fig. 8b) shows minimum warpage and only transverse shrinkage when unconstrained. If there are constraints, the hindered warpage and shrinkage can cause internal stresses in the weld area. As a general rule, full penetration EB welds have a tendency to be more parallel than partial penetration welds that have a wider nail head and are tapered at the root.

Joint Design

Procedures which relate to the joint design, the material and its preparation, and the welding tooling are important factors that have a major influence on the weld quality and rate of production obtained. Various joint designs, including butt, corner, T-, lap, and edge joints,

Fig. 7 Use of sacrificial metal to fill a large gap in a square-groove weld

Fig. 8 Variation in beam velocity and subsequent warpage of 0.25 mm (0.10 in.) thick type 304 stainless steel joined by a butt weld. (a) Beam traverse, 7110 mm/min (280 in./min); triangular melt zone. (b) Beam traverse, 4190 mm/min (165 in./min); parallel-sided melt zone. Weld parameters: 12 kW beam power; 11.4 mm (0.45 in.) standoff; helium shielding gas

can be made by the EBW process using square-groove or seam welds. Square-groove welds require fixturing to maintain fit-up and alignment of the joint. They can, however, be self-aligning if a rabbeted joint design is used. Self-alignment is particularly important in batch loading the vacuum chamber for efficient work manipulation. Most joints are designed to be welded in a single pass with full penetration or penetration to a specified depth.

Figures 9 to 13 show the commonly used joint and weld types for EBW. Different joint

preparations, joint designs, and welding positions are used to meet special requirements. For preferred joint configurations and shrinkage stresses encountered in various joint designs, see the section on weld geometry for EBW in this article.

Welds in Butt Joints

Butt joints are the most common of the five basic joint types used in EBW. The basic square-groove weld, which is shown in Fig. 9(a) to (c),

Fig. 9 Types of butt joints and welds typically generated by electron beam welding

Fig. 10 Types of corner joints and welds typically obtained with electron beam welding

Fig. 11 Typical welds produced by electron beam welding of T-joints

needs only the simplest and least expensive joint preparation. It is suitable for either partial- or full-penetration welds. Good fit-up and external fixtures are needed. The flush joint (Fig. 9b) is preferred to the stepped joint (Fig. 9c) for joining unequal thicknesses, chiefly because control of conditions for making sound full-penetration welds is less critical than for the stepped joint. A wider beam is used in welding the stepped joint, and the beam angle must be carefully controlled to avoid scarfing the upper edge of the thicker member (angle too small) or missing the bottom of the joint (angle too large), especially if the thinner member is more than approximately 9.5 mm (3/8 in.) thick.

In Fig. 9(d), the joint is rabbeted to make it self-aligning, but the offset is small to avoid leaving an unwelded seam near the root of the weld (compare to Fig. 9e). In Fig. 9(d) to (g), the joints are self-aligning and may be self-fixturing in circular, circumferential, and certain other joint arrangements. In Fig. 9(e) and (f), the joints are both self-aligning and self-backing; each, however, leaves an unwelded seam near the root of the weld. Ideally, a slight gap should be incorporated at the nonwelded step portion at the joint shown in Fig. 9(f) to allow for weld shrinkage.

In Fig. 9(g) and (h), two ways are shown of providing integral and filler metal. The lip of the joint in Fig. 9(g) provides more filler metal than the shoulder of the joint in Fig. 9(h), but because it conceals the joint, a scribed line or other means for beam placement and for scanning must be provided before the welding operation can proceed.

The slant-groove weld (also called angular or scarf) shown in Fig. 9(j) is used in butt joints to facilitate fixturing. It is also used where limitations on the beam location prevent fusion for

the entire groove depth if the basic square-groove weld (Fig. 9a) were used. Greater weld depth, as measured parallel to the beam axis, is needed for full penetration of a given metal thickness than with the square-groove weld. This type of weld and variations of it are used both in butt joints and in corner joints.

A slant-but joint can also be welded with beam alignment set at 90° to the surface of the work. This beam angle permits the production of defect-free welds where fit-up is poor or where the joint opening is larger than can be tolerated when the beam is aligned with the groove. In a related type of weld, the joint has a square-groove preparation, and the beam is at an angle to the groove. This type of weld is used mainly under circumstances in which other types of welds would be hard to access.

Welds in Corner Joints

Eight types of electron beam welds frequently made in corner joints are shown in Fig. 10. Corner joints are second only to butt joints in frequency of use with EBW. Important differences between butt and corner joints are notch sensitivity and suitability for nondestructive testing. To compare alignment, self-fixturing, and the occurrence of portions of unwelded seam, see Fig. 9 and 10.

Fig. 12 Typical welds obtained by electron beam welding of lap joints

The two simplest and most economical welds in corner joints are the melt-through (Fig. 10a) and basic square-groove (Fig. 10b) welds. Neither is self-aligning or self-fixturing; manipulation of the work for the weld in Fig. 10(b) can be simplified by using a horizontal electron beam and corresponding work orientation (rotated 90° from the orientation shown). The melt-through weld (Fig. 10a), unless made with a fusion zone wide enough to eliminate the unwelded seam completely, is weaker than the square-groove weld and is notch sensitive. The corner-flange weld (Fig. 10h), usually made only on thin stock, requires precision forming of the 90° bend. Welds in corner joints are subject to high stress concentrations.

A corner joint weld and heat-affected zone (HAZ) of the electron beam process are compared with those of gas tungsten arc welding (GTAW) in Fig. 14. The joint designs differ between the two processes. For GTAW, multiple weld passes are required to fill the open-corner V-groove. For EBW, only a single weld pass may be required. However, because of

Fig. 13 Typical welds generated by electron beam welding of edge joints having components of equal and unequal section thicknesses

Joint type	Corner	Welding power:		Beam oscillation	None
Weld type	Square groove	Penetration pass	30 kV at 170 mA	Welding position	Flat
Machine capacity	30 kV at 500 mA	Cosmetic pass	19 kV at 95 mA	Welding speed:	
Vacuum chamber size	2845 × 760 × 1575 mm (112 × 30 × 62 in.)	Welding vacuum	1.3 mPa (10 ⁻⁵ torr)	Penetration pass	1525 mm/min (60 in./min)
Maximum vacuum	13 μPa (10 ⁻⁷ torr)	Pumpdown time	10 min	Cosmetic pass	815 mm/min (32 in./min)
Fixtures	Assembly jig; travel carriage	Beam focal point, penetration pass	At surface	Preheat and postheat	None

Fig. 14 Schematic of cross sections through corner joints and welds to show variation in the size of welds and heat-affected zone that are obtained with electron beam welding and gas tungsten arc welding

occasional undercutting, a second (cosmetic) pass may be used. Even when the second pass is used, the weld and the HAZ are much narrower than those created by arc welding. The effect of the cosmetic pass on the weld cross section is shown in Fig. 14; the machine settings for the defocused beam used to make the cosmetic pass are in the table with Fig. 14.

Welds in T-Joints

Three types of electron beam welds made in T-joints are shown in Fig. 11. The melt-through or blind weld (Fig. 11a), like melt-through welds in butt or corner joints, leaves an unwelded seam with resulting low strength, notch sensitivity, and corrosion susceptibility. Figure 11(b) shows another method for T-joint welding that may be best suited for thinner sections so that the entire joint is consumed with the weld. A joint clearance area may be employed, as shown in Fig. 15, to allow more unobstructed access to the T-joint area. The double-square-groove weld (Fig. 11c) is used primarily on sections 25 mm (1 in.) or more thick. For welds similar to Fig. 11(b) and (c), filler metal can be added.

Welds in Lap and Edge Joints

Three types of electron beam lap joint welds are shown in Fig. 12. An example of an EBW melt-through lap joint is illustrated on the rupture-disk assembly shown in Fig. 16. For this assembly, leak-tightness rather than high tensile strength is the objective. Originally, the components were joined in one pass by GTAW, using the design illustrated in the upper right corner of Fig. 16. A circular groove was cut in the nozzle wall to help localize the weld bead, which was made without filler metal. Light pressure was applied at both ends of the assembly to hold the parts in alignment for welding. However, the GTAW weld procedure resulted

in numerous rejects because of leaks due to excessive heat and disk burnback. To eliminate these difficulties, the operation was converted to EBW. Each assembly was fitted into a cylindrical receptacle or pot that was equipped with a hold-down ring that forced the periphery of the disks and caps into close alignment, as shown by the improved method of Fig. 16. A melt-through or lap weld was made, rather than an edge-flange weld at the periphery.

Three types of electron beam welds made in edge joints are shown in Fig. 13. Thick sections can be joined by deep, narrow square-groove welds (Fig. 13a). Shallow welds made with a low-power, partially defocused beam are used to join thin sections to each other or to thick sections, as shown in Fig. 13(b) and (c). Shallow edge welds can be made at high speed. Welds of this type are particularly useful on hermetically sealed assemblies, which may be designed for planned salvage by removal of the weld region and subsequent rewelding.

Butt Joints versus Corner and T-Joints

The concentration of bending stresses at the weld in corner and T-joints is sometimes

avoided by designing the work for a butt joint on a straight section near the corner or T (flange neck or welding neck construction). This principle of design is applicable also to butt joints between members having different thicknesses, and it can be applied to straight line, circular, and circumferential joints.

In welding such a joint in magnetic metals, if the beam path is too close to the corner, T, or shoulder, the beam may be deflected away from the metal that it passes near on its way to the joint, causing it to enter the work at an angle and possibly to miss the lower portion of the joint. To avoid this problem, the beam clearance should be 0.8 mm (0.030 in.) or more, depending on the height of the magnetic projection (Fig. 15).

Special Joints and Welds

Many variations of the basic joint and weld types described in the preceding section and illustrated in Fig. 9 through 16 are used to meet the needs of individual applications. Some of these special joints and welds are discussed as follows.

Fig. 15 Joint location and beam clearance for an electron beam welded butt joint near a projecting corner, T, or shoulder consisting of magnetic work metal

Joint type	Circular, three-piece corner	Welding vacuum	0.65 mPa (5×10^{-6} torr)
Weld type	Melt-through (spike)	Pumpdown time	10 min
Machine capacity	50 kV at 250 mA	Working distance	38 mm (1.5 in.)
Gun type	Diode; fixed during welding	Beam focal point	Sharp at work surface
Vacuum chamber	Steel: 1370 × 1220 × 1220 mm (54 × 48 × 48 in.) with full-width end doors	Beam spot size	~0.51 mm (~0.020 in.) diam
Fixtures	56-piece holding tool with individual rotation; table with x-y motion	Welding speed	2540 mm/min (100 in./min)
Welding power	26 kV at 16 mA	Number of passes	One, plus 30° downslope
		Setup time	48 min
		Production rate	44½ pieces/h

Fig. 16 Comparison of electron beam and gas tungsten arc welds applied to a type 304 stainless steel rupture disk assembly

Plug and Puddle Welds

Plug and puddle welds are usually made by manually (or automatically) manipulating the work under a fixed beam at low power. Filler metal used for plug welds is often preplaced at the weld site. Puddle welding is used mainly to fuse shallow defects together locally.

Multiple-Pass Welds

Most electron beam welds produce the desired penetration in a single pass. Tack welds and cosmetic or smoothing passes are not considered penetration passes. Welds several inches deep can be made in most metals in a single pass. Weld depth obtainable in a single pass can be nearly doubled by welding from both the face and the back of the work.

In a variation on straight-through two-pass welding from opposite sides, separate welds that meet or almost meet can be made at an angle of 90° to each other in a rabbeted square-groove joint.

Tangent-Tube Welds

Tangent-tube welds are longitudinal welds joining two parallel tangent tubes (or cylinders). The tubes may differ in size; the beam is perpendicular, or nearly so, to the common axial plane of the two tubes. Added filler metal may be used for reinforcement. Thinner-walled tubes can be joined more easily by EBW than by arc welding methods.

Three-Piece Welds

Welds can be made that join three or more pieces in which there is penetration in a single pass into all of the pieces. Many of the difficulties encountered in welding very thin metal or foil are eliminated by sandwiching it between two thicker sections.

Multiple-Tier Welds

Multiple-tier welds are welds made simultaneously in in-line, separated joints (usually butt joints) in a single pass of the electron beam. A more detailed discussion is given in the section of this article on multiple-tier welding.

Welds Using Integral Filler Metal

Welds using integral filler metal may be of the types shown in Fig. 9(g) and (h), in which an overhanging lip or a shoulder provides filler metal to a butt joint, or both members may be made thicker at the joint than elsewhere.

EBW in Vacuum

Most EBW is done in a vacuum environment where the maximum ambient pressure is less than 0.13 Pa (1×10^{-3} torr). Maintenance of this degree of vacuum is important because of the effect that ambient pressure has on both the beam and the weld produced. High-precision applications that require welding to be done in a high-purity environment to avoid contamination by oxygen or nitrogen are ideally suited for high-vacuum EBW (EBW-HV).

Electron beam welding in a medium vacuum (EBW-MV) is usually performed at a welding (work) chamber pressure of approximately 10 Pa (7.5×10^{-2} torr), or at a work chamber pressure ranging from 0.4 to 40 Pa (3×10^{-3} to 3×10^{-1} torr)—the total partial-vacuum region. The gun chamber, where the beam is generated, is held at 1.3 to 13 mPa (10^{-5} to 10^{-4} torr), as in high-vacuum welding. The chief advantage of welding in medium vacuum, compared with welding in high vacuum, is the short pumpdown time for the welding chamber; however, this benefit comes at the cost of a welding environment that is less pure.

In nonvacuum EBW (EBW-NV), where the ambient pressure is 10 MPa (760 torr) and above, the scattering dispersion of the beam increases so that the working distance and penetration are reduced significantly below values obtained in either high- or medium-vacuum processes. Electron beam dispersion characteristics and their effect on weld penetration at various pressures are shown in Fig. 17.

High-Vacuum Design Considerations

The high vacuum minimizes contamination of the molten weld zone by oxygen or other gas elements. Therefore, high-vacuum welding is best suited for metals that are reactive or refractory in nature, such as zirconium and titanium. Typical products include nuclear fuel elements, pressure vessels for rocket propulsion systems, special alloy jet engine components, and hermetically sealed vacuum devices. High depth-to-width weld ratios can be best achieved in high-vacuum conditions, thereby minimizing weld shrinkage and distortion.

Effect of Pressure on Beam. Under ambient high-vacuum conditions, the frequency of collisions between beam electrons and residual gas molecules is extremely low, and any dispersion (i.e., beam-broadening effect) that would result from such scattering collisions is minimal. However, because the frequency of scattering collisions increases with the density of gas molecules present, this effect becomes greater as the surrounding environment pressure is increased. Only at ambient pressure values below 0.13 Pa (1×10^{-3} torr) is the effect of scattering insignificant enough that the beam

can be held in sharp focus over distances of several feet (depending on the particular characteristics of the electron gun and electron optics being employed) to achieve maximum effectiveness in producing relatively deep, narrow welds.

The presence of a high vacuum in the work chamber protects the weld metal and the HAZ from oxidation and contamination by harmful gases, serving the same function as inert shielding gases in arc welding, while also degassing the weld. The nearly complete absence of gaseous impurities eliminates the serious contamination difficulties that are usually encountered when attempting to arc weld relative metals such as titanium and zirconium. The contamination of air (total concentration of gases present) is proportional to pressure, as shown in Table 1.

Width of Weld and Heat-Affected Zone.

Electron beam welds made in a high vacuum are narrower and have a narrower HAZ than comparable welds made in medium vacuum or at atmospheric pressure, and they are much narrower than the narrowest welds made in production welding by GTAW. The narrow width of the HAZ in hardenable steels and other hardenable alloys permits welding of these metals after heat treatment, in many instances without loss of strength.

Medium-Vacuum Design Considerations

The primary advantage to welding in a medium-vacuum environment is the reduced time for pumping the work chamber as compared to welding at high vacuum. The gun chamber, where the beam is generated, is held at 1.3 to 13 mPa (10^{-5} to 10^{-4} torr), as in high-vacuum welding. A diffusion or turbomolecular pump is required to provide this gun chamber vacuum; however, only a mechanical-type pump is required to evacuate the work chamber to the final partial-vacuum welding pressure desired, which typically ranges from 0.4 to 40 Pa (3×10^{-3} to 3×10^{-1} torr). The work chamber evacuation time ordinarily does not exceed 40 s for a general-purpose chamber (of approximately 0.11 m³, or 4 ft³). Accordingly, EBW-MV permits mass production of parts, using a chamber of minimum volume. Production rates for welding in medium vacuum depend on part design and other factors; maximum production rate is typically approximately 60 pieces per hour for general-purpose, manually operated equipment, and upwards of 600 pieces per hour for specially tooled automatic machines.

Effect of Pressure on Beam. Medium-vacuum welding is done at pressures with a considerable amount of residual gas molecules, as compared to high-vacuum conditions. The greater concentration of gas (approximately 100 parts per million) increases the collisions between the air and the beam of electrons,

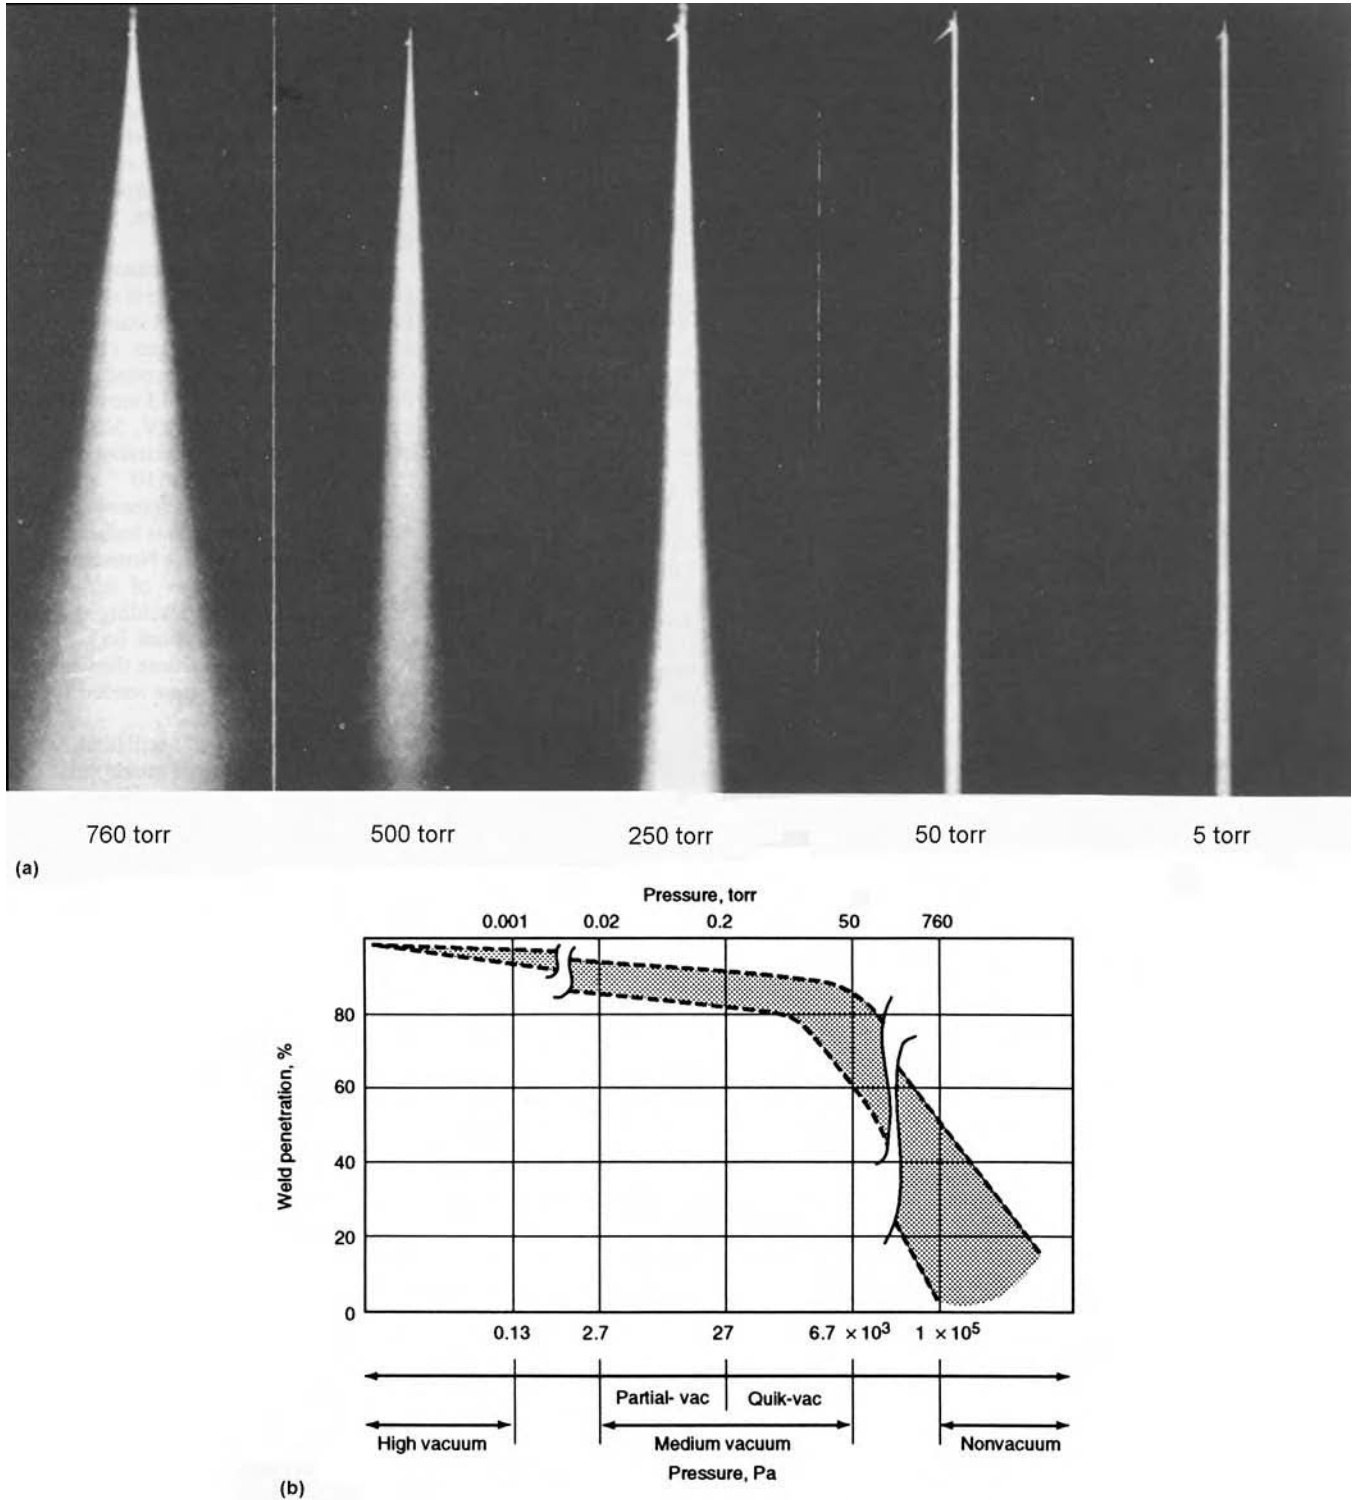

Fig. 17 Effect of pressure on beam intensity and resulting weld quality. (a) Dispersion patterns of electron beam at selected pressures. (b) Weld penetration as a function of ambient pressure level. Additional parameters, such as beam voltage, beam travel distance, and type of ambient gas used, can produce a wide range of values, thus accounting for the spread in the penetration data.

which results in a beam-broadening effect. This increases the beam diameter and decreases the power density, which results in welds that are generally greater in width and less in penetration

as compared to high-vacuum welds. Beam scattering from collisions with residual gas molecules begins to occur at ambient pressures above 0.13 Pa (1×10^{-3} torr). This scattering

effect reduces the maximum working distance that can be employed at these pressures for producing a similar electron beam weld to that obtained under high-vacuum conditions.

Width of Weld and Heat-Affected Zone. Electron beam welds made in a medium vacuum are wider and have a wider HAZ than comparable welds made in high-vacuum conditions. However, the medium-vacuum welds are still narrower than the narrowest welds made in production welding by GTAW. The effect of welding chamber pressure on penetration and weld shape is shown in Fig. 18 for welds made on type 304 stainless steel, using a beam length of 405 mm (16 in.) without changing focus. Maximum penetration, shown in Fig. 18, is approximately 13 mm (½ in.). Welding conditions are 150 kV, 30 mA, and 1525 mm/min (60 in./min). Penetration drops off rapidly at pressures of 13 Pa (10⁻¹ torr) or more at this beam length and at somewhat lower pressures when the beam path is longer.

General Vacuum Limitations

A major limitation in the use of high vacuum in the work chamber is the effect on unit production time, because of the need to pump the chamber down before each load is welded. Pumpdown time is typically approximately 3 min for a 0.85 m³ (30 ft³) chamber and 10 min for an 8.5 m³ (300 ft³) chamber. These pumpdown times are realistic only for a very clean and well-maintained system. In production, pumpdown may be nearly double the aforementioned times. The effect of this limitation on unit production time is reduced by welding a number of assemblies in each load and by keeping chamber size as small as possible. Small chambers specially designed for use with small workpieces have typical pumpdown times of 1 min (3.69 × 10⁶ mm³, or 225 in.³, chamber) and, in some cases, 15 s or less (1.0 × 10⁶ mm³, or 60 in.³, chamber).

A second major limitation in the use of high vacuum is that work size is limited by chamber dimensions. This limitation is sometimes circumvented by the use of a chamber bolt on threshold that facilitates special openings, and seals that permit oversize work to extend within a portable clamp-on extension chamber.

Vacuum Welding Conditions

Welding in high vacuum is done with low-voltage as well as high-voltage equipment. Beam voltage ranges from 15 to 185 kV; beam current, 2 to 1000 mA; and welding speed, 100 to 5000 mm/min (4 to 200 in./min) for most applications. However, higher welding speeds are typically used for

Table 1 Proportionality of weld pressure to contamination level in a vacuum chamber

Pressure		Gases, ppm
Pa	torr	
0.0013	10 ⁻⁵	0.01
0.13	10 ⁻³	1.3
13	10 ⁻¹	132
50	4 × 10 ⁻¹	500

special thin-section applications. The energy input to the work needed to produce a weld of the required depth of penetration and width is the basis for selecting the welding conditions.

Depth of penetration is increased by increasing the voltage or current for greater beam power, or by decreasing the welding speed. Table 2 lists approximate energy inputs per inch of weld length for making narrow single-pass electron beam welds 6.4 to 75 mm (0.25 to 3 in.) deep in the weldable alloys of copper, iron, nickel, aluminum, and magnesium. These values are intended to serve as guidelines for establishing conditions for welding work for which no previous experience is available. Energy-input requirements for specific applications depend on the alloy composition and special operating conditions, such as the use of beam oscillation or a defocused beam.

EBW in Nonvacuum

Unlike high- and medium-vacuum welding, EBW in nonvacuum can offer greater work-envelope capability. Welding at atmosphere may not include the limitations on work size that are imposed by the need to enclose the work in a vacuum chamber and the time needed for the chamber to pump down.

Explanation

In EBW-NV (workpiece out-of-vacuum), which is also referred to as atmospheric EBW,

the work to be welded is not enclosed in a vacuum chamber. Instead, it is welded at atmospheric pressure. A radiation-tight enclosure or chamber, similar to that used in high- or medium-vacuum EBW, surrounds the weld area. A vacuum, however, is not provided in this welding enclosure. A nonvacuum electron beam is generated at high vacuum in the same manner as in high- and medium-vacuum welding. It is focused down through a series of individually pumped stages, each connected to the other by concentrically aligned orifices, decreasing in diameter in the direction of increasing pressure; this differential pumping scheme provides the high vacuum (gun region) to atmospheric (workpiece region) pressure gradient necessary to allow the beam to pass down through the column and exit into the ambient atmosphere.

Operating Conditions

Conditions for nonvacuum welding differ substantially from those for welding in high or medium vacuum. Because beam dispersion increases in proportion to pressure and distance traveled, at pressures above the high-vacuum level, the nonvacuum beam becomes dispersed at relatively short travel distances.

To provide an electron beam of sufficient energy to minimize the scattering effect of collisions with residual gas molecules within the electron beam transfer column (i.e., the differentially

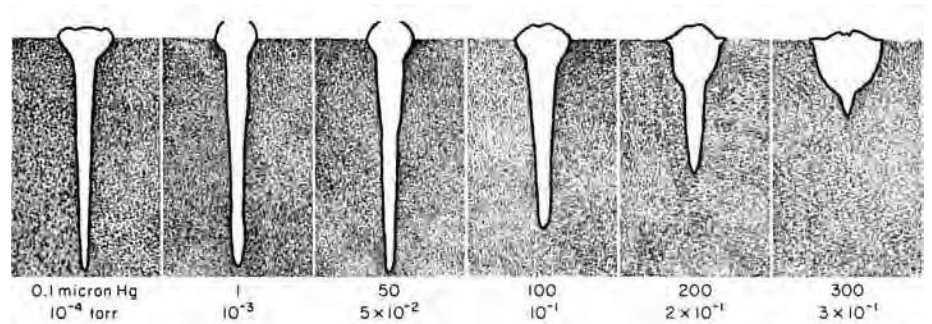

Fig. 18 Effect of welding-chamber pressure on penetration and weld shape for type 304 austenitic stainless steel

(a) Values are approximate and apply to the commonly welded alloys of the metals. They are intended to serve as starting points for establishing conditions for making narrow welds. Energy input may vary substantially from these values in specific applications, depending on the composition of the alloy and special operating conditions. Energy input at weld = [(beam voltage) (beam current) 0.6]/welding speed, where energy input is in kJ/in.; beam voltage is in kV; beam current is in mA; and welding speed is in in./min.

pumped gun/column assembly), the applied gun voltage is held at a constant high value (typically from 150 to 200 kV). This also helps extend the work distance of the beam after it has exited the column and entered the ambient atmosphere. The practical working distance (standoff distance) for nonvacuum welding, as measured from the bottom of the final exit orifice to the top of the workpiece, ranges from 13 to 50 mm ($\frac{1}{2}$ to 2 in.), although some nonvacuum welding is performed at both shorter and longer standoff distances. With voltage held constant, beam current, working distance, and welding speed are selected to provide the required penetration and weld shape for a sound weld. Because it is usually desirable to keep working distance as short as possible and welding speed high, beam current is the primary control variable in nonvacuum welding.

The small size of the exit orifice on the electron gun makes it necessary to focus the beam at or very close to the exit orifice. Accordingly, it is not possible to vary weld characteristics to a significant degree by changing focus. Similarly, beam deflection and oscillation are not possible. The absence of these adjustment capabilities in nonvacuum welding may be a handicap, depending on material and weld-quality requirements.

The limitation on workpiece shape imposed by the need for a short working distance can be overcome to some degree by the use of electron gun nozzles specially designed to extend into restricted spaces. Filler metal is not ordinarily used except where necessary for weld reinforcement to produce the desired weld properties or to avoid cracking.

A stream of dry filtered air, or an inert shielding gas such as argon or helium, is passed across the weld region in the space between the work and the electron gun, or may be supplied through a special insert nozzle assembly that is part of the exit orifice and is designed to minimize entrance of welding vapors and other contaminants into the gun. Auxiliary inert-gas shielding is supplied where needed for complete protection of the molten weld metal and the HAZ from gaseous contaminants. Welds are sometimes made on carbon and alloy steel and other readily weldable metals without using shielding gas. However, shielding gas is often used, and helium is the preferred gas. Weld shape can be changed by varying the flow of helium.

Weld Shape, Penetration, and Heat Input

Nonvacuum electron beam welds are generally wider and more tapered than high-vacuum welds (medium-vacuum welds differ only slightly in shape from high-vacuum welds). EBW-NV is seldom deeper than 9.5 mm ($\frac{3}{8}$ in.). Welds having penetrations greater than 25 mm (1 in.) are not common and would require a significant reduction in welding speed and use of a helium shield to improve power density. Studies

made of nonvacuum welding of steel pipe showed that, at speeds of 2.5 to 25 m/min (100 to 1000 in./min), full-penetration welds could be made in metal twice as thick if helium shielding gas was used instead of air. Table 3 gives the results of this comparison in terms of welding speed for joining steel pipe 1.3 to 3.8 mm (0.050 to 0.150 in.) thick in air or in helium. Welding speeds were 2.16 to 2.24 times greater in helium as in air. Beam power used was 12 kW. Weld shrinkage across nonvacuum electron beam welds is generally less than half that of gas tungsten arc welds on the same work metal and thickness and is typically approximately twice that for high-vacuum electron beam welds.

Tooling

Tooling in nonvacuum electron beam welding is generally designed specifically for welding a particular assembly in mass production. Providing fixtures and equipment that permit welding at high speeds and efficient work handling is the key to obtaining high production rates and low cost. The work-handling equipment is at atmospheric pressure instead of in a

vacuum; hence, general-purpose welding positioners and related fixtures are usually satisfactory. Hold-down clamping devices can be simpler than those often needed for arc welding similar parts, because angular distortion or dihedral warpage is generally low. Locating and alignment mechanisms are simpler than for welding in a vacuum, because of their accessibility and because beams are wider and lower accuracy is required in tracking the joint.

Applications

Nonvacuum EBW is typically used in high-volume production of industrial components where the size or production rate precludes the need to weld in a vacuum environment. The applications include the production of transmission-train components, steering column jackets, die-cast aluminum intake manifolds, and catalytic converters. In addition, several appliance (and other consumer-related) items may also be produced using the EBW-NV process. Figure 19 shows a catalytic converter that was nonvacuum electron beam welded with the beam in a horizontal position.

Table 3 Speeds for nonvacuum full-penetration welding of carbon and low-alloy steel pipe at a beam power of 12 kW

Wall thickness		Welding speeds				Relative welding speed in helium(a)
		In air		In helium		
mm	in.	m/min	in./min	m/min	in./min	
1.27	0.050	10.6	417	22.9	900	2.16
2.03	0.80	6.12	241	13.4	528	2.20

Tooling/Fixturing

Because EBW is typically used in high-precision joining applications, special attention should be given to the tooling fixtures employed to grip or fasten the piece/part(s) to the work platen or manipulator. These considerations include the selection of the tooling material, the precision of the fixturing, and the reliability of the hardware. Furthermore, the design of tooling fixtures must take into account part distortion, part specifications, welding parameters, and the vacuum environment. Because EBW tooling may be used in a vacuum environment, tooling materials that outgas under vacuum conditions should be avoided. Also, when under vacuum, tight cavities or blind holes in the part fixturing may present a virtual leak condition that could add more time than desirable to pump down the weld chamber. Therefore, in tooling designs, unnecessary cavities should be avoided or properly vented.

Design for Heat-Input Control

Due to the high energy input of EBW that can serve to fuse metals with extreme melting temperatures, the tooling may need to be designed to withstand excessive heat buildup. To address this, heat sinks or chill bars may be employed as part of the tooling to better control the heat effects. Also to address the high heat input, refractory metal tooling may be used on the part contact surfaces. However, as a general rule, to avoid backspatter contamination in the welds, tooling is often made from the same material as the workpiece. Heat buildup can also cause excessive outgassing and distortion in the fixturing, which may impact joint alignment and weld repeatability.

Design for Weld Repeatability

Materials used for electron beam tooling should not induce magnetic fields in the weld region. Magnetic fields near the weld can cause the beam to deflect and not fully consume or altogether miss the weld joint. Ferritic steels used in electron beam tooling should be degaussed and the residual magnetism monitored. To minimize the development of electrostatic fields in the weld region (which can also influence beam positioning), avoid electrically insulating the tooling from the weldment to better facilitate a common electrical ground path.

Avoid the use of nonmetallics (ceramics, plastics, etc.) in tooling, and provide sufficient lateral pressure to minimize gapping during welding. When making girth welds on light-gage material, spring loading may be incorporated to allow for follow-up pressure. Maximum support and clamping close to the weld joint should be considered when welding sheet metal or light-gage material. Assuming that the tooling has the appropriate clamping

force and it does not present any stray movement of the electron beam, control system joint-tracking improvements over the years have paved the way for relaxing some of the precision requirements for part tooling.

Welding of Thin Metal

Electron beam welding can be advantageous for joints in which at least one member is made of thin metal. Applications include instrument parts, instrument enclosures, pressure or hermetic seals, diaphragms, encapsulations, electrical connectors, and electronic devices, of various metals. Even with the aid of the heat-sink capacity, heat input by arc welding often cannot be localized sufficiently and controlled closely enough to avoid damage to metal foil thickness. In some applications, using EBW instead of gas metal arc welding can eliminate excessive melting in thin materials.

Explanation and Ranges

Thin material (<2.4 mm, or $\frac{3}{16}$ in., and as thin as 0.025 mm, or 0.001 in.) can be successfully welded with EBW so long as proper parameters and part fit-up are incorporated. The joint area must be heated to melting temperatures in joining thin sections, just as in joining thick sections, but the rate of heat transfer away from the joint is much lower because of the reduced cross section. Hence, local heat buildup is greater, which increases weld width and decreases depth-to-width ratio. In addition, minimum beam spot size has a much greater effect on depth-to-width ratio in joining thin metal than in joining thick metal. The minimum usable beam spot size obtainable generally ranges from approximately 0.13 to 0.51 mm (0.005 to 0.020 in.) in diameter. Because of these conditions, depth-to-width ratio for full-penetration welds joining two sections thinner than approximately 2.4 mm ($\frac{3}{16}$ in.) usually does not exceed approximately 5 to 1 and may be less than 1 to 1.

When voltage, current, welding speed, and other variables have been optimized for a specific joint, use of a heat sink may still be necessary to avoid overheating thin material, depending on the base-metal properties (melting point, specific heat, and thermal conductivity) and metal thickness. Best results usually are obtained by the use of copper chill blocks machined to fit the workpiece closely at the joint area. Fixtures made of other metals may be effective as chill blocks if the contact area is sufficiently large and close to the heat source. Also, the joint gap for thinner parts becomes critical; typically, the thinner the material, the tighter the joint gap. As a general rule for thin materials, the fit-up should be as tight as possible and should never exceed 0.13 mm (0.005 in.).

Joining Thin Sections to Thick Sections

In joining thin sections to thick sections by EBW, the joint is usually designed so that the thick member serves as a heat sink for the thin member, and the point of beam impingement is slightly removed from the thin metal. When these precautions are taken, welding behavior and heat dissipation are generally the same as in welding thick sections under similar conditions. Depth of penetration in the thicker section is usually made only slightly greater than the thickness of the thin section.

Partial-Penetration Welds

The precise control of heat input obtainable in EBW permits partial-penetration welds having uniform depth to be made in metals as thin as or thinner than 0.25 mm (0.010 in.). Work-metal thickness must be uniform, and workpiece fixture arrangement and dimensions must be selected to provide a constant rate of heat loss adjacent to the path of the weld along its entire length, with special provisions made for weld starting and stopping. Beam power, focus, and workpiece travel speed must be closely regulated to minimize variation in penetration.

For the closest control of penetration, both beam power and focus can be regulated by sensitive, fast-response closed-loop servomechanisms or feedback controllers. Also, workpiece travel speed can be held within extremely narrow limits by precision, mechanical worktable, gun linear, or rotary-motion systems. To compensate automatically for the effect of any variation in voltage on focus, the control system regulating the beam focus can be coupled to the high- (accelerating) voltage supply to facilitate a rapid response time (typically less than 17 μ s).

Partial-penetration welds in thin metal are not subject to root voids, root porosity, or cold shuts, which are flaws frequently encountered in partial-penetration welds in thick metal, because such welds in thin metal have relatively low depth-to-width ratios and a wide-angle V-shape with a gently radiused bottom. Data on the relation of depth to width for high-vacuum partial-penetration welds in thin sections are given in Table 4. The ratio of depth to width is lower for the welds in the thinner sections. Penetration is from 50 to 85% of the work-metal thickness, and all welds are made with chill bars in intimate contact with the underside of the work at the weld location.

Depth of penetration generally varies 10 to 15% from a mean value for a work thickness of approximately 0.51 mm (0.020 in.), and the percentage variation is greater for welds in thinner metal. Accordingly, partial-penetration welds are not ordinarily made in metal of approximately 0.25 mm (0.010 in.) thickness.

Beam oscillation is sometimes used to smooth out variations in penetration, but such oscillation must be controlled closely to be effective.

EBW of Thick Metal

One of the major principal advantages of EBW is the capability to weld thick metals, including those with refractory and reactive material properties. Typically, EBW penetrations are considered thick as the weld depth approaches 25 mm (1.0 in.) or greater. For joining thick sections, EBW in a vacuum has a number of advantages over other welding processes. As in any welding process, the depth of penetration for a given output power level is dependent on the material type (melting temperature, density, etc.). However, because the majority of deep-penetration EBW is carried out in a vacuum environment, the vacuum level can also play a part in the obtainable weld depth.

Advantages/Disadvantages

For joining thick sections, EBW in a vacuum has three principal advantages over other welding processes:

- Much deeper penetration can be obtained in a single pass. Extremely narrow, only slightly tapered welds and a small HAZ can be produced.
- For joints on most weldable metals, no filler metal is needed. Where a filler metal is required, the quantity is usually very small.
- Joints have closely fitted parallel groove faces requiring no edge preparation, instead of V- or U-grooves.

Deep welds made in a vacuum are usually narrow; weld width for penetration deeper than 6.4 mm (¼ in.) is typically approximately ⅓ to ⅒ of the section thickness, except for a somewhat greater width at the crown of the weld. Welds may be either full or partial penetration. The disadvantages of EBW for joining thick metal may include equipment cost, size limitations imposed by the dimensions of the vacuum chamber in which the work must be placed, and the time needed for evacuating the chamber.

Effects of Pressure

Penetration capability is greatest for EBW-HV. The effect that welding pressure has on penetration of steel is shown in Table 5. A constant weld speed of 890 mm/min (35 in./min) and beam power of 7.5 kW from 150 kV/50 mA for high and medium vacuum, and 175 kV/43 mA for nonvacuum were used to obtain the data in Table 5.

Table 4 Relation of depth to width (*D/W*) for partial-penetration electron beam welds of thin sections in a high vacuum

Work metal(a)	Weld dimensions(a)						<i>D/W</i> for weld
	Thickness,		Depth, <i>D</i>		Width, <i>W</i> (b)		
	mm	in.	mm	in.	mm	in.	
Aluminum alloys							
6061-T6	0.13	0.005	0.008	0.003	0.38	0.015	0.2

	0.51	0.020	0.43	0.017	0.38	0.015	1.1
Stainless steels							
17-4 PH	0.13	0.005	0.10	0.004	0.36	0.014	0.3
Type 301	0.25	0.010	0.15	0.006	0.28	0.011	0.5

(a) Chill tooling was in intimate contact with the underside of the work at the weld location. (b) Width of the weld at the crown, which was the greatest width for the gently radiused, wide-angle V-shaped welds

Table 5 Typical pressure and beam travel distance specifications required to obtain maximum weld penetration of steel(a)

Type of system	Ambient workpiece pressure		Beam travel distance		Maximum penetration	
	Pa	torr	mm	in.	mm	in.
High vacuum	0.013	1×10^{-4}	455	18	25	1
Medium vacuum	130	1	205	8	16	⅝
Nonvacuum	1.0×10^5	760	13	½	4.0	⅝ ₂

For 7.5 kW welds moving at 890 mm/min

Full-Penetration Welds

In welding carbon steel, single-pass, full-penetration, vacuum (high/medium) electron beam welds are made commercially in thicknesses up to approximately 100 mm (4 in.); production EBW-HV has been done on aluminum alloy plates 150 mm (6 in.) thick, and 230 mm (9 in.) thick aluminum alloy sections have been welded experimentally under near-optimum conditions.

Two-Pass Full-Penetration Welding

Penetration can be nearly doubled by making two passes, one on each side of the work, but cold shuts, voids, and porosity are encountered at the root of the second weld unless conditions are adjusted for the pass made on the second, or back, side. A broader second-side weld with a larger radius at the root helps to reduce the incidence and severity of these flaws.

Partial-Penetration Welding

Welds that do not penetrate completely through the work metal are satisfactory in many applications in welding thick metal; joint design and product requirements often rule out full penetration.

Effects of Gun Orientation (Vertical/Horizontal)

There are a number of EBW applications that, based on the geometry of the component and/or the working envelope of the vacuum chamber,

require the EBW gun to be in either the horizontal or the vertical position. Changing the gun orientation from vertical to horizontal and back can be done either through programmed control of a gun tilt mechanism (typically with internal moving gun systems) or by remounting the gun to another chamber port location (typically with external gun systems). However, with deep-penetration welding, the gun orientation may also play a part in minimizing weld defects such as porosity, cold shuts, or spiking.

Vapor pressure of the elements in the materials being welded, plays an important role in maintaining a weld-cavity keyhole EBW. However, a very important additional force tending to close the cavity is due to the surface tension. During heavy-penetration welding, the cavity is assumed to resemble a deep and narrow depression with liquid walls, and the force of gravity acting on the liquid metal in the keyhole may not overcome the surface tension forces when welding in the down-hand or vertical position. This may result in trapped gases or nonfused areas in the weld joint. Therefore, EBW of deep penetrations (typically welds >38 mm, or 1.5 in.) may be best performed horizontally. However, when welding in the near-horizontal configuration, a drip edge may be employed just below the weld seam to catch and prevent the molten weld from running out of the joint and leaving voids in the weld.

Problems and Flaws

In making vacuum electron beam welds 3.2 to 13 mm (⅛ to ½ in.) deep in weldable metals, weld quality is ordinarily equal to or better than

that of arc welds in the same metal. Special precautions are needed to avoid certain types of discontinuities, such as porosity, gas pockets, and cold shuts, in welds approximately 13 mm ($\frac{1}{2}$ in.) deep or deeper. Reducing the welding speed usually helps to reduce porosity and gas entrapment. Extreme care in cleaning the work metal may be necessary where the problem is severe. When flaws are found near the root of the weld, they can be avoided or minimized by any adjustment of welding conditions that broadens the weld and increases the radius of the weld at the root. Sometimes, the joint can be designed so that any root flaws are in a non-critical region, or in integral or separate backup metal that will be machined away after welding.

As in arc welding, cold shuts (incomplete fusion) are sometimes encountered at the root of a deep partial-penetration weld or of a full-penetration weld that has a poorly fitted backing strip. These discontinuities are troublesome because they are difficult to detect. Normally, they cannot be detected by radiographic methods. Ultrasonic testing can detect the larger cold shuts. Many cannot be observed on roughly polished macrosections of electron beam welds but require a metallographic polish and examination at high magnification for detection. Cold shuts can usually be avoided or minimized by reducing the welding speed or by otherwise changing conditions so as to broaden the weld and increase the radius of the weld at the root.

Poor fit-up or excessive joint gap can cause excessive shrinkage, underfill, undercut, voids, and cold shuts. Joint gap should not exceed 0.25 mm (0.010 in.) for narrow welds in most metals, although sound welds have been obtained using larger joint gaps by use of a procedure that increases the weld width.

Excessive mismatch can cause discontinuities of the same general types as poor fit-up; mismatch limits depend on joint design and dimensions and on operating conditions. Weld quality in joining thick sections is ordinarily unaffected by changes in surface roughness of the joint faces between approximately 1.60 to 2.50 μm (63 and 1000 $\mu\text{in.}$).

A problem that is unpredictable and inconsistent in making electron beam welds deeper than approximately 13 mm ($\frac{1}{2}$ in.) is arc-outs, or sudden failures of electron emission during welding. However, problems of arc-out can be decreased with routine gun cleaning and system maintenance. Work-metal composition and quality also influence arc-outs, which are more frequent in the welding of materials with low vaporization points, materials susceptible to outgassing in a vacuum, and materials that contain nonmetallic inclusions.

Use of Filler Metal

Fusion of closely fitted groove faces generally provides sufficient weld metal. If not, extra

metal can be provided by including extra stock thickness or integral shoulders or lips in the joint preparation. However, filler metal may be required where product requirements or other circumstances prevent the use of a joint preparation and welding conditions that will provide sufficient weld metal or chemistry.

Prevention and Cracking

Filler-metal (shim stock) additions can prevent cracking in electron beam welds in a crack-susceptible metal or combination of dissimilar metals. It may be needed even when joint design, fit-up, and operating conditions are selected to achieve minimum joint restraint and residual stress. In other applications, the use of preplaced filler metal can provide weld metal that is less brittle than would be obtained by welding a base metal (or metals) alone.

Among the base metals for which added filler metal is often required are heat treatable aluminum alloys 6061, 6063, and 6066, free-machining steels, and other free-machining alloys. Many combinations of dissimilar metals that are susceptible to cracking when welded directly, usually because of the formation of brittle intermetallic phases, can be electron beam welded with the aid of filler metal that has a composition compatible with both metals of the combination.

Preventing Porosity

The EBW of rimmed steel without filler metal ordinarily results in severe porosity in the weld, even when welding speed is slow and other conditions are selected to increase the time during which gas can escape from the molten weld metal. Inserting a filler metal that contains a deoxidizer, such as aluminum, manganese, or silicon, helps to minimize porosity.

Copper alloys C11000 (tough pitch copper) and other types of copper that do not contain residual deoxidizers also produce porous welds when joined without filler metal, but sound welds can be made with the aid of nickel filler metal or a deoxidizing filler metal.

Preplacement of Filler Metal

The technique most frequently used for the addition of filler metal in EBW, especially for deep welds, is preplacement. A shim of filler metal, usually of foil thickness, can be inserted between the groove faces when the joint is assembled for welding, or a wire or other suitable shape can be preplaced over the joint, being held in position by tack welding, if necessary.

Filler-Wire Feeding

Electrical or servo-operated filler-wire feeding systems that may be similar to wire-feed equipment used in GTAW are sometimes used

in the vacuum chamber. Usually, filler-wire feeding does not help in joining incompatible metals unless they are very thin.

The design of the wire-feeding nozzle and the technique with which it is used are important in guiding the wire so that it intercepts the weld pool. Any filler metal inserted into the beam path absorbs energy and affects penetration.

A prime consideration for proper implementation or use of wire feed relates to the precision of the wire-feed system itself. The unit must deliver the wire to a known location with a high degree of repeatability. The design of the wire-delivery system and welding technique demand that the energy beam and the incoming wire intercept at the same relative location over time. Inconsistency in the beam-to-wire alignment will result in irregular penetration and dilution of material in the fusion zone of the weld.

Wire-feed systems can be incorporated to provide edge buildup for repair of worn or damaged piece/parts. Many such applications exist in the jet engine and overhaul and repair industry. For example, during normal operation of a jet engine, various critical components undergo wear, for example, knife-edge seals, Z-notches, and vane surfaces. Because these expensive components are vital to maintaining the proper internal pressures required for the efficient operation of the engine, a repair procedure is developed to refurbish the worn component, which can represent a substantial cost-savings per engine.

Wire-Feeding Equipment

Several design features are desirable in a wire feeder for EBW. These include means of making positioning adjustments from outside the vacuum chamber during welding, such as changing the proximity of the nozzle to the weld pool, changing the angle of incidence between the workpiece and nozzle, and controlling the movement of the wire relative to the beam to ensure accurate interception. Figure 20 gives a view of a wire-feed system integrated with a moveable EBW gun.

A wire-feed system to be integrated in an electron beam welder must be capable of consistent and repeatable operation inside the weld chamber. These conditions include vacuum levels approaching 1 μtorr , x-ray bombardment associated with the process, metal vapor deposition, dissipation of radiant heat, and so on. Desirable characteristics for a wire-feed system of this type would include:

- Programmable closed-loop control of the wire-feed rate
- An x-, y-, z-positioning system for the wire nozzle, with jog capabilities
- Programmable automatic retraction of filler wire
- Forward and reverse jogging of the wire with positive drive rollers

Fig. 20 Moveable electron beam welding gun assembly with wire-feed system. Courtesy of Sciaky, Inc.

- Control of the nozzle angle
- A wire-straightening system
- Easily changeable details to accommodate changing wire sizes

It is desirable to be able to control the timing so that wire feed can be started and stopped independently of the beam and table. A wire-feed servo system may be employed to precisely control the feed rate and timing to control the build size and to eliminate the sticking of the wire to the workpiece at the end of the weld. In some control systems, wire-feed synchronized pulsation with beam current may be employed to precisely control the heat input for fine buildup or special feature requirements. Also, an optical viewing system can enhance the wire-feed performance by allowing visual confirmation of the wire location relative to the joint or seam.

Welding Technique When Feeding Filler Wire

The wire-feed rate is usually set at approximately the same rate as the welding speed. Beam power must be sufficient to melt the wire as fast as it is fed. The wire diameter is selected so as to provide 1.25 times the volume of filler metal needed to fill the joint cavity. Where needed, backing strips or rings are used to prevent loss of molten weld metal.

The wire-feeding nozzle is normally held as close to the weld pool as possible without damage to the nozzle, and the wire is directed into the forward edge of the pool. The tip of the nozzle should be made of a heat-resistant

material, coated to prevent molten weld metal from inadvertently adhering to it. The nozzle is usually pointed in the direction of workpiece travel.

The filler metal can be deposited during the weld pass, using a low welding speed to allow time for the molten metal to fill the joint gap, but for deep welds it is better to deposit it in a separate pass. If cracking is a problem, another method used on thin metal is to deposit filler metal on the joint, and then make the welding pass to distribute the filler metal more effectively. Additional information on the wire-feed process and related equipment can be found in the section "Electron Beam Welding as a Repair Method" of this article.

Direct Manufacturing

A heavy-duty version of the wire-feed assembly previously described may be used with an EBW system to facilitate direct manufacturing (EBDM). Direct manufacturing uses the electron beam that impinges on the wire-fed alloy to build near-net shape metallic parts using a layer-by-layer additive process. Generally, part-path planning is executed through a software processing method, whereas a three-dimensional computer-aided design model is used to command the path of the beam and wire melt formations on a substrate plate until the desired near-net shape or geometry is formed (Ref 3). The substrate plate may be an integral part of the assembly, or it may later be machined away. This EBDM process using wire feed is also known as electron beam additive manufacturing and electron beam free-form

fabrication. For additional information with regard to these processes, refer to the section "Electron Beam Near-Net Shape Processing" in the article "Nontraditional Applications of Electron Beams" in this Volume.

EBW for Poorly Accessible Joints

There are attributes of EBW that facilitate welding of joint designs that are not easily accessible. This is primarily due to the beam diameter, directionality, and the broad capability to manipulate the beam in various orientations by both electromagnetic and mechanical means. However, as with other welding processes, there are weld component clearance requirements that must be taken into consideration.

Advantages

One of the advantages of EBW is the ability to reach into areas lying deep within narrow openings. This is possible because the electron beam has a small diameter, a long working distance, and, frequently, the ability to be projected at an angle. Many joints that are inaccessible for welding by other processes can be electron beam welded. This capability is used both in fabrication and in repair work and is especially useful in salvaging intricate castings.

Workpiece Requirements

For limited-access welding, the workpiece must satisfy three general requirements:

- The weld area must be on a line-of-sight path from the beam source.
- There must be sufficient sidewall clearance to avoid beam-fringe interference.
- The beam path must be free of magnetic fields.

Beam Characteristics

Beam characteristics that determine applicability of EBW to poorly accessible joints are beam diameter and the working distance, or effective beam length, available between the exit end of the beam transfer column and the work. These characteristics in turn depend on the beam power used, which is selected to produce the desired penetration, and on beam focus, which is influenced by the design of the gun, the chamber, and the focusing coil.

Sidewall Clearance

Parts intended for fabrication by EBW can often be designed with sufficient sidewall clearance for the beam power required. Where insufficient sidewall clearance exists in repair welding, lowering the beam power or slightly changing the angle of incidence of the beam

often avoids interference. In repair welding, tests should be made on simulated joints, using the same type of work metal and the required beam power, rather than risking damage to difficult-to-replace parts.

Where close sidewall clearances are involved, it is especially important to avoid magnetic fields, which can cause damage to the part by deflecting the beam. A test run on low power is commonly used to detect beam deflection; however, allowance must be made for the increase in deflection at full welding power. Magnetically soft materials with induced magnetism can usually be demagnetized with magnetic-particle inspection equipment or with degaussing coils.

Minimum beam clearance for making welds close to magnetic metal that projects above the work surface at the joint is given in Fig. 15.

Design for Scanning/Joint Tracking

The development of feedback servomechanisms for controlling variations in beam power and beam spot size, as well as in work travel and speed, permits EBW to be accurately controlled within tolerances of a few thousandths of an inch. Depending on machine characteristics, beam spots effective for most welding purposes can be set up in the range of 0.25 to 0.76 mm (0.010 to 0.030 in.) in diameter without difficulty. Assuming a very small beam variation, an application requiring a beam spot of only 0.25 mm (0.010 in.) diameter would require a means of holding the joint-to-beam coincidence with a runout of less than ± 0.13 mm (± 0.005 in.).

For welding with a 0.25 mm (0.010 in.) diameter beam, a pileup of manufacturing tolerances could easily cause the beam to miss the joint. Therefore, for most production purposes, scanning and joint location systems are necessary to better ensure the beam-to-weld joint alignment.

Accuracy of Beam Alignment

For external EBW gun systems, beam alignment is generally a matter of workpiece alignment, as even guns of the adjustable type are usually fixed during welding. For these systems, most joints are designed for simple path shapes—straight lines and circles—that can be adequately traced with precision-made carriages, cross-feeds, turntables, eccentric tables, and spindles. With internal moving gun systems, beam alignment accuracy is also dependent on the rigidity and performance of the motion mechanics that support, drive, and manipulate the gun. In either case, precision motion mechanics are required to hold the joint-to-beam alignment with an accuracy of ± 0.05 mm (± 0.002 in.) or better.

Scanning/Joint-Tracking Procedure

The workpiece is fixtured, and the joint is aligned for travel direction and is moved to its approximate location under the gun. The chamber is closed and pumped down to a vacuum sufficient for safe operation of the gun. A low-power beam is turned on and focused sharply on the workpiece surface. The specific power settings will vary with the working distance selected and the power ratings of the machine; however, they should be sufficient only to create a detectable spot without overheating the workpiece. All of this may be done through the selection of a scanning program.

The low-power beam is typically rastered at the same voltage as that used for welding and is made to sweep back and forth on the part surface at a right angle to the welding path; these settings are typically controlled automatically by the scanning program. The secondary emission feedback through the control system, which may be displayed on an oscilloscope or monitor, provides the operator with a beam-to-seam position displacement. The operator can then position the gun or the part to correct the alignment, or use the autocorrection feature if there is one. With autocorrection, servo drive direction and speed data can be defined or programmed to permit precise placement of the beam on the seam. If tooling is within acceptable tolerances, production parts ordinarily need only periodic scanning as a quality-control measure.

Joints that have a path that deviates from a straight line or circle usually require an automatic tracking device for EBW of production quantities. For small production lots, manual tracking, using a coordinate drive having separate controls, can sometimes be used. Whether the method is controlled manually or automatically, the motion required to generate the curve is usually imparted to the workpiece, although with precise moving gun motion mechanics, motion can be imparted to some guns.

Scanning Techniques

Scanning techniques vary in detail, depending on the type of equipment used as well as on joint design. It is not always necessary to position the beam spot precisely on the joint line. When welding dissimilar metals, dissimilar thicknesses of the same metal, or certain self-locating joints, it is often necessary to position the beam a short distance from the visible joint line. A corner edge or a scribed line can often serve as a reference, or measurement can be made with an optical grid.

Beam-to-seam alignment using secondary emission scanning systems may be more difficult for an operator to interpret when the joints are at an angle, near a projected corner, or stepped. However, with continued use with the special joint configuration, an operator can obtain

sufficient experience to use the scan signal to align the beam with the seam. Also, depending on the control system architecture, some later EBW systems may incorporate wave shaping or other signal conditioning that can filter scanned signals received from the gun antenna plate to increase scan performance. This type of scan-filtering system generally works in conjunction with the computer control system to autocorrect angular or unique joint configurations.

Scanning Problems

Some of the causes of excessive runout and other difficulties encountered during scanning are as follows:

- Poor joint design, inaccurate joint preparation
- Improper fit-up, inadequate fixturing
- Lack of precision in workpiece traversing mechanism
- Obstructions in the beam path
- Indistinct or undetectable joint line
- Beam deflection by electric or magnetic fields

The corrections required for mechanical discrepancies are self-evident; the effects of electric and magnetic fields may be less obvious.

The negatively charged electrons that comprise the electron beam constitute a negative space charge. When the electrons strike an insulated metal part, negative charges are built up, causing mutual repulsion between the part and the beam. By grounding the part, excess electrons are conducted away. To avoid unintentional deflection of the beam by nearby magnetic fields, workpieces, fixtures, and tooling components made of magnetic materials should be demagnetized before welding.

Optical Joint Locating

On newer machines, an optical system typically consists of a video camera that is directed toward the work and a monitor on which the image is displayed. On older EBW systems, such a system may consist of a horizontally mounted monocular or binocular telescope. For either case, internal illumination and reflecting mirrors are used to provide a line of sight coaxial with the beam path. Magnifying power may be 10 to 40 times, depending partly on working distance. High-precision alignment can be obtained.

There are two common methods of using this equipment. One method makes use of a low-power beam that is sighted on the workpiece surface. Using a calibrated grid, measurements to 0.025 mm (0.001 in.) can be made. In the other method, the beam is centered on a cross-hair reticle embodied in the viewing system. The beam is then turned off and the workpiece joint is moved into coincidence with the cross-hair, under internal illumination. The advantage of the latter method is that, after the beam is turned off, the chamber need no longer remain

under vacuum, and further alignment work can be done with the chamber opened, if necessary.

Before joint locating, the mirror surfaces (which are generally protected with glass shields within the internal optics system) should be cleaned, because vapor deposition takes place during welding. The frequency of cleaning may vary, depending on the amount of vapor created and the proximity of the weld. Typically, the glass shields can be removed for cleaning or replacement.

Electronic Scanning

The previous descriptions primarily refer to an electronic scanning system. For this device, the system displays the relationship on an oscilloscope or monitor. As previously mentioned, the equipment makes use of a low-power electron beam that is made to oscillate across the joint. The amplitude of the oscillation is sufficient to display the workpiece surface for a short distance on either side of the joint, as well as the joint line itself. At the point where the beam crosses the seam, a loss of reflected electrons at the antenna feedback signal enables the control to determine the seam location relative to the scan sweep (gun beam sweep) (Ref 4). Joint correction can be incorporated to provide accurate beam placement on the seam. Figure 21(a) shows a simplified view of an electronic scanning system; current systems incorporate more complex signal arrangements, but the overall concept is the same. Figure 21(a) shows the display condition for a beam centered exactly on the joint. The "V" represents the joint line, with the beam spot centered accurately; the two horizontal arms (of equal length with a centered beam) at the top of the "V" represent the adjacent workpiece surface. The broken lines above the work (at left in Fig. 21a) show the plane of oscillation; the wavy line along the joint in the same view shows the approximate amplitude of oscillation. If the beam location were displaced to the right of the joint, the display would look like Fig. 21 (b); an opposite-handed display would indicate displacement to the left. By the relative depth of the "V," the display also indicates the amount of joint separation from apparent zero to approximately 0.15 mm (0.006 in.). A joint mismatch of a few thousandths of an inch is indicated by the relative height of the horizontal arms. In setting up for electronic scanning (under vacuum), the work is provisionally aligned as for optical scanning, making sure that the joint line is parallel to the direction of travel.

Manual and Automated Joint Tracking

In manual tracking, the welding operator must closely observe the joint at the point where the weld is being made to anticipate any change in direction. The conditions best suited to this type of operation are as follows:

- A joint path consisting of a smooth curve
- Slow travel speed
- A low-power beam with oscillation, to form a weld as wide as possible.

The welding operator is capable of regulating two motions of the workpiece (or gun) by manually adjusting the remote controls of the travel mechanism. For a low heat input, to permit the use of the low welding speeds needed when manual tracking is used, beam pulsation can be combined with beam oscillation.

In automated joint tracking, mechanical, electromechanical, numerically controlled, and computerized systems are sometimes used for welding joints that deviate from straight lines or circles. The use of computerized numerical control has become highly prevalent in EBW equipment over the past decades. The capability of CNC for allowing the weld seam path of a part to be quickly "digitized" and "edited" makes it an ideal tool for programming and tracking the actual weld seam path (Ref 5). Axes position tables and autocorrection features may be implemented within the control system program to automatically scan, correct, collect, and store weld points along a joint path, to be subsequently run in a weld program.

Electron Beam Welding as a Repair Method

Restoration of worn or damaged components has traditionally been an important application for welding technology. Some repairs are approached by welding a new detail in the area requiring restoration. However, it is frequently more suitable and cost-effective to use a weld buildup process to restore the dimensions and structural integrity of the affected area.

Welding processes such as manual or automatic GTAW or gas metal arc welding (GMAW) have traditionally been used for this type of repair; these processes facilitate the addition of filler wire to accomplish a weld buildup. Although these processes enable efficient and relatively fast buildup of filler metal, they have the potential drawback of relatively high heat input, which may cause distortion when section thicknesses are small.

Explanation

The EBW process has been employed extensively for original equipment manufacturers mainly because of its ability to minimize or eliminate distortion on welded components through high weld speed, small HAZ, and small bead size. In the past, application of EBW for repair has been relatively limited, confined primarily to butt welding of repair insert details, penetration of parent metal (e.g., to eliminate a crack), or melting of preplaced filler wire. The matching of automatic wire-feed equipment to EBW equipment, however, has led to the development of a system that incorporates the inherent advantages of EBW systems and offers the additional capability of achieving a precise, multiple-pass weld buildup with minimum heat input. The addition of this capability has greatly increased the utilization of EBW as a repair mechanism.

Electron Beam Wire-Feed Process and Equipment for Repairs

Electron beam welding units used for weld buildup repairs are generally high-vacuum machines (13 mPa, or 10^{-4} torr). The availability of a highly controlled welding atmosphere is a

Fig. 21 Electronic scanning apparatus with cathode ray tube display to show alignment of electron beam relative to weld before welding operation is carried out. (a) Electron beam centered along length of joint. (b) Electron beam displaced from centerline of joint

distinct advantage for the electron beam process, particularly when welding reactive materials such as titanium. The EBW machines are typically equipped with signal generators or deflection control systems that oscillate and deflect the beam in the x - y directions. They are also capable of making circles and other geometric figures. Beam deflection frequency can be varied, and the beam can be focused above or below the point of impingement. Beam pulsing and modulation of the pulse are also possible. All these tools can be used in weld buildup repairs. Current electron beam vacuum chambers can accommodate parts exceeding 1525 mm (60 in.) in diameter. On the floor of the chamber is an x - y table; a rotary table is generally fixed to this table. The component to be repaired, typically a cylindrical ring or case, is fixtured to this rotary table. An automatic wire feeder delivers wire to the beam impingement point, enabling a continuous multiple-pass weld buildup when the component is rotated under the beam.

The wire-feed equipment is an adaptation of standard GTAW wire-feed equipment, and the technique is similar to that employed in cold wire circumferential automatic GTAW. The precision wire feeder delivers wire through a nozzle, which can be positioned in the x -, y -, and z -directions and which is visible in the coaxial optical or camera system of the EBW machine. Wire entry angle, nozzle position, wire speed, weld speed, accelerating voltage, focal position, deflection, and amperage are critical factors in EBW buildup. Both inside and outside surfaces can be restored, depending on the position of the wire feeder within the chamber.

A relatively small filler-wire diameter (≤ 0.89 mm, or 0.035 in.) typically is employed to attain a precise low-heat input and a weld buildup typically 1.0 to 1.3 mm (0.040 to 0.050 in.) wide and 2.54 to 7.62 mm (0.100 to 0.300 in.) high, although much larger buildups could possibly be attained by multiple applications of the process or larger wire (> 2.30 mm, or 0.090 in.), as used in EBDM. Electron beam weld buildup lends itself readily to automation, thereby opening the process to use by less skilled operators. On some machines, all parameters are preset. The operator merely lines the machine up on the surface to be welded and pushes the start button. The wire feeder automatically activates and adjusts itself to produce a smooth, precise buildup.

Application of Electron Beam Wire-Feed Process for Repairs

The electron beam wire-feed process has been applied primarily for restoration of worn or damaged gas turbine aircraft engine components, which are typically cylindrical in shape with diameters ranging from 100 to 1525 mm (4 to 60 in.), lengths from 25 to 915 mm (1 to 36 in.), and section sizes from 1.3 to 12.7 mm (0.050 to 0.500 in.). Repair of gas turbine engine components

has become increasingly attractive to commercial and military operators because of the cost and lead time involved in the procurement of spare parts. Repairs are typically conducted at 50 to 70% of the cost of a new component, with three to six times improvement in replacement time.

One of the key gas turbine engine component repairs is the restoration of the rotating labyrinth-type air seals used to maximize engine pressure gradients. As seals wear or are damaged, engine efficiency drops and fuel consumption rises. Hence, restoring minimal seal clearances has become increasingly attractive. Seal design is typically of the straight knife-edge or tapered knife-edge type (Fig. 22). Materials vary from iron-base alloys (AMS 6508 and A-286) to high-nickel alloys (Incoloy 901 and Waspaloy) to titanium alloys (Ti-6Al-4V, Ti-8Al-1Mo-1V, and Ti-6Al-2Sn-4Zr-2Mo).

Currently (2011), virtually all air seal restoration is done by welding. Gas tungsten arc welding, gas metal arc welding, and electron beam welding have all been successfully applied, depending on requirements of engine manufacturers, component design, material, and experience and equipment of repair stations. Prior to the establishment of the electron beam wire-feed process, utilization of the standard electron beam weld process for this type of repair was limited to competitive weld buildup processes (GTAW and GMAW) and was primarily applied where distortion and HAZ size were a primary concern.

Initial application of the standard electron beam process involved welding a machining ring onto a premachined pedestal on which the worn air seal was removed, as shown in Fig. 23a. The knife-edge configuration was then machined into the welded ring. Later, a splitting concept was introduced. In this procedure, an edge-rolled ring was assembled into a

shallow groove premachined into the pedestal top (Fig. 23b). Circumferential spike welds from each side welded the ring in place, and the ends of the split ring were radiused to blend the discontinuity in the ring. The wall thickness of the as-rolled ring was the finished thickness of the knife edge, typically approximately 0.25 mm (0.010 in.), and the outside diameter was finish machined after welding. Disadvantages of this weld buildup system include ring detail cost and the amount of postrepair machining required.

The application of the precision wire-feed electron beam process (Fig. 23c) to gas turbine seal repairs provides both the material application efficiency and cost advantages of weld buildup systems and the inherent low heat input and controlled atmosphere advantages of the EBW process. A typical automatic wire-feed electron beam air seal repair, applied to a compressor rotor spacer for a gas turbine engine, is shown in Fig. 24. This part is made from a titanium (Ti-6Al-4V) forging. The outside diameters of the knife edges wear in service, and the knife edges must be restored to maintain the proper tip clearance. The knife-edge material is machined close to the diameter of the pedestal; a weld buildup is made using Ti-6Al-4V titanium filler wire, and a new knife edge is machined. The multiple-pass technique typically deposits 0.25 to 0.38 mm (0.010 to 0.015 in.) of radial buildup per pass. Penetration of the HAZ below the pedestal top typically does not exceed 0.38 mm (0.015 in.). Because the entire weld buildup operation is performed in a vacuum, there is no weld metal or HAZ oxidation. Cost is minimized by the high speed of the EBW process, which substantially exceeds that of the standard GTAW buildup process.

Air seal repairs also are routinely performed on steel and nickel alloy parts. Experience with

Fig. 22 Schematic comparing cross sections of straight and tapered air seals

nickel-base superalloys containing relatively high percentages of gamma prime that form hardening elements has shown these alloys to be crack-sensitive during welding or postweld heat treatment. Crack-free precision wire-feed EBW buildup repairs, however, are achieved when appropriate process parameters are used.

Quality-Assurance Testing

Quality-assurance testing is an integral part of all gas turbine engine repairs. The high degree of control inherent in the precision wire-feed electron beam repair process facilitates in-process control and quality assurance. Because of the high degree of control the electron beam process offers, process variables can be kept to a minimum. This built-up consistency tends to ensure a long-term high level of quality assurance.

Weld parameters are developed by the analysis of microsections of sample welds and by nondestructive testing. Once an acceptable process has been established for a component, a weld schedule is initiated and weld parameters are maintained. Any changes in equipment or process must be qualified by the analysis of new microsections. Quality of finished air seals is ensured by one or more of the following tests, depending on customer requirements:

- Visual
- Liquid penetrant
- Fluorescent magnetic particle
- X-ray
- Etch inspection

Future Applications for Repair

Although the most common application of the precision wire-feed electron beam buildup process has been in the repair of gas turbine engine air seals, the process is not limited to this type of application. Various other wear-restoration applications have been developed, including spline and groove buildups. Although the process is most efficiently used as a continuous multiple-pass process on cylindrical components, planar buildup can be achieved by using sequential weld pass patterns or oscillation. The process is also potentially applicable for new part manufacture

to enable a component to be machined from a smaller, less costly forging with selective electron beam buildup to provide material for specific structural features (for example, outside-diameter bosses on cylindrical cases).

With the advent of EBDM, there are many other potential applications for the repair of assemblies using this high-deposition wire-feed process. Applications for near-net shape repair of damaged or worn metal parts can consist of common or high-value metal alloy components on items such as airframes, landing gear, jet engines, guided missiles, and military vehicle parts. For additional information with regard to this process, refer to the section "Electron Beam Near-Net Shape Processing" in the article "Nontraditional Applications of Electron Beams" in this Volume.

EBW Process Control Plans, Codes, and Specifications

The applications that use EBW often include high-quality, high-precision components and specialty materials. Therefore, weld requirements are generally critical in nature, and process control plans, weld codes, and specifications may be required to achieve the ultimate goal of part performance.

Explanation

Control plans provide a written summary description of the systems used in minimizing process and product variation and how this information can be documented. The EBW process control plan (PCP) typically outlines all the product and procedural control operations implemented in the weld production process. A single PCP may apply to a group or family of welded products that are produced by the same process at the same source. Sketches, as necessary, may be attached to the PCP for illustration purposes.

In effect, the PCP describes the actions that are required at each phase of the EBW process, including receiving, in-process, outgoing, and periodic requirements to assure that all process outputs will be in a state of control. The PCP is maintained and used throughout the weld product life cycle. Early in the product life

cycle, its primary purpose is to document and communicate the initial plan for process control. Subsequently, it guides manufacturing in how to control the process and ensure product quality. Ultimately, the PCP remains a living document, reflecting the current methods of control and the measurement systems used, and is updated as systems and control methods are evaluated and improved. The PCP should be a central part of the supplier's overall process to meet

Fig. 24 Micrograph of a typical automatic wire-feed electron beam repair of an air seal. Original magnification: 15×

Fig. 23 Sequence of operations required for electron beam welding repair of an air seal. See text for details.

quality, cost, and delivery goals. The EBW process control plan may include the following:

- Verification of weld parameter settings on test samples
- Weld part cleaning requirements
- Part preparation for assembly
- Weld fixture details and loading requirements
- Weld vacuum requirements
- Preweld scanning and joint alignment procedures
- Weld program selection and identification of process characteristics
- Vacuum venting requirements
- Weld inspection and quality-control procedures
- Document certification and/or applicable procedure qualification record

The PCP may include a process flow chart, the applicable prequalified welding procedure specification, and weld rework, repair, and storage operations, if applicable. Almost all design, welding, fabrication, material, repair, testing, and inspection requirements are covered under governing organizations. For EBW, these include the American Welding Society (AWS), the Society of Automotive Engineers (SAE) International with the associated aerospace standards (AS), the American Society of Mechanical Engineers (ASME), and the Aerospace Material Standards (AMS). Even the Department of Defense has either adopted many of these codes or used them as a basis to develop their own codes, known as Mil-Specs. The codes are recognized by the American National Standards Institute (ANSI).

Weld Procedure Specifications

A welding procedure specification (WPS) is a formal document describing welding details to guide welders in the accepted procedures so that repeatable and trusted welding techniques and process parameters are used. A WPS should be developed for each material alloy and for each welding configuration used (Ref 6). Specific codes and/or engineering/welding societies are often the driving force behind the development of a company's WPS. The WPS may be supported by a welding procedure qualification record (WPQR), whereas the WPQR can provide a record of test welds performed to ensure that the procedure can produce acceptable welds. For EBW, typical items that should be recorded on a WPS include:

- Machine type (model/serial number)
- Electron beam gun type with gun component details (filament type/size, anode type/size, etc.)
- Process parameters and tolerances (accelerating voltage, beam current, beam focus, welding speed, gun-to-work-distances, beam deflection/oscillation values, etc.)
- Material details, such as base-metal type, filler type (if applicable), backing material (if applicable)
- Weld component characteristics (joint type, joint depth, fit-up gap, fixture type, etc.)

- Pre- and postheat treatment (if required)
- Other related welding requirements and techniques (part-cleaning method, gun angle, tack and cosmetic pass requirements, run-on/run-off tabs, vacuum level, etc.)

The WPS should contain sufficient details to enable any competent person to apply the information and produce a weld of acceptable quality for production. The amount of detail and level of controls specified on a WPS is dependent on the application and criticality of the joint to be welded.

Boiler and Pressure Vessel Codes

As with other welding codes, the Boiler and Pressure Vessel Code contains documents establishing legal obligations spelled out through laws and rules to be complied with whenever engaging in the manufacture of boilers and pressure vessels. The code covers requirements essential to guarantee public safety and reliability.

The ASME Boiler and Pressure Vessel Code (BPVC), which is issued once every three years, comprises a number of volumes that establish rules of safety governing the design, fabrication, and inspection of boilers and pressure vessels, including nuclear power systems. Section IX of the ASME BPVC relates to the qualification of welders, welding operators, and the procedures employed in welding in accordance with the code and the ASME B31 code for pressure piping. Section IX of the ASME BPVC establishes the basic criteria for welding (including EBW) and brazing in the preparation of requirements that affect procedure and performance for component manufacture when the maximum allowable working pressure exceeds 15 psi (1.03 bar). Also, welding variables are covered that are used in the preparation and qualification of the WPS.

Various Customer Quality Specifications

In most cases, quality standards are driven by a variety of customer-specific or general standards. These standards and specifications are used to provide consistent output quality to meet industrial and/or aerospace welding product requirements. For EBW, these quality specifications have been published by a number of committees and organizations, including the Aerospace Material Standards, the American Welding Society, General Electric, Pratt & Whitney, and Boeing.

The specifications serve to define the procedures for joining metals and alloys using the EBW process and to determine engineering and quality requirements for the production of these welds. The specifications may cover the requirements for weld joint design; written instructions for all preweld, weld, and postweld operations; inspection methods; and allowable limits. Also, process monitoring and control

plans may be implemented to assure fusion, process completion, and provisions for the certification and use of welding schedules, as well as the qualification of operators and equipment.

The general EBW specifications and the associated issuing groups are outlined as follows:

- AMS 2680, "Electron Beam Welding for Fatigue-Critical Applications," SAE International—Aerospace Material Specification
- AMS 2681, "Electron Beam Welding," SAE International—Aerospace Material Specification
- AWS C7-3, "Electron Beam Weld Process Specification," American Welding Society
- AWS D17.1, "Fusion Welding for Aerospace Applications," American Welding Society
- P8TF10, "Electron Beam Welding," GE Aircraft Engines
- PWA 16, "Arc, Gas, Electron Beam, Laser Beam and Inertia-Friction Welding," Pratt & Whitney
- RA1607-077, "Electron Beam Welding for ELV Requirements," Boeing North American, Inc.

At the time of this writing (2011), the aforementioned specifications are some of the most common relative to the EBW process; additional specifications may also apply on EBW or equipment contracts. Some older specifications may be superseded by later documents. For instance, the Aerospace Material Specification AMS-STD-1595, "The Qualification of Aircraft, Missile and Aerospace Fusion Welders," has been replaced by AWS D17.1. When conformance to one or more EBW specifications is stipulated in a contract, all provisions within the document may be required unless specifically listed or outlined as exempt by the contract authority.

SEVERAL SOLID FREEFORM FABRICATION TECHNIQUES developed over the past decade have the ability to produce structural metal parts directly from computer-generated designs (Ref 1, 2). These techniques also lend themselves to fabrication of unitized structures that reduce part count, decrease weight, reduce assembly time and cost, and improve structural efficiency, as compared to conventional fabrication and assembly methods.

Electron Beam Near-Net Shape Processing

This section covers the details for near-net shape processing using an electron beam (EB) generated from a fixed or moveable gun in a vacuum environment. The gun may be the same or similarly configured as that used for electron beam welding (EBW). As with EBW, the process environment is ideally suited to a wide range of aerospace materials, including many reactive and refractory alloys. The EB process offers unique advantages over other current available near-net shape processing methods in terms of power efficiency and deposition rate.

Process Description and Definitions

There are two main classes of EB deposition processes currently in use for near-net shape fabrication of three-dimensional (3-D) parts. These classes are based on the type of feedstock used and how it is delivered to the molten pool. One class uses a wire-feed-based feedstock method, and the other uses a powder-bed feedstock approach. Myriad other EB deposition processes also exist for depositing thin films, coatings, or performing surface modification and etching. These processes are typically used in the electronics and semiconductor industries and are generally focused on coverage of precise layers on a microscale (such as EB sputtering, physical vapor deposition, lithography,

EB-induced deposition, etc.). The focus of this article is restricted to the former, concentrating on the buildup of 3-D metallic components using an EB as the heat source and wire or powder feed as the material-delivery method.

Electron beam additive manufacturing (EBAM), electron beam free-form fabrication (EBFFF or EBF³), electron beam melting (EBM), and electron beam direct manufacturing (EBDM) are several of the acronyms used to describe various processes that correlate to the use of an EB power source for near-net shape processing. The majority of the EBAM, EBF³, and EBDM work performed has used wire as the feedstock, whereas powder primarily serves as the feedstock for EBM. In each case, 3-D EB deposition processing takes place by introducing metal feedstock into a molten pool that is created and sustained using a focus-controlled EB in a high-vacuum environment (1×10^{-4} torr or lower).

Electron beam additive manufacturing typically refers to a process where new material is added to a substrate to fabricate components. The term *additive manufacturing* has been used in the context of deposition of metallic and polymeric materials. In this article, *additive manufacturing* is used in the context of using metallic substrate and feedstock materials for the purpose of building up near-net-shaped components. For this process, the wire is directed toward the molten pool and melted by a focused EB. Parts are built up layer by layer by moving the EB and wire source across the surface of the underlying material, which is commonly referred to as the substrate, as shown in Fig. 1. The substrate material can become an integral part of the finished product. In this manner, free-standing shapes, or preforms, are generated without molds or dies. Conventional techniques then machine the component to the final part geometry (Ref 3). Depending on the wire size and the work envelope of the vacuum chamber, this process is well suited to building large assemblies or structures with high deposition rates (Ref 4). Bulk metal deposition at rates

in excess of 2500 cm³/h (150 in.³/h) as well as finer detailed deposition at lower deposition rates can be provided with the same piece of equipment, limited only by the positioning precision and wire-feed capabilities (Ref 5, 6).

Electron beam melting operates in a powder bed, tracing the part in a layer of powder with a high-energy EB and repeating for subsequent layers. In this case, the beam is steered magnetically and can be split into multiple beams running in a pattern to melt the layer of powder. While the layer is hot, the surrounding area is heated and a subsequent layer of powder is added. The heating of the surrounding area sinters the powder particulate, preventing material repulsion and improving the material quality of the down-facing surface. This specific process is typically used for small part fabrication (to fit within the powder bed), similar to standard industry practices in stereolithography (Ref 7).

Electron beam direct manufacturing can be considered a more generic term (no trademark) for the previously described EBAM, EBFFF/EBF³, and EBM processes. Although the majority of EBDM work performed has been with wire-additive processing using a substrate plate, the process term can be considered to include powder-based feedstock with or without substrate requirements. Therefore, the EBDM acronym is used in this article for general references to EB near-net shape processing.

Modeling/Tool-Path and Computer-Aided Design/Computer-Aided Manufacturing Tools

Regardless of the specific machine being used, the majority of components fabricated using EB deposition processes start with a 3-D model designed in a computer-aided design (CAD) environment. In this operation, the deposition path and process parameters are generated from the virtual 3-D model, which is typically executed by a real-time computer control. Any CAD package may be used to develop

Fig. 1 Schematic diagram of the electron beam (EB) direct manufacturing process. Courtesy of Sciaky, Inc.

the solid model, as long as the data can be exported into a format that can be interpreted by the software that develops machine codes to build the components. Software may slice the solid model into layers and then generate a tool path to control the beam and motion system (depending on the EB deposition arrangement). Some systems can also take the computer-aided manufacturing outputs from standard CAD packages to develop the tool paths and output the results into standard G-code.

Thermal residual stresses are generated within parts built using EB deposition because of the thermal gradients induced between the baseplate at ambient temperature and the molten region below the EB. Thermal modeling can calculate the distribution of residual stresses, predict the distortion expected as a result of the EB deposition processes, and guide the processing parameters and tool paths to mitigate or minimize the generation of thermal residual stresses. Process modeling has also been performed to help guide the closed-loop control development and to help with understand the effects of processing parameters on the resulting geometry, microstructure, chemistry, and mechanical properties of the deposited material (Ref 8).

Process Quality and Control of Essential Variables

The EBDM process has numerous variables that control the resulting microstructures, chemistry, and shape of the deposit. These variables have been refined in the control system to make reproducible parts. There are much greater variances possible with the EB deposition systems where feedstock material is fed directly to the molten pool. Due to the challenges of feeding powder to the beam in a vacuum, only powder-bed systems have been

deployed with powder feedstock using EB; powder actively fed directly to the molten EB pool has not yet been demonstrated in production.

Wire-Feed Systems. For wire-feed systems, four of the most significant process variables that are easily controlled are the translation speed, wire-feed rate, beam power, and beam focus. The diameter of the wire feedstock is the controlling factor that determines the smallest detail attainable using this process. Fine-diameter wires may be used to add fine details, and larger-diameter wires can be used to increase deposition rate for bulk deposition (Ref 6). Due to spreading of the molten pool, a good rule of thumb for the smallest-width feature possible is on the order of $1\frac{1}{2}$ to 2 times the diameter of the wire. This general rule does not apply to the widest width possible; that is determined by the volume of wire being fed into the molten pool and sufficient power being delivered to melt large amounts of wire.

Multiple wire feeders have also been demonstrated to operate simultaneously, enabling either an increase in the volume of wire delivered to the molten pool or a functionally graded alloying where the alloy chemistry is changed over time. In this case, the width and depth of the layer being deposited is limited more by the ability to fully capture and melt wire being fed at a high wire-feed rate. For higher translation speed, the lower heat input and lower volume of wire being fed into the molten pool results in a smaller-diameter, shallower molten pool. This combined effect produces a decreasing taper in both the width and height of the deposit as the translation speed increases. The higher translation speed produces more rapid cooling and results in a homogeneous microstructure with smaller equiaxed grains (Ref 9).

Deposition rate in wire-feed systems is directly controlled by the wire-feed rate, but beam power and translation speed are also

important factors in defining the final dimensions of the deposited layer. Increasing the beam power and decreasing the translation speed increases the heat input into the part, resulting in a deeper and wider molten pool. The increased wire-feed rate adds more material to the molten pool, resulting in the greater deposition rate (Ref 9).

Powder-Bed Systems. In powder-bed processes, the diameter of the feedstock powder defines the minimum size of the layer and feature that can be produced using EB deposition. The layer thickness is controlled by the powder spreader when a new layer of powder is distributed after each previous layer of melting has been accomplished (Ref 7). The typical deposition rate for EB powder-bed processes is $60 \text{ cm}^3/\text{h}$ ($3.66 \text{ in.}^3/\text{h}$). The deposition rate is not readily changed in powder-bed processes, because the scan time with the EB is very short compared to the time consumed with spreading and leveling the powder layer.

Material Quality. Because the EBDM process is typically operated within a high-vacuum environment, this provides for an oxygen-free atmosphere, and secondary inert gases are not required to ensure the chemical integrity of the material. Furthermore, the quality of substrate and feedstock material may be traced for critical applications, and the degree of traceability would be specific to an end user's industry. At this writing (2011), a majority of the EBDM development work has been performed on aluminum and titanium alloys. However, a variety of weldable alloys can be processed using the EBDM processes, and new research on nonequilibrium processing is also being pursued on nonweldable alloys, functionally graded alloys, and selectively reinforced materials (Ref 10).

The EBDM process offers the potential for improved performance through control of microstructures and compositions at a much finer scale than parts machined from thick products. Typical thick sections have high degrees of microstructural inhomogeneity, leading to anisotropic mechanical properties. This is a direct result of differences in cooling rates and an inability to impart work evenly through a thick section. Working with smaller billets in conjunction with layer-additive processes can result in more optimal microstructural features, potentially improving the mechanical properties of the resultant part as compared to a similar part machined from a thick-section billet. Finally, compositional gradients offer improved performance and reduced cost by allowing grading from an inexpensive material for the bulk of the product to an expensive material at the surface for enhanced wear resistance, corrosion resistance, and so on (Ref 5).

Over the range of parameters tested for 2219 aluminum, resultant microstructures varied from a fine-grained, equiaxed grain structure to a solidification microstructure with larger grain sizes and dendritic growth. Representative microstructures for high and moderate heat

input (as influenced by the combination of translation speed, wire-feed rate, and beam power) are shown in Fig. 2 for as-deposited 2219 aluminum in the short-transverse plane of the deposit. The light-colored bands are dendrites that formed in the interpass region, where portions of a previous layer are remelted during deposition of a subsequent layer. Although dendrites can be seen contained within the grains, pervasive dendritic formation is minimal in the interpass regions of the deposit produced with the moderate heat input conditions (Ref 5).

Over the entire range of beam powers, translation speeds, and wire-feed rates tested, the deposits exhibited very little porosity, no cracking, and complete fusion between deposited layers. The chemical composition of the deposits compared with the starting 2219 aluminum wire feedstock confirmed that the alloy compositions were unaffected by the EBDM process. The tensile properties were also very consistent over a wide range of processing conditions. The results indicated that the EBDM process

provides a wide processing envelope from which 100% dense deposits can be made with useful mechanical properties. Refer to Fig. 3 to note the tensile properties of the EBDM-deposited 2219 aluminum as compared to typical handbook values for this material.

Experiments performed on Ti-6Al-4V resulted in the formation of large columnar grains growing epitaxially from the substrate, as shown in Fig. 4(a). At higher magnification, as shown in Fig. 4(b), α - β laths typical of the microstructures of α + β titanium alloys can be seen. Through rigorous process control, it has been demonstrated that the size of these columnar grains can be controlled by limiting the heat input during the deposition process (Ref 5).

As previously stated, following deposition, components are built near-net shape. Subsequent postdeposition processing steps may be required, depending on the requirements for the component. Final machining to provide surface finishes and precise geometry is required, as well as inspection for any internal flaws. Heat treatments

may also be performed, because the as-deposited materials tend to be in an annealed condition. Traditional heat treatment schedules used for forged materials, for stress relief, as well as for solutionized and aged conditions may be performed following deposition to achieve mechanical properties within approximately 5% of those of forged materials.

Process qualification may be required to adopt EBDM methods for select applications. This qualification requirement would be more evident for critical applications, such as those implemented in the aerospace industry. Aerospace Material Specification draft number 4999 was originally created for titanium alloy direct-deposited products using laser-additive manufacturing and has now been modified to allow alternate processes, including EBDM using wire (Ref 4). However, process qualification requirements may be the challenge preventing swift adaptation of the EBDM processes into numerous applications.

At this writing (2011), several efforts are underway to collect a database of material properties and to identify an appropriate process specification. Because the EB deposition processes tend to operate continuously in transient rather than steady-state thermodynamic conditions, maintaining consistent output parameters (such as molten pool width and depth and base temperatures) requires real-time monitoring and adjustments to one or more of the input parameters (beam power, scan speed, translation speed, wire-feed rate, etc.). This presents challenges in defining an applicable process specification, because the starting input parameters are actively modified throughout the deposition process.

Closed-loop control is being introduced into the market to provide the process with consistency to enable reproducibility from part to part, machine to machine, and day to day (Ref 8). After the process control has been translated into a process specification that can truly be representative of the conditions required to achieve a given end product, and the material database has proven that these

conditions are reproducible, process qualification can be realized.

Certification efforts are currently underway to enable application of EB deposition parts to enter into service trials for the aerospace industry as structural aircraft components and in the medical industry as custom-designed medical implants (Ref 7). Within a short period of time after certification has been achieved, applications and uses may accelerate for components fabricated using the EB deposition processes.

General Applications (Target Parts and Applications)

Large-scale EB deposition processes such as EBDM are capable of producing large components directly on plate, rather than hogging-out large volumes of chips from a forging. Direct cost savings can also be realized through repair and salvage of parts, reduced machining time,

and reduced waste. Electron beam direct manufacturing can repair broken or out-of-tolerance parts at a fraction of the cost of remanufacturing. This can be particularly significant when there is a large investment, either in capital expenditures, high-value materials, or large amounts of time already invested in a part. The EBDM processes can build an entire structure or add detailed features to a simplified casting or forging. However, the replacement technology must be cost-competitive. Thus, issues such as high deposition rates, process efficiencies, process quality, and material compatibility are paramount to insertion of a new technology into a competitive metals-forming market. Implementing these processes can thereby reduce the material wasted during machining operations, reduce lead time and raw material costs by reducing billet sizes, and enable production of a generic, simplified part by conventional methods with the addition of specific details at a later time. Besides the raw material cost-savings, there is an ease in handling smaller billets of raw feedstock and the by-products or scrap produced from a less-extensively machined part (Ref 5).

Case Study. The following case study representing an aerospace component (structural chord) was explored to develop process techniques, feasibility, and proof of concept when compared to conventional manufacturing methods. In this example, the part integrity and economic models were analyzed to determine the viability of the process. This part was selected because of the high cost and lead times associated with obtaining Ti-6Al-4V, as well as the large mass of material that must be removed to produce the finished part. The CAD model was used to generate a computer numerical control (CNC) weld path offline, as shown in Fig. 5.

It was determined that a minimum of 5 mm (0.2 in.) excess material would be deposited such that a final net shape part could be machined from

the preform. A 150 mm × 1520 mm × 13 mm (6 in. × 60 in. × 0.5 in.) Ti-6Al-4V substrate plate was clamped to a work platen and processed using a moving-gun EBDM system. The preform was deposited at a rate of approximately 700 cm³/h (43 in.³/h). The parameters selected resulted in a single-pass buildup with approximate dimensions of 16 mm wide by 3 mm high (0.6 in. wide by 0.12 in. high). The preform shape was built to a height of 90 mm (3.5 in.). After thermal processing of the preform, it was machined to net size. Figure 6 depicts the chord in process and its final finished form.

A comparison of material volume is shown in Fig. 7, which depicts the material required for fabricating the chord with the EBDM approach as well as the “hog-out” method. It is easy to extrapolate that with nearly 80% more raw material required to fabricate the chord from the hog-out method, the EBDM method for fabrication would be proportionally less in costs for material and machining.

The actual cost of using the EBDM process depends on a few interrelated variables. These cost elements are associated with market pricing of raw materials, deposition rate, finish machining costs, and any required auxiliary services that may be necessary, such as thermal processing. Table 1 shows some relative cost percentages for each specific approach, with a net savings of over 40% that can be realized with the EBDM process.

The estimates assume the use of typical machining parameters for Ti-6Al-4V material. It should be noted that this estimate has been generated for comparison purposes and should not necessarily be construed as the only way to generate the subject part. The cost of raw materials is independent of the process and is driven by industry demand and availability. Deposition rates for titanium have been demonstrated up to 3996 cm³/h (244 in.³/h). It should be noted that

techniques to allow for higher deposition rates for EBDM are continually being refined.

Dynamic Beam Deflection Processing

General Description

Accelerated electrons travel through a vacuum in straight lines, as long as they are not affected by electric or magnetic fields. Magnetic or electromagnetic fields are used to intentionally deflect electrons from the straight flight path for various reasons, such as to focus the stream of electrons into a small beam spot with the help of a static field or to deflect the electron beam with a low-frequency (<1 kHz), low-amplitude dynamic field to influence the keyhole of the welding process. Lower-frequency and higher-amplitude deflection can be used for creating the weld without gun or part motion for making plug welds, for instance. High-frequency, dynamic fields (>100 kHz) are used to enhance traditional welding processes, typically consisting of one weld, by temporarily deflecting the EB out of the keyhole to perform another task, such as a second weld. In addition, the high frequency enables the creation of raster fields that can be used for heat treatment purposes as well.

Controlling Essential Variables

Dwell Time, Deflection, Accelerating Voltage, Beam Current, and Beam Focus. For fully CNC electron beam welders, all welding parameters are controlled by the welding

machine CNC and can be stored in the part program. The length of dwell time for the EB at each particular spot can be programmed and allows maximum process flexibility in terms of heat input into components.

A method for distributing the power of the EB over a surface to be pre- or post-heat treated or hardened consists of dividing the area into a number of points adequately spaced so that no hot spots exist when using a defocused beam. These locations may be spaced as required to obtain the necessary power density distribution, which is defined by the values of the accelerating voltage, beam current, and beam focus. The EB is successively positioned at each specific location, dwelled for a programmable time interval, and then translated at very high speed to the next coordinate point, producing a pattern that conforms to the contour requirements of the surface to be hardened or heat treated.

The beam deflection angles are determined by the working distance as a setup function and the distances of dwell points. As with traditional processes, the high (accelerating) voltage is typically held constant between 40 and 60 kV for low-voltage guns and 90 and 150 kV for high-voltage guns. The beam current can be changed in the part program if necessary. Fast beam deflections in combination with fast focus changes between dwell points enable the processing at different working distances.

Effective Power Density. The EB is capable of impinging power densities on the order of 3 MW/cm² (20 MW/in.²) when sharply focused for welding. However, this powerful energy concentration is easily controlled in power magnitude (accelerating voltage and beam current), power density (defocused beam), and beam position (computer-controlled deflection).

The extremely high power density in the EB focal spot combined with the constant transformation of beam energy into thermal energy in the high-90% range makes the process very flexible and robust at the same time. With an increasing spot size, achieved either through a defocused beam or the use of an increased deflection pattern, the beam power density can be continuously scaled down, to the point where a keyhole process turns into a conduction-mode welding process.

It is characteristic in dynamic beam deflection processes that the beam is moved or “shared” between different locations, in contrast to traditional processes where the beam impinges on one spot only. The extremely high-speed beam movement between points may be referred to as beam splitting or multibeam processing, because the speed of deflection makes the single beam appear to be more than one. In addition to the standard EBW parameters, the ratio of dwell time at each location influences weld penetration (or heat input) in such a way that the smaller the ratio in one spot, the shallower the resulting weld. The reduced power input per time at each dwell point can be compensated with an increased EB power. Also, depending on the speed of deflection, the beam power and focus can be dynamically changed to match the beam location to better tailor the power density of each spot.

For selective surface treatment, application of beam energy is such that the surface of the part is heated rapidly to a temperature just below the melting point (approximately 1480 °C, or 2696 °F, for steel) of the metal being hardened (Ref 11). Refer to Fig. 8 to note the graph of EB energy input as it applies to heat treating. As the thermal gradient becomes steeper, the surface temperature will tend to

Fig. 7 Comparison of material volume for electron beam direct manufacturing (EBDM) buildup vs. hog-out

Table 1 Total relative percentage cost comparison case study for a chord

Cost summary in dollars	
Electron beam direct manufacturing (EBDM)	Hog-out/machining
Raw material (substrate plate): 8%	Raw material: 63%
EBDM deposition (includes cost of wire): 26%	...
Auxiliary processes (thermal processing): 14%	Finish machining: 37%
Finish machining: 8%	...
Total: 56%	Total: 100%

rise. This is countered to keep the surface temperature just under the melting point by decreasing the surface power density with respect to time. This is done to achieve the desired case depth by using the ability of the controls to rapidly adjust EB power for a specific duration. When the desired depth of austenite is prepared, the EB power is turned off. Extremely rapid heat flow to the interior of the part (self-quench) continues until the temperature is equalized throughout the workpiece. The cooling rate is rapid enough (in excess of 2200 °C/s, or 3960 °F/s) to exceed the critical cooling rate and convert the austenite to hard martensite. Transformation to martensite to achieve maximum surface hardness and case depth depends on several factors, such as the mass of the part, the percentage of carbon, and the initial condition of the base metal (normalized or quenched and tempered) (Ref 12).

General Pattern Designs

Split or Multibeam Processing. There are many EBW applications that involve two or more process steps, for example, a weld and a cosmetic pass to smooth the surface. Typically, they are carried out in series, one discrete process step after another, which requires long floor-to-floor cycle times. With the beam-splitting feature, it is possible to change from series to parallel processing, where two or more processes are executed at the same time with one EB (Fig. 9). Technically seen, one EB is switched between different locations with defined, multimillisecond-long dwell times. The length of dwell time influences weld

Fig. 9 Weld and cosmetic pass. Courtesy of PTR-Precision Technologies, Inc.

penetration in such a way that the longer the hold time in one location, the deeper the resulting weld. This means that weld penetrations are no longer influenced only by traditional parameters such as focus, beam power, and deflection pattern but also by the ratio of dwell time to nonimpinging time.

To provide maximum process flexibility, the dwell time can be programmed in the CNC for each individual beam position (Fig. 10). Process improvements with multipool welding depend on the particular application and often go beyond the shorter floor-to-floor production times. For example, multipool axial welding with four “simultaneous” weld pools on the same diameter balances the heat input much better than traditional processes with only one weld pool. The improved, balanced heat input results in a more balanced part distortion and, in addition, shortens cycle times.

High-Speed Raster Generation. The split or multibeam process requires only one dwell point for each individual melt puddle, such as welding and a cosmetic pass. If large numbers of dwell points are needed to form a grid for the purpose of heat treating selective surface areas, one or more predefined heat field with many dwell points must be preprogrammed as a raster. The individual dwell points of the raster (grid pattern) are programmed independently from each other in terms of location and dwell time. It allows precise control of temperature increases, temperature dwell times, and cooling rates. The high self-quenching rates, which are determined by material, mass, and geometry of the individual part, can be further influenced through timed thermal inputs after heating to accomplish nonlinear cooling rates with one or more heating cycles during quenching (Fig. 11).

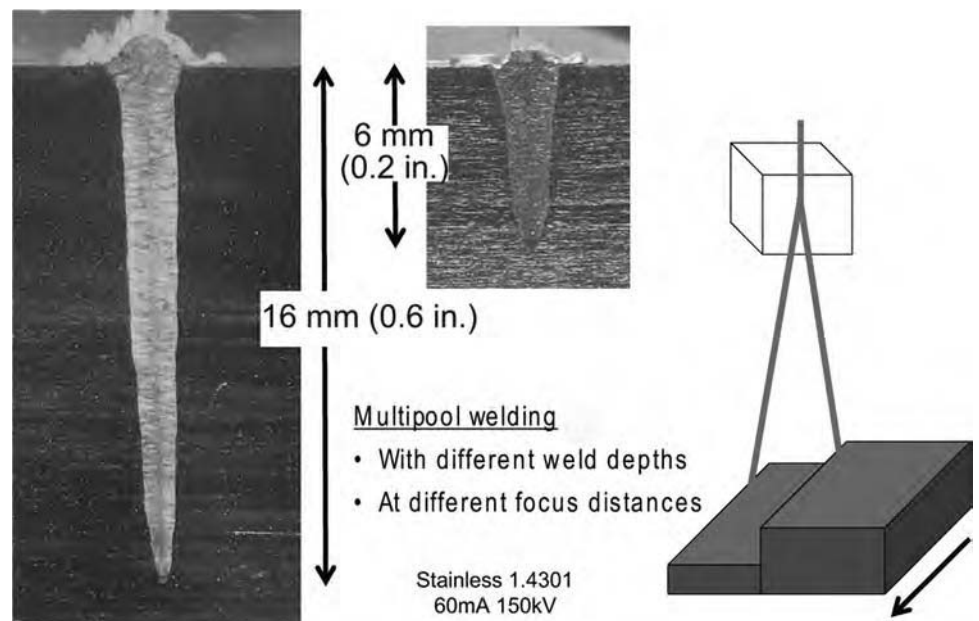

Fig. 10 Multipool welding with different focus and penetration. Courtesy of PTR-Precision Technologies, Inc.

The energy raster can be applied to the work surface using two distinct methods: static pattern (for fixed localized areas) or traveling pattern (for linear or circular stripping of larger surface areas). Surfaces can be flat, domed, or irregular, as in the case of gear teeth or splines. Line of sight between the workpiece and the EB gun is necessary, and demagnetization of parts is recommended (2.0 gauss or less) to ensure beam placement.

Applications of High-Frequency, Multibeam Processes

Selective Surface Treatment. The advantages of this selective heat treatment process are being used in mass production of camshafts. The EB equipment is used in automated, single-piece flow manufacturing lines to harden camshaft surfaces by deflecting an EB on a rotating part (Fig. 12). The self-quenching properties of the material are maintained through an extremely fast and localized temperature increase in the surface layer while maintaining the original room temperature underneath this heated layer. The extremely efficient self-quenching effect of the material is further influenced by the beam through a second heating pattern that is applied with a split beam shortly after the first heating pattern. This nonlinear cooling rate results in improved material characteristics and reduced wear of the camshaft surfaces compared to other heat treatment processes.

A cross section of a camshaft lobe made of pearlitic gray cast iron after heat treating and supercooling is shown in Fig. 13. For this camshaft, a beam pattern deflection technique was developed to optimize the heat treat pattern

density, which allowed four separate patterns to be independently varied on each of four camshaft lobes as the beam moved between the flat areas of the camshafts to the apex areas to provide a uniform heat profile around each camshaft lobe. Due to the pearlitic gray cast iron material, after heat treating, the camshafts were supercooled in liquid nitrogen (LN₂) to reduce the amount of retained austenite and to increase the hardness values from nominally R_C 55 to approximately R_C 60.

Other applications for selective surface heat treatment include camshaft followers, one-way clutch assemblies, rocker arms, and so on. Figure 14 shows a sketch of an EB gun with a heat treat pattern directed on the contact area of a rocker arm component to be hardened. This application is referred to as a static heat treat application because the beam pattern is rastered on the piece-part without moving the EB gun or the part. With the pattern raster applied for 1 s, a case depth of nominally 1 mm (0.04 in.) can be obtained on a cast iron contact area that would have a Rockwell hardness of approximately R_C 60. Also, unlike conventional heat treat methods such as induction or flame hardening, additional postoperative steps for

Fig. 11 Heat treatment for selective surface areas. Courtesy of PTR-Precision Technologies, Inc.

Fig. 12 Camshaft hardening. Material is 51CrV. Courtesy of PTR-Precision Technologies, Inc.

external quenching and finish grinding would be eliminated by processing this component using the EB surface treatment method. Figure 15 shows a cross section of a similar nodular cast iron rocker arm melt pad that produced a 0.6 mm (0.025 in.) deep white iron layer backed up by a 0.4 mm (0.016 in.) deep hardened zone. The white iron layer had a hardness value of R_C 64.

Multiple-Pool Welding with a Split Beam.

Two-pool welding is applied in mass production on radial welds. The disk-shaped damper assemblies are rotated underneath the EB, which switches back and forth from the outer to the inner joint, thereby welding both joints

Fig. 13 Cross section of camshaft lobe. Material is pearlitic gray cast iron. Courtesy of Sciaky, Inc.

Fig. 14 Sketch of gun/coil and heat treat pattern on rocker arm assembly. Courtesy of Sciaky, Inc.

“quasi” at the same time (Fig. 16). The parallel processing of both joints shortens the floor-to-floor time compared to the traditional process, which performs in series, one weld after another.

Automotive transmission gear assemblies are conventionally welded with either the EB or laser process using a single-beam weld pool. This procedure typically requires the gear assembly to be tack welded first to maintain a balanced joint/stress configuration, and then the tack passes are overlapped with a single continuous weld pass. By contrast, in multipool welding, the components are welded at several points simultaneously along one and the same welding seam (Fig. 17), up to an overlapping portion in the area that already has been welded. With this approach, the welding time is reduced and the distortion is minimized because of the lower heat applied to the parts. The number of welding pools depends on the size and geometry of the part and on the deflection width of the EB.

It is important to note that the welding seam is not typically perpendicular to the surface with multipool EB welding. Therefore, the incidence angle of the EB and consequently the seam depend on the welding diameter of the welding circle and the distance between beam source and component (Ref 13). The weld seam may need to be configured to be directly in line with the beam trajectory, so that the weld consumes the joint (Fig. 18).

Pre- and Post-Heat Treating. Electron beam welding may employ leading or trailing deflected beams serving as additional heat regions around the weld. This may be done more frequently on materials that tend to

Fig. 15 Cross section of rocker arm contact area after heat treatment. Courtesy of Sciaky, Inc.

Fig. 16 Two-pool welding with one electron beam. Courtesy of PTR-Precision Technologies, Inc.

produce hot cracking with conventional welding methods. These additional pre- or post-heat treating beams would typically be defocused so as not to melt the piece-part, and they would serve to heat the surrounding areas of the weld to compensate for the large temperature gradient between the solidifying weld pool and the surrounding material. This compensation reduces the thermal stresses to better minimize crack formations in the weld.

Quality Control of Electron Beams and Welds

T.A. Palmer, Pennsylvania State University
P.W. Hochanadel, Los Alamos National Laboratory
K. Lachenberg, Sciaky, Inc.

THE ISSUE OF QUALITY CONTROL in electron beam (EB) welding is similar to that in other welding processes, where the primary goal is to consistently produce defect-free and structurally sound welds. Existing process controls in EB welding typically are directed at controlling the essential machine settings, which include the accelerating voltage, beam current, focus coil current, vacuum level, travel speed, and work distance (Ref 1). Additional quality-control checks are performed after the completion of the weld, with nondestructive evaluation (NDE) techniques, such as eddy current, radiography, or ultrasonic evaluation, to detect any potential defects in the components. An overview of the relevant NDE techniques is provided in *Nondestructive Evaluation and Quality Control*, Volume 17 of *ASM Handbook*, 1989.

A primary assumption in these existing process-control techniques is that the machine settings are highly accurate and reproducible and have a direct correlation with the resulting beam characteristics (Ref 2). Each of these machine settings is quantifiable and tightly controlled before and during the welding process, except for the focus coil current. This machine setting is used to define the focus condition of the beam, usually with respect to an operator-determined "sharp focus" setting. However, the actual beam characteristics, defined in terms of specific quantifiable parameters, such as the beam diameter and power density distribution, at this sharp focus setting can vary significantly with different operators, machines, and operating conditions.

The use of diagnostic tools for probing the beam characteristics has been growing over the last two decades with the development of several diagnostic tools (Ref 3–15). These beam probing techniques are based primarily on modifications to a traditional Faraday cup and use direct measurements of the EB current to obtain a profile of the beam energy distribution as the beam passes over an edge, slit, or pinhole. The resulting signal obtained as the beam passes over the edge or slit can provide

information about both the beam shape and size and the power density distribution. Several commercially available systems for measuring the EB characteristics over a range of powers have been developed and are in use (Ref 6–14).

In the following sections, common procedures for controlling the EB welding process are discussed. In addition to the control of the essential machine parameters, the introduction of closed-loop controls and diagnostic feedback systems in EB welding systems are also addressed. One quality-control tool fairly unique to EB systems interrogates the beam to produce a reconstruction of the power density distribution and provide additional information on the size and shape of the EB. Knowledge of these beam parameters can be used to improve process understanding and control. Based on existing practices, future directions for EB quality control are also discussed.

Process Control of Essential Variables

Like other common welding processes, the control of specific processing parameters is essential to controlling the process. In EB welding, the primary variables that are controlled include the accelerating voltage, beam current, focus coil current, vacuum level, travel speed, and work distance (Ref 1). These essential parameters are then verified prior to welding, in accordance with the requirements of the weld process specification and other relevant procedures with which the welder is required to comply. This documentation then becomes the basis for the quality-control paperwork that follows the welded component.

The majority of essential parameters are controlled primarily by using calibrated machine gage settings. In selected cases, the beam current can be measured through the use of a Faraday cup. A Faraday cup is an electrically conductive beam trap designed to contain and measure the beam current. In most cases

though, a Faraday cup is used only to confirm machine performance after maintenance and is not commonly used as a process-control tool. To maintain control over these machine settings, the calibration of the gages controlling these settings is performed at selected intervals to ensure that the machine output is consistent.

Calibration of the primary variables used in EB welding may be performed as follows:

1. The accelerating voltage may be verified using a calibrated voltage divider as the standard. The voltage divider reduces the high voltage (such as 150 kV) to a workable voltage (such as 1.5 or 15 V). This equipment is quite specialized and typically is used at the equipment manufacturing facility during the manufacture of new equipment or refurbishment of older equipment. Unless a serious anomaly occurs with the high-voltage system, this voltage is assumed to be fairly constant over the life of the equipment. Further details on calibration of the high voltage in EB welding can be found in the latest revision of ISO 14744-2 (Ref 16).
2. The beam current may be verified using a Faraday cup arrangement that contains a calibrated ground path resistor. Additional details can be found in the latest revision of ISO 14744-3 (Ref 17).
3. The focus position may be verified with a diagnostic tool such as the enhanced modified Faraday cup tool, provided the ground path resistor is calibrated. Details are given throughout this article.
4. The vacuum level is calibrated using a calibrated vacuum gage that is either calibrated or replaced at selected intervals based on the recommended schedule provided by the machine manufacturer.
5. The travel speed should be verified with a calibrated standard, such as a stopwatch. Typically, times are sufficiently long that this standard is sufficient. Some additional details can also be found in the latest revision of ISO 14733-4 (Ref 18).

6. The working distance is measured from a set location on each machine, typically the top of the welding chamber, and is easily verified with a calibrated standard-length measuring device, such as a calibrated tape measure or meterstick.

Modern control systems are commonly employed in EB welding systems to control these essential variables and to perform other desired quality-control functions. These modern systems employ a range of computerized controls to provide much-improved control of the essential parameters over that possible with older, open-loop, analog-based controls. Computer real-time processing, using feedback mechanisms, facilitates rigid command of critical process parameters. For EB welding, control circuitry that interfaces with the computer and the associated discrete supplies allows the gun power level (beam current, accelerating voltage, etc.) and effective energy density (beam focus, deflection, etc.) to be accurately maintained to specified requirements. Figure 1 shows a block diagram of a typical modern closed-loop gun control system. Additional feedback systems may be incorporated to control the part and/or gun motion mechanics to facilitate fully synchronized process and motion control.

Additional closed-loop systems allow for these improved controls to be further improved by both monitoring and altering the desired parameters. With these closed-loop systems, any observed changes in the weld shape or heat input can be mitigated by corresponding changes in the welding parameters to bring the desired properties back into target. Although this technology is in the early stages as of this writing (2011), these closed-loop systems will become an increasingly important tool in EB welding and other associated processes. For example, this type of closed-loop control is well suited for EB deposition processes. Because these processes tend to operate continuously in transient rather than steady-state conditions, the ability to maintain consistent output parameters requires real-time monitoring and adjustments to one or more input parameters.

In addition to monitoring the essential welding parameter settings, other in-process monitoring controls, based on phenomena resulting from the EB-material interaction, have been explored. Backscattered electrons, x-rays, and visible emitted light emanating from the weld region have been explored with varying amounts of success (Ref 2). These in-process observations can be used in a number of capacities, including employing it as an *in situ* seam

tracker, and allow a near-real-time diagnosis to be made as to whether the weld is proceeding as expected. Much like the closed-loop systems described earlier, these systems are currently not in widespread use, but as the supporting technologies mature further, they will become much more common.

Beam Diagnostic Tools for Determining Beam Focus

Process control of EB welding is based on control of machine settings, such as accelerating voltage, beam current, travel speed, and vacuum level. A variety of control systems are used to ensure that these machine settings are accurate and meet the process requirements. On the other hand, the focus coil current setting, which allows the operator to adjust the beam focus position in the weld chamber, is difficult to replicate, due to the manual nature in which the beam focus setting is controlled.

During focusing, the strength of the magnetic lens in the focus coils is manually adjusted by the operator to change the focal length of the magnetic focusing lens and to move the beam cross-over location in the work chamber. The focus coil current setting at which the cross-over

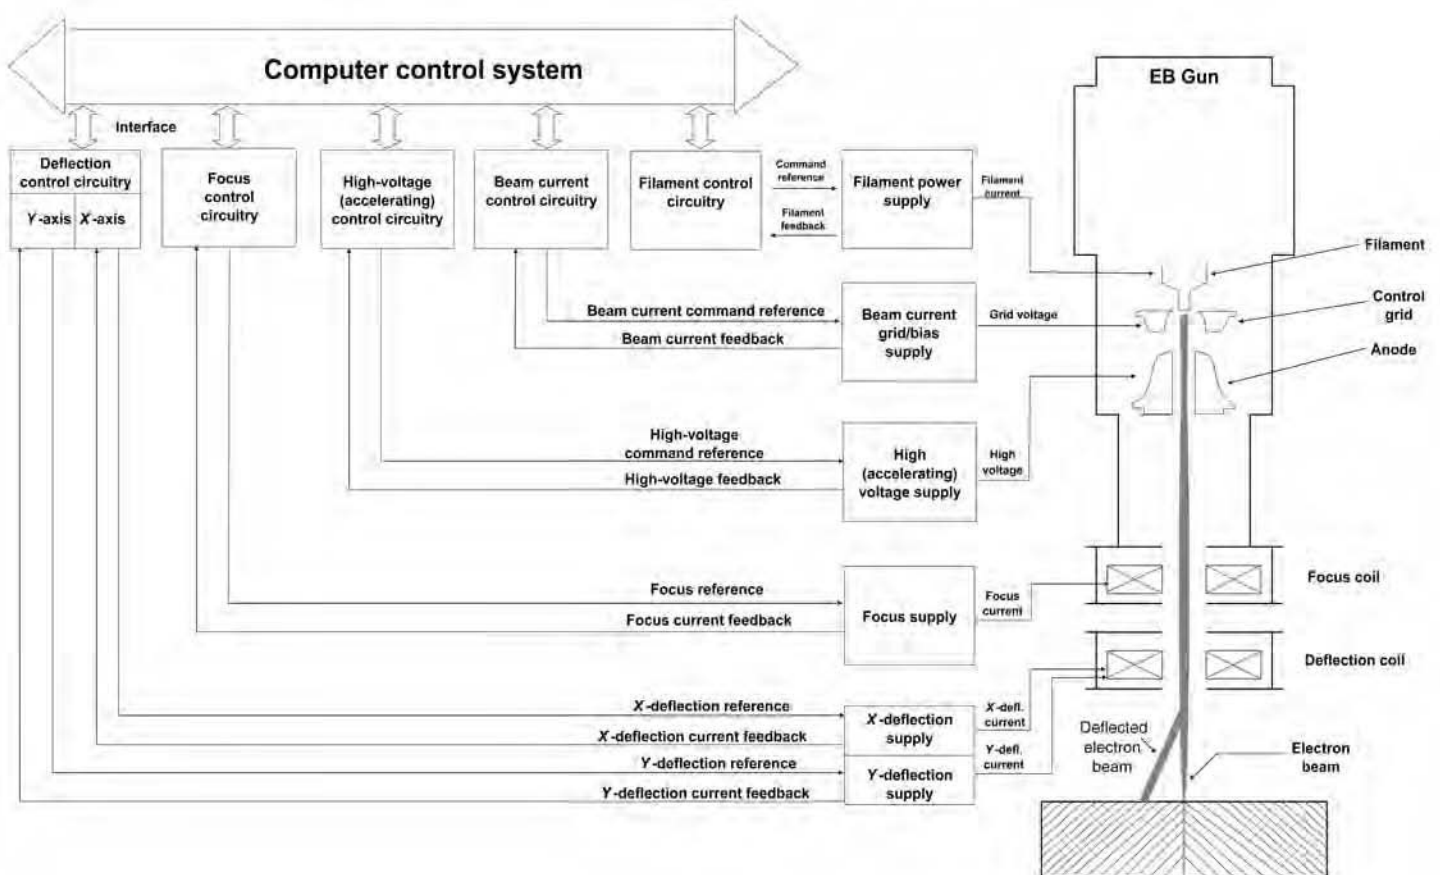

Fig. 1 Block diagram showing a typical modern closed-loop gun control system. EB, electron beam

point is located at the surface of the workpiece is referred to as the sharp focus setting. To determine the sharp focus setting, the operator directs the beam onto a high-melting-point target material, such as tungsten, and adjusts the focus coil current setting while observing the intensity of the light emitted from the target. When the emitted light reaches a maximum intensity, the beam is considered to be at sharp focus (Ref 1).

It is typical for the operator-determined sharp focus setting to be the only means for defining the beam properties. However, it is difficult to define and reproduce the sharp focus condition, and the reproducibility of a sharply focused beam at a given focus setting on even a single machine is not guaranteed. Various operators may interpret the brightest emission from the target material differently, resulting in different, operator-dependent definitions of sharp focus. In addition, changes in the sharp focus setting are commonly observed between evacuations of the work chamber. As a result, beams with different properties may be mistakenly used in the welding of potentially high-value components.

The inability to consistently control the beam properties and to define the focus condition in an easily quantifiable manner can be addressed through the use of beam diagnostic tools. This issue has been recognized for a number of years, resulting in the development of several rudimentary tools for characterizing the sharp focus condition of EBs. An early attempt at determining the sharp focus location for a given beam is embodied in the Arata beam (AB) test (Ref 4). In this test, an EB is run over a comb-shaped angled plate at a given travel speed. As the beam passes over the material, which is typically stainless steel, it either cuts or melts the thin vertical plates making up the comb-shaped angled plate, shown in a transverse orientation in Fig. 2 (Ref 4). The sharp focus location for the EB corresponds to the location where the width of the melted material is a minimum.

The AB test is designed to find the cross-over location of the EB for a given set of voltage, current, and focus coil current settings. This cross-over location corresponds to the sharp focus condition of the EB, where the minimum beam width is expected. After measuring the widths of the EB spots produced at each location on the AB test stand, the sharp focus position is correlated with the location where the narrowest weld is produced. Overall, the test is very similar in construction to the angled plate tests used in laser welding to determine the cross-over location for laser optics.

Even though the use of this test provides previously unavailable empirical data concerning the performance of the EB welder, it displays a number of drawbacks that limit its usefulness and applicability to production environments. For example, the test setup must be removed from the chamber to be analyzed, thus changing the conditions in the chamber and requiring an additional pump-down before welding. Also, the results of the AB test are only applicable for the welding conditions and materials with

which the test was conducted. Changes in the weld settings or materials will have an impact on the physical location of the beam cross-over. Therefore, any change in welding parameters or material will require additional testing, which can result in the need for a rather significant number of tests to be performed if multiple materials and welding conditions are needed. Finally, the results of the test reveal only the physical location of the beam sharp focus and nothing about the characteristics of the beam.

More modern techniques have begun to focus on the characterization of the beam produced by an EB welder rather than just identifying the beam cross-over location. To better understand the beam characteristics, techniques designed to directly probe the beam and provide quantitative information have been developed (Ref 5–14). These beam probing techniques include a rotating wire device and modifications to a traditional Faraday cup using either an edge, slit, or pinhole detection system (Ref 13). Each of these techniques uses a direct measurement of a portion of the EB current.

In the wire probing system, a small-diameter wire is passed or rotated through the beam, and the resulting beam current is measured. This system provides a means for measuring the beam current but is limited by the poor heat dissipation of the wire. Those systems that rely on the modification of a traditional Faraday cup are based on the capture of a selected portion of the beam intensity, from which a power density distribution can be computed. In the edge detection probing system, the beam is passed over the edge of a piece of electrically isolated refractory metal. As the beam passes over the edge, a portion of the beam current is obtained as a function of time, based on the speed that the beam is traversed. The current varies as the beam passes over the edge, resulting in a

beam profile from which energy density and beam width measurements can be made.

In the slit probing system, the beam is passed over a refractory metal containing a thin slit with a width typically in the range of 0.02 to 0.1 mm (0.0008 to 0.004 in.). Because the width of the slit is smaller than the width of the beam, a small portion of the beam current is captured in a Faraday cup as the beam is swept over the slit. The resulting signal obtained as the beam passes over the slit is similar to that obtained in the edge detection system and can provide information about the beam shape and size along the scan direction of the beam. In addition, the power density can be estimated from this measurement.

A pinhole detection system is based on principles similar to the slit probing system, but it uses a small hole instead of a slit to obtain profiles of the beam. In this system, the beam is rastered in both the x - and y -directions over a pinhole, usually less than 0.10 mm (0.004 in.) in diameter, producing a map of the power density distribution of the beam. Because the beam is continuously rastered over the pinhole to obtain a complete beam profile, precise beam control is required. Power density distribution can be measured with this technique, but it is limited because the technique has an inherently low signal-to-noise ratio.

Using the data obtained with these different systems, estimations of the sharp focus setting, the beam diameter, and the general beam profile can be made. However, because the edge and slit beam probing systems take only a single profile of the beam, it must be assumed that the beam is radially symmetrical and has a circular cross section for the results to be generally useful. While this assumption may be valid for typical sharp-focused beams, it is also known that beams can take on elliptical and

Fig. 2 Schematic diagrams showing the basics of the Arata beam test for measuring the electron beam (EB) focus position. Source: Ref 3, 4

noncircular shapes or power density distributions, especially when out of focus.

The use of diagnostic tools for probing these beam characteristics has been growing over the last two decades with the development of several diagnostic tools (Ref 4–14). These beam probing techniques are primarily based on modifications to a traditional Faraday cup and use direct measurements of the EB current to obtain a profile of the beam energy. Several diagnostic systems are commercially available and have been applied to the control of EB welding systems. These systems include the DIABEAM system from ISF-Aachen (Ref 5–8), the TWI slit probing system (Ref 13), and the enhanced modified Faraday cup tool developed at Lawrence Livermore National Laboratory (LLNL) (Ref 9–12). Even though each system uses a different method for obtaining data on the EBs that they are interrogating, they all rely on these same basic modifications to the traditional Faraday cup. All of the systems also rely on the rapid deflection of the beam, which allows the systems to be permanently placed in the EB chamber and used for a range of different characterization activities.

The DIABEAM system uses both a slit and a pinhole diaphragm to characterize beams up to powers of 100 kW. By employing both a slit and a pinhole, a rapid evaluation of the beam and a more in-depth analysis of the beam can be obtained. The TWI slit probing system uses multiple slits to probe the beam to estimate the focus, beam profile, beam asymmetry, beam current, and beam diameter. This system can be permanently attached to the EB welder and used to either characterize the machine or serve as a quality-control tool (Ref 13). Finally, the LLNL enhanced modified Faraday cup uses a series of 17 radial slits that interrogate the beam at a number of different angles, so that the resulting power density distribution can be reconstructed.

In addition to the diagnostic hardware described previously, specialized data-acquisition, signal-processing, and data-analysis software have been developed. The signal obtained by the diagnostic hardware is converted into a voltage drop across a known resistor and captured by a fast-sampling analog-to-digital converter before being transferred to the data-acquisition software. The resulting signal obtained as the beam passes over the edge or slit can provide information about both the beam shape and size and the power density distribution.

Computer tomography (CT) methods can be applied to multiple sets of data obtained through slit systems to produce a complete reconstruction of the beam profile. One method for producing a reconstruction of the beam is to take data from multiple slits positioned at various angles to obtain multiple slices of the beam. These multiple sets of data are reconstructed using CT algorithms (Ref 10–12) by first separating the individual beam profiles,

normalizing the areas under the peaks, filtering the data, creating a sinogram of the profiles, and reconstructing the power density distribution (Ref 10).

Once reconstructed, a number of measurements are made to characterize the size, shape, and power density distribution of the beam. The peak power density and two distribution parameters are the most used of these measurements. Figure 3 provides an illustration of how these parameters are determined. The first distribution parameter is the full width of the beam at one-half its peak power density (FWHM). This parameter represents the width at 50% of the beam peak power density. The second parameter is the full width of the beam measured at $1/e^2$ of its peak power density (FWe2). This parameter represents the width of the beam at 86.5% of the beam peak power density. Because the cross section of the measured beam is not always circular, the area of the beam at these two points is measured, and the diameter of a circle having the same area is used to represent both values. These approximations are good representations for most beams with generally circular cross-sectional shapes, such as the Gaussian-like distributions typically found near the sharp focus setting. The FWHM value is used to represent the beam width, while the FWe2 value is used to represent the beam diameter.

Application of Beam Diagnostics

The development of these various beam probing systems has led to the use of these tools in a number of different applications. Using the basic concepts described, several application areas, primarily involving machine characterization, weld parameter transfer, and weld quality control, can be pursued using diagnostic tools. It is shown in the following discussions that the use of beam diagnostics to monitor the beam characteristics provides a valuable quality-control tool and does much to improve the understanding of machine performance and beam characteristics.

Machine Characterization. The primary use of these EB diagnostic tools has been directed at characterizing individual machines and comparing the performance of different machines under similar operating conditions. A good example of the differences in beam characteristics for different machines has been obtained using the enhanced modified Faraday cup (EMFC) (Ref 14). In this study, the differences in the beams produced by two EB welders were characterized. Sharply focused beams were shown to display different shapes and peak power densities that vary by nearly 20% for the same welding parameters on two welders. Reconstructed beam profiles are shown in Fig. 4. The beams produced by each welder at the respective sharp focus settings vary both in shape and power density distribution. The

Fig. 3 A slice through the center of the reconstructed beam with the peak power density, full width at half maximum (FWHM), and full width at $1/e^2$ (FWe2) measurements indicated. Source: Ref 14

first welder (Fig. 4a) displays a slightly oblong shape and has the highest power densities located in the center of the beam. The power densities then decrease rather rapidly as the edges of the beam are approached. On the other hand, the second welder (Fig. 4b) produces a fairly round beam with a much more uniform peak power density distribution across the beam diameter and a less clearly defined hot spot in the center.

With knowledge of the respective beam characteristics for each welder, the correlation between the beam properties and the resulting weld pool size and shape can be examined. Autogenous welds are first made at the sharp focus setting of each welder on a 304L stainless steel sample at an accelerating voltage of 100 kV, a beam current of 10 mA, and a travel speed of 17 mm/s^{-1} (0.7 in./s). Figures 5(a) and (b) show the resulting weld cross sections produced by each welder.

Each welder produces similarly-shaped weld cross sections, showing keyhole-type behavior at the respective sharp focus settings. However, differences in the characteristics of sharply focused beams also result in differences in the measured depth and width of each weld. The measured weld depths produced at the respective sharp focus settings show a difference of 7%, with the second welder producing the deeper weld. Based on these observations, the higher peak power density weld shows the lower penetration. However, spiking, which is defined as a sudden increase in penetration above the average line of penetration at the root of the weld, is apparent on the weldment produced on the second welder. Unlike the cross section shown in Fig. 5(a), a rather large pore appears at the root of the weld shown in Fig. 5(b). The presence of root porosity such as this is indicative of spiking (Ref 19–23). In this case, the depth of the weld at both the top

Fig. 4 Plots comparing reconstructed beams produced at sharp focus settings for 100 kV, 10 mA beams at a work distance of 229 mm (9 in.) on two different electron beam welders. Source: Ref 14

Fig. 5 Weld cross sections produced in 304L stainless steel samples at sharp focus setting for 100 kV, 10 mA beams at a work distance of 229 mm (9 in.) and travel speed of 17 mm/s^{-1} (0.7 in./s) on (a) welder 1 (peak power density = 520.0 kW/mm^{-2}) and (b) welder 2 (peak power density = 515.7 kW/mm^{-2}). Source: Ref 14

(3.42 mm) and bottom (4.26 mm) of the pore is measured, resulting in a 20% difference in the measured weld depth.

When the depth measurement is made at the top of the pore, the weld shown in Fig. 5(b) is 14% shallower than the weld shown

in Fig. 5(a). Other studies have indicated that beams with higher peak power densities produce deeper welds (Ref 24), especially when produced on the same equipment. When the depth at the top of the pore is taken into account, a shallower weld with a lower peak

power density beam is produced. A comparison of the peak power densities of the beams produced by the two machines shows a difference of 22%, while the depths of the two welds differ by 14% when taking into account the spiking. This difference is in agreement with prior observations of the peak power density weld-depth relationship.

The size and shape of the welds produced by each machine can also be affected by the different beam orientations and power density distributions, both of which are not detectable without the use of this diagnostic tool. First, the orientations of the beams vary, with the beam shown in Fig. 4(a) being more elongated along its x -axis, which corresponds to the direction of welding. The beam shown in Fig. 4(b), while not entirely circular, lacks the well-defined orientation of that shown in Fig. 4(a). Differences in the power density distribution and beam orientation lead to variations in how the EB energy interacts with the workpiece. As a result, differences in the weld dimensions are observed, even though the total power input is the same.

Weld Parameter Transfer. Based on the previous characterization of EB welding systems performed using these diagnostic tools, the ability to more efficiently transfer parameters between different machines can be accomplished. Until the development of these diagnostic tools, the inability to characterize and control the focus of EBs used for welding was a limiting factor in transferring welding parameters between different machines and different facilities. The process for transferring a set of EB welding parameters from one machine to another can be broken down into three consecutive steps: weld development, weld transfer, and production. Each of these categories includes a number of independent operations performed on a dedicated

development welder and one or more dedicated production welder(s). Significant redundancy is introduced into the development and transfer of these welding parameters. As a result, a series of costly and time-consuming weld development cycles are typically required before the transfer of a set of welding parameters is complete.

Using the data obtained with a given diagnostic system, estimations of the sharp focus setting, the beam diameter, the general beam profile, and the power density distribution can be made, assuming that the machine has been properly calibrated (Ref 25). Unlike existing qualitative methods based on the transfer of machine settings, a diagnostic tool-based procedure uses quantitative measurements of specific beam parameters, which can be correlated to the size and shape of the welds produced by the different welders.

To replicate the beam produced by a production welder on the development EB welding system, the beam is defocused. Reconstructions of the power density distribution for the defocused beam on the development welder and the sharp focused beam on the production welder are shown in Fig. 6 (a) and (b), respectively (Ref 25). With a +11 increment change in the focus coil current setting, the peak power density for the development welder decreases by 40%, and the FWHM and FWe2 values increase by approximately 22 and 28%, respectively. After the defocus correction is made to the beam produced by the development welding system, the resulting peak power density values vary by only approximately 2%, while the difference in the beam distribution parameters is 7% for the FWHM values and 4% for the FWe2 values. Even though the orientations of the beams differ, the power density distribution and general size of the beams produced by the two welding systems are very similar.

Cross sections of the welds made on the development and production welding systems using the beams described previously are shown in Fig. 7(a) and (b), respectively (Ref 25). In general, the two welds display similar depths, differing by only 0.30 mm (0.01 in.), or approximately 8%, with the weld produced by the development welding system being the deeper of the two. Even though the width of the beam produced by the production welding system is larger, the width of the weld produced by the development welding system, as measured at the top surface of the weld, is approximately 0.5 mm (0.02 in.) wider than that produced by the production welding system, corresponding to a difference of nearly 25%. This difference in width can be attributed, in part, to the orientation of the beam produced by the development welding system, which is elongated along the axis lying parallel to the direction of welding. On the other hand, the widths of the welds, as measured at the half-depth level, are fairly similar, varying by only approximately 10%.

The previous experiments show that it is possible to produce welds that are similar in shape and size by considering the differences in the performance of two machines determined through the use of the EMFC diagnostic tool. With this tool, the characteristics of the EB are quantified to a level that allows similar beams to be reproduced with ease on different welding systems. Using these results as a baseline, a procedure for the transfer of EB welding parameters between two machines can be adapted to specific needs. In any modified procedure, the EMFC diagnostic tool is integrated into each step of this procedure. Beginning with the weld development stage, the EMFC diagnostic tool provides a means for quantitatively characterizing the beam and ensuring that it exhibits the same characteristics each time it is used. During the transfer of weld parameters, the use of the EMFC diagnostic tool significantly streamlines the process by removing redundant test welds on each machine and minimizes the time and cost required to move a part from development to production. Therefore, traditional methodologies that rely on multiple test welds to transfer welding parameters from development to production can be replaced by a much more streamlined methodology that is based on a thorough knowledge of machine performance.

Quality Control

Process control with EB welding typically relies on the control of the machine settings during welding. These settings must fall within a set tolerance range for a weld to be considered acceptable. This tolerance range, as defined in the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel code (Ref 26), can be rather wide, with beam current being allowed to vary by up to $\pm 5\%$, which allows for a rather significant amount of variability in the process parameters and the resulting beam characteristics. Even though this quality-control philosophy, termed the "goalpost" philosophy (Ref 27), can produce acceptable parts, there are no guarantees that the resulting components meet the nominal customer specifications.

More modern quality philosophies, such as the Taguchi loss function, recognize that customers desire the products to fall more consistently around the nominal specifications (Ref 27). From a process-control standpoint, the ultimate goal is to minimize these variations in the beam characteristics, particularly at the extremes of the tolerance band over the course of a production run, and for all of the parts to be near the nominal specifications. Enhanced process control is one means for meeting the ultimate goal of producing a product that meets customer expectations. In

EB welding, the integration of modern diagnostic tools provides a means for achieving this goal.

With beam diagnostic tools, these beam characteristics, including the peak power density and FWHM and FWE2 values, can be quantified on a regular basis. Previous work (Ref 28) has shown that machine performance, in terms of the measured beam characteristics, varies over time. Testing has shown that the variability of the beam characteristics can be measurably decreased with the use of a diagnostic tool. With the implementation of this diagnostic tool in the process-control procedures, variations in each of the measured beam parameters can be controlled at levels below $\pm 2.2\%$, which is smaller than the 5% tolerance band suggested by ASME for other welding parameters. Such an enhanced level of control allows product throughput to be increased by decreasing the number of rejected parts through the elimination of unexpected variations in beam characteristics (Ref 28).

The variation of the measured beam parameters for a single production run can be minimized with the integration of EB diagnostics into the process-control methodology. Such a powerful tool can have a significant impact on conventional process-control techniques for EB welding by incorporating previously unavailable quantitative information concerning the beam characteristics. With this new information, several areas should be explored further, and general improvement of available quality-control methods in EB welding will be realized. Three of these areas, primarily involving the enhanced process control afforded by this diagnostic tool, are addressed in the following discussion.

With the aid of beam diagnostic tools, allowable tolerance levels for the various beam parameters can be decreased in size. Currently, there is no standard accepted tolerance level for the beam characteristics measured by this diagnostic tool. In addition, maintaining tight control on the machine settings is not a sufficient guarantee of sufficient process control. By more tightly controlling the beam parameters, variations in the resulting weld properties can be diminished, and parts more closely meeting customer expectations can be produced more reliably and to increasingly stringent quality standards.

Secondly, by quantitatively characterizing the beam, the tighter beam requirements can lead to more imaginative joint designs. It is currently accepted in production environments that some level of postweld machining and rework is required for EB-welded components. Much of this rework is the result of the inability to provide adequate beam control in the absence of a beam diagnostic tool. As a result, joint geometries are designed to compensate for the lack of precision in beam control. With the

integration of beam diagnostic tools, joint geometries can be minimized and the need for follow-on machining reduced or even eliminated by guaranteeing consistent beam properties.

Finally, enhanced process knowledge gained through the use of this diagnostic tool can lead to higher levels of machine up-time and increased awareness of potential maintenance issues. Changes in the peak power density of the operator and diagnostic-determined sharp focus settings are good indications of the overall machine performance. For example, previous work has identified decreases in the peak power density measurements to correspond to a change in machine performance, which required unexpected maintenance. This degradation in performance would not be observed without the use of a diagnostic tool, which allowed the machine to be repaired before its degraded performance resulted in the fabrication of any unacceptable welds (Ref 28).

Laser Beam Welding*

Tim Webber, IPG Photonics
Thomas Lieb, L·A·I International
J. Mazumder, University of Michigan

LASER BEAM WELDING (LBW) uses a moving high-density coherent optical energy source called a laser as the source of heat. *Laser* is an acronym for light amplification by stimulated emission of radiation. The coherent nature of the laser beam allows it to be focused to a small spot, leading to high energy densities of 10^5 to 10^7 W/cm² (6×10^5 to 6×10^7 W/in.²). (See the article “Introduction to High Energy Density Electron and Laser Beam Welding” in this Volume for an introduction to the nature of laser beam radiation.)

Lasers have been promoted as potentially useful welding tools for a variety of applications. By 1965, a variety of laser systems had been developed for making microwelds in electronic circuit boards, inside vacuum tubes, and in other specialized applications where conventional technology was unable to provide reliable joining. Until the 1970s, however, laser welding had been restricted to relatively thin materials and low speeds, because of the limited continuous power available. Since then, the availability of high-power continuous-wave lasers has expanded the interest and use of lasers in welding applications (Fig. 1). High-power continuous-wave lasers include:

- Carbon dioxide (CO₂) lasers with wavelength of 10.6 μm
- Neodymium-doped yttrium-aluminum-garnet (Nd:YAG) lasers with wavelength of 1.064 μm (including both lamp-pumped and diode-pumped rod)
- Ytterbium-doped yttrium-aluminum-garnet (Yb:YAG) disc lasers with wavelength of 1.030 μm
- Yb: fiber lasers with wavelength of 1.070 μm

The ability of the laser to generate a power density greater than 10^6 W/cm² (6×10^6 W/in.²) is a primary factor for its potential in welding. Table 1 compares the energy consumptions and efficiencies of LBW with other major

welding processes. Numerous experiments have shown that the laser permits precision (that is, high-quality) weld joints rivaled only by those made with an electron beam (Ref 2).

Laser beams also are used for a number of industrial processes other than welding, including shock hardening, ablation, drilling and cutting, cladding, and transformation hardening. Figure 2 shows how the laser processing parameters interact for various industrial laser beam processes. Many of the other nonwelding applications of lasers are discussed in separate articles.

Laser Beam Welding Advantages and Limitations

Industrial applications of lasers have found that laser welding offers many advantages to conventional welding methods (Ref 3–5). These advantages include:

- Light is inertia-less (hence, high processing speeds with very rapid stopping and starting become possible).
- Focused laser light provides high energy density.

Fig. 2 Process map for various industrial laser beam processes

- Laser welding can be used under ambient atmospheric conditions or controlled gas-mix environments.
- Difficult-to-weld materials (for example, titanium, quartz, etc.) can be joined.
- Workpieces do not need to be rigidly held.
- No electrode or filler materials are required.
- range of weld geometry aspect ratios can be produced.
- Precise welds (relative to position, diameter, and penetration) can be obtained.
- Welds with little or no contamination can be produced.
- The heat-affected zone (HAZ) adjacent to the weld is very narrow.
- The laser beam can be directed a considerable distance from the laser source.
- Intricate shapes can be cut or welded at high speed using automatically controlled light-deflection techniques (remote welding, cutting).

- The laser beam can also be time-shared and/or energy-shared through the use of multiple optical paths.

Limitations of LBW include:

- Precise part fit-up and alignment are much more critical in laser welding than in ordinary arc welding, because the typical focal spot diameter for a laser beam range is small (ranging in size from 0.1 to 1 mm, or 0.004 to 0.04 in.).
- Laser welding equipment is almost 10 times more expensive than comparable power arc welding systems, although laser welding can provide much higher throughput relative to conventional arc welding, with economic advantage when a considerable amount of welding is to be done.
- The penetration depth obtained in laser welding is less than that observed in electron beam welding.

The penetration depth obtained in laser welding is less than that observed in electron beam welding, because the kinetic energy of electrons with rest mass (inertia) is greater than that of the photons (with zero rest mass) in the laser beam. For example, the maximum thickness of type 304 stainless steel plate that can be welded using a 77 kW CO₂ laser is 50 mm (2 in.) (Ref 6), whereas electron beam welding (EBW) can produce welds in type 304 stainless steel up to several inches in thickness. However, the penetration depth of EBW extends only a relatively short distance under atmospheric pressure. Welding under a vacuum is required to obtain optimum efficiency in EBW.

When the capital cost of LBW is compared to EBW, laser beam welding can be a cost-effective option, because no vacuum enclosure is necessary for LBW. A laser beam can propagate an appreciable distance through the atmosphere without serious attenuation or optical degradation, because of its coherent nature. Laser beam welding thus offers an easily maneuverable, chemically clean, high-intensity, atmospheric welding process with narrow HAZ and subsequent low distortion. Laser welding also can be conducted in controlled gas-mix environments (glove boxes) with locally applied inert gas shielding or no shielding, although the use of pressure-controlled environments increases the capital costs.

Peak penetration, A_{max} , is the maximum penetration in millimeters, where P is the incident laser power in watts and is defined by:

$$A_{max}(\text{mm}) \cong 2.5 \times 10^{-2} P^{0.7} \quad (\text{Eq 1})$$

Peak penetration (A_{max}) occurs at very slow speeds, and the weld is wide with respect to the depth. In terms of weld width (w) and depth (d), both conduction-mode welding ($w/d \geq 1$) and deep-penetration welding ($w/d < 1$) can be obtained with lasers.

Laser Beam Welding Fundamentals and Process Physics

Welding with laser beams is a process that takes place in a series of steps as the concentrated laser energy, in the form of electromagnetic energy, interacts with a material. The steps involved are inherently multidisciplinary, requiring knowledge from several branches of physics. A brief summary of the nature of laser beam interactions with materials and how heat is delivered from the beam into the part being welded is presented here. More detailed information on laser/material interactions can be found in the literature, such as by von Allmen (Ref 7) and those in the Selected References at the end of this article.

Laser interactions with metals are dominated by the effects of conduction (free) electrons at the metal surface. Absorption of the laser energy by these electrons occurs very rapidly, on the order of 10^{-13} s, and in a very shallow region of the metal surface, 10 to 100 nm, which is shorter than the wavelength of the laser. The photon energy is ~ 1.2 eV for Nd:YAG and 0.12 eV for CO₂ lasers, which is sufficient to excite the free electrons and give them excess kinetic energy. The excess kinetic energy is then transferred to the metal atoms through large numbers of elementary collisions and various energy-transfer mechanisms, creating heat as the excited electrons deposit their excess energy into the atomic lattice (Ref 7). This process of converting the laser energy into heat is called thermalization, and it produces a highly localized heat pulse on the surface of the metal where irradiation occurred. The thermalized heat can then macroscopically flow from this region into the remaining portion of the substrate, as described by classical heat-flow methods (conduction, convection, and radiation heat-transfer mechanisms).

During laser welding, the temperature rise must be sufficient to melt the surface, and during keyhole welding, the temperature rise must be sufficient to vaporize the substrate. Under the conditions where vapors are being created, the laser interaction becomes more complicated, because it must pass through this vaporized column to reach the metal surface. The hot vapor column becomes partially ionized and can absorb photons through interactions with the thermally excited atoms and through the ions or free electrons in the ionized plasma via a process known as bremsstrahlung absorption.

Bremsstrahlung absorption is defined as the process by which an inner-shell electron absorbs a photon and consequently realizes a higher energy state. Inverse bremsstrahlung (IB) absorption is the opposite effect, in which an electron emits a photon and descends to a lower energy state. These processes produce continuous absorption or emission spectra. The level of the free energy states at initiation and conclusion can take on any value. These spectra are quite similar to metallic spectra in that the

plasma can be either highly absorbing or highly reflecting, depending on its frequency.

The IB absorption is the means by which most of the power absorption within the plasma occurs. The degree to which IB occurs depends on the laser wavelength, the laser irradiation, and the molecular species in the plasma. It is an undesired effect because it partially blocks the laser beam and reduces the amount of energy that reaches the metal surface. Methods to minimize IB through plasma-suppression methods are discussed later in this article. It is important to note that free electrons must be present for the IB absorption mechanism to operate. These electrons can be created by thermionic emission through the vaporization of small flakes or protrusions on the metal surface. The prevalence of these flakes and other surface defects will significantly affect the threshold of plasma initiation. Once either of these mechanisms causes an electron cascade to begin, a plasma will form. The plasma will then be maintained by the IB absorption mechanism.

Modes of Laser Welding

Lasers are capable of both conduction-mode welding and deep-penetration welding.

Conduction-Mode Welding. Momentum transfer or convection dominates conduction-mode welding. High power density (10^5 to 10^7 W/cm², or 6×10^5 to 6×10^7 W/in.²) in laser welding produces a temperature gradient of the order of 10^6 K/cm (5×10^6 °F/in.), which in turn leads to surface-tension-driven thermocapillary flow (Marangoni convection) with surface velocities of the order of 1 m/s (Ref 8, 9).

Convection is the single most important factor affecting the geometry of the laser melt pool (that is, pool shape, aspect ratio, and surface ripples) and can result in defects such as variable penetration, porosity, and lack of fusion. Convection is also responsible for mixing, and it therefore affects the composition of the melt pool during laser welding. The pool configuration in conduction-mode laser welding is a function of the Prandtl number of the materials (Pr_m)—defined as the ratio of kinematic viscosity to molecular diffusivity (Ref 9). In materials with low Prandtl numbers (for example, aluminum with $Pr_m = 0.02$), the pool shape is more spherical and is dominated by conduction heat transfer. In contrast, a material with a high Prandtl number (for example, steel with $Pr_m = 0.1$) results in a pool shape that is shallow and wide, because it is dominated by the surface-tension-driven flow (Ref 9). Free surface deformation leading to defects such as undercuts is also influenced by convection. A small amount of surface reactant elements (for example, sulfur or oxygen) can change the convection direction. For most metals, thermocapillary flow drives the hot metal to the cold side (Fig. 3), but the addition of sulfur changes the sign of the temperature-dependence function of the surface tension and drives the liquid metal to the center of the pool.

Deep-Penetration-Mode Welding. The mechanism of deep-penetration welding by a laser beam is very similar to that encountered with an electron beam (that is, energy transfer is via “keyhole” formation) (Ref 10–12). This keyhole may be produced when a beam of sufficiently high power density causes vaporization of the substrate and the pressure produced by the vapor in the crater causes displacement of the molten metal upward along the walls of the hole (Fig. 4). This hole acts as a blackbody, aiding the absorption of the laser beam as well as distributing the heat deep in the material. The energy in most conventional welding processes is deposited at the surface of the workpiece and brought into the interior by conduction.

The conditions of energy and material flow during beam welding were investigated theoretically by Klemens (Ref 13). According to Klemens, the keyhole or cavity is formed only if the beam has sufficient power density. The keyhole is filled with gas or vapor created by continuous vaporization of wall material by the beam. This cavity is surrounded by liquid that, in turn, is surrounded by solid.

The flow of the liquid and the surface tension tend to obliterate the cavity, while the vapor, which is continuously generated, tends to maintain the cavity. There is a continuous flow of material out of the cavity at the point where the beam enters. For a moving beam, this keyhole achieves a steady state (that is, the cavity and the beam associated with the molten zone move forward at the speed set by the advance of the beam). The material lost by vaporization shows

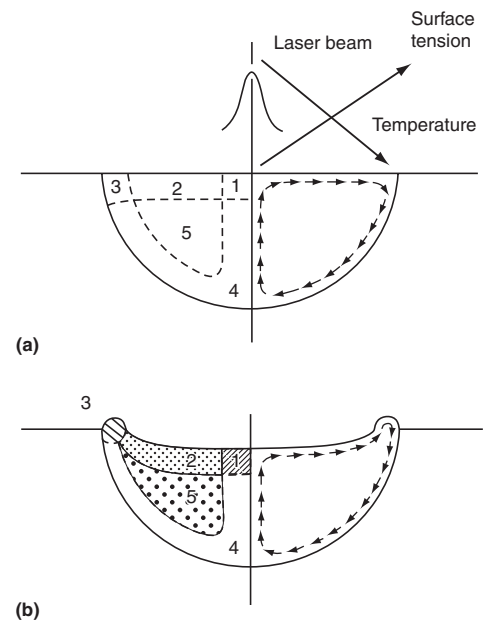

Fig. 3 Schematic showing effect of convection on laser beam welding melt pool configuration. (a) Spherical shape with flat surface typical of low- Pr_m materials. (b) Shallow and undercut free surface characteristic of high- Pr_m materials. Numbers in the figure identify specific regions: 1, stagnation flow region; 2, free surface boundary-layer region; 3, cooled corner region; 4, solid-liquid interface boundary-layer region; 5, isothermal inviscid core. Source: Ref 8

up as a depression in the solidified melt as porosity, as an inward deformation of the workpiece, or possibly as a combination of these effects. The requirement that sufficient vapor be produced to maintain a steady state leads to a minimum advance speed for a steady state. While the cavity moves through the solid and liquid material at a speed determined by the motion of the beam, materials must be moved continuously from the region ahead of the cavity to the region behind it. This is confirmed by the experimental work of Sickman and Morijn (Ref 14) and Arata et al. (Ref 15). Figure 5 shows how the laser beam interaction with the workpiece produces a keyhole plasma in the workpiece and a surface plasma above the workpiece. The relative positions of the HAZ, weld pool, and convection pattern within the weld are also shown.

An interesting experiment on the mechanism of deep-penetration welding with a continuous-wave CO₂ laser has been reported by Sickman and Marijn (Ref 14). It was conducted on transparent fused quartz so that the formation of the weld as a function of time could be photographed. The tip of the hole appears to bend toward the direction in which the workpiece is moving. This process is caused by the reflection of laser light from the leading edge of the hole. Material evaporated at this surface is effectively trapped by the cooler trailing edge. Thus, material is transported across the laser beam from the hot leading edge to the cooler trailing edge without significant ejection of material back out toward the beam. For welding speeds in the range of 10 to 45 mm/min (0.4 to 1.8 in./min), the depth of penetration was linearly related to welding speed. As expected, the minimum penetration was obtained at maximum welding speed.

Fluid flow during penetration welding was also studied by Arata et al. (Ref 15), using laser beam irradiation of low-viscosity glass at high temperature. High-speed photography of the phenomenon, taken at 8000 frames per second, clearly shows melt flow and the motion of the cavity. Molten fluid, which forms at the front wall of

the cavity, accelerates at an angle along the wall as it is driven by the forces of the turbulence generated by laser vaporization. In this process, a large vortex is formed behind the cavity near the weld surface. This vortex is considered to be the cause of the so-called “wine-glass” beads that are produced by the process.

The transport of material is mainly due to flow in the liquid. However, part of the material is transported in the vapor phase, and this vapor transport generates the excess pressure that drives the liquid flow.

Transport Phenomena (Heat, Momentum, and Mass)

Transport phenomena modeling is needed to estimate the weld pool size and cooling rate. The literature is abundant with sources describing one- to three-dimensional models for LBW and other laser processing. Steen and Mazumder (Ref 5) provide a detailed description of modeling of laser processing, although many practitioners still use the Rosenthal equation published in the early 1940s (Ref 16). It, of course, has a known error resulting from the point-source assumption used to derive the analytical solution, but it can be calibrated for a set of experiments using absorption coefficients to smooth out the errors created by the simplifying assumptions. To account for detailed process physics, numerical solution is needed. (See, for example, the article “Numerical Aspects of Modeling Welds” in this Volume.)

Process Parameters

The major independent process variables for laser welding include:

- Incident laser beam power
- Incident laser beam diameter
- Material-dependent absorptivity
- Traverse speed of the laser beam across the substrate surface

Parameters such as weld design, shielding gas, gap size for butt welds, and depth of focus with respect to the substrate also play important roles. These parameters are discussed in the section “Procedure Development” in this article.

The dependent variables are considered to be:

- Depth of penetration
- Microstructure and metallurgical properties of the laser-welded joints

The effects of some of the important variables are briefly discussed as follows.

Laser Beam Power. The depth of penetration with laser welding is directly related to the power density of the laser beam and is a function of incident beam power and beam diameter. For a constant beam diameter, penetration typically increases as the beam power is increased. Locke et al. (Ref 17) and Baardsen et al. (Ref 18) report that penetration increases almost linearly with incident laser power. It is generally observed that for LBW of a particular thickness, a minimum threshold power is required to initiate melting and form a weld pool.

Laser Beam Diameter. This parameter is one of the most important because it determines the power density. However, it is a challenge to measure for high-power laser beams. This difficulty is due partly to the nature of the beam diameter and partly to the definition of what is to be measured. A Gaussian beam diameter, d_G , can be defined as the diameter where the power has dropped to $1/e^2$ or $1/e$ of the central

Fig. 4 Forming of a narrow and deep capillary of vapor, or a keyhole

Fig. 5 Schematic of keyhole plasma and surface plasma. HAZ, heat-affected zone. Courtesy of Air Liquide

value. The beam diameter defined on the basis of $1/e^2$ of the central value contains more than 80% of the total power, whereas the power contained for $1/e$ beam definition is slightly over 60% (Ref 19). Therefore, the $1/e^2$ beam diameter is recommended.

Many techniques have been used to measure the beam diameter, but most are unsatisfactory in some respect. Single isotherm contouring techniques (for example, charring paper and drilling acrylic or metal plates) suffer because the particular isotherm they plot depends both on power and on exposure time. These techniques are also highly unlikely to coincide with either the $1/e$ or $1/e^2$ diameters. Multiple isotherm contouring techniques overcome these difficulties but are tedious to interpret. However, several commercial systems are now available that allow the direct measurement of the focused spot size and are discussed in the section "Procedure Development" in this article.

Absorptivity. The efficiency of LBW depends on the absorption of light energy by the workpiece. Any heat-transfer calculation for laser processing is based on the energy absorbed by the workpiece.

The infrared absorption of metal largely depends on the conductive absorption by free electrons. Therefore, absorptivity is a function of the electrical resistivity of the substrate material. Arata and Miyamoto (Ref 20) and McCay et al. (Ref 21) measured the absorptivity of polished surfaces of various materials and concluded that absorptivity is proportional to the square root of the electrical resistivity. This agrees closely with:

$$A = 112.2\sqrt{\rho_r} \quad (\text{Eq 2})$$

where A is the absorptivity, and ρ_r is the electrical resistivity ($\Omega \cdot \text{cm}$). A temperature-dependent relationship between the electrical resistivity and emissivity of the metal was derived by Bramson (Ref 22). Bramson's formula can be used for theoretical calculation of the absorptivity from the electrical resistivity because absorptivity is related to the emissivity. However, Bramson's formulas (Eq 3) will be valid only for metals without surface oxide layers (when heating occurs in a vacuum). The presence of an oxide layer will increase the absorptivity. The relationship between the emissivity and the electrical resistivity of a substrate for the perpendicular incidence of radiation of long wavelength derived by Bramson is:

$$\epsilon_\lambda = 0.365 \left[\frac{\rho_r(T)}{\lambda} \right]^{1/2} - 0.0667 \left[\frac{\rho_r(T)}{\lambda} \right] + 0.006 \left[\frac{\rho_r(T)}{\lambda} \right]^{3/2} \quad (\text{Eq 3})$$

where $\rho_r(T)$ is the electrical resistivity at absolute temperature, T , expressed in Ohm-centimeter ($\Omega \cdot \text{cm}$), and $\epsilon_\lambda(T)$ is the emissivity

of the substrate at temperature T (in $^\circ\text{C}$) for radiation having a wavelength λ (cm).

The estimated absorptivity for Ti-6Al-4V at 300°C (572°F) using Bramson's formula is approximately 15%. Experimental data published by Arata and Miyamoto (Ref 20) and Bramson (Ref 22) indicate that the absorptivities of aluminum, silver, and copper are between 2 and 3% and those of stainless steel (type 304), iron, and zirconium are below 15% even in the molten state. Reflection losses of this magnitude are significant. Therefore, when a sheet metal product form is welded, measures must be taken to avoid reflection losses. Applying an absorbent powder to the surface or forming an anodized film on the surface are two techniques that are considered to be very effective (Ref 21).

Absorptivity can also be increased by the use of reactive gases. Jorgensen (Ref 23) reported that the addition of 10% O_2 to an argon shielding gas gives an increase of up to 100% in welding depth. Jorgensen also found that gas flow had no significant effect on weld depth. However, an increase in depth was associated with a decrease in reflectivity, which was obtained by the addition of a small amount of oxygen.

Although metals are poor absorbers of infrared energy at room temperature, above a certain threshold, approximately 10^6 to 10^7 W/cm^2 (6×10^6 to 6×10^7 $\text{W}/\text{in.}^2$), energy transfer via the keyhole leads to much higher effective absorptivity. This occurs by multiple reflections within the keyhole, once a keyhole has formed. Because of this, the effective absorptivity increases rapidly and enables deep-penetration welding by the laser, despite the large convergence angles for laser beams relative to electron beams (Ref 21). However, the threshold energy required for keyhole formation in laser welding is higher than that required for an electron beam (1.5×10^5 W/cm^2 , or 9.5×10^5 $\text{W}/\text{in.}^2$) because of the poor absorptivity. Nevertheless, energy transfer by this keyhole mechanism permits the laser to provide efficient welding of even highly reflective materials (for example, aluminum) (Ref 24).

Traverse Speed. The correlation of penetration depth relative to welding speed with both LBW and EBW processes was studied by Duley (Ref 10) and Locke and Hella (Ref 17). The penetration in the laser weld is consistently less than that obtained with an electron beam, but the relative difference between the two penetration depths diminishes as the welding speed is increased. However, Duley (Ref 10) found this somewhat surprising because, as pointed out by Baardsen et al. (Ref 18), the time to form a void or keyhole depends on the illumination time for a particular area on the surface of the workpiece as the welding speed is increased. When this occurs, the average power dissipated in the sheet is expected to drop because the keyhole is no longer a completely effective trap for the incident laser radiation. For an electron

beam, absorptivity of the material is independent of the shape and extent of the keyhole. Hence, the total power dissipated in the workpiece is less dependent on the welding speed. However, Crafer (Ref 25) reports that the keyhole penetration threshold for laser beams or electron beams of radius 0.1 mm (0.004 in.) incident on a steel surface of thermal diffusivity $10 \text{ mm}^2/\text{s}$ ($0.4 \text{ ft}^2/\text{h}$) is achieved in 1 ms. This could be regarded as instantaneous. Again, for very low welding speeds, the penetration depth of laser welds becomes significantly less than that attainable with the electron beam. According to Locke et al. (Ref 17), this can be attributed to the formation of a plasma cloud, which attenuates the incident beam.

Process Selection

Laser beam welding is characterized by its low distortion and low specific energy input. It is an accurate, inertia-less method capable of high welding speeds for most materials, including many difficult-to-join materials. The process is often selected for high-volume, high-speed applications for joining materials/components that pose problems during arc welding, such as titanium alloys used for pacemakers. Often the selection criteria depend on economics, which is related to joining rate, welding speed, distortion, and postwelding treatment needs, among many other considerations. Another important consideration is whether the higher speeds can offset the higher initial capital costs within a reasonable time period. Low specific energy input is responsible for applications such as pacemakers, because it reduces the possibility of thermal damage of the sophisticated electronics contained in such devices. Some manufacturers of cigarette lighters are now using LBW as an alternative to resistance welding because of the lower porosity in laser welds.

Economics combined with the smaller HAZ and higher overall weld toughness associated with LBW makes it a popular joining method for high-volume automotive applications. For example, multiple pieces of different compositions are joined by LBW to form blanks for automobile body components such as side-frame panels. These blanks need considerable weld toughness to withstand the stresses induced during subsequent press forming operations. Weld geometry is another consideration for the selection of the process. Because a smaller volume of material is melted due to the low specific energy input, weld defects such as undercuts are also minimized. This is especially important for applications involving dissimilar workpiece thicknesses, which have a higher probability of undercuts.

Another example where the narrow HAZ combined with high welding speed makes LBW a preferred method is the welding of planetary gears used in automobile powertrains. Planetary gear teeth are so closely spaced that it

is difficult to access the weld joint without melting the neighboring gear teeth using conventional (arc) welding. This is one of the oldest LBW applications, and it is routinely carried out worldwide.

Metallurgical considerations are sometimes responsible for the selection of the LBW process. The characteristic low specific energy input for this process results in a higher cooling rate. Higher cooling rates are often needed to suppress precipitation of harmful intermetallic compounds (which may promote brittle fracture) during the solidification of the weld pool. This is an important criterion for welding of many nickel-base superalloys. For titanium alloys, a high cooling rate limits grain growth and oxidation during solidification, making it possible to weld titanium alloys outside a vacuum chamber with modest inert gas shielding. High cooling rates also help to avoid sensitization during welding of stainless steels. On the other hand, high cooling rates may cause problems in many ferrous alloys by promoting martensitic transformation and higher residual stresses; however, this is often balanced by the smaller size of the HAZ.

In many applications where resistance spot welding has been traditionally used, laser welding can offer many advantages, including single-side access and reductions in weight and costs by removing the tab needed in resistance welding. Tabs consist of extra material provided during the fabrication of the square frame in resistance welding that enable the electrodes to push the excess material together to complete the welding process. Adapting joint designs such as butt welding to the laser welding process eliminates the need for tabs. For example, up to 60 kg (130 lb) of steel can be saved from an automobile by replacing resistance spot welding with laser welding and taking advantage of the design flexibility (Ref 26).

Another key factor in the successful implementation of laser welding is the selection of the appropriate laser for a given application. An excellent source of laser beam device vendors is *Laser Focus World* buyer's guide, which is published annually (Ref 27) and is available online. Characteristics and parameters of commercial lasers available for welding are listed in Table 2. Carbon dioxide (CO₂) lasers with up to 25 kW power capacities and pulsed Nd:YAG lasers with up to 500 W peak power have been the workhorses for the industry until recently. The majority of the CO₂ laser applications involve lasers up to 6 kW. Recently, disc and fiber lasers have, in general, exceeded the power level of CO₂ lasers used in the welding industry.

In addition to welding speed and depth of penetration, which are the most important LBW attributes, the flexibility and precision of beam delivery are also important criteria for selecting LBW. Multi-axis workstations and robotics are already available in the market for

CO₂ laser applications. However, one of the major advantages of the 1 μm laser family (disc, fiber, and Nd:YAG laser) is its capability to deliver the energy through an optical fiber cable. Unfortunately, no fibers are yet available for CO₂ lasers with a 10.6 μm wavelength that are of a power level for welding metals. Much of the high-speed and deep-penetration welding is carried out with lasers with power in excess of 1 kW.

Continuous-wave 1 μm lasers can outperform CO₂ lasers with the same power capacity (Fig. 6). For materials with relatively high reflectivity, such as aluminum and copper, Nd:YAG, disc, and fiber lasers have better coupling, especially for conduction-mode welding, because of their shorter wavelength (1.06 μm). When conduction-mode welding of all materials, and even in keyhole welding of reflective material, care should be taken to prevent reflected energy from entering the beam-delivery system and/or impinging on beam-delivery hardware. Considerable damage can be done because a substantial percentage of the laser power can be reflected. A good guideline is to employ a beam angle 1.5 times the cone angle of the focused laser beam normal to the workpiece (Fig. 7).

Procedure Development

The key factor for procedure development is the selection of optimum independent and dependent process variables. The independent process variables for laser welding include incident laser beam power, incident laser beam diameter, traverse speed, absorptivity, shielding gas, depth of focus and focal position, and weld design and gap size. The important dependent variables are depth of penetration, microstructure and mechanical properties of laser-welded joints, and weld pool geometry. Detailed discussions of most of these variables are provided in Ref 1. They are discussed subsequently in view of their role in procedure development.

Power density is defined as the incident power per unit area. In any welding process, it is the power density that determines the depth of penetration and joining rate of the process, as much as the total power of the source. Therefore, beam diameter and spatial distribution of the laser beam energy play an extremely important role because they determine the area of incidence. Two other variables affecting the ultimate power density driving the welding process are absorptivity and plasma beam interaction, such as refraction. Position of focus with respect to the substrate and depth of focus of the beam also affect the power density and penetration depth.

Spatial distribution of the energy is generally constant for a given laser, whereas absorptivity is a function of the substrate, its surface condition, and the laser beam wavelength. Therefore, the most common practice for process development with a given laser and material is the selection of focusing optics for optimum power density and working distance by controlling the beam diameter. Thus, a working knowledge of the focusing optics is important for an engineer developing the laser welding process. Important formulas related to the laser as a welding tool are summarized in following subsections dealing with process variables.

Interaction time is defined as the time a particular point on the substrate spends under the laser beam. In simple terms, it is the ratio of the beam diameter to the traverse speed. Strictly on the basis of heat transfer, one should account for the total time of heating and cooling at the point above the ambient temperature. This is, however, a much more difficult quantity to keep track of compared to the ratio of the traverse speed and beam diameter. Again, it is the interaction time that controls the weld pool profile, not the traverse speed alone. Laser welding procedure development involves the selection of optimum power density and interaction time after the selection of the laser.

Table 2 Parameters for selected pulsed and continuous-wave lasers used for laser beam welding applications

Laser	Pulse length, ms	Pulse energy, J	Peak power, kW	Maximum weld thickness(a)		Welding speed	
				mm	in.	mm/s	in./min
Pulsed							
Ruby	3–10	20–50	1–5	0.13–0.50	0.005–0.020	1.2	3.0
Nd:glass	3–10	20–50	1–5	0.13–0.50	0.005–0.020	0.63	1.5
Nd:YAG(b)	3–10	10–100	1–10	0.13–0.60	0.005–0.025	2.1	5.0
CO ₂	5–20	0.1–10	1–5	0.13	0.005	1.2	3.0
Continuous wave							
Nd:YAG(b)	1.8	5.56	0.022	5.8	14.0
CO ₂ (direct current excited)	1	0.60	0.025	12.7	30.0
CO ₂ gas dynamic	20	19.0	0.750	21.2	50.0
CO ₂ gas dynamic	77	50.8	2.00	26.7	63.0
CO ₂ (radio-frequency excited)	5	10.0	0.4	10.8	25.6

Laser beam power is one of the primary variables in determining the penetration depth in laser welding. For process development, the first action one should take is to calibrate the laser output power with the power delivered at the substrate. There is often a measurable loss due to the reflective and transmissive optics used to deliver the beam from the laser to the workpiece. Almost all commercial lasers are equipped with some kind of power-measuring device based either on a flowing-water

calorimeter where the full beam is dumped, or a solid-state detector where a fraction of the laser energy is continuously deposited. Additional calorimetric devices should be maintained to measure power at the workpiece for periodic calibration of output power with the power delivered at the weld pool.

For lasers with power in excess of a few hundred watts, water-cooled calorimeters are the most popular. For on-line monitoring, many multikilowatt systems also use precalibrated

Fig. 7 Beam angle for welding reflective materials. Angle B is equal to 1.5 times angle A to minimize the risk of damaging the optics through back reflections.

solid-state detectors, usually behind one of the cavity mirrors that has a small leak of approximately 1% or less. Several vendors offer both types of power meters. In addition to the absolute power measurement, power density is also strongly influenced by beam diameter and beam mode (that is, the spatial distribution of energy, as described in the section “Laser Beam Spatial Distribution” in this article). Thus, beam diameter and beam mode also should be monitored to control power density.

Laser beam diameter is one of the most important variables because it determines the power density for a given total power. The focused beam diameter will also influence weld width, which is often an important weld requirement (Ref 29, 30). The spatial distribution of energy in the beam affects the focusing characteristics of the beam. For a Gaussian beam, the diameter is defined as $1/e^2$ of the central value (Fig. 8), and it contains almost 86% of the total power. The diffraction-limited focal spot size (d_{min} in mm) for such a Gaussian beam is given by the following relationship:

$$d_{min} = \frac{1.27f\lambda}{D} \tag{Eq 4}$$

Fig. 8 Variation of relative intensity and percentage of total power with radius for a Gaussian beam. Source: Ref 19

where D is the unfocused beam diameter (in mm), f is the focal length (in mm) of the focusing optics, and λ is the wavelength (in mm) of the laser beam. Note that 1.27 is $4/\pi$. This is an ideal situation, and often the focused beam diameter will be larger due to aberrations and other imperfections in the focusing optics.

Light can be considered to take the form of a wave that can interfere constructively or destructively, depending on the phase angle between intersecting waves. Diffraction is one way that interference occurs with light, and it will occur when a beam is interrupted by an edge or aperture. A diffraction pattern will form of maximum and minimum light intensity. When a lens is introduced into the diffracted beam, the angle between each minimum can be approximated and thus the focused spot size. Diffraction-limited spot sizes for various types of laser beams can be estimated using the relationships given in Eq 5 to 7. For a rectangular beam with a plane wave front:

$$d_{\min} = \frac{2f\lambda}{D} \tag{Eq 5}$$

For a circular beam with a plane wave front:

$$d_{\min} = \frac{2.44f\lambda}{D} \tag{Eq 6}$$

For a multimode beam with a plane wave front—where the transverse electromagnetic mode (TEM) is described in indexing convention, TEM_{*m*} (as described in the following subsection on laser beam spatial distribution)—the diffraction-limited spot size is:

$$d_{\min} = \frac{2.44f\lambda}{D}(2m + n + 1) \tag{Eq 7}$$

For example, if a 25 mm (1 in.) TEM₀₁CO₂ laser beam is focused by a 100 mm (4 in.) focal-length lens, the diffraction-limited spot diameter is:

$$d_{\min} = \frac{2.44 \times 100 \times 10.6 \times 10^{-3}}{25} (2.0 + 1 + 1) = 0.21 \text{ mm}$$

However, as indicated earlier, these are estimates for the theoretically possible minimum spot size. One of the more useful means for evaluation of beam quality is the M^2 concept (Ref 5, 31). M^2 is the ratio of the divergence (θ) of the actual beam to that of a theoretical (ideal Gaussian) diffraction-limited beam:

$$M = \frac{\theta_{\text{Actual}}}{\theta_{\text{Gaussian}}}$$

The correlated beam diameter based on the M^2 concept is:

$$d_{\min}(\text{mm}) = \frac{4M^2f\lambda}{\pi D} \tag{Eq 8}$$

In this case, M must be measured at two known locations in the beam propagation path. This reinforces the point that a proper measurement technique for beam diameter is imperative for estimating the actual beam diameter and the power density.

There are several commercial systems now available for beam diameter measurement. Sasnett et al. (Ref 31) describe one system that is specifically designed for beam evaluation based on the M^2 concept. This instrument is capable of measuring the beam width within 0.5 μm accuracy in two mutually perpendicular transverse directions. Knife edges are used to scan the beam, and a set of lenses are traversed in the direction of the beam propagation to change the positions of the beam width. The measurement procedure and data acquisition and display are computer controlled.

Another commercial system is based on a hollow rotating needle, which samples the beam. This is based on the research carried out by Loosen et al. (Ref 32) and Lim and Steen (Ref 33), which resulted in the development of a laser beam analysis system based on a rotating needle that reflects part of the beam to a set of detectors.

Although beam quality related to the ideal Gaussian beam is a good starting point, there is evidence that for high-power laser processing, this characterization may not be sufficient (Ref 34). Spatial coherence and temporal and local fluctuations are generally ignored, but they do affect the processing behavior. Many European research groups are working on characterizing the beam in terms of the mode coherence coefficient, which is based on a set of suitable modes and averaged intensity distribution and which takes into account the partial coherence properties of the beam.

Another complication of high-power laser welding is interaction with the plasma column. Rockstroh et al. (Ref 35) found that free electrons in the plasma column cause absorption and refractions. For welding of aluminum with a CO₂ laser, as much as 30% of the energy is lost in the plasma, and the refracted beam diameter is 8% larger. This measurement is based on the

electron density measurement using the emission spectroscopy technique. This observation is subsequently supported by similar measurements by Lober et al. (Ref 36, 37). Complete characterization of beam diameter will require both measurement at the focal spot before processing and monitoring of the beam refraction during the process using spectroscopic techniques.

Laser Beam Spatial Distribution. Every laser resonator cavity, defined by the mirrors of the laser, has certain stable configurations of the electromagnetic field called modes. A well-defined mode has a definite spatial distribution for the laser beam. As evident from Eq 7, the mode affects the focused beam diameter and leads to higher spot size for a given $f\lambda$ focusing optics. The general convention for indexing a mode is TEM_{*m*} (transverse electromagnetic mode with m number of radial zero fields and n number of angular zero fields). TEM₀₀ is the ideal Gaussian beam and will provide the smallest focused spot and highest power density. Most of the fast axial-flow lasers offer a TEM₀₀ or TEM₀₁ beam. Most of the transverse-flow lasers offer TEM₀₁ (doughnut-shaped spatial distribution).

Intensity distribution for different modes can be calculated using the Hermite polynomial for rectangular coordinates and the LaGuerre polynomial for polar coordinates using the expressions for a TEM_{*m*} mode beam given in Eq 9 to 11. For a rectangular coordinate:

$$\sqrt{I_{mn}(x,y)} = \{H_m(\sqrt{2gx/R_b})H_n(\sqrt{2y/R_b})g \exp[-2r^2/R_b^2]\} \tag{Eq 9}$$

For a polar coordinate:

$$I_{mn}(r, \theta) = [L_m^n(2r^2/R_p^2)]^2 (\sqrt{2gr/R_0})^{2n} g \exp[-2^2/R_b^2] \cos^2 n\theta \tag{Eq 10}$$

For a Gaussian beam with TEM₀₀ mode:

$$I(\lambda) = \exp(-2r^2/R_b^2) \tag{Eq 11}$$

In Eq 9 to 11, x is a variable, r is the radial position, θ is the angular position of the beam, R_b is the beam radius at the $1/e^2$ point, H_m is the Hermite polynomial of order m , and L_m^n is the generalized LaGuerre polynomial.

A schematic of intensity distributions for different beam modes is shown in Fig. 9. For process development, the lowest-order mode available is the best choice for achieving the highest power density from a given power.

The position of focus with respect to the substrate surface influences the weld pool profile and penetration during laser welding. The optimum position for the focal point of the laser beam with respect to the substrate was investigated by Wilgoss (Ref 39). Figure 10 shows the transverse profiles generated by moving the focus point in 2.5 mm (0.1 in.) steps

perpendicular to the plane of the workpiece. The reported plate thickness for this study was 6 mm (0.25 in.). When the focal point was positioned deep inside the workpiece, a V-shaped weld resulted, necessitating more precise alignment than that for a parallel-side weld of the same cross section. When the beam was focused well above the level of the workpiece surface, a large “nail head” with a consequent loss of penetration was observed.

Wilgoss et al. (Ref 39) concluded that the optimum focus is approximately 1 mm (0.04 in.) below the level of the workpiece surface. This produced welds with little or no “nail head” and nearly parallel sides.

Engel (Ref 40) reported that for several metals, the optimum position of the focus is 1.25 to 2.5 mm (0.05 to 0.1 in.) below the surface. Research by Alexander (Ref 41) using a 10 kW laser and 1.9 mm (3/4 in.) thick AISI 1020 steel revealed that the optimum position of focus was 2 mm (0.08 in.) below the surface. When the beam was focused 4 mm (0.16 in.) below the surface, the depth of penetration was almost the same as that for the 2 mm (0.08 in.) focus depth. The general consensus is that the optimum position for the focal point is below the surface, but the exact distance is

dependent on the thickness of the workpiece and the laser power used.

Depth of focus is extremely important for welding thin-section materials because for a shallow depth of focus, the substrate comes in and out of the focal position due to thermal distortion. Depth of focus is defined as the distance over which the focus beam has the same approximate intensity. According to the Laser Institute of America, depth of focus is defined as the range over which the focus spot radius is increased by 5%. Based on this definition, the depth of focus (Z) is given by:

$$Z = \pm \frac{0.32\pi R_b^2}{\lambda} = \pm \frac{R_b^2}{\lambda} = \frac{2.33(F\lambda)^2}{\lambda} = 1.488F^2\lambda \quad (\text{Eq 12})$$

where F equals f/λ of the optics.

One can see from the previous expression that as the F number of the focusing optics increases, depth of focus also increases. However, this is also accompanied by an increased beam diameter and decreased power density. As a result, these variables must be optimized for each particular application.

Focus position can be taken from optics specification and/or instrumentation. Various empirical strategies can be employed to determine focus. A common practice in determining the focal position and depth of focus is to carry out a trial bead-on-plate weld on an inclined plate and use the position where the plasma seems to be the visually strongest. This is a quick, but not necessarily the most accurate, approach for establishing the focal position. Ultimately, the desired fusion-zone shape is obtained by adjusting focus position with respect to the initial focus determination and surface location.

There is some wisdom in developing a welding process where the work is being done at or approximately the depth of focus of the optics. It allows the maximum accommodation of

errors or variation in the Z -position. It is tempting to work outside the depth of focus when a larger image size is desired than an optics set can provide. Realize that sensitivity in spot size to Z -position change will be twice what it would be if the work is done within the depth of focus.

Absorptivity. The importance of absorptivity and its role in laser welding was discussed earlier. For deep-penetration welding with power densities exceeding 10^6 W/cm², keyhole formation leads to high absorption by trapping the beam inside the hole by total internal reflection. However, the absorption during the initial transient period is dependent on wavelength and surface conditions. There are several techniques to enhance the initial absorption (Ref 42). They include:

- Nonmetallic absorbent coatings
- Preheating
- Surface roughening
- Application of an electric field of the correct sign
- Periodic surface structure or induced grating structure

Surface periodic structure can be used to enhance absorption of the wavelength of interest, much like the use of optical gratings with spacing for preferential absorption of a certain wavelength of laser light.

Traverse Speed. The welding speed increases with increasing laser power to produce a constant penetration depth, as shown in Fig. 11. For a given thickness and power, a range of speed can be used to make successful welds. However, the fusion-zone size will increase with the decreased speed within that range. For process development, the nugget size or fusion-zone size and shape is often prescribed by the design engineer for strength considerations. The laser welding engineer needs to select an optimum combination of speed, power, and focus spot size to deliver the required nugget size.

Welding charts of speed versus power and the resulting weld penetration are useful to investigate and plan a welding solution. With CO₂ lasers, the task of generating a chart was a reasonable task for the equipment supplier, because there are usually a limited number of optical combinations available. With a given beam diameter and M^2 value, there exist only a few practical focal length lenses and resulting spot sizes to work with. Charts of weld performance can be produced for a few engineering alloys for a given laser make and model by the laser manufacturer's applications engineering staff. These kinds of charts do have a number of shortcomings, however. They are most often done for a bead-on-plate rather than a real weld joint. They are, at best, an estimate of the effect of process parameters on a resulting joint. The 1 μm laser family, in contrast, has available many combinations of optical components and configurations, providing a wide range of focus spot sizes and

Fig. 9 Beam cross sections for four different transverse electromagnetic modes (TEM). Source: Ref 38

Source: Ref 39

F -numbers. Charting weld performance for every useful optical combination is simply too large an undertaking for the equipment manufacturer.

Laser welding efficiency has been found to be relatively consistent over a reasonable range of weld parameters (Ref 44, 45). It is also interesting to note that significant changes in alloy content, for example, between low-carbon steel and stainless steel, do not significantly impact laser welding efficiency. These facts, in the absence of a chart, allow a simple calculation to obtain an approximation of weld performance for a given set of weld parameters, provided a laser welding efficiency for the material is known.

Welding efficiency can be defined as the fraction of the amount of energy required to take a volume of metal from a base temperature to its melt temperature plus the heat of fusion energy required to melt the metal divided by the amount of energy actually used. This concept of welding efficiency must be differentiated from the concept of transfer efficiency. Arc welding processes have energy-transfer efficiencies of 70 to 90%; however, they only have welding efficiencies of 5 to 10% (Ref 12). Note that some authors use the term *melting efficiency* interchangeably with *welding efficiency*. This means the workpiece is heated by the transferred energy that did not produce a fusion zone. It is this excess heat that contributes to distortion and unwanted material transformation. The advantage of the laser is that energy-transfer efficiencies of 70 to 90% are found by the keyhole mechanism, but welding efficiency can be 30 to 60% (Ref 46–49). Substantially more of the laser energy transferred to the material generates fusion than occurs with arc welding processes.

Ream (Ref 44) defines laser welding efficiency, E , as “melt volume per unit of laser energy” in mm^3/kJ :

$$A_f V / P = E \quad (\text{Eq 13})$$

where A_f is the fusion-zone area in mm^2 , V is the traverse speed in mm/s , and P is the laser power on the workpiece in kW . Ream found that for both mild steel and stainless steel the value of E was 50 to 60 mm^3/kJ for a range

Fig. 11 Welding speed versus laser power for a 5 kW CO_2 laser. The base metal is Ti-6Al-4V. Source: Ref 43

of parameters and laser types. The work of Bermanns and Faerber (Ref 30) supported Ream's finding and also discovered that weld width is consistently inversely proportional to traverse speed. For example, at 3 kW and 50 mm/s (2 in./s) with a 100 μm focus spot, the weld width calculated from the 5.8 mm (0.2 in.) penetration and a fusion-zone area of 2.5 mm^2 (0.004 in.^2) is 0.43 mm (0.02 in.). At a welding speed of 167 mm/s (6.6 in./s), the weld width was 0.19 mm (0.007 in.). If it was desired to increase weld width, a question would be: What would the resulting weld look like if a 200 μm focused spot size was used with 3 kW? The assumption is that the weld width will increase by the spot size increase and the area of the welds will remain the same. A simple calculation reveals that the new weld width with a 200 μm focus spot will be 0.29 and 0.53 mm (0.01 and 0.02 in.) at 50 and 167 mm/s (2.0 and 6.6 in./s), respectively. The weld penetration will be 4.7 and 2.5 mm (0.2 and 0.1 in.), respectively. This calculated result is not an exact match, but it does agree with the chart in Fig. 12 that was generated from weld trials.

Plasma Suppression and Shielding Gas. The plasma produced during laser welding absorbs and scatters the laser beam. It is therefore necessary to remove or suppress plasma. The higher the power, the more clearly the phenomenon can be observed. This negative effect of plasma can be reduced by diluting it with injection of high-ionization-potential gas, such as helium, argon, nitrogen, and mixtures of these gases. Shielding gas may also be required to protect the hot resolidifying weld surfaces from oxidation. Both the composition and flow rate of the plasma suppression gas and shielding gas influence the depth of penetration (Ref 50, 51). In most literature, plasma suppression gas and shielding gas are referred to as shielding gas altogether.

Seaman (Ref 50) studied the role of shielding gas in high-power continuous-wave CO_2 laser welding. Weld cross sections made with various shielding gases and gas mixtures show a 60% difference in penetration. However, gases that permit the greatest penetration do not necessarily blanket (displace air from above the weld rapidly) the weld effectively at characteristically high laser welding speeds. This means that compromises are necessary to permit sound, deep-penetration laser welds (Ref 50).

The effect of the composition of the shielding gas on depth of penetration was studied by Seaman (Ref 50) and Rein et al. (Ref 51). Generally, helium is used as the shielding gas for high-power CO_2 laser welding. As shown in Fig. 13, helium seems to improve beam transmission, whereas argon can cause severe beam blockage (Ref 50). This is probably caused by the lower ionization potential of argon (15 eV) compared to that of helium (25 eV). The effects of air and CO_2 on beam transmission lie between the extremes represented by argon and helium (Fig. 14). Rein et al. (Ref 51) have shown that the addition of small quantities of

hydrogen, sulfur hexafluoride, and CO_2 to the helium enhances penetration at welding speeds below 40 mm/s (95 in./min).

The ionization potential of the shielding gas is not the only consideration for laser welding, especially at higher speeds. This is because gases with higher ionization potentials have lower atomic numbers and lower masses. These lighter gases are less effective in displacing air from the laser/material interaction area in the short time available in high-speed welding. Heavier gases are better able to displace air in a short time. Therefore, a mixture of heavier and lighter gases will result in optimum penetration. Figure 15 shows that as speed increases, the improvement resulting from the addition of a small amount of argon to helium (10% Ar and 90% He) becomes more noticeable. Newer studies found that it is even possible to replace helium with argon altogether by using appropriate new nozzle design technology that displaces the plasma away (Ref 52).

For mass-scale production, the cost of shielding gas is also an important consideration. Recently, Chrysler Corporation replaced helium with CO_2 for plasma suppression during laser welding (Ref 53). The shielding gas is delivered from the side at an angle to suppress the plasma and remove metal vapor from the interaction point. For 14 kW laser power, a welding speed of 20 m/min (65 ft/min), and a shielding gas flow rate of 40 L/min (85 ft^3/h), CO_2 shielding resulted in a wider weld nugget size, but the mechanical properties were acceptable. The cost of helium gas is much higher (e.g., approximately 5 times in 2011) than for CO_2 gas, and helium prices tend to be much more volatile. Therefore, for process development, there is room for optimization of gas selection. However, one should remember that the use of CO_2 gas for a CO_2 laser may cause problems for the concentric gas shield due to preferential absorption.

Proper implementation of a shielding gas for plasma suppression can also be applied for joining difficult-to-weld materials with volatile alloying elements such as aluminum alloy 5083. Blake and Mazumder (Ref 24) demonstrated that with a properly designed helium suppression jet, magnesium losses and porosity formation could be minimized during laser welding of 5083 aluminum alloy. The resulting weld had a tensile strength equal to its parent material. This demonstrates that for process development, shielding gas can also be used to control the chemistry and weld defects.

Plasma suppression/shield gas selection and implementation for the 1 μm laser family is less complex than for the 10.6 μm laser. The metal vapor above the weld does not absorb the shorter wavelength light to the degree it does the longer wavelength. The result is that less plasma is formed in the metal vapor to interrupt and disperse the focused beam. In general, industry uses argon for shielding welds made with 1 μm lasers (Ref 30).

Health and Safety

Laser beam welding hazards differ substantially from hazards encountered in other welding techniques. The primary wavelengths for lasers used in welding are invisible to the human eye. The hazards are not readily apparent, and inexperienced or unaware personnel may suffer permanent injury before the existence of hazardous conditions is recognized. For this reason, the United States Federal

Occupational Safety and Health Administration (OSHA), through its “Alliance” program, has fostered the adoption of the American National Standards Institute (ANSI) specification ANSI Z136 series as its enforcement text for laser workplace safety. ANSI Z136.1, “Safe Use of Lasers” (2007 or later edition), requires that each facility using lasers designates an individual as laser safety officer. This individual should be familiar with laser safety and ANSI Z136.1. The officer should implement a laser

safety management program, and, among other things, monitor the procurement, care, use, and disposal of lasers in the organization to ensure adherence to safe laser practice and the ANSI requirements. Because of the complexity of laser safety, this approach is virtually mandatory. The following brief review of laser safety is an introduction but, by itself, is not sufficient to ensure personnel safety.

Injury Hazards

Eye Hazards. Any laser beam capable of welding metals is also capable of causing serious damage to human tissue. Personnel exposure to the beam and any specularly reflected beam must therefore be prevented at all times. Certain lasers, however, are also capable of producing diffuse reflections that can cause permanent eye damage. Hence, viewing of the impact area of the laser beam or reflected beams also must be prevented. While wearing tested and marked laser protective eyewear is the minimum protection from this hazard, the preferred method for safeguarding is complete enclosure.

Enclosures can range from a simple sleeve between the laser optic and the part to be welded to fully automatic operations in enclosed rooms. The following are general guidelines:

- Laser enclosures (called protective housings in the pertinent safety and standards regulations) must be class I anywhere and everywhere the radiation is not needed for the function of the product. The enclosure must be opaque to the laser wavelength. When purchasing a complete system, including the enclosure, the manufacturer (usually the machine integrator) of that equipment must provide a certified laser product that incorporates all the necessary performance features. Any assembly which incorporates, or is intended to incorporate, a laser is itself a laser product. Therefore, automation and other machine integrators become laser product manufacturers when they marry the laser with other equipment and/or protective housings. Laser product manufacturers must certify and report their products to the Food and Drug Administration (FDA) prior to entry into commerce. The purchaser of complete certified products should see the certification label (nameplate) on the product and ask the supplier for the accession number, which is the FDA’s tracking number for reports filed.
- Protective enclosures built on site (not purchased as part of the system) must follow the performance requirements in 21 CFR 1040.10 and .11 and ANSI Z136.1 clause 4, “Control Measures.” The enclosure must be interlocked to prevent firing of the laser beam when personnel could be exposed.

Fig. 14 Comparison of CO₂ laser weld penetration achieved with different shielding gases. Source: Ref 38

When the piece to be welded is a part of the enclosure, the interlocks should also prevent firing, unless the piece is in place. In the case of pulsed lasers, breaking of the interlocks should also discharge the stored energy into a dummy load.

- If the enclosure is large enough to walk in, the walk-in area is called the laser controlled area (LCA). Signs are required at access points to the enclosures in accordance with ANSI Z136.1. (If a complete system with a walk-in enclosure was purchased, it is called a walk-in workstation, and it must meet FDA Laser Policy 37 and ANSI Z136.1 clause 4.3.1.2.)
- Viewing of the weld area can be accomplished in several ways. Most common are viewing ports with filters and television monitors. For microwelding, microscopes should have filtered viewing optics or flip mirrors that permit either welding or viewing. (If a filtered port is installed separately from the certified product purchase, it must be labeled in accordance with ANSI Z136. If it is purchased as part of a certified product, the label is not required.)
- Alignment of laser welding systems should be accomplished using low-power lasers.

Laser welding can also be performed with personnel in attendance. When done in this manner, the hazard must be evaluated for each welding process using the ANSI standard. General requirements include:

- The laser welding area must be completely enclosed, and access must be restricted (see LCA requirements in ANSI Z136.1).
- In most cases, laser eye protection is required for all personnel in the area. The optical density of the eye protection must

be calculated to reduce the potential eye exposure to less than the maximum permissible exposure (MPE) level. In addition, much of the eyewear designed for laser protection will not afford protection from weld (plasma) radiation, so welding faceshields with AWS 3-5 may also be required. (Both protections are necessary together; some dual-purpose eyewear may be commercially available.)

- The welding beam must be carefully controlled and should still be enclosed to the greatest extent possible. There is no eyewear available that will withstand a direct viewing of the main multikilowatt beam. Even at powers below 1000 W, eye protection is likely to fail on exposure to the primary beam. Always avoid viewing angles that are at risk of line-of-sight viewing down the axis of the beam or its specular reflection.
- Compliance with personnel training requirements is exceedingly important.

Skin exposure to the primary beam obviously can result in thermal burns and must be prevented by complete enclosure and operator training. Even in attended operations where the operator is permitted to view the welding process, provision of partial enclosures to prevent personnel from placing any part of the body into the beam path is desirable.

The ANSI standard also prescribes MPE values for skin exposure. In the visible and near-infrared regions, these are much greater than the MPE values for the eyes; hence, a problem from excessive exposure due to diffuse reflections at these wavelengths rarely occurs. Excessive skin exposures in the ultraviolet and far-infrared regions are possible, however. Typically, ultraviolet exposures can be controlled with clothing of tightly woven material and

Fig. 15 Improvements in weld penetration resulting from the blanketing of a 10% argon addition to a helium shielding gas. Source: Ref 38

barrier creams applied to exposed skin. Harmful levels of ultraviolet light can also be generated by flash lamps; hence, covers should be kept in place. Harmful levels of ultraviolet are also generated by the weld process. Prolonged or repeated exposure to ultraviolet is a known carcinogen (causes cancer). The MPE limits for ultraviolet include limits in a single day and repeat exposures with any 24 hour period. Always protect eyes and skin from the laser and the weld radiation.

Associated Hazards

Electrical Hazards. All lasers used for welding employ high voltages capable of inflicting lethal electric shocks. Therefore, maintenance shall be performed only by personnel familiar with high-voltage safety procedures. (Accidents resulting in fatalities around lasers have all been by electrocution.)

Power supplies for high-power lasers contain capacitors capable of lethal shock even after initial discharge due to a phenomenon known as charge buildup. To facilitate safe maintenance access, the following provisions should be included:

- An automatic discharge and grounding circuit that is actuated when the laser is turned off
- Discharge and grounding interlocks on all access panels
- Grounding rods for manual verification of complete discharge. Safety glasses should be used, because explosion-like discharges are possible on partly charged capacitors.
- Grounding straps to short out capacitors to prevent charge buildup

In addition, all capacitors should be discharged and grounded before any work is performed on or near high-voltage components.

Control of laser performance usually requires switching of capacitors. Insulated switches that do not expose personnel to electric conductors are preferred. If switching requires work on

bus bars, the previously listed procedure should be followed, and the use of insulated tools should be considered. Cooling-water leaks are not acceptable, especially when electrical and cooling lines share the same umbilical.

Chemical Hazards. Laser welding generates metal fumes similar to other welding processes, and the hazard is largely dependent on the composition of the welded metals. Ventilation is required to meet OSHA standards and American Conference of Governmental and Industrial Hygienists threshold limit values. In high-power welding applications, fumes can be generated in sufficient quantities to make local exhaust ventilation, in addition to general room ventilation, both necessary and economical.

Harmful fumes of vapors can also be generated when laser energy is deposited in unwanted materials, such as breakdown of plastic enclosure materials due to laser exposure and failure of exotic lens materials due to thermal runaway. These conditions are best controlled by careful materials selection and monitoring of welder performance. Finally, laser optics cleaning agents may be toxic and flammable and should be handled accordingly.

Training, Medical Examinations, and Documentation. ANSI Z136.1 requires that training in the potential hazards and control measures be provided to operators, engineers, technicians, and maintenance and service personnel. Special training on subjects such as potential hazards (including biological effects), control measures, and applicable standards is required for the laser safety officer. A model safety and training program is outlined in Appendix A of the standard.

Routine medical surveillance of laser users is no longer mandated by the standard. However, an employer may wish to provide such for medical/legal reasons (that is, to document what eye damage existed prior to commencement of laser work and that no additional damage has occurred). Therefore, initial hiring or assignment exams and departure exams may still be a reasonable consideration.

Documentation may include:

- Listing of lasers, duration of use
- Results of hazard surveys and calculations of accessible laser radiation
- Interlock tests
- Laser use procedures
- Employees working in laser area
- Date and extent of employee training
- Dates and results of medical examinations (if any)
- Training and qualifications of laser safety officer

Laser Beam Weld Design, Codes, and Quality Assessment*

J. Mazumder, University of Michigan

Randolph Paura, Dynamic Laser Solutions

MOST WELD JOINT GEOMETRIES used in conventional fusion welding processes (for example, autogenous automatic gas tungsten arc welding or electron beam welding) are suitable for laser beam welding (LBW). However, it must be remembered that the laser beam is focused to a spot of a few hundred micrometers in diameter, and thus, fit-up tolerances and alignment requirements are also of that order of magnitude.

As with fusion welding processes, joints are designed to meet the design requirements of the weldment for structure, function (e.g., sealing), assembly, and so on. The high power density and the ability to achieve high-aspect-ratio (depth-to-width) welds offers distinct capabilities and advantages for joint design but imposes more stringent requirements on how the weld seam is presented to the laser beam. Some of the important joint geometries are illustrated in Fig. 1 and 2, and Table 1 summarizes joint selection criteria for a few categories of joint design. Different types of joint design reported for LBW were reviewed by Shewell (Ref 1).

Design of Laser Beam Weld Joints

Joint Preparation, Fit-Up, and Design

Butt Joint—Full-Penetration Type. Material to be laser welded does not need beveled edges. Sheared edges are acceptable if square and straight (Ref 2, 3). The fit-up tolerance should be within 15% of the workpiece thickness. Misalignment and out-of-flatness should be less than 25% of material thickness, as shown in Fig. 3(a), to keep the laser beam from

wandering. The transverse alignment should be kept within half of the focused beam diameter (Ref 4, 5). Clamping is recommended, and bucking is not troublesome except when welding material thinner than 0.25 mm (0.01 in.) (Ref 2).

Lap Joints. Air gaps severely limit penetration and welding speeds (Ref 2). Compressive clamping, as shown in Fig. 3(b), should be used to maintain a separation of less than 25% of the material thickness (Ref 3). For welding of dissimilar thicknesses, the thinner material should be placed on top to be welded to the thicker one (Ref 3). Lap joints require fusion width to generate weld strength. Laser type, optics, and weld parameter selections are made to generate weld width efficiently to meet design strength requirements (Ref 6). Caristan (Ref 7) also shows an unpeelable lap joint in which the faying surfaces are completely fused. (See the article “Laser Beam Welding” in this Volume for information regarding welding parameters and optics.)

Pulsed laser spot lap joints demand tighter tolerances than joints produced with continuous power laser welding. The maximum gap for ferrous and nickel alloys is 15% of the material thickness, and the gap must be less for higher-conductivity materials (Ref 1). Baranov et al. (Ref 8) studied the influence of gap size on the formation and strength of spot lap joints in laser welding. They reported that for laser spot lap joints of 0.4 mm (0.016 in.) thick steel and 0.33 mm (0.013 in.) thick nickel, a gap of up to 0.1 mm (0.004 in.) has little influence on joint strength, because there is almost no change in the diameter of the fusion zone. On the other hand, the shape of the weld pool changes with the gap size. It has also been observed that the presence of air in the gap

may lead to the formation of porosity and non-fusion (Ref 8). Micropores sometimes form in the fusion zone, and the number of pores and their size increase with increasing gap size.

Flange joints, as with butt joints, require straight, square edges, good fit-up, clamping, and precise transverse alignment. Flange joints are suitable for welding high-shrinking metals such as aluminum (Ref 2).

Kissing Welds. This type of joint is called a kissing weld because the weld pool forms where two pieces just “kiss.” This offers a small angle between the two parts that traps most of the energy of the laser beam. Very little (if any) pressure is required during welding, but the facing surfaces must fit well (Ref 1). A gap between the sheets will allow radiation to escape. This joint successfully joins thin foils in situations where spot welding would produce melt-through.

Polarization Effect on Kissing Weld. One of the unique advantages of a kissing weld is the ability to take advantage of the polarization behavior of the laser light. If the laser light is polarized perpendicular to the wall of the metal, the beam is preferentially reflected, and it delivers all the energy at the joint. This increases the joint efficiency considerably. This idea was originally proposed by Sepold in 1987 (Ref 9). Subsequently, this concept is used for laser welding of tube and pipe.

Wire Joints. The joint configurations for wires shown in Fig. 2 were developed by the electronics industry. For wire-to-wire joints, the two wires must share the incident laser energy. In a cross joint, for example, the laser beam should be directed at the intersection of the wires so that both wires are exposed directly to the beam.

Use of Consumables and Special Welding Practices

Laser welding is ideal for autogenous welding. The main consumable for laser welding is the shielding gas. For thick-section welding, a filler wire can be used to make multipass welds. Sometimes filler metals (or injected powders) are used during laser welding to control the weld bead geometry. The most common use of filler metals, however, is to prevent undercutting. The use of filler materials to control the weld chemistry is also common. For example, insertion of aluminum foil during butt welding of semikilled steel results in a porosity-free sound weld. Vaporization losses during

laser welding of some alloys can be compensated for by the addition of filler materials or powder of desired composition. Energy consumption during LBW is lower with powder injection than with wire-fed filler metals. The wire surface reflects considerable amounts of energy and reduces the energy efficiency of the process.

As with arc welding processes, metallurgical considerations such as preweld and postweld heat treatments are also applicable to laser welding. Under special circumstances, it is possible to use the welding laser for pre- and post-heat treatments (Ref 10). The primary differences between LBW and other welding processes are the narrower heat-affected zone

associated with laser welds as well as the high cooling rates that result in higher localized residual stresses. These high cooling rates can be used beneficially for materials with brittle intermetallic phases. High cooling rate leads to extension of solid solubility and avoids brittle precipitates for many alloys.

Laser Welding of Engineering Alloys

Penetration Welding. The scope of technically and commercially feasible LBW applications has increased greatly since the demonstration of penetration welding using a multikilowatt continuous-wave CO₂ laser by Brown and Banas (Ref 11). Numerous experiments have shown that the laser produces precision weld joints of high quality in ferrous alloys, nickel alloys, and titanium alloys that are rivaled only by those made by electron beam welding. (See the articles in this Volume on electron beam welding.) Data describing the plate thickness of different laser-welded materials are given in Table 2.

Aluminum and its alloys have recently generated much interest in the laser welding community because of their potential application in the auto industry for their weight-reduction properties (Ref 13–18). During the 1970s and 1980s, aluminum alloys were reported to be rather difficult to weld due to the high initial surface reflections of 10.6 μm (417 $\mu\text{in.}$) radiation emitted by CO₂ lasers (Ref 3, 19–25). Surface coating often reduces this problem. Low melting point and relevant fluidity sometimes lead to “drop-through” problems, and thus, energy input is a critical parameter for laser welding. Another critical factor involving laser welding is the vaporization of alloying elements such as magnesium. Suppression of the plasma with a properly designed shielded gas nozzle can be used to avoid the loss of alloying elements (Ref 23). The other alternative is to use filler metal (Ref 16).

Although the welding of aluminum is difficult with LBW, it has already been demonstrated that, with proper precautions, welds having tensile strength equivalent to the parent materials can be obtained.

Steels. A great deal of laser welding research has been conducted on ferrous alloys. Most of the initial parametric studies were carried out on stainless steel (Ref 11, 25, 26). Stainless steel was investigated (Ref 26, 27) because of its importance in the power plant and chemical industries. Laser welding of rimmed steel sheet was evaluated for automotive applications by Baardsen et al. (Ref 28). High-speed LBW of tin plate and tin-free steel for container industries was reported by Mazumder and Steen (Ref 29). Results in HY-alloy steels were evaluated and reported by Banas (Ref 30) and by Metzbowler and Moon (Ref 20). Laser beam welding of modified 4340 alloy was reported by Seaman and Hella (Ref 31). Several other

Fig. 2 Joint designs for laser beam welds on wire. Arrows show direction of laser beam. (a) Butt weld. (b) Round-to-round lap weld. (c) Cross-joint weld. (d) Spot weld for T-joint. (e) Terminal or lug weld

ferrous alloys that have been studied for the applicability of laser welding include X-80 Arctic pipeline steel (Ref 32), tanker construction steels (Ref 33), D-6ac low-alloy, ultrahigh-strength steel (Ref 34), and high-strength, low-alloy grade steels (Ref 34).

One of the earliest applications of LBW was for the welding of planetary gear assemblies for the automotive industry. Welding was carried out at 10 m/min (400 in./min) using a 5 kW laser. Subsequently, LBW was applied to produce automobile powertrain components. A most recent mass production application is in the production of the “body-in-white” tailored blank shown in Fig. 4. An LBW process developed by Fraunhofer Institute at Aachen that uses a polarized beam was applied by Krupp's Steel to produce steel pipe (Ref 35).

Titanium and Titanium Alloys. Until recently, the electron beam welding (EBW) technique has been the most popular method used to weld Ti-6Al-4V, which is the most widely used titanium material in the aerospace industry due to its remarkable strength-to-weight ratio. However, the deep penetration of EBW can be obtained only up to a short distance under nonvacuum conditions. For optimum efficiency, EBW must be carried out in an evacuated chamber (Ref 3). In contrast, CO₂ laser beams can be transmitted for appreciable distances through the atmosphere without serious attenuation or optical degradation. Even pulsed neodymium: yttrium-aluminum-garnet lasers (Fig. 5) can provide considerable penetration (Ref 37).

The application of the laser technique to a metal such as a titanium alloy, which is normally difficult to weld, is not only of direct interest to the aerospace and chemical

industries but also is of interest to those who need to weld chemically sensitive metals with complex temperature-dependent structures. The need for better joining methods for titanium and its alloys resulted in several investigations of LBW techniques over various power ranges (maximum 16 kW). A detailed review is available in Ref 12 and 38. Welding speeds in excess of 15 m/min (49 ft/min) were used to weld 1 mm (0.04 in.) thick Ti-6Al-4V with a 4.7 kW CO₂ laser, and materials up to 12.5 mm (0.492 in.) thick were joined using an 11 kW CO₂ laser.

Laser Beam Weld Quality

The American Welding Society has identified six weld process classes, which are defined according to their mechanisms (pressure, temperature, thermal energy delivery method) of achieving materials fusion/joining. These are:

- Gas welding
- Arc welding
- Resistance welding
- Solid-state welding
- Thermochemical welding
- Radiant energy welding (EBW, LBW)

In the radiant energy class, the continued increase of capabilities from such new laser technologies as the ytterbium:disc and ytterbium: fiber have made new welding process regimes possible due to the increase in:

- Output power
- Beam quality
- Electrical-optical conversion efficiency

Reduced cost of ownership, increased lifespan of the power supply, and corresponding reduced consumable and maintenance needs of these and other solid-state lasing technologies are bringing these new industrial laser power sources into more facilities and enabling greater production capacity and capabilities. Industrial lasers are opening new opportunities in manufacturing and are competing with and, in certain cases, replacing some established high-radiant welding power sources, such as the electron beam.

Given the high-energy beam delivery of both the electron beam and the laser to achieve the weld process, some weld quality specifications address both processes. Note that the actual equipment setup and associated health and safety concerns (regulations, codes, and consensus standards) will be different between these two processes, although the characteristics of the weld achieved can be very similar by virtue of the high-radiant-energy beam delivery to achieve the fusion joining process.

This section provides a definition of laser weld quality, surveys prominent laser weld quality specifications available to various industries, and discusses how quality is an important metric by which a company understands how its operations contribute to providing repeatable and reliable laser welds that meet the target value in performance and profitability.

Weld Quality Defined

In a broad sense, weld quality is defined as those measurable characteristics and features of the weld that allow the weldment to have the inherent integrity, functional performance, and, where necessary, appearance over the lifespan of the weldment.

With regard to the quality characteristics of the laser and electron beam weld, terms and definitions are important for determining process-tolerant parameters, for example, relating weld testing performance to weld parameters and procedures development.

For quality control of the weld process, in general, there are weld procedure specifications and weld quality specifications. These are derived by either referencing industry standard specifications or through an internal weld process and quality specification program, such as through proof-of-process work and design of experiments.

Weld quality characteristics can be categorized as geometrical, mechanical, or metallurgical. Quality characteristics include but are not necessarily limited to:

- *Geometrical:* Size and shape of the weld cross-sectional area, undercut, mismatch, concavity, convexity, continuity

Table 1 Joint design and considerations for use

Joint type	Applicability	Considerations for use	Design
Bull	Very commonly used in ferrous, other alloys having medium to high viscosity when molten	<ul style="list-style-type: none"> • Maximum allowable gap = $0.05 \times$ thickness • Beam/seam alignment requirement approx. $0.5 \times$ focus spot diameter • Joint strength dependent on degree of penetration and weld-metal strength 	
Bolt with backing	Commonly used with aluminum-bronze alloys and others with low viscosity when molten	<ul style="list-style-type: none"> • Consumable backings of same composition as base material most common • Root porosity found in partial-penetration laser welds may be removed by machining backing strip in some applications • Ceramic and nonconsumable (e.g., copper backings not usually applicable) 	
Lap welding	Commonly used in all materials	<ul style="list-style-type: none"> • Maximum allowable gap – $0.05 \times$ thickness of thinner member • Tolerant of beam/seam misalignment • Thin-on-top/thick-on-bottom joints easily accommodated • Thick-on-top/thin-on-bottom joints less desirable • Joint strength determined by weld-metal strength, weld width (multiple passes can increase joint strength) 	
Stake weld	Can produce 'blind welds' that are difficult or expensive to accomplish using arc processes	<ul style="list-style-type: none"> • Laser beam/web plate alignment tolerance dependent on web thickness, beam diameter • Maximum gap = $0.05 \times$ flange thickness • Joint strength determined by weld-metal strength and weld width (multiple passes can increase joint strength) 	
Edge weld	Usually applied in thinner gages where the laser weld bead consumes all or most of the thickness of both members	<ul style="list-style-type: none"> • Wide range of included angles possible with appropriate forming of edges (as illustrated) • Maximum gap = $0.05 \times$ thickness of thinner member • Joint strength dependent on degree of penetration and weld-metal strength • Determination of metal an important design strength consideration 	
"Skid" fillet weld	Full penetration possible with sufficient power	<ul style="list-style-type: none"> • Small beam centerline/flange angle (approx. 10° or less) • Maximum gap = $0.05 \times$ thickness of web plate • Beam/seam alignment approx. $0.5 \times$ focus spot diameter • Joint strength dependent on degree of penetration and weld-metal strength 	
Corner weld	Full penetration possible with sufficient power	<ul style="list-style-type: none"> • Beam/seam alignment (approx. $0.5 \times$ focus spot diameter) • Joint strength dependent on degree of penetration and weld-metal strength • Maximum gap = $0.05 \times$ thickness of web plate 	

- *Metallurgical:* Porosity, pinholes, cracks/cracking, heat-affected zone, penetration, slag
- *Mechanical:* Ultimate tensile and yield strengths, fatigue limits, elongation, cupping test (e.g., ball punch deformation); ASTM E 643

For process control, consideration should be given to documenting and establishing respective nominal values and bound values for the controllable aspects of the process, some of which are:

- *Laser:* Total power, focus optic arrangement (determining power density, spot size and caustic waist profile, depth of focus, angle of beam divergence), beam mode and quality, polarization, focal position with respect to workpiece

- *Process parameters:* Weld speed, sequencing of power for start and close of weld bead, shield gas selection and delivery (style, flow rate, volume)
- *Workpiece/tooling:* Weld joint presentation allowables (material mismatch, gap tolerances, focal position alignment tolerance with respect to weld seam)
- *Material properties:* Material thickness, material specifications (type), material surface conditions (e.g., oily, dry, scale, etc.)
- *Tooling:* Repeatability and reliability for presentation of the workpiece and the weld seam to the laser focus optics

When documenting and defining the weld procedures and qualification requirements within a facility or for a specific program/project, it is important to reference and define those terms employed.

Additional information can be found in Ref 39 to 42.

Weld Quality Assessment

The profile for the laser weld seam (cross-sectional geometry) can vary depending on the process parameters, optical configuration, and whether it is autogenous or augmented with metal inert gas, metal active gas, tungsten inert gas, plasma, other thermal power supplies, or filler wire.

Two elemental modes of LBW are conduction-limited and penetration (keyhole) welding. In the application of conduction-limited welding, as the name implies, the irradiance of the laser beam is sufficient to achieve melting of the base metal via absorption, but conduction of the thermal

Fig. 3 Clamping and tolerances for (a) butt joint and (b) lap joint. Dimensions are in units of percent of material thickness, t . Source: Ref 3

Fig. 4 Sequence of operations required to produce "body-in-white" tailored blank automotive bodies using laser beam welding. (a) Arrangement and welding of divided-type body panels before forming. (b) Tailored blank obtained after structural components have been formed in a press. Source: Ref 36

energy determines the melt pool shape (weld bead). As the laser beam irradiance increases and exceeds the capacity of the base metal to dissipate (conduct) the thermal energy, the temperature of the impinging material is elevated to its boiling point, where the material is vaporized. This process is dynamic, and the absorption level of the laser beam irradiance on the material increases as well as the metal vapor depth (Fig. 6a). The weld bead geometry of laser keyhole (penetration) welding is readily identified by the high aspect (depth/width) ratio of the weld seam (Fig. 6b).

Figure 7 illustrates changes of an autogenous laser weld profile, progressing from conduction-limited (left side of graph) to penetration (keyhole) welding (right side of graph). The transition from conduction to keyhole will occur at significantly different power densities, depending on materials and somewhat on shield gas type.

Table 2 Parameters for high-power laser beam welding relative to alloy type for bead-on-plate joints

Material	Type of joint	Thickness		Laser power, kW
		mm	in.	
Ship steel, grades A, B, C	Butt	28.6	1.125	12.8

(a) Neodymium: yttrium-aluminum-garnet (Nd:YAG) laser. (b) CO₂ laser. (c) Continuous-wave Nd:YAG laser. Source: Ref 3, 12

The dimensions of the laser weld bead (cross section) are important components of weld quality specification. Dimensional features can include but are not necessarily limited to:

- Cross-sectional area
- Penetration depth
- Upper seam weld width
- Lower seam weld width

It is important that the weld quality specifications of an application identify appropriate nominal dimensional information of the laser weld profile. Figure 8 shows the difference in cross section between a conduction-limited laser weld and a penetration (keyhole) weld. Figure 9 shows how the dimensional shape of laser weld geometry can be quantified.

Because laser welding is a fusion process, the evaluation of weld quality is similar to other allied processes. Table 3 and Fig. 10 and 11 illustrate the common types of discontinuities

that are assessed for weld quality of an application.

Table 4 (Ref 45) identifies and compares discontinuities commonly (but not always) associated with various welding processes. The relative high power density applied for the fusion process of both electron beam and laser beam welding leads to them have similar weld defects, namely:

- Porosity
- Incomplete fusion
- Incomplete joint penetration
- Cracks

Standards and Specifications

There are a number of domestic and international organizations that develop codes, standards, and specifications for welding and allied processes as well as provide laser welding quality specifications and procedure

Curve	Welding mode	Average output, W	
		Pulsed	Continuous wave
A	Penetration	400	...
B	Conduction	400	...
C	Conduction	150	...
D	Conduction	...	400

Table 5 Standards and specifications

Standard or specification	Remarks
American Welding Society (AWS), www.aws.org	
AWS A3.0M/A3.0:2010 Standard Welding Terms and Definitions; Including Terms for Adhesive Bonding, Brazing, Soldering, Thermal Cutting, and Thermal Spraying	This AWS standard is a glossary of the technical terms used in the welding industry. It establishes standard terms to aid in the communication of welding information. Because it is intended to be a comprehensive compilation of welding terminology, nonstandard terms used in the welding industry are also included. Alphabetical sequence
AWS C7.2:2010 Recommended Practices for Laser Beam Welding, Cutting, and Drilling	This document presents recommended practices for laser beam welding, cutting, and drilling. Its scope is limited to common applications of the subject processes. Process definitions, safe practices, general process requirements, and inspection criteria are provided.
AWS C7.4/C7.4M:2008 Process Specification and Operator Qualification for Laser Beam Welding	This specification on laser beam welding discusses applicable specifications, safety, requirements, fabrication, quality examination, equipment calibration and maintenance, approval of work, and delivery of work.
AWS B2.1/B2.1M: 2009 Specification for Welding Procedure and Performance Qualification	This specification provides the requirements for qualification of welding procedure specifications, welders, and welding operators for manual, semiautomatic, mechanized, and automatic welding. The welding processes included are electrogas welding, electron beam welding, electroslag welding, flux cored arc welding, gas metal arc welding, gas tungsten arc welding, laser beam welding, oxyfuel gas welding, plasma arc welding, shielded metal arc welding, stud arc welding, and submerged arc welding. Base metals, filler metals, qualification variables, welding designs, and testing requirements are also included.
AWS WHC3.14 Laser Beam Welding, Cutting and Associated Processes	Chapter 14 from <i>Welding Processes, Part 2</i> , Vol 3, <i>Welding Handbook</i> , 9th ed. has been selected by the AWS Product Development Committee. This chapter covers fundamentals of laser beam welding and cutting processes, modes of operation, and equipment. Other topics include laser beam welding operating systems, applications, joint design and preparation, weld quality, and the economics of using these processes. Similar information is presented for laser beam cutting, drilling, and related processes. The chapter concludes with a discussion on safety issues specific to laser beam operations and the safety codes that must be followed to provide the best working environment where lasers are in use.
Note: Subcommittee D8E Automotive Laser Welding	The D8 AWS/SAE Joint Committee on Automotive Welding is responsible for the development of AWS standards on all aspects of welding in the automotive industry. Laser weld quality specifications are currently in development by subcommittee D8E.
American National Standards Institute (ANSI), www.ansi.org	
ANSI Z136.1-2007 American National Standard for Safe Use of Lasers	The parent document and cornerstone of the Z136 series of laser safety documents, this standard provides recommendations for the safe use of lasers and laser systems that operate at wavelengths between 180 nm and 1 mm.
ANSI B11.21-2006 American National Standard for Machine Tools. Machine Tools Using Lasers for Processing Materials. Safety Requirements for Design, Construction, Care, and Use	This standard is part of the ANSI B11 series and pertains to the safety requirements for lasers used in machine tool applications as described in this document. It is limited to the requirements of safeguarding of personnel, installation, verification, operation, maintenance, training, and documentation for individual machines.
International Organization for Standardization (ISO), www.iso.org	
ISO 6520-1:2007 Welding and Allied Processes. Classification of Geometric Imperfections in Metallic Materials, Part 1: Fusion Welding	Serves as the basis for a precise classification and description of weld imperfections
ISO/TS 17845:2004 Welding and Allied Processes. Designation System for Imperfections	Gives a system for the designation of imperfections in welding and allied processes. It applies to metallic and nonmetallic materials (e.g., thermoplastics).
ISO 13919-1:1996 Welding. Electron and Laser Beam Welded Joints. Guidance on Quality Levels for Imperfections, Part 1: Steel	Gives guidance on quality levels of imperfections in electron and laser beam welded joints in steel. Three levels are given that refer to production quality.
ISO 13919-2:2001 Welding. Electron and Laser Beam Welded Joints. Guidance on Quality Levels for Imperfections, Part 2: Aluminum and Its Weldable Alloys	Gives guidance on quality levels of imperfections in electron and laser beam welded joints in aluminum and its weldable alloys. Three levels are given that refer to production quality.
ISO/TR 17671-6:2005 Welding. Recommendations for Welding of Metallic Materials, Part 6: Laser Beam Welding	Gives general guidance for laser beam welding of metallic materials in all forms (e.g., cast, wrought, extruded, forged) and associated processes
ISO 9956-11:1996 Specification and Approval of Welding Procedures for Metallic Materials, Part 11: Welding Procedure Specification for Laser Beam Welding	Revised by ISO 15609-4:2004
ISO 15609-4:2004 Specification and Qualification of Welding Procedures for Metallic Materials. Welding Procedure Specification, Part 4: Laser Beam Welding	Specifies requirements for the content of the welding procedure specification for laser beam welding processes, including overlay welding. It is not applicable to other processes for cladding (e.g., thermal spraying).
ISO 15614-11:2002 Specification and Qualification of Welding Procedures for Metallic Materials. Welding Procedure Test, Part 11: Electron and Laser Beam Welding	Specifies how a welding procedure specification for electron or laser beam welding is qualified by a welding procedure test
ISO 15616-1:2003 Acceptance Tests for CO ₂ Laser Beam Machines for High-Quality Welding and Cutting, Part 1: General Principles, Acceptance Conditions	...
ISO 15616-2:2003 Acceptance Tests for CO ₂ Laser Beam Machines for High-Quality Welding and Cutting, Part 2: Measurement of Static and Dynamic Accuracy	...
ISO 15616-3:2003 Acceptance Tests for CO ₂ Laser Beam Machines for High-Quality Welding and Cutting, Part 3: Calibration of Instruments for Measurement of Gas Flow and Pressure	...
ISO 22827-1:2005 Acceptance Tests for Nd:YAG Laser Beam Welding Machines. Machines with Optical Fiber Delivery, Part 1: Laser Assembly	Editor's note: This should also be applicable for other near-infrared laser power sources, such as the ytterbium:fiber and ytterbium:disc.
ISO 22827-2:2005 Acceptance Tests for Nd:YAG Laser Beam Welding Machines. Machines with Optical Fiber Delivery, Part 2: Moving Mechanism	Editor's note: This should also be applicable for other near-infrared laser power sources, such as the ytterbium:fiber and ytterbium:disc.
European Committee for Standardization (CEN), www.cen.eu	
EN 1011-6:2005 Welding. Recommendations for Welding of Metallic Materials. Laser Beam Welding	This European Standard gives general guidance for laser beam welding and associated processes of metallic materials in all forms of product (e.g., cast, wrought, extruded, forged).
EN 1011-6:2004 Welding. Recommendations for Welding of Metallic Materials. Electron Beam Welding	This document may be used for the electron beam welding of weldable metallic materials according to PD CR ISO 15608. It does not contain data on permissible stresses on weld seams or on the testing and evaluation of weld seams. Such data can either be seen from the relevant application standards or should be separately agreed between the contracting parties. A requirement for the application of this document is that the recommendations should be used by appropriately trained and experienced personnel.
SAE International (SAE), www.sae.org	
SAE AS7110/6D:2007 Nadcap Requirements for Laser Welding. This Aerospace Standard (AS) is to be used to supplement AS7110. In addition to the requirements contained in AS7110, the requirements contained herein shall apply to suppliers seeking Nadcap accreditation for laser welding.	SAE AS7110/6D:2007 revision work has been cancelled as of March 2010. The prior version, SAE AS7110/6C:2003, is available. Reference the SAE website for additional information.

Laser Beam Delivery Optics and Manufacturing Economics

Tim Webber, IPG Photonics

LASER ENERGY is transmitted from the laser to the workpiece via a system of beam-delivery optics. The optical system can be an open system of mirrors or a fiber optic system. Properly designed beam-delivery optics are essential to the quality of the beam acting on the workpiece and to the economics of the manufacturing process.

Optics for Beam Delivery

The beams of the 1 μm wavelength family of industrial lasers can be directed to the workpiece by means of mirrors, the same way CO_2 laser beams are directed. Their advantage is to use a fiber optic beam delivery. Just a few ionic salts (ZnSe, ZnS, GaAs) have useful transmission properties in the 10.6 μm wavelength of the CO_2 laser for welding. The 1 μm wavelength, however, is transmissive to most materials that appear transparent to the eye, most importantly silica-base glass, SiO_2 . This glass can be drawn into a fiber that can flexibly transport considerable laser power over useful distances. Optical fibers have achieved intrinsic attenuation limits of 0.2 dB/km (Ref 1), which equates to 99.5% transmission over a kilometer. The damage threshold for fused silica has been found to be approximately 400 GW/cm^2 (Ref 2). This would suggest that up to 30 MW can be transmitted by a 100 μm core optical fiber without internal damage. The challenge is to be able to launch a useful amount of laser energy into an optical fiber, because the air-to-glass interface has a significantly lower damage threshold than the bulk material (Ref 3). Minute pits, scratches, and contamination on the fiber face (cross section) can act as sites for absorption of moisture and lead to material failure.

One method to circumvent this surface damage is to bond a fused silica cylinder to the fiber end (Ref 4). The laser light will diverge to a dramatically lower power density as it is emitted from the cylinder compared to the fiber. By applying an antireflection coating to the emission end of the cylinder, reflected losses can be reduced from approximately 4% to less than 1% at each end of the fiber cable. The photograph in Fig. 1 depicts a fiber optic cable connector using this technology.

An optical fiber propagates light down its length through the principle of total internal reflection. The numerical aperture (NA) is the solid angle over which the fiber optic can accept light. A fiber optic input NA will be the same as its output NA, provided that the fiber optic core/clad relationship remains constant. The NA is described by:

$$\text{NA} = ((n_1)^2 - (n_2)^2)^{1/2} \quad (\text{Eq 1})$$

or

$$\text{NA} = \sin \theta = n_1 \sin \theta' \quad (\text{Eq 2})$$

where n_1 is the refractive index of the core, n_2 is the refractive index of the clad, $n_1 \gg n_2$, $\theta' = \theta_c$, and $\theta_c = \cos^{-1} n_2/n_1$ is the critical angle for total internal reflection to occur.

The fused silica clad is doped to alter its refractive index, and the core is pure fused silica. The fiber optic types used by the 1 μm

wavelength family of industrial lasers for welding are shown in Fig. 2. The NA and core diameter of a stepped-index fiber optic cable are engineered to match the optical

Fig. 1 Fiber optic cable connector. Courtesy of IPG Photonics

Fig. 2 (a) Multimode stepped-index and (b) single-mode optical fibers. Adapted from Ref 5

characteristics of the laser to which it is connected. There will be a practical lower limit of core diameter into which a laser of a given brightness can be launched successfully and reliably. The single-mode fiber optic is exclusive to the fiber laser.

Each laser provider will supply a family of compatible fiber cables with their product, or recommend a qualified accessory supplier. Fiber cables are specified primarily by their core diameter and length. Lengths of 10, 20, and 30 m (33, 66, and 98 ft) are typical. Stepped-index core diameters of 100, 200, 400, and up to 800 μm are used for welding. Fiber cables outside of these figures are available also but tend to be made to

order for custom specifications. The single-mode fiber and a 50 μm core stepped-index fiber optic are outputs of fiber lasers.

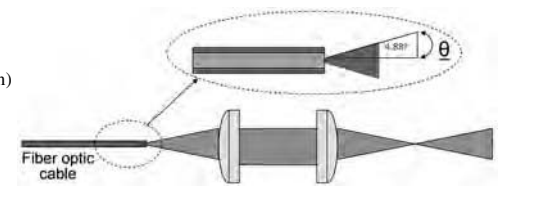

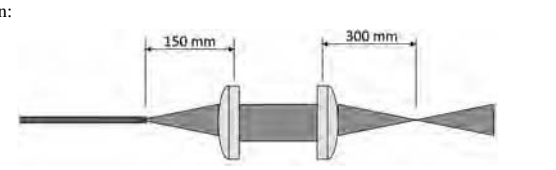

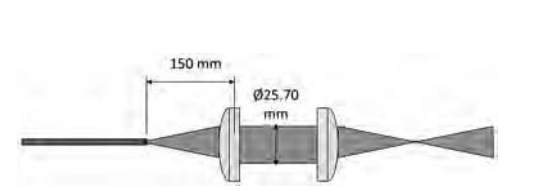

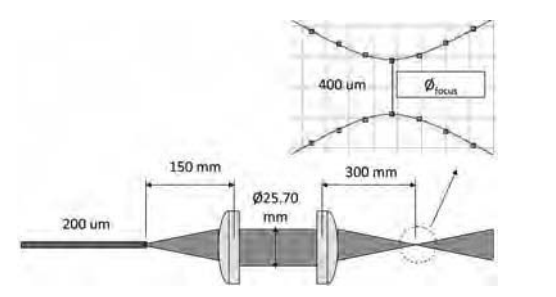

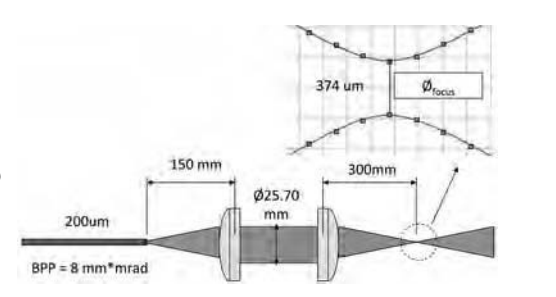

The cable will have a minimum bend radius specification provided by the supplier. This specification protects not only the fiber optic but also the cable protective coatings and armor jacket and prevents overstraining of the fiber cable connector.

The output of a fiber optic cable is imaged onto the work by careful selection of optical elements. These are shown schematically in Table 1 as single-lens elements, although multielement designs are often used. These lens elements can be reflective or transmissive. Collimator focal

lengths of 60, 75, 100, 120, 150, and 200 mm are common. Focus lenses range from 100, 125, 150, 200, 250, to 300 mm. Even longer focal lengths are used in remote welding (Ref 6). The economic availability of these optics provides considerable flexibility to the laser welding engineer to configure an optical solution specific to the task at hand. In contrast, CO₂ laser optics are limited in availability and impose constraints on the welding engineer.

A single-mode fiber laser uses a single-mode fiber to deliver its energy. The core diameter is approximately 10 μm and the NA is typically 0.065. These specifications are taken from the laser under consideration for the job. Using the relationships from Table 1, a fully corrected 60 mm collimator will produce a slightly less than 8 mm diameter beam. If a 120 mm focus lens is used, a 20 μm focus spot will be produced.

Table 1 Selection and configuration of optical elements for delivering laser beam from fiber optic cable to workpiece

Description	Optics configuration
<ul style="list-style-type: none"> • Half-angle numerical aperture (NA) of the emergent laser beam (depending on construction) is 0.084–0.090. • For working example, the emergent laser beam shall be taken as 0.085. • $NA = \sin(\theta) = 0.085$ • $\theta = 4.88^\circ$ 	
<p>Working example used in this document is based on:</p>	
<p>Spot size reproduction on the collimation lens can be determined as:</p>	
<ul style="list-style-type: none"> • $\phi_{spot, coll} = 2 \times f_{col} \times \tan(4.88) + \phi_{fiber}$ • For a 200 μm process fiber: $\phi_{spot, coll} = 2 \times 150 \times 0.085 + 0.200$ $= 25.70 \text{ mm}$ 	
<ul style="list-style-type: none"> • Optical determination of focus spot size: $\phi_{focus} = \phi_{fiber} \times f_{focus} / f_{collimation}$ $= 0.200 \times (300/150)$ $= 0.400 \text{ mm}$ $= 400 \mu\text{m}$ 	
<ul style="list-style-type: none"> • Beam quality determination of focus spot size: $\phi_{focus} = 4 \times f_{focus} \times BPP / \phi_{spot, coll}$ $= 4(300) \times (8/1000) / (25.7)$ $= 0.374 \text{ mm}$ $= 374 \mu\text{m}$ <p>(This compares well with the optical calculation.)</p>	

Design Considerations

The focal length of the collimator is constrained by the clear aperture of the optics used. For welding optics 25, 30, and 50 mm diameters are common specifications seen in product literature. Also, the designer must allow a safety factor. For a single-mode fiber optic, the beam has a Gaussian power density distribution profile. Measurements of the beam diameter to determine the NA are based on the outline that contains approximately 86.5% of the total beam power. See Fig. 3(a) and 4 for the case where $r/w = 1.0$ (r is the displacement off axis, and w is the laser spot size; units must be the same). This is also known as the $1/e^2$ profile. The designer must allow sufficient clear aperture for the power that resides outside the $1/e^2$ diameter of the calculated collimated beam diameter.

The stepped-index fiber optic output profile is sharply delineated (Fig. 3b). Significantly less safety factor is required compared to the single-mode case.

A very compact optical package can be designed where the collimator and focus lens sets are in close proximity. The only consideration regarding placement of the focus lens in relation to the collimator lens is the accuracy of collimation. The focus lens can be a considerable distance from the collimator, in a glove box perhaps, with a window between the respective lens elements to separate the atmospheres. In this case, a well-collimated beam is necessary.

Transmissive versus Reflective Lens Elements

Transmissive lenses absorb a percentage of the laser energy. The edges will be cooled, and some amount of thermal energy will be lost to convective heat transfer out of the surfaces. In a short amount of beam-on time, the center area of the lens will be at a higher temperature. A combination of thermal expansion and change in index of refraction caused by elevated temperature will change the focal length (Ref 7). Figure 5 schematically shows how thermal shift occurs.

Fig. 4 Gaussian beam profile

Fig. 3 Output profiles for (a) single-mode fiber optic and (b) stepped-index fiber optic. Courtesy of IPG Photonics and Primes

The amount of focus shift may be small and inconsequential to the process, or it can be significant and troublesome. The amount of focus shift can be mitigated by careful selection of optical substrate materials and configuration (Ref 8). In some automated systems, the focus axis can be programmed to move to accommodate the focus shift. The use of reflective lens elements virtually eliminates focus shift. Figure 6 depicts focus assemblies for a fiber-delivered laser that uses 90° parabolic mirrors for both the collimator and the focus lens.

A valuable accessory to the 1 μm laser family is the beam switch (Fig. 7). In an energy-sharing situation, 100% of the laser power can be directed to one of several fiber optic cables. Two-, four-, and six-way switches are commonly offered by manufacturers. Fiber core sizes, lengths, and processes can be different from each port. Switch time is typically less than 0.1 s.

Energy sharing is where some percentage of the laser is directed down multiple ports at the same time. A hypothetical example of a situation where energy sharing may be used is on a part where three tack welds need to be placed on the circumference of a part and are equally spaced. Once these tack welds are made, the complete circumference weld is made with 100% power. The first three ports each deliver 33% of the laser power, and the fourth port delivers 100% of the laser power.

Optics for CO₂ Beam Delivery

The CO₂ beam is directed to the final focus optics by a combination of 90° turning mirrors (Fig. 8). The beam path is enclosed, sealed, and purged. A simple system may have only one turning mirror, or a complex system can have multiple mirrors with telescoping sections and rotating mirror sets that allow two- or three-dimensional processing envelopes to be addressed. A turning

Fig. 5 Focus shift mechanism. Source: Ref 7

mirror has precision adjustments that allow very accurate alignment of the beam to be made to the beam-delivery path. The mechanical structure that supports the beam delivery must be quite stable and vibration free.

A telescope can be used provide more consistent optical results at the final focus optics as the beam path changes length. The beam properties from the laser mm-mrad product remain constant. A telescope expands the beam diameter a given factor; this then reduces beam divergence by the same factor.

The cleanliness of the beam path is critical to the propagation of the laser beam and to the life of the optical surfaces. The beam-delivery system and component supplier will specify the quality and volume of the purge gas. With a telescoping beam path, the purge supply volume must be such that it anticipates a telescoping section extension. The beam path pressure must not be allowed to go negative during this extension or ambient contamination may enter the beam delivery. The gas in the beam tube must not be stagnant. Turbulence must be maintained

Fig. 6 (a) Reflective and (b) transmissive fiber optic focus assemblies with charge-coupled device camera. Courtesy of Laser Mechanisms

by the purge gas. Heating of the beam tube atmosphere by the passing laser beam will allow thermal gradients and local index of refraction changes. This effect will disrupt the beam propagation and beam properties (Ref 9, 10).

Manufacturing Economics

Engineers should expect to be asked two questions during a project or investigation: “Does it work?” followed quickly by “How much does it cost?” An engineer can turn to many resources for technical information. There are numerous technical conferences to attend and published proceedings to review. The most esoteric metallurgical effect often can be found fully documented. Reliable cost information, however, is much more difficult to determine, because this is the part of a study that does not get published. Having management shoot down a project with the argument “too expensive” is an unpleasant reality.

Project costs can be broken into two components: fixed costs and variable costs. Fixed costs comprise items such as the initial cost of the equipment, shipment, installation, and other such details. Variable costs are incurred with the operation and ongoing use of the equipment, such as electricity consumption, maintenance, consumables, and repair. The equipment provider will recommend a periodic maintenance schedule and the costs associated with it. Application-specific variable cost items will need to be identified by studies conducted prior to purchase. Repair costs are difficult to project because the source of a repair requirement can be well outside of the normal operation of the equipment.

The following two case studies review typical economic environments found in laser welding applications.

Case Study—1/M CO₂ versus Disc Laser Welding

A manufacturer has a product that is used in the aerospace and defense industries. This product requires a number of welding operations in its manufacture. The company relies on several job shops to provide electron beam, laser beam, and manual tungsten inert gas welding. All but one of the weld joints occur at sub-assembly stages so that the scheduling and transportation of the components is critical to the manufacturing process.

The company’s engineering department planned an evolution of this product that would be challenging to manufacture but would offer enhanced performance and features that the market was demanding. The change that impacts the welding operations is the use of electronics and rare-earth magnets in the product, which eliminates electron beam welding as an option for the final closing seam.

Fig. 7 Fiber optic beam delivery

Fig. 8 CO₂ beam delivery

The sales group forecast that the new product would sell at a volume of 10,000 units the first production year and projected that the volume would grow at a rate of 20% per year for at least the first three years.

Historically, production schedule predictability has been unreliable. After reviewing operations, company management decided to target improving relationships with vendors, especially welding job shops, to better control production.

A sister division had a similar product in production but for a different market and application. This division's manufacturing strategy was also different, because they had considerable internal welding capability. The two divisions were combined, and the sister division's obsolete laser welding equipment was auctioned off. A considerable amount of manufacturing know-how and documentation were retained by the engineering staff. Records showed that their 2 kW CO₂ laser cost \$11.25/h average over the first five years of operation. This amount included maintenance parts, service parts, labor, laser resonator gas mix, and electricity. Service interventions increased operating costs 10% over the operating cost estimate provided by the equipment manufacturer. The beam delivery was all reflective except for a final focus lens of ZnSe, which was replaced approximately twice a month. Lens costs and other beam-delivery maintenance details, such as purge air filters, resulted in an operation cost of \$6.50/h. A significant service intervention occurred when a damaged air hose in the beam delivery was replaced with one that was not cleaned. The hose contaminated several optics that then needed to be replaced. It was estimated that an average of \$13.68/h of helium shield gas was used. The actual welding time was considered to be 24 min out of every hour.

A project was undertaken to determine the economics of bringing welding in-house and to develop a five-year plan. Of the weld joints that are used, two were identified as difficult and critical: the spider support weld and the closing seam weld. The economics will be established by the equipment selection to successfully weld these two joints. A volume of sample joints of each type were prepared for weld development. Part fixturing was designed and fabricated. Equipment vendors were identified and selected to do weld samples. It took several iterations of development to fully explore the capability of the equipment and to develop welds that met requirements.

The spider support weld joins four components with a circumferential weld, two of which are 304 stainless steel and the other two are 17-4 PH. The weld must have a minimum width of 1.5 mm (0.06 in.), and the fusion zone depth should be no more than 0.8 mm (0.03 in.).

The closing seam requires 4 mm (0.16 in.) weld penetration on a 125 mm (5 in.) diameter. The weld must be completed in less than 12 s to avoid thermal damage to internal components.

Mounting flanges, fixturing, and other external features restrict weld joint access. To produce this weld, the laser beam must have a minimum F-number of 12. The material in most configurations is 17-4 PH (focal length/beam diameter); however, Ti-6Al-4V also is used for special applications. Most of the weld studies were conducted on titanium to develop a safe shielding strategy.

CO₂ Laser Welding. The CO₂ laser vendor advocated using a controlled-atmosphere glove box for the closing seam weld. This solution seemed expensive, so instead, a simple welding chamber was designed and fabricated. The chamber closely contained the rotating part during welding and could be purged with helium. The laser beam entered the chamber through a port on top of the chamber, which was also used to vent the helium.

After a number of weld trials, it was found that the vendor's 3000 W laser could complete the closing seam at a rate of 2.5 m/min (8.2 ft/min) and exceed the required minimum with 5 mm (0.2 in.) weld penetration. The part was rotated at 6.36 rpm. The laser power was ramped up to 3000 W in 0.2 s to provide a smooth weld initiation. The dwell at 3000 W was 10.4 s to ensure weld overlap. The laser power was ramped down in 1.4 s to minimize the risk of generating a crater crack at the weld termination. The weld zone temperature did not exceed 100 °C (212 °F). The beam delivery used all reflective elements, and the final focus was F12. A purge of 30 s at a rate of 150 L/min (317.83 ft³/hr) ensured that the weld area was fully inert prior to welding. Helium use cost \$1.82/part.

The spider support weld proved to be a considerable challenge. The required weld aspect ratio was not obtainable. The solution was to join the four parts with three separate circumferential welds. Local shielding was quite

satisfactory at a rate of 25 L/min (53 ft³/hr) of helium, which amounted to a cost of \$0.36/part. Because this solution did not conform to the weld geometry that had a considerable history of reliable service, a full fatigue study would be required.

Disc Laser Welding. The closing seam was accomplished with a local shield gas lens and 25 L/min (53 ft³/hr) of argon. A 2000 W disc laser with welding optics having an F-number of 14 completed the weld to the required weld penetration, with a schedule that was identical to the CO₂ laser. This allowed for a close comparison between the two lasers. The argon cost \$0.04/part. After reviewing the shielding strategy required for helium, it was decided to try the purged chamber with argon. A flow rate of 25 L/min (53 ft³/hr) for 30 s worked well. This additional gas cost \$0.14/part, but it put the component at much less risk for oxygen contamination than the local shielding strategy.

The spider support weld was accomplished by positioning the weld optics out of focus so that a weld width of 1.5 mm (0.06 in.) was produced. Numerous combinations of laser power and weld speed were found that produced the required results. Argon at 25 L/min (7 gal/min) was again used.

Cost Comparison. Each laser vendor was requested to provide a five-year itemized operating cost estimate, shown in Table 2. Based on prior production experience, it is expected that one-third of every production minute will be welding time. During the remaining two-thirds of every production minute, the laser is in stand-by mode while parts are loaded and unloaded.

Also, facility management charges each department for floor utilization at a rate of \$15.75/m² per month. The beam delivery of

Table 2 Comparison of five-year estimate of operating costs for CO₂ and disc laser

Itemized operating	Estimated five-year operating cost		
	CO ₂ , 3 kW	Disc, 2 kW	
On time	20	20	
Off time	40	40	
Duty cycle	33%	33%	
\$/kW/h	\$0.09	\$0.09	
Hours/year	2000	2000	
Laser on, kW	50	12.5	
Chiller, kW	25	3.25	
Total power on, \$/h	6.75	1.42	
Laser standby, kW	2.5	0.5	
Chiller standby, kW	25	1.5	
Total standby, \$/h	2.48	0.18	
\$/h production	3.9	0.6525	Electricity consumption
Laser gas mix, \$/h	1.27		He, N ₂ , CO ₂
PM parts, \$/h	1.63	0.15	Resonator optics, filters
Service parts, \$/h	3.45	1.36	Mechanical, electrical parts
Chiller, \$/h	0.75	0.22	Filters, additives, clean water
Beam delivery, \$/h	0.25		Filters, dryer, and air compressor maintenance
Labor, \$/h	3.25	0.62	
Total	\$14.50	\$3.00	
Area, m ²	8.25	4.5	Laser, chiller, and beam delivery
Floor rate/month	\$15.75	\$15.75	\$/m ² per month
Per hour	\$0.78	\$0.42	
Total, \$/h	\$15.28	\$3.78	
Total, \$/min	\$0.25	\$0.06	

the CO₂ laser was given an area, while the fiber optic cable of the disc laser was not because it was routed overhead with the other power cables, control cables, and water cooling lines. The workstation design remained almost identical for each laser, except for accommodating minor differences in beam delivery.

Break-Even Analysis. The purchasing department provided a total cost from each laser vendor for the laser, chiller, and beam delivery. The calculated CO₂ laser total costs were \$185,000. The calculated disc laser total costs were \$215,000. Because the operating costs for the CO₂ laser were more than the disc laser, it is necessary to consider how part volume, *X* in Eq 3, impacts the economic decision. The closing seam weld costs were used to simplify the economic analysis according to Eq 3:

$$\begin{aligned} & (\text{CO}_2 \text{ fixed cost}) + (\text{Variable cost})X \\ & = (\text{Disc fixed cost}) + (\text{Variable cost})X \end{aligned} \quad (\text{Eq 3})$$

Solving Eq 3 with values taken from Table 2 gives:

$$\begin{aligned} & (\$185,000) + (\$1.82 + \$0.25)X \\ & = (\$215,000) + (\$0.14 + \$0.06)X \end{aligned}$$

$$X = 16,046$$

Thus, at part volumes greater than 16,043, the disc laser will cost less than the CO₂ laser. However, this part volume is not expected until well into the third production year (Ref 10).

Case Study—1/M Robotic Metal Inert Gas versus Robotic Laser Welding

An automotive parts manufacturer had a contract to supply in excess of 375,000 completed fabrications per year to a major auto company. The component is a resistance spot welded steel stamping design. The contract is up for renewal but has target cost reductions. The company considers this an opportunity for a new design that can improve performance, reduce weight, and enhance their profit margins as well as meet the target costs. Their customer will consider these design improvements as well as meet the cost targets in their vendor selection process.

The new design can be accomplished with robotic metal inert gas (MIG) or robotic laser welding. The resistance spot welded design was eliminated because of weight and limited corrosion resistance compared to other designs. The electrical costs of resistance spot welding were also substantially higher than the alternatives. Prototype parts were sent to various vendors of robotic MIG and robotic laser equipment for a review of the design and budgetary proposals

for systems with the required productivity. The company's manufacturing engineering team selected several vendors to engage in a more in-depth study, the purpose of which was to weld prototypes that would be used for structural, fatigue, and corrosion evaluation. The studies would also test weld joint design, fixturing requirements, and welding economics.

The selected laser system was configured with a two-way beam switch and two robots. The beam switch directs 100% of the laser power to the selected robot. Switch time is 0.10 s. This configuration allowed the full weld path to be reached by the two robots without part repositioning. The robots and fixtures were located such that load and unload occurred on one fixture while a part was being welded in the other fixture.

The robotic MIG system was configured such that load and unload occurred without incurring robot idle time. The fixtures were arranged so that multiple robots could address a set of loaded fixtures.

When the two studies were compared (Tables 3, 4), the laser-welded part had a weight advantage because of the absence of filler material, and thinner section components could be used because of less process-induced distortion and no risk of burn-through. Both processes produced favorable results in the evaluation of corrosion resistance and mechanical properties. The laser system had clear advantages for initial cost, operating cost, floor space requirements, and manpower requirements. However, the laser welding fixtures were heavier and more expensive than the MIG fixtures because they needed to hold the components more accurately and the mating surfaces needed to be forced into intimate contact prior to welding (Ref 11).

As the two case studies illustrate, there are subtle trade-offs between process parameters, component design, manufacturing efficiency, technological capability, and economics. Time spent conducting a rigorous evaluation of the trade-offs will pay dividends throughout the product manufacturing run.

Laser Deposition Processes

J.O. Milewski, Los Alamos National Laboratory
T. Palmer, Pennsylvania State University

LASER BEAMS provide a well-controlled heat source, both in terms of the power delivered and the spatial precision of the directed energy. The interaction of the laser beam with the material being processed is substantially different than that of other thermal processing methods, such as plasma spray, arc, or flame processing, offering distinct advantages over competing thermal processing methods used for material deposition. Numerous variants of the process are being developed that use a wide range of lasers, material delivery, motion, and control systems optimized for specific applications. The disadvantages of laser deposition processes include process cost and complexity, which must be considered during process selection and development.

The deposition of weld material on metallic substrates, commonly known as cladding, is an industrial process used to improve the corrosion resistance and wear resistance of common structural materials. This deposited material forms a coating on the substrate material that alters its surface properties and supplies a combination of desired properties not found in any one metal. When a cladding process is adopted, a base metal can be selected for cost or structural properties, and another metal added for surface protection or some other desired property, such as electrical conductivity. Common welding processes, such as gas metal arc, gas tungsten arc, or plasma transfer arc, have been adapted to deposit a range of corrosion- and wear-resistant materials in industrial applications. By using these welding-based processes, the thickness of the cladding can be made much heavier and more durable than that obtainable by electroplating. Other comparable coating technologies include thermal spray and plasma spray processes, which deposit thinner coatings than those possible with these arc-based processes. Unlike these coating technologies, welding-based deposition processes produce a metallurgical bond between the clad and substrate materials, because fusion of the clad material to the substrate occurs.

Laser deposition involves the articulation of a laser beam and the introduction of material into the beam path to fuse the material onto a substrate or into a functional shape. It can be

divided into two broad categories: cladding and near-net shape processing. Laser cladding has evolved from weld-metal deposition processes relying on the modification of an existing substrate surface or base component. Laser near-net shape processing has evolved from laser cladding or rapid prototyping technology of nonmetals to create complex parts or features without the reliance on a function substrate that remains integral to the part (Ref 1). A wide range of laser power sources with wavelengths between 1 and 10 μm are used. Articulation of the laser beam relative to the part ranges from simple linear or rotational movement to sophisticated computerized numerical control (CNC), computer-aided design and manufacturing (CAD/CAM) modeling, and programming. The materials being delivered are typically in powder or wire form and can range from metals to plastics, composites, and ceramics. The most common materials used are plastics for three-dimensional (3-D) models and those metals commonly processed by melting.

The primary advantages of using lasers is that of reduced heat input, providing metallurgical and geometric advantages, precision of the deposit, and economic advantages (speed, material savings, reduced product development time, etc.). These advantages must be assessed on a case-by-case basis with the understanding that a greater degree of process development and control may be required in comparison with more mature, better understood, and more widely applied conventional alternatives.

The application of lasers for deposition is a rapidly evolving field primarily driven by the rapid evolution of laser power sources. As the cost and complexity of lasers decrease, successful applications will continue to overtake existing well-established processing methods as well as develop new and unique applications. As with other competing processes, advances in process sensing, control, and modeling are being integrated to optimize process performance. In addition, research, development, and new applications continue to expand our understanding of the properties and performance of the deposited materials. A growing list of successful applications has demonstrated

substantial economic return and continues to justify further development of the technology.

Laser Cladding

Process Description

Laser cladding uses a high energy density laser heat source to deposit selected corrosion- or wear-resistant materials on structural material substrates. Historically, the development of high-power gas lasers led to the initial development of laser cladding processes in the late 1970s (Ref 2). In the 1980s, the process became more refined with improved system development and process understanding (Ref 3–9). Through this development work, laser cladding processes are now widely used in a range of industries, including the automotive, aerospace, energy exploration and production, medical, and marine industries.

The characteristics of the laser heat source give the laser cladding process several advantages over other arc-based cladding processes. For example, lasers are typically characterized as being highly monochromatic and coherent with a high degree of directionality, allowing the laser to be sharply focused to extremely high power densities, on the order of 10^{17} W/cm². These energy density levels far exceed those of other arc-based deposition processes but are similar to the electron-beam-based deposition process parameters. Because the laser is a high energy density heat source, the energy provided by the laser can be directed at a specific location on the substrate, resulting in a much lower overall heat input into the substrate than what is produced by an arc source. This low heat input level minimizes the impact of the process on the substrate material, thus allowing the process to be used in both thin- and thick-section parts.

In addition to the CO₂ systems with which the laser cladding process was developed and still are in common use, a number of other solid-state laser systems are becoming more widely used. The more common types of laser systems used in industry have been expanded to include not only CO₂ lasers but also solid-

state laser systems, such as neodymium: yttrium-aluminum-garnet (Nd:YAG) lasers, ytterbium: fiber lasers, and direct-diode lasers. With the increasing power available and decreasing costs of Nd:YAG, direct-diode, and fiber laser systems, these solid-state laser systems have become much more prominent in the development of new applications. These solid-state lasers also offer the benefit of increasing process flexibility and automation because of the ability of the laser energy to be directed through the use of fiber optic cables. Several examples of the industrial application of laser cladding include the repair of commercial aircraft gas turbines and the application of corrosion-, wear-, and oxidation-resistant coatings on shafts of drilling tools, engine valve seats, tool hardfacing, hydraulic pump components, and molds (Ref 10–17).

The laser cladding process produces a macrostructure similar to what is observed in arc-based cladding processes, albeit with smaller sizes for selected zones. Figure 1(a) shows a schematic diagram defining the structure of a laser clad and includes the clad metal, a mixed zone between the clad and substrate materials, a heat-affected zone in the substrate material, and the unaffected substrate base metal. These distinct regions display variations in properties, with the clad material imparting the desired surface properties on the material, and the mixed and heat-affected zones resulting from the interaction of the heat source and the clad material with the substrate. The small sizes of these

Fig. 1 (a) Schematic diagram of a laser cladding cross section with the primary structural regions identified. Adapted from Ref 10. (b) Underwater laser deposition. two zones result in minimal impact of the cladding process on the substrate material. These different regions of a laser clad are shown in Fig. 1(b) for a 304L stainless steel deposit.

The resulting microstructures in each region of the clad macrostructure can be significantly different. Figures 2(a) and (b) show the microstructures present in the clad material and the mixed and heat-affected zones of an Inconel 625 laser clad made on a structural steel substrate. Figure 2(a) shows the dendritic structure formed in an Inconel 625 clad layer. Because the clad material has been melted and deposited on the substrate, it is primarily dendritic. The size and distribution of the dendrites will depend on the heating and cooling rates experienced during the laser cladding process. These thermal cycles will be dependent on the processing parameters, to include laser power and travel speed.

The thermal cycles produced by the laser cladding process will also have an impact on the underlying substrate material. Figure 2(b) shows the mixed and heat-affected zones formed in the structural steel substrate material during the laser cladding of Inconel 625. A gradient of microstructures appears as the distance from the clad metal interface is increased. The

Fig. 2 Common microstructures observed in (a) the Inconel 625 laser-clad layer on high-strength steel and (b) the mixed and heat-affected zones. Courtesy of Applied Research Laboratory, Pennsylvania State University

common features of the heat-affected zone in a steel weld, to include the large and fine-grained regions caused by the heating and rapid cooling of the steel during the laser cladding process, are also present. Probably the most important consideration in examining this figure is the small size of the mixed and heat-affected zone. In Fig. 2(b), the heat-affected zone extends only approximately 2 mm (0.08 in.) from the clad metal interface. This small heat-affected zone is the result of the high energy density and low heat input characteristic of the laser cladding process.

Because a metallurgical bond is formed between the clad and substrate materials, some level of dilution between the clad material and the substrate material is expected. When viewing a laser-clad cross section, a region where the clad layer consumes some amount of the substrate material can be observed. This level of dilution can be defined geometrically across the cross section of the clad layer, with the amount of base metal consumed by the clad metal defining the level of dilution. In laser cladding, the extent of geometric dilution is typically rather small, usually not exceeding several millimeters in depth. Dilution levels in clads produced by arc-based processes are typically much larger, because these processes melt a much larger amount of substrate material.

Another means for measuring dilution levels involves the direct measurement of the chemical composition of the clad layer. Figure 3 shows a characteristic chemical composition profile of selected alloying elements measured across the depth of the clad material starting at the substrate interface for an Inconel 625 clad on a high-strength steel substrate. In this figure, the change in chemistry, primarily of the iron level, can be observed up to 2 mm (0.08 in.) into the clad layer. The presence of iron from the substrate material in the clad metal shows how the base metal is diluted into the clad material, resulting from the convection and transport of material caused by the laser cladding process. A measure of the level of dilution of the iron is the distance into the clad material needed for the iron level to reach the iron level present in the original clad material (just under 2 mm in Fig. 3). In laser cladding, this distance is significantly lower than what is observed in arc-based cladding processes, where additional clad layers are typically required to obtain the desired clad-metal chemistry.

Material Combinations

Laser cladding has been used to deposit a wide range of corrosion- and wear-resistant materials on compatible substrate materials. There are three main categories of materials and material combinations that are commonly deposited using laser cladding processes. These different material combinations include the deposition of a single corrosion- or wear-

resistant material on a structural material substrate, the formation of functionally graded or composite material structures (Ref 17, 18), and the fabrication of particulate composites containing high-melting-temperature particles (Ref 12, 13).

The deposition of corrosion- and wear-resistant materials on structural steel components is probably the most common use of laser cladding processes in industrial applications (Ref 12, 13). These materials are typically cobalt-base alloys, such as the Stellite family, for wear-resistant coatings (Ref 16); nickel-base alloys, such as the Inconel family, for corrosion-resistant applications; and iron-base alloys, such as austenitic and martensitic stainless steels, for both wear and corrosion applications. The laser deposition of coatings on magnesium (Ref 14), titanium (Ref 15), and aluminum components is also industrially relevant.

The selection of suitable material combinations is driven by material compatibility and similar thermal expansion coefficients between the clad and substrate materials. Metallurgical compatibility is one of the primary considerations. Because the clad and substrate materials will be fused together, alloy combinations that will result in the formation of undesirable intermetallic phases cannot be clad. For example, the deposition of cobalt-base alloys on titanium substrates is not recommended, because of the formation of these undesired intermetallic phases. It is worth noting, however, that the low levels of base-metal dilution prevalent in laser cladding, particularly at low heat inputs, can limit the formation of these undesired phases. This characteristic of the laser cladding process has led to the development of other additive manufacturing processes, which are discussed in later sections.

In addition to the deposition of these materials, laser cladding, particularly when using a powder precursor, allows for the production of composite microstructures. Two types of composite microstructures can be formed: graded microstructures and uniformly dispersed particulate microstructures. The low dilution levels prevalent in laser cladding processes allow for the formation of graded structures, such as those produced in aluminum-base and other compositionally graded materials (Ref 18, 19). This ability to functionally grade materials can lead to the development of materials with unique properties unobtainable through conventional processing routes. In wear-resistant applications, the addition of high-melting-temperature particles, such as WC, TiC, and other hard carbide materials, imparts the desired wear resistance to the surfaces of common structural materials, thus extending the usefulness of these materials in high-wear applications.

Process Characteristics

Laser cladding is a flexible process in which a range of process parameters can be varied to

Fig. 3 Electron microprobe measurements made across the laser-clad/substrate interface in the laser cladding of Inconel 625 on a high-strength steel. Courtesy of Applied Research Laboratory, Pennsylvania State University

produce a wide array of different coating thicknesses and process efficiencies. Several of the important process parameters used in laser cladding include laser power, beam diameter, travel speed, clad material-introduction mode, and beam manipulation methods. The combination of these various process parameters can impact the types of materials deposited by the laser cladding process, the process efficiency as defined by the deposition rate of the clad material, the thickness of the coating, and the impact of the cladding process on the underlying substrate material.

Of these various processing parameters, the impact of different clad material-introduction modes, which are defined primarily by powder and wire feeding, and the impact of beam scanning are described subsequently. Depending on the laser power used and the mode of material introduction into the laser, the range of material deposition rates can span from very low rates of less than 0.5 kg/h (1 lb/h) to very high depositions that can reach levels approaching 15 kg/h (30 lb/h). The width of a clad pass can also be altered by the width and the scanning of the laser beams. In cases where the beam is scanned, clad pass widths can reach sizes of 25 mm (1 in.) or more, depending on the capabilities of the scanning optics. When a non-scanned beam is used, clad pass widths are the same size as the defocused laser beam, which is typically on the order of up to 5 mm (0.2 in.) or less.

Powder and Wire Feeding. In laser cladding processes, clad material can be deposited using either powder or wire feeding. Figures 4 (a) and (b) show schematic diagrams of powder-based and wire-based cladding, respectively. In both cases, the laser beam is directed at the powder or wire, which is then melted on the substrate surface. Each material-

Fig. 4 Schematic diagrams showing (a) powder-fed and (b) wire-fed laser-cladding processes. Courtesy of Applied Research Laboratory, Pennsylvania State University

introduction mode, however, has unique properties, along with its characteristic advantages and disadvantages. This range of characteristics and different material-introduction modes increases the flexibility of the laser cladding process and makes it applicable to a range of applications, where different deposition rates are required or varying geometries must be processed.

When cladding with powder, the deposition of unique material combinations becomes possible, allowing for the fabrication of composite and graded structures. In addition, the use of powder allows for a range of deposition rates, with both low and high deposition rates being possible. For example, low-deposition-rate laser-clad layers can be produced with low heat inputs, resulting in minimal distortion and allowing for the deposition of thin clad layers. On the other hand, high-deposition-rate cladding is also possible, resulting in the deposition of thick clad layers on applications such as shafts or other components where thick corrosion- and wear-resistant coatings are needed. However, the use of powder feeding limits the cladding of components to specific geometries and welding positions, because some substrate configurations make it impossible to place the powder. Powder cladding is most often performed in the downhand or 1G position, so that the powder can be laid easily on the surface.

The use of wire-fed cladding is a technique that is finding wider use in the deposition of clads in repair and other unique applications. In many repair applications, the geometry and placement of the component may preclude the performance of the clad in a downhand position. Wire feeding

provides a means to easily introduce material into the laser beam without the issue of powder flowing out of the beam in a horizontal geometry. It is also possible to use commercially available filler-metal wire rather than powder, which may reduce issues with process qualification or the qualification of a new material for an existing application. Deposition rates, however, are limited with wire-fed cladding by the speed that the wire can be fed into a molten metal pool of limited size.

During powder-fed laser cladding, the powder can be introduced into the laser by either preplacing the powder in front of the advancing laser beam or by coaxially feeding the powder directly into the laser. Schematic diagrams of preplaced powder cladding and coaxially-fed powder cladding are shown in Fig. 4(a) and 5, respectively. These two different means of feeding the powder can be used to alter the deposition rates needed for specific applications. For example, when higher deposition rates or thicker coatings are desired, preplaced powder can be used instead of wire or coaxially-fed powder. By preplacing the powder in front of the advancing laser beam, more powder can be melted, thus maximizing the deposition rate.

Many of the advantages of the laser cladding process can be traced to the absorption of the laser energy by the preplaced powder bed (Ref 20). An analysis of the absorptivity of powder beds has shown that these powder beds are highly efficient absorbers of laser energy. As a result, only a small amount of laser energy reaches the substrate, thus minimizing the size of the mixed and heat-affected zones in the substrate material. This increased absorptivity is particularly prevalent in preplaced powder beds and is responsible for the low levels of dilution and minimal impact on the substrate material, even during high-power and high-deposition-rate laser cladding.

Coaxially-fed powder cladding, however, has limited capability for high deposition rates, because the amount of material to be deposited is limited by how much powder can be fed into the laser beam. As a result, this process typically produces much thinner coatings than those obtained using preplaced powder. This limited deposition rate also allows for the coaxially-fed powder process to produce more easily functionally graded structures and particulate material composites. The heat input into the part is also lower, thus minimizing the clad-metal dilution of the laser cladding process on

the substrate material to even lower levels. Along with these decreased dilution levels, the size of the heat-affected zone in the substrate material is also minimized.

Scanned versus Defocused Beams. During laser cladding, a defocused beam is typically used, because the goal of the process is to avoid excessive melting of the underlying substrate material. The beam diameter can vary from 1 to 5 mm (0.04 to 0.2 in.), depending on the laser power and the desired thickness and width of the clad layer. For coaxially-fed powder and wire-fed systems, the beam is defocused to provide a larger interaction area for the laser and the wire or streaming powder.

It is also possible to shape the laser beam into a desired shape. Beam-shaping optics are available to convert a circular beam into other shapes. For cladding, a linear heat source is used because it allows for a wider clad pass. Direct-diode lasers, which are becoming more widely available, can produce a linear heat source that will allow a wide clad pass to be deposited. The beam can also be scanned over a predetermined path to increase the size of the heat source. With the increased size of the heat source, a wider clad pass can be deposited.

Comparison with Arc Cladding Processes

Laser cladding is characterized by lower heat-input levels and lower base-metal dilution than widely used arc-based cladding processes. High-power laser systems also provide the ability to deposit large quantities of material at much higher travel speeds. A comparison between high-deposition laser cladding and several other common high-deposition-rate arc-based cladding processes is provided in Table 1. In this table, process parameters, such as deposition rate, travel speed, heat input, and base-metal dilution, and manufacturing considerations are compared for high-deposition-rate laser, pulsed gas metal arc, gas tungsten arc, submerged arc welding, and electroslag strip cladding processes.

A comparison of the processing parameters in Table 1 shows that the laser cladding process has a number of favorable characteristics when compared to other high-deposition-rate processes. In addition to the high deposition rate, the laser cladding process has high travel speeds and lower heat inputs than the other processes. These two characteristics make the laser cladding

Fig. 5 Schematic diagram showing coaxially-fed powder laser cladding. Source: Ref 18

Table 1 Comparison of characteristics of laser and arc-based cladding processes

	Laser	Pulsed gas metal arc	Gas tungsten arc, hot wire and cold wire	Submerged arc welding	Electroslag strip cladding
Process parameter					
Deposition rate, kg/h (lb/h)	13–15 (25–30)	6 (12)	6–7 (12–13)	6–13 (12–25)	22 (44)
Travel speed, mm/min (in./min)	0.7–0.8 (18–20)	0.2–0.3 (6–8)	0.3–0.4 (7–9)	0.2–0.3 (6–8)	0.2 (6)
Heat input, kJ/mm (kJ/in.)	1.3 (33)	2.0 (51)	1.4–1.7 (36–42)	2.2 (56)	12 (300)

Labor and material	Low	High	High	High	High

process attractive, particularly when considering the enhanced process efficiency afforded by the increased travel speed. The lower heat-input levels also minimize the impact on the substrate material, thus minimizing distortion and follow-on operations that may be required to bring the part back into specification.

When compared with manufacturing considerations of arc-based cladding processes, the laser cladding process has a number of advantages in terms of process control and improved product quality. For example, laser cladding produces lower levels of distortion in the product being clad than what is typically obtained in higher-heat-input arc cladding processes, which results in less postprocessing rework. The accuracy in the placement of the laser heat source also results in greater precision in the placement of the deposited material, which reduces postprocess machining. Laser cladding is also well suited to greater automation or mechanization, which improves process control. The reduced base-metal dilution leads to greater compositional control.

Future Directions for Laser Cladding

Because laser cladding is an additive process, it can be applied to a wide range of components as an advanced manufacturing process to overcome many of the shortcomings of other fabrication technologies and materials. Several benefits include the enhancement of corrosion and wear properties and improved thermal control. In addition, a reduction in production time, the production of functionally graded parts, and increased application to part repair and remanufacturing can be realized.

The application of corrosion- and wear-resistant coatings on structural materials using the laser cladding process is becoming more common with the introduction of new and more powerful laser systems. Laser cladding is commonly used in the manufacture of new components and the refurbishment of existing components. In addition, it is used increasingly for the repair of in-service components. An example of a laser-cladding-based repair process of aluminum components is shown in Fig. 6.

As described, the laser cladding process has great potential for a range of industrial applications. However, the utilization of laser cladding processes is limited because of its high cost, particularly of the laser power supply, and the limited process efficiency. With the increasing capabilities of the new-generation direct-diode, disc, and fiber lasers, process efficiencies can be improved, particularly as available laser powers continue to increase and costs decrease concurrently.

Near-Net Shape Processing

Process Characteristics

Near-net shape laser deposition processing features many attributes common to laser cladding when considering applications to metals or cermets. The range of metals processed and metallurgical properties of the deposited metals are often similar but may be affected by cooling rate or dilution by the substrate materials. As with laser cladding, materials commonly deposited range from aluminum-, iron-, nickel-, and

cobalt-base alloys to more exotic and difficult-to-process materials such as titanium alloys; refractory, reactive, or reflective metals; ceramics; and composites. Metals can be deposited up to 100% density, with properties ranging from those found in cast materials and, in some cases, even exceeding those of wrought material. In all cases, adequate and consistent material properties require the appropriate levels of verification during process development and prove-in. Near-net shape processing is differentiated easily from cladding when considering applications to plastics and ceramics. Another primary difference is the decreased reliance on a substrate component and the increased degree of process control and planning required to create a complex shape and to ensure that the desired properties of the deposit are met. Justification of the costs associated with the increased process complexity and development are being found in applications for low-volume, high-value-added components or with materials that are difficult to fabricate using conventional means. Early development of the technology is described in Ref 21 to 24. A comparison of the technology with other competing powder deposition processes and near-net shape processes is provided in Ref 25. A comprehensive review of the technology, including its historical evolution, is provided in Ref 26.

Process Applications

Three-dimensional prototype part models, offering form and fit testing, often are produced by using plastics and sintering layer by layer within a powder bed. Applications using plastics are well established and widely supported by vendors of equipment and commercial services. Functional material properties in metals may be obtained by either a powder bed method of deposition or direct injection of material into a molten pool and deposition along a traversed laser path to produce the desired shape. Each of these two methods has distinct advantages depending on the application.

Powder Bed Methods

Powder bed methods raster or direct the laser beam across a bed of powder material to selectively melt and fuse the material by turning the laser beam on and off. The powder bed is indexed downward, and a new layer of powder is applied and selectively fused layer by layer into a 3-D component; the process is shown schematically in Fig. 7. Process variants and trade names as of this writing (2011) include additive layer manufacturing, LaserCusing, selective laser sintering, and direct metal laser manufacturing.

Advantages of this method, when compared to direct powder injection, include relative process simplicity because the traversal paths are generally linear, and the x - and y -motion can be accomplished using laser beam rastering and an incremental z -axis motion. Powder

Fig. 6 Laser cladding repair of aluminum components. Courtesy of Naval Undersea Warfare Center Division, Keyport

delivery is accomplished using a layer-by-layer rolling technique to preplace new powder for successive laser paths. Planar slicing of the 3-D solid model uses software technology previously developed and refined for laser sintering of plastic models and offers a simplified programming and control interface. Dimensional accuracies of up to 0.1 mm (0.004 in.) and deposition rates of 2 to 20 cm³/h (0.12 to 1.2 in.³/h) may be achieved but are material-dependent. Support structures may or may not be required, depending on the geometry of the components being fabricated. Primary process parameters include laser power, laser spot size, raster speed, path overlap, planar z-step size, and powder type and size.

Disadvantages of this method include limitations of the processing chamber size and the inability to add near-net shape features to the existing base component for repair, refurbishment, or part modification. Full density of the deposited material may be more difficult to achieve than processes that maintain a larger molten pool.

Variants of the process include powder heating to increase deposition rates and powder recycling to reduce process waste. Full enclosure of the process within an inert chamber can offer class I isolation of the laser beam and containment of environmental and health hazards associated with powder processing. Multiple instances of the same part may be fabricated at the same time within the working envelope of the chamber. Complex internal structures are easily fabricated using this method. Applications include functional prototypes for use in the medical, defense, and space industry as well as applications for the tool and die industry, where complex cooling channels

may be easily formed within the deposited part. An example of direct metal laser sintering of a titanium structure for a competition bicycle is shown in Fig. 8.

Directed Powder Methods

Direct powder methods inject powder into the molten pool formed by the laser beam and produce a relative motion between the part or features being formed and the laser. Fusion of the deposit into adjacent and underlying material forms the near-net-shaped feature (Fig. 9). This method is an evolution of multipass 3-D laser cladding, with the primary differences related to the sophistication of powder delivery, process planning, and control. The process may be performed within a class I laser enclosure, an inert chamber, or in the open, with due consideration paid to hazards associated with the laser, powders, and associated motion system. The CNC motion or robotic motion and control are typical to the complex deposition paths required. Typically, the powder is delivered to the molten pool by inert gas through multiple jets within the laser head. Near-net shape cladding using wire feed is less suitable for laser net shape deposition because the articulation of wire feed into the molten pool limits the use of omnidirectional movement and out-of-position deposition. Process variants and trade names include DMD (direct metal deposition), LENS (laser-engineered net shape), solid freeform manufacturing, laser powder additive manufacturing, laser powder deposition, and LAM (laser additive manufacturing).

In comparison with conventional cladding methods, a near-net-shaped feature or part is

designed and the control sequence for deposition of the feature is planned using CAD/CAM or direct programming techniques. Deposition of the feature is begun on a substrate material that is either integral to the final part or is removed after deposition is complete. A high degree of sophistication may be incorporated within the deposited feature at the cost of more complicated process planning, refinement, and control. Trial and error is sometimes required to arrive at an acceptable deposit in terms of geometric shape, metallurgical considerations, and overall deposit morphology.

To reduce the complexity and speed to fabrication, a relatively simple substrate component may be fabricated by conventional means, with high-value-added features being added later using near-net shape laser deposition. Other high-value-added features may include the addition of intellectual property or specialty materials inappropriate for outsourcing. In other applications, entire parts may be fabricated or partially fabricated as modification to an existing CAD design and may be performed as in the case of complex shape repair or modification. Examples of a rebuilt turbocharger blade and a feed screw are shown in Fig. 10. Remanufacturing of components into a higher-value product is possible. In the case of repair or modification of existing components, the process has the potential of being applied in situ or on site, thus eliminating the need to transport large parts.

When compared to laser cladding of large objects, such as shafts and valve seats, small, precise features are formed at the expense of

Fig. 7 Selective laser sintering. Courtesy of Castle Island Co.

Fig. 8 Direct metal laser sintering of a titanium structure for a competition bicycle. Courtesy of EOS

Fig. 9 Laser-engineered net shape process. Courtesy of Castle Island Co.

deposition rate but may result in materials savings. By the previous definition, the deposition of large titanium alloy backbone structures for aircraft that require extensive machining may be considered 3-D cladding, while repair or modification of turbine components, molds, or dies requiring less finishing may be considered near-net shape additions. Direct powder methods for near-net shape deposition use sophisticated powder-delivery systems and laser heads to allow the precise delivery of powder to the pool and laser focal region, allowing rapid omnidirectional movement and out-of-position deposits. The process is not limited to vertical deposition or gravity-assisted powder feed. The inert delivery gas is typically argon, although nitrogen or other gas mixes are possible.

In comparison with powder bed methods, directed powder methods are not limited by chamber size constraints. Switching powders or mixing powders to obtain functionally graded deposits is more easily facilitated with the use of multiple powder feeders, although precise control of powder mixing remains a technical challenge. Active control of a wider range of process control parameters is possible to optimize the quality, uniformity, and repeatability of the deposit and deposition rate at the cost of process complexity. As with welding or cladding, the resultant microstructure and properties of the deposit are highly dependent on the process parameters and fabrication environment. Qualification, standardization, and acceptance of the materials remain a challenge

when proposed for critical components such as those for aircraft, aerospace, or nuclear applications. To meet these standards, material properties must be duplicated across laser deposition platforms and vendor machines from one fabrication event to the next. Given the process sensitivity and the large number of variables to control, the need for real-time process control and sophisticated process planning is needed.

A 3-D solid model is often used as a starting point for both processes. The powder bed method will often create a tessellated shell structure and two-dimensional planar slices to produce profile and raster paths for the fusing of the powder bed. In addition, the directed powder method may use conventional CNC path-planning algorithms, such as those used for CNC milling. This technique can be used to create multiaxis deposition paths, increasing process flexibility at the cost of programming complexity. Adaptive sensing and control has been demonstrated for directed powder methods. To fully realize the optimization of all process parameters and the part itself, future systems may require rule-based or intelligent system integration of CAD, computer-aided engineering, finite-engineering analysis, CAM, and real-time control.

Variants of the process include multiple powder feeders and mixing to create functionally graded deposits and powder recycling to reduce process waste. Full enclosure of the process within an inert chamber can offer class I isolation of the laser beam and containment of environmental and health hazards associated with

powder processing, but is not required. Multi-axis movement of the laser head out of a vertical orientation, such as typical with robotic or CNC articulation, creates the additional hazards of protecting personnel from class IV laser hazards. Multiple instances of the same part may be fabricated at the same time within the working envelope of the chamber. As with the powder bed method, complex internal structures are easily fabricated using this method. As with powder bed methods, dimensional accuracies of up to 0.1 mm (0.004 in.) are achievable, while deposition rates of 10 to 100 cm³/h (0.6 to 6 in.³/h) may be achieved but are material- and laser-dependent.

Process parameters include laser power, laser focal spot size, speed, path overlap, path step-up distance, and powder type and size. In

addition, other key parameters include powder feed rate, delivery gas type and flow rate, and nozzle configuration and orientation. Powder feed material considerations affecting precise and consistent delivery include powder morphology (spherical, angular, or agglomerated) and powder size, density, and purity. Substrate material considerations include degree of dilution, metallurgical compatibility, cleanliness, and other heat-sinking (thermal) or mechanical constraints that could lead to undesirable characteristics of the deposited material.

Future Directions for Near-Net Shape Processing

The future of near-net shape processing using laser powder fusing will benefit greatly by advances in laser cladding technology development, since those applications are likely to achieve greater near-term acceptance because of process simplicity and as direct replacement of existing cladding applications. Standardization and qualification of deposited materials will be driven by applications in the aerospace and nuclear industries, while the ability to create materials with uniquely designed properties will be driven by innovation. To fully realize the potential of near-net shape laser deposition, an entirely new set of tools will be required to fully integrate design through manufacturing. A new methodology is needed, from concept through computer-aided design, engineering, fabrication, and control, to fully optimize and use the many process parameters and to break free from conventional processing constraints. Challenges identified a decade ago, such as surface finish, accuracy, deposition rate, and control of residual stress and distortion, are being met through evolutionary changes to the processes, diagnostics, modeling, and control. Significant advances in the past decade have moved the technology out of universities and national laboratories and into industrial application. Future technology development (Ref 27) promises a greater pace of technology adoption and many new applications.

Laser Weld Quality Monitoring

Randolph Paura, Dynamic Laser Solutions

WELD QUALITY MONITORING is an integral part of manufacturing operations. In the early years of accelerated deployment of laser welding (pre-mid-1980s) in fully automated environments, it occurred to manufacturing engineers that there was no indication or display that told them that the laser beam had reached the part, let alone a quality weld had been produced. From investigations into the strategies and technologies to supply this information, it was found that emissions from the laser welding process could be detected and analyzed in such a way that weld quality could be ascertained to a useful degree (Ref 1–4). The integration of laser weld quality monitoring into the automated welding systems was found to be a useful and necessary addition to the existing quality program.

Laser weld inspection entails various monitoring options. This article reviews weld quality monitoring considerations for automotive materials (steel and aluminum), with a focus on photosensor technology. Radiative emission monitoring has seen considerable progress over the past years and can reliably determine weld quality. To establish a weld quality monitoring system with confidence and reliability, an appropriate selection of equipment, procedures, and people is required. Weld quality monitoring is part of a manufacturing strategy to ensure that weld defects are held to a very low number (for example, less than 5 parts per million). Working toward 0% product defects requires 100% laser weld inspection.

Numerous works are available regarding laser weld quality monitoring, and improvements in the process are continually being made. By understanding the elements of a quality weld, the weld process indicators and inspection options will provide the means for a company to select and implement the appropriate equipment. The goal is to maximize productivity, achieve and maintain confidence with the quality monitoring system, and reduce downtime for weld destruction inspections. As much as weld quality monitoring has been viewed as imprecise in the past, there are robust and reliable considerations available.

Overview of Laser Welding

Although other articles provide extensive details on laser welding, this section is a brief

review to establish the foundation for understanding the application of weld quality monitoring. Some basic process parameters are introduced first, followed by some application aspects related to automotive manufacturing. Laser welding of automotive frames and components has a demonstrated track record for operations efficiency and product optimization in Europe, with increasing levels of acceptance in North America.

Although laser welding is not a direct substitute for gas metal arc welding (GMAW) or resistance welding methods, laser welding does have benefits to offer for an automotive assembly. Most applications in the automotive industry center on the deep-penetration laser welding process, because it provides the speed necessary for economic justification. Benefits include:

- Contact-free processing
- High process speed (higher production rate or reduced floor space)
- Controlled heat input (smaller heat-affected zone)
- Joint geometry flexibility (single-sided accessibility, small flanges)
- Material process flexibility (metals, plastics)
- Process flexibility from one power source (heat treatment, cutting, welding)
- Process integration (potential to eliminate production steps)

- Process substitution (potential to alter production process steps)

The cost of a laser welding system is considerably higher than other traditional welding systems, but there has been a steady growth in applications for laser welding. This is due in part to the continuing improvements in power source reliability, laser power and beam quality, and power source diagnostics.

Laser Welding Process Description

Lasers produce coherent electromagnetic radiation that can be focused to a small spot size, resulting in a high power density. If the power input is greater than the heat dissipation capabilities of the material, melting occurs. At even greater power densities (above the critical or threshold limit), the material is vaporized, resulting in keyhole (or penetration) laser welding. (See the article “Laser Beam Welding” in this Volume for more details.)

Penetration (keyhole-mode) laser welding occurs when laser power density is above the vaporization threshold for the parent material (Fig. 1). Penetration (keyhole) welding is accomplished when the focused beam achieves a power

Fig. 1 Laser intensity and welding depth

density greater than the critical value ($\sim 10^6$ W/cm² for steels in atmosphere). With power levels above this threshold, vaporization of material is achieved, which allows for deeper and faster welding than can be accomplished with conduction-limited welding (Fig. 2). In laser welding for automotive components, welding speed is advantageous, and so most automotive applications concentrate on penetration laser welding.

Once a keyhole is produced, if the material and laser beam remain stationary, then a hole will be generated with no further results. Moving the focused laser beam relative to the workpiece to be welded produces the following actions:

- The material is partially vaporized and melted by the laser beam.
- The plasma plume generated is greater than the viscosity of the melt pool, forcing it away from the laser beam.
- As the beam proceeds through the material, the keyhole will collapse and a new one is generated.
- The collapsed keyhole (weld) solidifies as it cools.

The high energy density nature of the laser process then presents the following challenges:

- Ensuring the thermal gradient between the weld and the parent material is not excessive (which leads to cracking upon solidification)
- Excessive alloying elements are not lost in the weld through vaporization
- Controlling the size of the melt pool for the joint; too large or small results in poor weld quality (excess or insufficient heat input)

Understanding the material characteristics with appropriate laser weld equipment, configured for process tolerance, will result in welds that are able to meet specifications and, in turn, are dependable.

Penetration (Keyhole) Welding Process (Ref 5). Figure 3 is a schematic of the weld region from penetration laser welding. The laser beam is focused to provide sufficient power density above the critical threshold (10^6 to 10^7 W/cm²). For a 2 kW ytterbium (Yb): fiber, Yb:disc, or neodymium: yttrium-aluminum-garnet (Nd:YAG) (near-infrared) power supply, this equates to a focused beam diameter that is less than 0.5 mm (0.02 in.).

At this power density, the laser beam heats, melts, and vaporizes the steel in its path in a rapid manner. If no motion is introduced, all the metal is vaporized and a hole is “pierced” through the steel with no further action taking place. The laser beam is simply passing through the steel. By moving the laser beam along the weld joint, material is melted in the front half of the beam, with material solidifying along the trailing portion of the beam path.

To protect the molten metal from the atmosphere, a shielding gas is necessary, akin to the GMAW process, which is also referred to metal inert gas (MIG) welding. Common shielding gases for near-infrared laser welding are argon and/or helium. Helium is a common shield gas for CO₂ lasers, although argon may be successfully used for lower power levels (approximately <3 kW).

Various parameters influence the productivity and quality of the laser weld (Ref 6). Each must be assessed and addressed carefully:

- **Laser parameters:** Power (for pulsed laser beam welding, this should be either peak or average, pulse width, pulse repetition rate), beam mode, angle of divergence, focusing (includes spot size and caustic waist profile), polarization, focal position with respect to the workpiece surface
- **Process parameters:** Weld travel speed, shielding gas, weld joint gap
- **Workpiece/tooling:** Material(s), material thickness, workpiece surface (roughness, oxidation, cleanliness), workpiece properties, fixturing and tooling

Because laser welding is a high energy density process, the system requirements for quality and consistency are greater than with GMAW (also known as MIG welding).

In general, the high energy density allows for a rapid weld speed. Consequent to this, there is a small or narrow heat-affected zone. These features can be used to a great benefit when dealing with low-carbon steels. With high-carbon (or equivalent) steels, the rapid cooling of the weld zone can/will result in a hard/brittle weld. This can be overcome by reducing the weld speed or power density or by using other process parameter changes, such as dual-pass welding (one to preheat and one to weld). The result is that each weld application is unique and should be prototyped to verify the system requirements and the productivity capabilities.

Laser Weld Characteristics

Key Weld Quality Elements (Ref 7). The key weld quality elements include:

- **Weld penetration:** Readily verified with weld cross sections or visual inspection of the backside of full-penetration welded parts. Penetration depends on the cross-sectional size/shape of the weld.
- **Weld strength:** May be assessed by uniaxial tensile testing. The ultimate tensile and yield strength levels depend on the material, weld metallurgy, joint geometry, application of load, and weld-parent material interface.
- **Hardness and ductility:** Depends on material (s) welded, thermal experience during welding, and any postweld heat treatment/tempering

Fig. 2 Laser welding processes. (a) Conduction-limited laser welding. (b) Penetration (keyhole) laser welding

Fig. 3 Schematic of weld region from penetration laser welding

- **Cracking:** Although cracking is not desired, it may be allowed in certain cases, depending on the application of the weld (within limitations). If not allowed (as in welds subject to forming operations), relevant inspection methods are metallographic sectioning or nondestructive methods, such as visual, ultrasonic, dye penetrant, or radiographic inspection.
- **Undercutting:** Localized reduction in the weld cross section caused by metal flow into the weld joint
- **Porosity:** Voids can vary considerably within a weld. Like cracking, these are not desired (especially in stamping operations). The specifications should list the acceptable pore number/sizes allowed.
- **Hermeticity:** A weld providing a seal that encloses a volume will be subject to specifications such as a maximum leak rate and/or minimum burst pressure.
- **Cosmetics/appearance:** Can be quite subjective. Where welds are exposed and subject to postprocess operations (such as e-coating and/or painting), the visual appearance may be crucial from a customer-perception viewpoint.
- **Augmented laser weld process considerations:** Can enhance process tolerance and address metallurgical challenges (such as when welding certain aluminum alloys, high-carbon-content steels, or other alloys). Examples, which may include the use of cold or hot filler wire as appropriate to replace lost alloying elements, include hybrid welding, such as laser + MIG or laser + plasma, to extend the weld process tolerance window.

Figure 4 tables a schematic illustration of the different types of defects encountered when laser welding metallic materials (Ref 8).

Joint Configurations (Ref 9, 10). For laser-welded joints, gap tolerances are stricter than GMAW (MIG welding) joints, because the parent material is used for joint fusion with no filler wire added (except as may be required when welding aluminum). Gap limitations vary according to the joint configuration, as illustrated in Fig. 5.

Process Variables

The high beam energy and material interaction of the laser welding process gives rise to various parameters that affect the ability to achieve a quality weld. Grouping and understanding the various parameters that affect the quality of laser welds is necessary to configure a system that provides quality welds on a consistent basis. If parameters are fixed (with the equipment settings), then it is imperative that the quality of materials is maintained and there is process tolerance to allow for variations (within limits) that

will occur (with materials to be welded). Conversely, if adaptive controls are implemented, methods are needed to sense, interpret, calculate, and implement appropriate responses at a cycle rate that is greater than the process itself.

Defining the process parameters is essential in evaluating weld defects and monitoring weld quality. Details of the laser weld process have been the subject of various studies and discussions (Ref 11–13), but the depiction of a keyhole laser weld (Fig. 6) helps illustrate some basic elements of the process and the resulting weld. A more detailed description of the laser beam welding process is also found in the article “Laser Beam Welding” in this Volume.

By moving the laser beam along the weld joint, material is melted in the front half of the beam, with material solidifying along the trailing portion of the beam path. Surface tension of the molten metal helps to stop the melt flow, forming the weld pool behind the laser (Fig. 7).

To protect the molten metal from the atmosphere, a shielding gas is necessary, akin to the MIG welding process. Helium is a common or the first choice of shield gas for CO₂ lasers (10.6 μm). Argon and/or helium shielding gases are common for Yb: fiber lasers (1.07 μm), Yb: disc lasers (1.03 μm), or Nd-YAG lasers (1.064 μm).

Thermophysical properties (parent material) include:

- Absorptivity (an influencing factor to initiate keyhole welding)
- Melting point (influences required power level and weld speed for a given focused spot size)
- Surface tension (ability to form a weld joint; influences undercut and the molten material dynamics affecting penetration)
- Thermal conductivity (affects weld speed)
- Thermal diffusivity (affects weld size)
- Vapor pressure (affects stability of keyhole)
- Viscosity (affects stability of keyhole)

Defect	Explanation
 Cracks	Hot crack in the fusion zone or cold in the heat-affected zone
 Porosity and gas pores	Voids in the material: Spherical = gas bubbles Irregular = impurities
 Incomplete penetration	Not deep enough penetration
 Linear misalignment	The centerlines of two parts do not coincide.
 Lack of fusion	The two parts are not welded throughout the entire weld zone.
 Undercut Root sagging	Lack of material in upper weld zone Too much material in lower weld zone
 Reinforcement Root cavity	Too much material in upper weld zone Not enough material in lower weld zone
 Blowout	Crater formation on top surface

Fig. 4 Various types of defects that occur during laser welding. Source: Ref 8

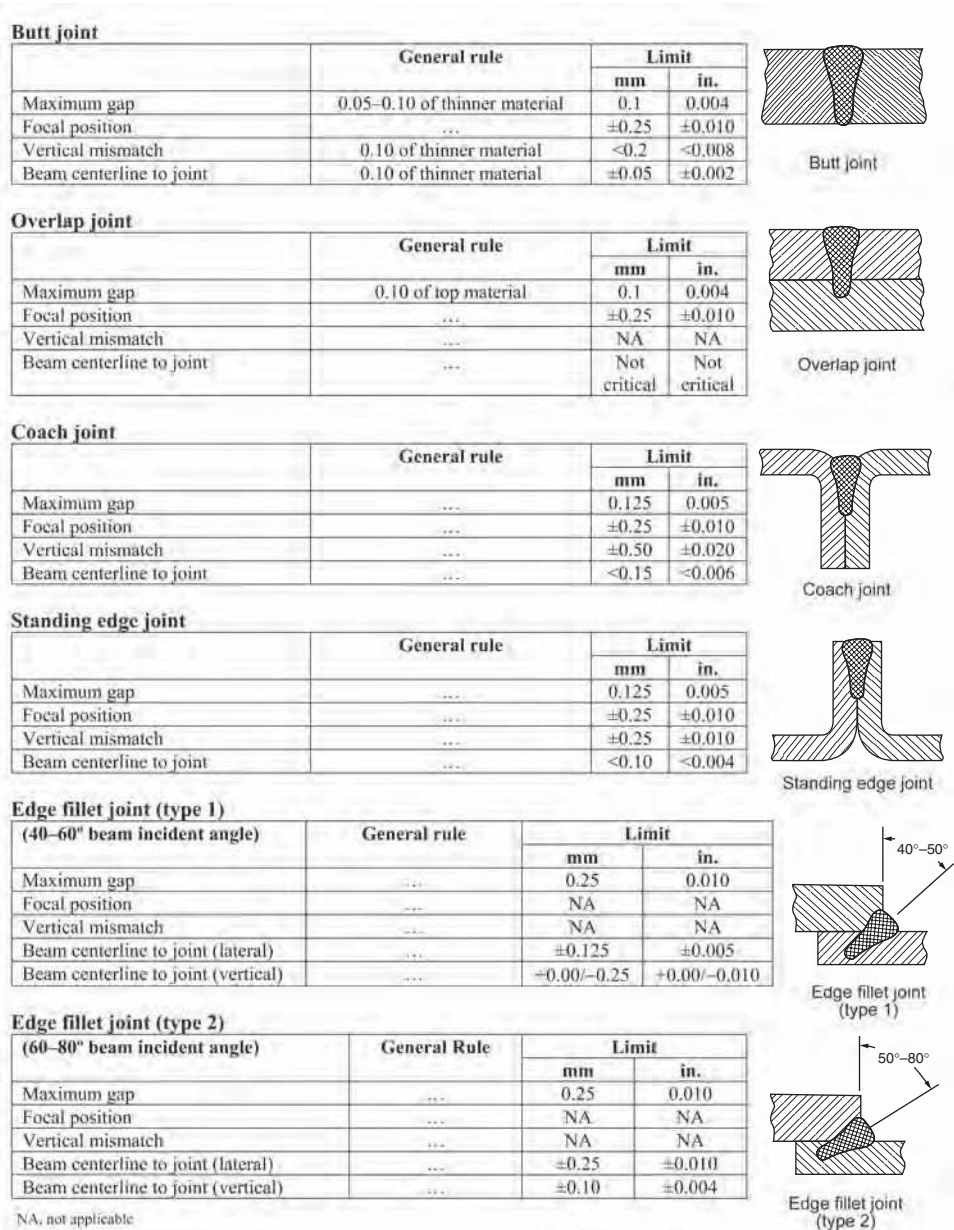

Fig. 5 Gap limitations vary according to the joint configuration for penetration (keyhole) laser welding.

- Loss of alloying elements (affects weld integrity and properties)

Process parameters (equipment configuration) include:

- Beam alignment (position relative to weld joint)
- Beam diameter (ability to bridge joint gaps)
- Beam focus position (influences weld profile)
- Beam irradiance (power density influences weld speed and depth of penetration)
- Joint geometry (affects allowable gap tolerances)
- Weld travel speed

- Shielding gap (influences plasma plume)
- Degree of process monitoring

Characteristic Laser Weld “Signals”

The product of the aforementioned parameters determines the behavior of the actual laser weld process, which, of itself, generates distinct signals (Fig. 8) that may be monitored. Knowing these characteristic signals and how they pertain to weld quality provides the means to achieve reliable weld quality monitoring. During the weld process, a portion of the laser light is reflected. Monitoring this energy level

can reveal if there is an excessive gap (little or no reflected energy) or poor coupling (excess reflection).

The creation and collapse of the keyhole when laser welding creates an acoustic signal (time dependence, frequency, and intensity) that has been used for weld quality monitoring. Acoustic signals generated from the laser weld process range from the audible (20 Hz to 20 kHz) and can extend to megahertz frequencies. Most useful information can be gathered over a smaller frequency range (20 to 100 kHz). The formation of metal vapor and plasma can be related to the actions of the melt pool and are characterized by acoustic frequencies generally less than 10 kHz. Hence, the core of acoustic emission (100 Hz to 20 kHz) relating to vaporization, plasma formation, instability, and mass motion of the melt pool in the keyhole is typically analyzed with quality monitoring (Ref 9).

The action of the molten pool and formation and collapse of the keyhole all generate structure-borne acoustic emissions that can be monitored as well. Structure-borne acoustic signals are generated by (Ref 12):

- Phase transformation of the parent material (solid-liquid) via the focused laser beam and conversely with the solidification of the weld pool
- Micromechanisms such as crack growth during phase transformation and subsequent cooling of the weld bead

The generation of metal vapor and subsequent plasma is another process indicator that can be monitored. Plasma conductivity (electron density) has been investigated as a diagnostic technique for weld quality monitoring (Ref 15, 16). An area that has received greater investigation is the spectral range of the electromagnetic radiation emission from the metal vapor/plasma plume. Monitoring this spectral range provides means to infer the quality of the laser weld process (immediately prior to keyhole collapse and molten pool solidification). Selective grouping of the spectral range monitoring provides more accurate means to analyze and infer weld quality. The metal vapor/plasma plume contains both ultraviolet and visible light electromagnetic radiation (1 to 700 nm).

The weld bead temperature can be measured with a near-infrared sensor, which can help assess weld quality. Spatter generated from the laser weld process also can be monitored for process consistency and stability with a near-infrared sensor.

Grouping the various radiative emissions from the keyhole and workpiece during laser welding helps to understand the greatest opportunity for data acquisition to analyze and infer weld quality. The chart in Table 1 (Ref 11) indicates radiative emission power (W) during laser welding of 1 mm (0.04 in.) steel with a 2.5 kW CO₂ laser (with 0.4 mm, or 0.016 in.,

spot size) at 60 mm/s (2.4 in./s). The infrared and ultraviolet spectra have the largest fraction of the radiated energy as possible signals for monitoring, supplemented by the visible spectrum, generated within the keyhole itself.

Real-Time or In-Process Monitoring

The quality of a welded component is determined by various means of weld inspection, process monitoring, and production control, depending on the required level of confidence determined by the functionality of the product and/or customer requirements. In the automotive sector, which typically requires a statistical probability of failure of components no greater than 5 parts per million, it is necessary to ensure that laser-welded components meet stringent quality requirements.

Monitoring methods include destructive testing and various nondestructive inspection methods common to other fusion welding processes. Real-time or in-process monitoring is also done with optical, acoustic, and/or charged-particle sensors. Real-time monitoring provides online validation and a database for monitoring process drift and deviations. Provided it does not interfere with production processes, real-time monitoring is becoming increasingly in demand as part of quality-assurance documentation. To be beneficial to production, a high degree of confidence must be statistically established to minimize the occurrence of both false positives and false negatives.

- Acoustic signals from the creation and collapse of the keyhole
- Electromagnetic signals from the laser weld process
- Imaging the weld after the keyhole (x-ray or other means)

An excellent review of sensor technology for weld quality monitoring can be found in Ref 17.

Acoustic Monitoring. Acoustic diagnostics is based on the premise that the behavior of good and bad welds generates a respective

Fig. 7 Cross section of weld pool. Source: Ref 14

Sensors

The reliability of various signals generated by the laser weld process requires statistical process control methods to demonstrate their consistency and dependability to accurately qualify the various aspects/feature of the weld quality being monitored. Nondestructive, real-time monitoring of the laser weld has been explored in the following areas:

Fig. 6 Depiction of a keyhole laser weld structure. Courtesy of Precitec-Jurca

Fig. 8 Signals from a penetration (keyhole) laser weld

acoustic signal that can be translated (via fast Fourier transformations) to discern between acceptable and unacceptable welds. New methods for analyzing acoustic emissions (AE) have demonstrated great promise (Ref 18).

Acoustic emission can provide significant process data, because it has a high signal-to-noise ratio, is noncontact, and can be accomplished in real-time. When the frequency data are broken down into discrete bands, it is possible to determine the weld quality with a reasonable degree of reliability. Acoustic emission analysis can also be used to complement other weld quality monitoring systems. As with any process-monitoring system, AE-based analysis must demonstrate reliability and confidence to be solely relied upon for critical components.

Numerous articles and resources are available regarding acoustic monitoring of laser weld quality (Ref 19–27).

Electromagnetic Monitoring. Thermal emission monitoring is proving to be quite reliable, as shown by its implementation for laser welding of air bag deployment canisters. Using single to multiple sensors, with recorded data of acceptable welds and some “fuzzy logic,” these units provide a reliable means for real-time weld quality monitoring. Electromagnetic sensors measure discrete ranges of energy/intensity from the laser weld process. The most common sensors are:

- Ultraviolet for detection of the plasma plume intensity
- Infrared detection of keyhole molten metal
- Temperature detection of the weld bead behind the weld pool at the solid-liquid interphase
- Reflected laser power detection

These signals will vary over the course of a single weld length; hence, it is necessary to capture a “signature” of an acceptable weld and set boundaries, which identify acceptable upper and lower limits to these signals.

The relationship between the detected signals and the occurrence of welding faults at the surface of the weld has been proven in extended tests. Sensors such as these do not directly monitor the welding depth but process emissions, which are closely correlated to the welding depth.

A variety of material is available regarding various spectra of sensor analysis and their relationship to weld quality (Ref 28).

Electromagnetic acoustic transducers (EMATs) are rising quickly in the field of non-destructive testing/evaluation of welds. The principle of operation for this technology is based on establishing a magnetic field in a conductive material and subsequently imparting a high-frequency (radio-frequency, or RF) pulse by way of a coil above the same material. The RF pulse interacts with the magnetic field to produce a mechanical force in the elastic material, resulting in an acoustic pulse at the same frequency as the RF pulse (usually ultrasonic). All of this can be accomplished without any physical contact or coupling fluid with the test material. The height of the EMAT is approximately 1 mm (0.04 in.) above the test material, which then allows for ultrasonic inspection of materials (Ref 29). This technology shows promise for postweld process quality-control monitoring.

Weld Process Signals

Different materials generate different signals when being laser welded. Figure 9 (Ref 30) depicts the stability of the keyhole for three different metals, from a single sensor. Single-sensor monitoring of the complex laser weld process does not ensure absolute quality assurance. A combination of sensors provides the best means for confidence.

Process Monitoring and Weld Defects. Different process monitoring means have demonstrated the ability to determine specific laser weld defects as they occur. Table 2 illustrates what can be expected of the various sensors available (Ref 28, 31). The best means of ensuring real-time weld quality monitoring are those systems that use multiple sensors (more than one) in a relational basis, which then leads to how the benchmark data are first acquired for an acceptable weld and how the data are used.

Data-Acquisition Rate. The required data-acquisition rate is generally a function of the weld speed and desired “resolution” of signal information. Consider a weld speed of 100 mm/s (6.0 m/min, or 234 in./min), with a requirement that a failure size be no greater

than 0.5 mm (0.02 in.). This equates to a signal rate of 200 Hz. Analog photodiode detectors can reach upward of 1 kHz for a signal rate. It is important to ensure that the data-acquisition unit (computer) can receive and process multiple signal sources while maintaining the individual signal rate without a loss of information.

Selection of Weld Monitoring System

For a description of selection factors, the following describes considerations with regard to radiative emission monitoring of welding with an Nd:YAG laser. The working example assumes a photodiode-based system, with three sensors at the workpiece and an additional fourth sensor for monitoring the laser power delivered. A computer stores signal data and provides software for analysis.

Selection of Weld Monitoring Sensors. Figure 10 illustrates the arrangement of a single sensor for monitoring the weld process quality within a defined spectrum (as determined by the sensor selection and additional filters). The adjustable aperture determines the location of the field of view for the sensor, providing the ability to inspect the weld bead temperature behind the keyhole. The adjustable lens determines the field of view for the sensor. The arrangement shown is for a 90° Nd:YAG weld head (other configurations are possible).

Appropriate selection of sensors depends on the makeup of the emission spectrum for monitoring (Fig. 11). The example shown in Fig. 12 has three sensors that are used at the welding head. The temperature sensor (T) ranges from 1000 to 1800 nm and is located a few millimeters behind the weld pool, which avoids any influence that the Nd:YAG laser may have at 1064 nm, rather than examining the actual temperature of the keyhole itself.

The reflected radiation sensor (RR) has a narrow spectral response, ~1064 nm, because it is detecting the amount of back reflection during the weld process, which is aligned with the keyhole. The plasma sensor (P) has a limited spectral range of 440 to 500 nm to provide a signal “signature” that is specific to the behavior of the plasma plume during the keyhole welding process.

A working example of such is provided with the laser keyhole spot weld of titanium (Ref 32). Data collected by two sensors—reflected laser power and temperature—are plotted in Fig. 13 for a peak laser power of 1200 W over 10 ms. From the data plot, the stages are:

- The initial laser beam is reflected by the material, until enough energy has been absorbed to initiate a keyhole.
- Within 0.8 ms, the reflected laser power has reached its maximum, whereupon the heating phase of the material has translated into melting and vaporization.

Table 1 Emitted radiation power from keyhole region and workpiece during laser welding

Spectrum	Spectrum wavelength, nm	Emitted radiation			Keyhole proportion, %
		From workpiece, W	From keyhole, W	Total radiation, W	
Infrared	700–2000	0.152	4.787	4.940	96
Visible	400–700	0.006	1.739	1.745	99

All	1–2000	0.161	14.646	14.808	99

Source: Ref 11

- Beyond 0.8 ms, the reflected laser beam decreases as it becomes increasingly absorbed in the keyhole. Note the rise in the material temperature.

An energy balance between heat transfer and energy deposition is achieved at 6.8 ms, characterized by the nearly constant back reflection signal and temperature signal. At 10 ms, the laser beam is turned off, with a simultaneous drop in the temperature signal (but at a slower rate).

Data Acquisition. The weld process is monitored with three sensors at the weld head and an additional power sensor at the laser power source. Online process monitoring also is connected to a computer for the selection of weld-monitoring programs, reception of bad part signal(s), and weld-start and weld-end signals.

Software is needed to identify acceptable weld signatures and to discern unacceptable welds during operation. A statistically significant number of good welds can be input to the system when in “learn” mode, with each component identified for subsequent testing and evaluation against the signatures collected. With “fuzzy logic” applied by the software and a relatively stable laser weld process, the reference data can be acquired with as little as 6 samples, although 12 to 20 samples per signature would provide a greater degree of confidence.

When establishing the reference weld data, it is important to review and monitor the data collected against the test specimens. Accordingly, a matrix could be established and maintained between signature data and periodic destructive test specimens to ensure that an appropriate correlation is maintained and achieved. General Motors has a specification for laser weld quality assessment (GM 4485M) that provides an excellent benchmark for such tests in terms of:

- *Weld inspection:* Cracks, concavity, continuity, convexity, mismatch, undercut
- *Sectioning:* Microhardness, macrostructure and microstructure, pinholes, inclusions, cracks, porosity
- *Mechanical tests:* Cupping tests (Olsen), strength, ultimate tensile, yield strength, fatigue limits, elongation

Achieving confidence is necessary if weld process monitoring is to be implemented and relied upon. A program of destructive weld tests is necessary to ensure that what is monitored during the weld process actually results in a quality weld. The frequency of such tests can be reduced as any corrective actions/adjustments are made and confidence is gained in the system.

After completion of the “learning” function, upper and lower tolerance limits are established by the software for each signal. Where the weld process may be volatile (as with magnesium

Fig. 9 Stability of the keyhole for three different metals (from a single sensor)

Table 2 Sensor capabilities in indicating weld features

Sensor	Feature	Weld characteristic/assessment(a)								
		Full/partial penetration	Penetration depth	Seam position	Lack of fusion	Focal position	Seam surface	Pores	Spatters	Cracks
Electro-optical with image processing	Melt pool	O	✓	✓	✓	✓	✓	O	✓	X
	Keyhole	O	✓	✓	✓	✓	✓	O	✓	X
Photodiodes for spectral density fluctuations	Weld spatter	O	✓	✓	✓	✓	✓	O	✓	X
	Plasma plume	✓	✓	O	✓	✓	✓	✓	✓	X

	Melt pool	✓	✓	O	✓	✓	O	X	✓	X
Capacitance diode	Airborne	✓	O	O	✓	✓	✓	O	O	X
	Structure-borne	✓	O	O	✓	O	✓	X	X	✓
Capacitance diode	Vapor conductivity (dc)	X	X	X	X	✓	X	X	X	X
	Vapor conductivity (ac)	✓	✓	O	✓	✓	✓	O	X	X

Note: dc, direct current; ac, alternating current. (a) ✓, possible; O, depends; X, not possible

welding), additional considerations are the amount total and clusters of signal spikes that may be allowed to exceed the tolerance bands, and/or “signal areas” that are allowed to exceed the nominal tolerance bands without affecting weld quality.

When in production mode, each signal then is evaluated to determine the probability of a characteristic failure. The group of signals (using a weighting function) is evaluated as a whole for the probability of an unacceptable weld.

Examples of Laser Weld Monitoring

The characteristic signal signatures from laser welding are useful in monitoring the welding process. Reference signals (with upper and lower boundaries) are established for key

variables such as keyhole temperature, applied laser power, and reflected laser power. A general example is illustrated in Fig. 14 (Ref 31), which depicts the temperature signal for Nd:YAG overlap welding of steel at 2000 W. The reference temperature signal was accomplished with laser power at 2000 W. Poor weld quality, indicated by the temperature signal outside of the bounded “good” range, is shown. Gap variations produced the out-of-range temperature signals.

Another example is monitoring of laser welding in the production of tailor-welded blanks (Ref 33). Tailor-weld blanks are a major application in automotive stamping operations. Production volumes are usually high, resulting in the need for 100% real-time quality-assurance monitoring. Because the laser weld bead is usually subject to drawing/formation in the subsequent stamping operation, quality must be assured.

Fig. 10 Arrangement of a single sensor for monitoring the weld process quality within a defined spectrum. Courtesy of Precitec-Jurca

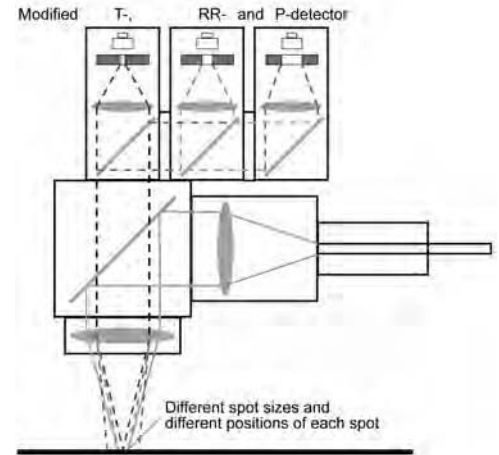

Fig. 12 Arrangement of sensors for monitoring temperature (T), reflected radiation (RR), and plasma (P)

The process problems that impact weld quality (to be detected by a weld quality monitoring system) include:

- Weld speeds on the order of 12 m/min (200 mm/s, or 472 in./min) and discontinuity sizes no greater than 0.5 mm (0.02 in.) equate to a detection rate of 400 Hz.
- Edge repeatability is critical. Weld edge mismatch, poorly trimmed edges, and improper clamping can lead to weld gaps that are too excessive to yield a quality weld.
- Hot dipped or galvanized zinc coatings and their variations may affect the baseline weld signature. In addition, they may introduce signal fluctuations that may or may not indicate an unacceptable weld.
- Variations of oil thickness on the steel to be welded may affect weld quality.
- Partial fusion must be detected, because this will affect the formability of the welded sheet for stamping operations.

Example: Real-Time Monitoring of Laser Welding in the Production of Tailor-Welded Blanks (Ref 28). This example illustrates various monitoring signatures for laser welding of 0.7 to 1.6 mm (0.03 to 0.06 in.) galvanized steel at 10 m/min (166 mm/s, or 393 in./min) with an Nd:YAG (3.4 kW) laser. Four sensors are used:

- Temp: Standard temperature sensor
- Plasma: Modified plasma sensor with 4 mm (0.16 in.) aperture
- Tempmod: Modified temperature sensor with 0.5 mm (0.02 in.) aperture
- HPTempmo: High-band-pass filtered sensor, as derived by the software from the Tempmod sensor data

Fig. 11 Emitted spectrum from laser weld

Fig. 13 Reflected laser power and temperature versus time

Fig. 14 Signals from overlap welding of steel at 2000 W with an Nd:YAG laser

The baseline or reference set of signatures for a good weld is shown in Fig. 15. Figure 16 depicts the signatures recorded (less the high-band-pass filter) for a weld that had two notches filed in the thicker sheet. This should have produced a weld fail condition, but the evaluation was not significant enough to do so.

Using the high-band-pass filtered sensor enables the software to determine a weld failure, as shown in Fig. 17. Two weld failures are noted over the length of the weld. The high-band-pass filter improves the ratio between noise and failure signature by approximately fivefold over the

unfiltered signal. In this example, other types of process variations that can be detected by monitoring with sensors include:

- Misalignment of the relative position of the focal point by 0.15 mm (0.006 in.) to the thinner sheet. This shift in relative location of the laser beam and weld seam was detected by the plasma and modified temperature sensors.
- Misalignment of the relative position of the focal point by 0.15 mm (0.006 in.) to the thicker sheet. Weld failure was detected only by the modified temperature sensor in this case.

Laser Cutting, Drilling, and Shock Peening

Charles Caristan, Air Liquide Industrial U.S. LP

IT IS WELL KNOWN that *laser* is an acronym for light amplification by stimulated emission of radiation. In this 21st century era of manufacturing, it also has proven to stand for lean, agile, safe, efficient, and rapid. These attributes help the transition from manufacturing into a new era of “laserfacturing,” the art of manufacturing with industrial lasers, in which laser-cutting applications represent the overwhelmingly dominant share.

This article brings to light fundamentals about the field of laser cutting from an industrial manufacturing perspective. For more in-depth information, the book *Laser Cutting Guide for Manufacturing* (Ref 1) is an exhaustive review on the subject and should be useful to anyone in this field.

Principles of Laser-Cutting Thermal Processes

Laser cutting can be performed either by thermal processes or nonthermal ablation processes or sometimes by a weighted combination of both. The overwhelming majority of laser-cutting applications are for cutting of metals by thermal processes. Nonthermal vaporization processes for laser cutting are used mostly in microfabrication of nonmetallic materials with high peak power pulses of duration of the order of nanoseconds going into the femtoseconds pulse duration (Ref 2) and are still in development in macrofabrication of metals (Ref 3). For the purpose of this article, microfabrication describes a combination of subkilowatt laser power and small-sized workpieces or small-sized processed features, whereas macrofabrication describes multikilowatt laser processing, such as for metal cutting.

Thermal laser-cutting processes are high-spatial-definition derivatives from traditional thermal-cutting processes, such as plasma torches and flame torch cutting; all of these thermal-cutting processes consist of inputting heat on a workpiece faster than it can dissipate away through conduction, convection, and

radiative heat transfer. The resulting accumulation of heat energy raises the temperature of the workpiece material so as to melt and even vaporize it. In the case of laser cutting, the torch consists of a highly focused laser light beam that reaches power densities on the workpiece of more than 100 times that of sunlight on Earth. This creates extremely high power densities of light radiation that are being absorbed by the material, to the point of actually melting and even vaporizing metals almost instantaneously. Pressurized assist gas flows through the nozzle tip of the laser-cutting torch to flush away molten and vaporized material. The double action of this liquefaction and vaporization, added to the flushing action of the assist gas, enables metal removal by forming a void in the material along the cut path, called kerf (Fig. 1). The high spatial definition of laser cutting can be achieved thanks to the relative small size of the focused beam spot on the workpiece,

typically 0.25 to 0.50 mm (0.010 to 0.020 in.) in diameter, such as for multikilowatt lasers for macrofabrication. The width of the kerf is of the same order of magnitude as the diameter of the beam spot on the workpiece. Consequently, the benefits of lasers over traditional cutting tools include higher contour definition and precision, superior edge quality, faster cutting speeds, narrower heat-affected zone, and more efficient melting process.

Thermal laser-cutting processes are of two kinds: fusion cutting and oxidation cutting (Ref 4). In fusion cutting, the laser beam is the sole source of heat transferred to the workpiece. Generally, a low- to nonreactive neutral gas such as nitrogen (N_2) or, more rarely, an inert gas such as argon is used as the assist gas. In oxidation cutting, a reactive gas such as oxygen (O_2) is used as the assist gas. At high temperature, O_2 reacts exothermically with most metals and thus substantially adds heat

Fig. 1 Principle of laser-cutting thermal process. The laser beam is highly focused so as to input more heat per square inch than the workpiece can dissipate away by conduction, convection, or radiative heat transfer. The accumulation of heat causes the workpiece temperature to elevate, melting and vaporizing the metal. Pressurized assist gas flushes the molten and vaporized material away to form a void along the cut path, called kerf. Courtesy of BLM Group

to that brought by the laser source. With both processes, global purity of the assist gas, control of specific impurities, and even types of gas mixtures of the assist gas have a substantial impact on cutting performance.

Laser processing calls for specific methods associated with the particular nature and properties of laser lights. Figure 2 lists the key input and output process parameters; an exhaustive study of these key parameters and their cause-and-effect relationships can be found in Ref 1. The principal set-up parameters are illustrated in Fig. 3 and are discussed in greater detail in the following sections.

Laser Output

The laser beam is the source of light energy, which, when absorbed by workpiece materials, can produce changes such as raising their temperatures. From an operator's numerical control screen, it can be set by three main parameters: commanded power, P_c , which generally sets the peak power of the pulse; commanded pulse duty; and commanded pulsing frequency, as illustrated in Fig. 4. The frequency represents the number of pulses of output energy emitted per second. Pulse duty is the percent of on-time per pulse period. For example, a pulse that is 1 ms long with a 4 ms pulse period has a 25% duty cycle. A 100% duty corresponds to continuous wave output.

Most laser resonators are equipped with a power meter sensor internal to the laser source. This sensor measures an actual average output power, P_a , which can be compared with the calculated $P_{avg} = P_c \times \text{Duty}$. Any abnormally substantial discrepancy between P_a and P_{avg} should be investigated.

Even though it could be a function of the material type and thickness being cut, P_c is, with few exceptions, generally set at the maximum rated power capability of the laser resonator in use. Notable exceptions are when cutting mild steel with O_2 assist gas; for edge-quality reasons, it sometimes must be processed at reduced commanded power to better control the heat input on the material and to reduce gouging formation on the cut edges.

Moreover, the commanded power (P_c), duty, and frequency can be programmed to vary around their preset values as a function of the radius of curvature and angular profile of the feature being cut and as a function of the actual linear cutting speed. These variations are set by numerically preprogramming subroutines to adjust the linear feed rate (i.e., cutting speed) of the motion system of the machine and thus adjust the peak power, duty, and frequency as a function of the cut features and linear speed. Such adjustment enables better cut-edge quality by controlling the heat input, particularly in small features such as angular fins and small-radius features. For example, a machine designed with a motion system with a maximum mechanical acceleration rating of 1 G

(i.e., $9.8 \text{ m} \cdot \text{s}^{-2}$, the acceleration of gravity) will not be able to move with precision along a radius of curvature R at speed exceeding the square root of $(R \times 1 G)$. If the commanded

feed rate is above such value, the intelligent numerical control automatically overrides the commanded feed rate and slows down the motion system to the maximum speed

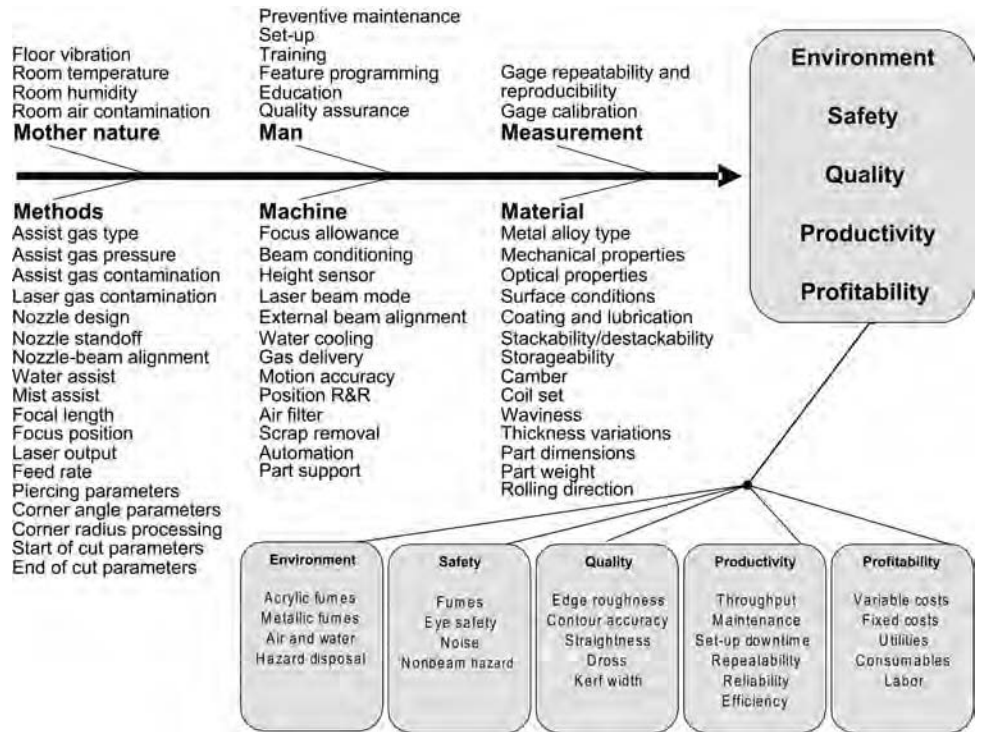

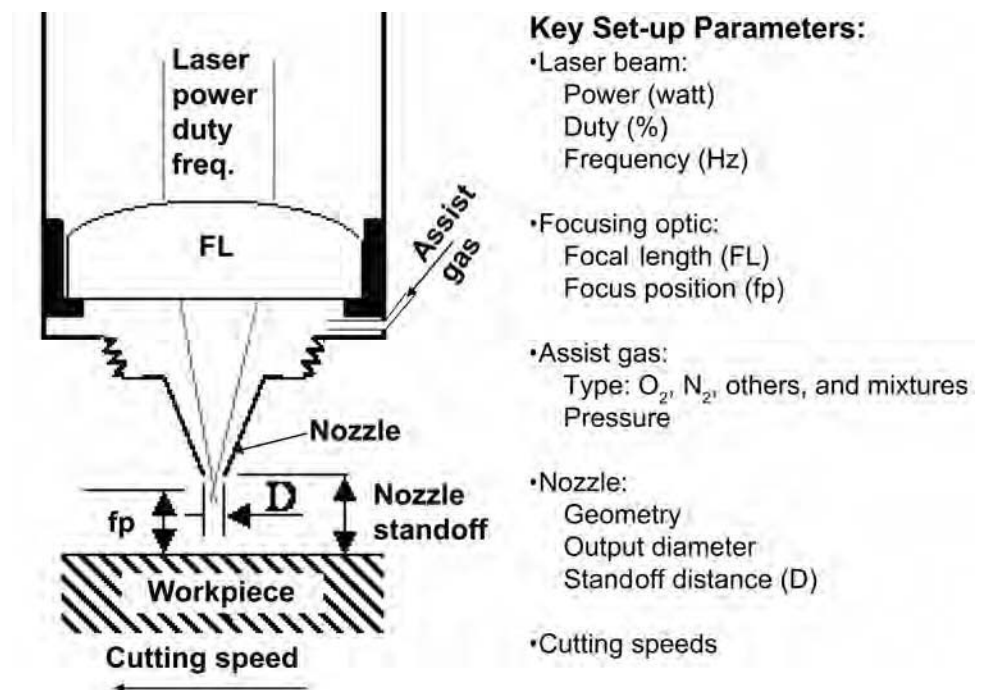

Fig. 2 Key process parameters for laser cutting. Inputs are categorized under the “6M” categories of Man, Machine, Method, Material, Measurement, and Mother Nature; outputs impact the environment, safety, quality, productivity, and profitability. See Ref 1 for a detailed discussion of the cause-and-effect relationship between inputs and outputs.

Key Set-up Parameters:

- Laser beam:
 - Power (watt)
 - Duty (%)
 - Frequency (Hz)
- Focusing optic:

 - Pressure
- Nozzle:
 - Geometry
 - Output diameter
 - Standoff distance (D)
- Cutting speeds

Fig. 3 Primary set-up parameters for laser cutting

corresponding to the radius of curvature of the feature. When such a slowing down occurs, it becomes wise to override the commanded laser output by adjusting it correspondingly to avoid burning and other edge-quality defects caused by excessive localized heat input.

Piercing

Cutting generally starts either from an outer periphery of the part or from a hole that must be pierced through the part. Piercing can be achieved by using a single high-peak-power laser pulse or by “peck-piercing” with several pulses of energy needed to progressively drill through the workpiece. Sophisticated machine numerical control program functions even enable the peak power, pulse duty, and frequency to change by increments during piercing. Generally, either neutral gas such as N₂ or reactive gas such as, in most cases, O₂ is used to assist piercing; in some cases, a cross-jet of air knife between nozzle and workpiece may be necessary to flush recoiled metal fumes and spatters during piercing.

Piercing time can fluctuate significantly depending on surface conditions or change in material or piercing process. Newer machines incorporate sensors that can detect when piercing-through is completed, thus enabling the optimization of piercing cycle time. Example processing parameters for peck-piercing are given in Table 1.

Focusing Characteristics

For metal-cutting applications, focusing of the laser beam is generally achieved through a transmissive optic, that is, a focusing lens. Use of focusing mirrors is reserved for very high-power processes, because mirrors are more efficiently and uniformly water cooled than lenses, resulting in smaller temperature gradients across their irradiated area and less heat-induced distortion of their focusing characteristics, also referred to as thermal lensing (Fig. 5). On the other hand, at equal focal length, an aspheric lens introduces less aberration and less astigmatism than a mirror; as a consequence, a lens generally focuses to a smaller spot than a mirror. Finally, the use of a focusing mirror complicates the ability to provide back-up pressure for using co-axial assist gas flow. Additional transmissive window optics and/or ancillary nozzle arrangements have been developed to enable pressure buildup of assist gas flow upstream from the nozzle exit when using a focusing mirror arrangement.

For a CO₂ laser beam at 10.6 μm wavelength, focusing lenses are generally made of zinc selenide (ZnSe) material that can be either polished or diamond-turned into any free-form shape. On the other hand, for solid-state lasers such as yttrium-aluminum-garnet (YAG) lasers with 1.06 μm wavelength, disk lasers at 1.03

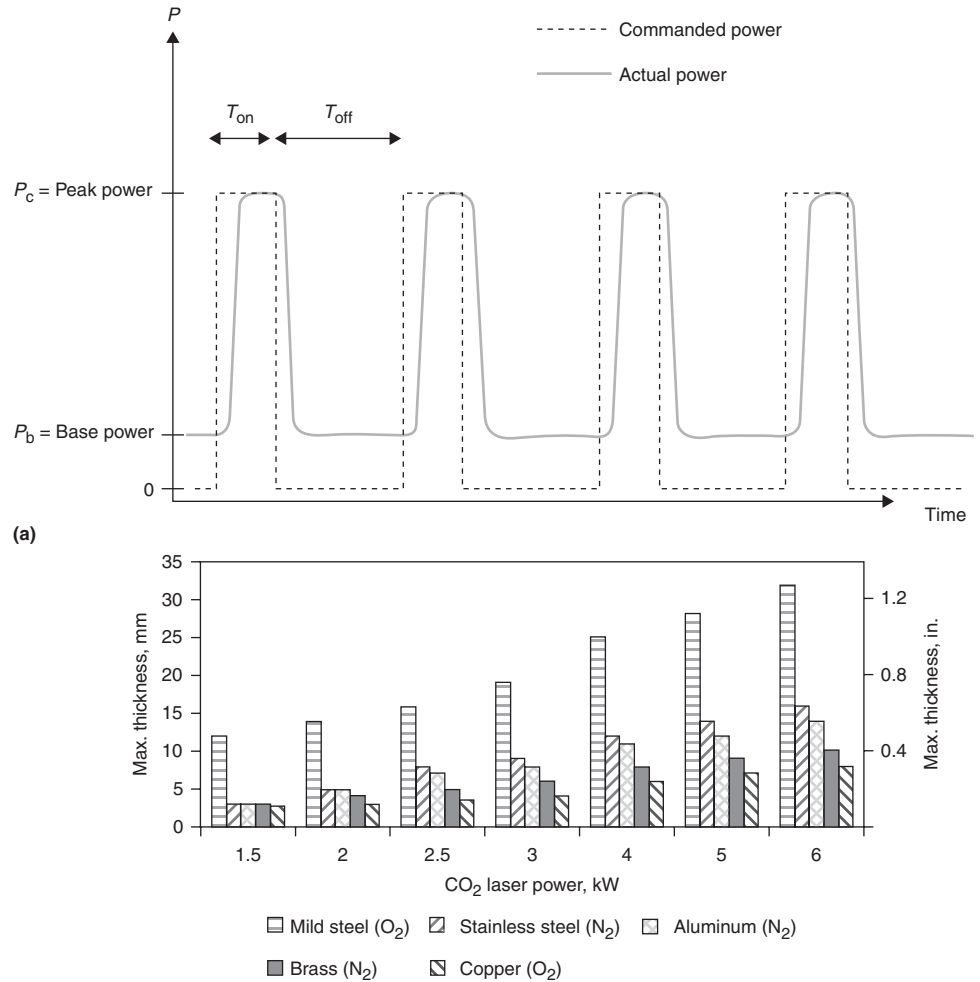

Fig. 4 (a) Example of power-time profile: commanded versus actual. Commanded power = P_c ; commanded frequency = $1/(T_{on} + T_{off})$; commanded duty = $T_{on}/(T_{on} + T_{off})$; calculated average power = $P_{avg} = P_b + (P_c - P_b) \times \text{Duty}$. (b) Maximum thickness cutting capability as a function of CO₂ laser power for various metal alloys

Table 1 Example of peck-piercing parameters on mild steel with a 2 kW peak power CO₂ laser, 190 mm (7.5 in.) focal length lens, and oxygen assist gas

Thickness	Initial	Initial	Frequency	Duty	Time between	Number of	Total piercing
mm in.	frequency, Hz	duty, %	increments, Hz	increments, %	increments, s	increments	time, s
6.5 ¼	10	20	1	1	0.1	10	3
12.5 ½	10	10	1	1	0.1	20	10

μm wavelength, and ytterbium-fiber lasers with 1.07 μm wavelength (all part of the “1 μm” laser family), focusing lenses are generally made of fused silica with special antireflecting coating. Other special coatings are being developed to compensate for thermal lensing and to reduce focus shifts (Ref 5). Fused silica (SiO₂) is turned to spherical shape by polishing, because it is too hard to be economically diamond-turned to free-form shapes. The radius of curvature of the lens shape determines its focal length. Alternatively, other materials such

as zinc sulfide (ZnS) can be used for focusing lenses for the aforementioned 1 μm lasers. As with ZnSe, ZnS can be diamond-turned into free-form shapes such as aspheric to reduce aberrations, toroidal to generate oblong focused beam spots, or bifocal optics (Fig. 6) to obtain a dual-focus effect for improved cutting speeds (Ref 6). Because of its superior thermal conductivity, a ZnS-made lens yields less thermal-lensing-induced focus shift. Table 2 compares mechanical, thermal, and optical properties of various materials for laser optics. The ZnS

Fig. 5 Thermal lensing results in focus shift. The laser mode refers to the profile of power distribution across a laser beam; a Gaussian-like profile is depicted here. However, some industrial lasers exhibit a “doughnut” mode, which generally results in less focus shift.

Fig. 6 Standard lenses have spherical curvatures that can be obtained by polishing. Aspheric, bifocal, toroidal, multifaceted, or other free-form curvatures can be achieved with diamond-turnable materials, such as zinc selenide for CO₂ lasers and zinc sulfide for solid-state lasers. Fused silica, often used for standard lenses with spherical curvatures for solid-state lasers, is too hard to be economically diamond-turned. Courtesy of II-VI Inc.

material yields better thermal properties than fused silica but has a light-scattering side effect that can require augmented cooling of the optics mount and assembly that absorbs the scattered light (Ref 7).

One important specification for a focusing lens is its thickness, which must be strong enough to sustain high-pressure assist gas. Lens manufacturers recommend and provide appropriate lens thicknesses based on the applications. Assuming a 90% clear-pressure aperture, a 38 mm (1.5 in.) diameter ZnSe lens of focal length between 125 and 190 mm (5 and 7.5 in.) and of 4 mm (0.160 in.) thickness can sustain approximately 120 psi (8 bar) pressure, whereas the same lens with a thickness of 8 mm (0.320 in.) can sustain almost 500 psi (35 bar). Typical industrial CO₂ laser-cutting systems have ZnSe focusing lenses of 38 mm (1.5 in.) diameter by 7.4 mm (0.29 in.) thick or 50 mm (2 in.) diameter by 9.7 mm (0.38 in.) thick.

Table 3 shows typical focal lengths chosen mostly as a function of workpiece thickness, whether for CO₂ laser systems or 1 μm laser systems.

Figure 7 describes a generic beam-delivery system having four optics of finite focal lengths, $f_1, f_2, f_3,$ and f_4 , which could be mirrors or lenses or any other kind of optical element, each characterized by at least one focal length. Folding mirrors with flat reflecting surfaces or simple transmissive windows are optics with infinite focal length.

Beam caustic (i.e., beam radius) downstream from the focusing lens is characterized by parameters such as focus diameter, 2^*w_{out} ; focus position, d_{out} , relative to the

Table 2 Properties of transmissive optics materials

For 1 μm wavelength compared to fused silica, multispectral zinc sulfide (MS ZnS) has a superior thermal conductivity to avert steep temperature gradient.

last downstream optic, f_1 ; and the Rayleigh range, Z_R . These parameters are bound by the following mathematical relationships for a laser beam of wavelength λ , of beam cross-sectional radius w_{in} , and of beam quality M^2 , knowing the optical path distances, d_1, d_2, d_3 , shown in Fig. 8, and distance d_{in} between the incident beam waist position and the first nonflat mirror optic, f_4 (for

detailed analytical derivations, see appendix B of Ref 1):

$$d_{out} = \frac{-\beta \delta - \alpha \gamma \frac{\pi^2 w_{in}^4}{M^2 \lambda^2}}{\delta^2 + \gamma^2 \frac{\pi^2 w_{in}^4}{M^2 \lambda^2}} \quad w_{out}^2 = \frac{w_{in}^2}{\delta^2 + \gamma^2 \frac{\pi^2 w_{in}^4}{M^2 \lambda^2}}$$

$$Z_R = \frac{\frac{\pi w_{in}^2}{M^2 \lambda}}{\delta^2 + \gamma^2 \frac{\pi^2 w_{in}^4}{M^2 \lambda^2}} \quad (\text{Eq 1})$$

$$W_{out}(z) = w_{out} \sqrt{1 + \left(\frac{z - d_{out}}{Z_R}\right)^2} \tag{Eq 2}$$

Parameters α , β , γ , and δ are analytical functions of d_{in} , d_3 , d_2 , d_1 , f_1 , f_2 , f_3 , and f_4 . In terms of units, α and δ are dimensionless, whereas β is proportional to a distance, and γ is inversely proportional to a distance. Generally, f_1 represents a focusing lens. For a CO₂ laser-beam-delivery system, f_3 and f_4 could represent collimator optics and f_2 a regular flat folding mirror. For a fiber-delivery optics system such as for YAG, disk, and fiber lasers, f_2 could be a collimating lens that receives the beam at the output of the delivery fiber, and $2 \cdot w_{in}$ is approximated to the diameter of the delivery fiber. Some optical elements have different optical properties in one plane versus another, in which case one can apply a different set of analytical formulas for the different planes. For CO₂ lasers, in the general case where one can approximate the

incident laser beam to a perfectly collimated beam, that is, with constant beam diameter along its optical propagation path, then the waist diameter $D = 2 \cdot w_{in}$ is approximately equal to the beam diameter incident on the focusing lens. The aforementioned equations can be used to determine the position and diameter of the focus point, simply by setting $d_{in} = d_3 = d_2 = d_1 = 0$ and $f_2 = f_3 = f_4 = \infty$. It yields $\alpha = 1$, $\beta = 0$, $\delta = 1$, $\gamma = -1/f_1$, and the following well-known approximations of Eq 1:

$$d_{out} = f_1 \quad w_{out} = \frac{M^2 \lambda f_1}{\pi w_{in}}$$

$$Z_R = \frac{M^2 \lambda f_1^2}{\pi w_{in}^2} \tag{Eq 3}$$

The beam quality factor, M^2 , is also called M-square or K or $1/k$; its absolute minimum theoretical value is 1. The factor M^2 is a measure of mode composition of a laser beam and also a proportional measure of its divergence once it exits

the cavity. For the 1 μm lasers, the beam quality is often evaluated in terms of the product of beam radius w_{in} at the waist position at the resonator exit by its beam natural divergence angle, θ , expressed in $\text{mm} \cdot \text{mrad}$ units rather than in dimensionless M^2 . A Rayleigh range, Z_R , represents a length around the beam waist, such as around the focus point of diameter $2 \cdot w_{out}$, within which the beam radius remains smaller than:

$$\sqrt{2} \cdot w_{out}$$

Z_R is representative of the depth of focus or tolerance to focus position of the process. The parameter w_{in} can be obtained from the laser manufacturer or measured with a precise digital beam analyzer or a more rudimentary-mode burn technique. $W_{out}(z)$ denotes the radius of the beam cross section as a function of optical distance z downstream from the last optic, f_1 : $W_{out}(d_{out}) = w_{out}$.

For most CO₂ laser machines, optical distances d_1 , d_2 , and d_3 vary with the cutting head position Z , Y , and X over the work envelope. Some CO₂ laser-cutting machine designs include an adjustable optical path retardation loop that maintains the total optical path length constant while position X , Y , and Z varies. This ensures constant focusing characteristics and, it is hoped, constant cutting performance regardless of the position on the work envelope. For solid-state 1 μm laser-cutting machines, the beam-delivery system is composed principally of a flexible fiber, which ensures a constant optical path length equal to the length of the beam-delivery fiber.

Figure 8 illustrates a near-perfect agreement between the calculated beam caustics using the analytical formulas of Eq 1 and the measured beam caustics using a digital beam scanning measurement analyzer. This near-perfect match illustrates the accuracy of these analytical formulas, which uniquely incorporate a dependency on the beam-quality parameter M^2 , without having to resort to complex integral calculation and software. Note that for 1 μm lasers, the beam-quality parameter is expressed as a beam parameter product (BPP) defined as the product of beam radius w at a waist position as the beam exits the resonator by beam divergence angle θ :

$$\text{BPP} = w \cdot \theta = \frac{\lambda M^2}{\pi} \tag{Eq 4}$$

Although the M^2 value, and thus the BPP, are dictated by intracavity design and cannot be altered once the beam exits the resonator cavity, multiple reflections inside a delivery fiber degrade the coherence property of the laser beam and thus its focusability. This degradation of coherence is equivalent to a multiplication of the M^2 and thus the BPP sometimes several folds. As an example, a 2 kW fiber laser delivered through a 100 μm diameter fiber could yield a BPP = 3 $\text{mm} \cdot \text{mrad}$, whereas the same laser coupled through a 150 μm diameter

Table 3 Typical effective focal lengths used in metal cutting

Maximum material thickness		CO ₂ laser system effective focal length		1 μm laser system effective focal length

3.2	1/4	250	10

Fig. 7 Generic laser-beam-delivery system with up to four optics, f_1 , f_2 , f_3 , and f_4 , that have finite focal lengths. The system is representative of most industrial beam-delivery systems for CO₂ as well as solid-state lasers, even those with fiber optic delivery. A flat mirror, such as a standard beam-bender mirror, has an infinite focal length. The optical path distances represented, such as d_2 between f_2 and f_3 and, more moderately, d_1 between f_1 and f_2 , can vary during cutting.

delivery fiber would yield an equivalent BPP of $5 \text{ mm} \cdot \text{mrad}$ by the fiber exit.

Equation 4 shows that for focusability evaluation, the so-called f -number $= f_1/w_{in}$ ratio of focal length to incident beam diameter is more important than the focal length taken alone, regardless of the laser resonator type and characteristics. Table 4 shows typical values of BPP for industrial multikilowatt lasers.

A smaller f -number yields a smaller focus waist diameter, 2^*w_{out} , and a smaller Rayleigh range, Z_R . For best cutting capability, a maximized Rayleigh range is preferred for positioning tolerance, while a minimized diameter, 2^*w_{out} , is preferred for higher power density. These two conflicting requirements must lead to a delicate balance and choice of f -number as well as choice of laser resonator, characterized by M^2 (or BPP), λ , and indirectly by radius w_{in} . For applications aimed at high-speed cutting of thin sheets, preference can be given to

lasers having a small M^2 factor close to a diffraction limitation minimum value of 1 or, for a $1 \mu\text{m}$ laser, a BPP of approximately $0.34 \text{ mm} \cdot \text{mrad}$, whereas a larger M^2 factor, that is, larger BPP, yields larger Rayleigh length favorable to better cutting performance of thick gages. Figures 9 and 10 represent typical comparison results of laser-cutting performance for CO_2 lasers versus current state-of-the-art solid-state $1 \mu\text{m}$ lasers (disk and fiber types). The superiority of $1 \mu\text{m}$ lasers must be qualified within certain ranges, but it translates roughly into a ratio of almost 2 in power; that is, a 2 kW fiber or disk laser performance is generally compared to that of a 3 to 4 kW CO_2 laser. The following rules of thumb can be deduced for the current state-of-the-art at equal laser power:

- *Under oxygen assist gas:* The superiority of the fiber laser performance is limited to

gages thinner than approximately 4 mm (0.2 in.). Above 4 mm thickness, CO_2 lasers still produce superior edge quality and speed.

- *Under nitrogen assist gas:* The superiority of disk and fiber lasers for nitrogen-assisted fusion cutting of thinner gages is clear up to approximately 8 mm (0.3 in.) in thickness and actually grows dramatically for gages thinner than approximately 4 mm (0.2 in.), as is illustrated for both disk and fiber laser cutting in Fig. 9. However, as the thickness increases beyond 8 mm, the edge qualities in terms of dross and edge roughness, as well as the speed performance of $1 \mu\text{m}$ lasers, degrade much more rapidly than that of CO_2 lasers, leaving CO_2 lasers still the superior resonator type for cutting of such thick gages of mild steel, aluminum, and stainless steel with nitrogen assist gas. On the other hand, due to their shorter wavelength, $1 \mu\text{m}$ lasers are superior

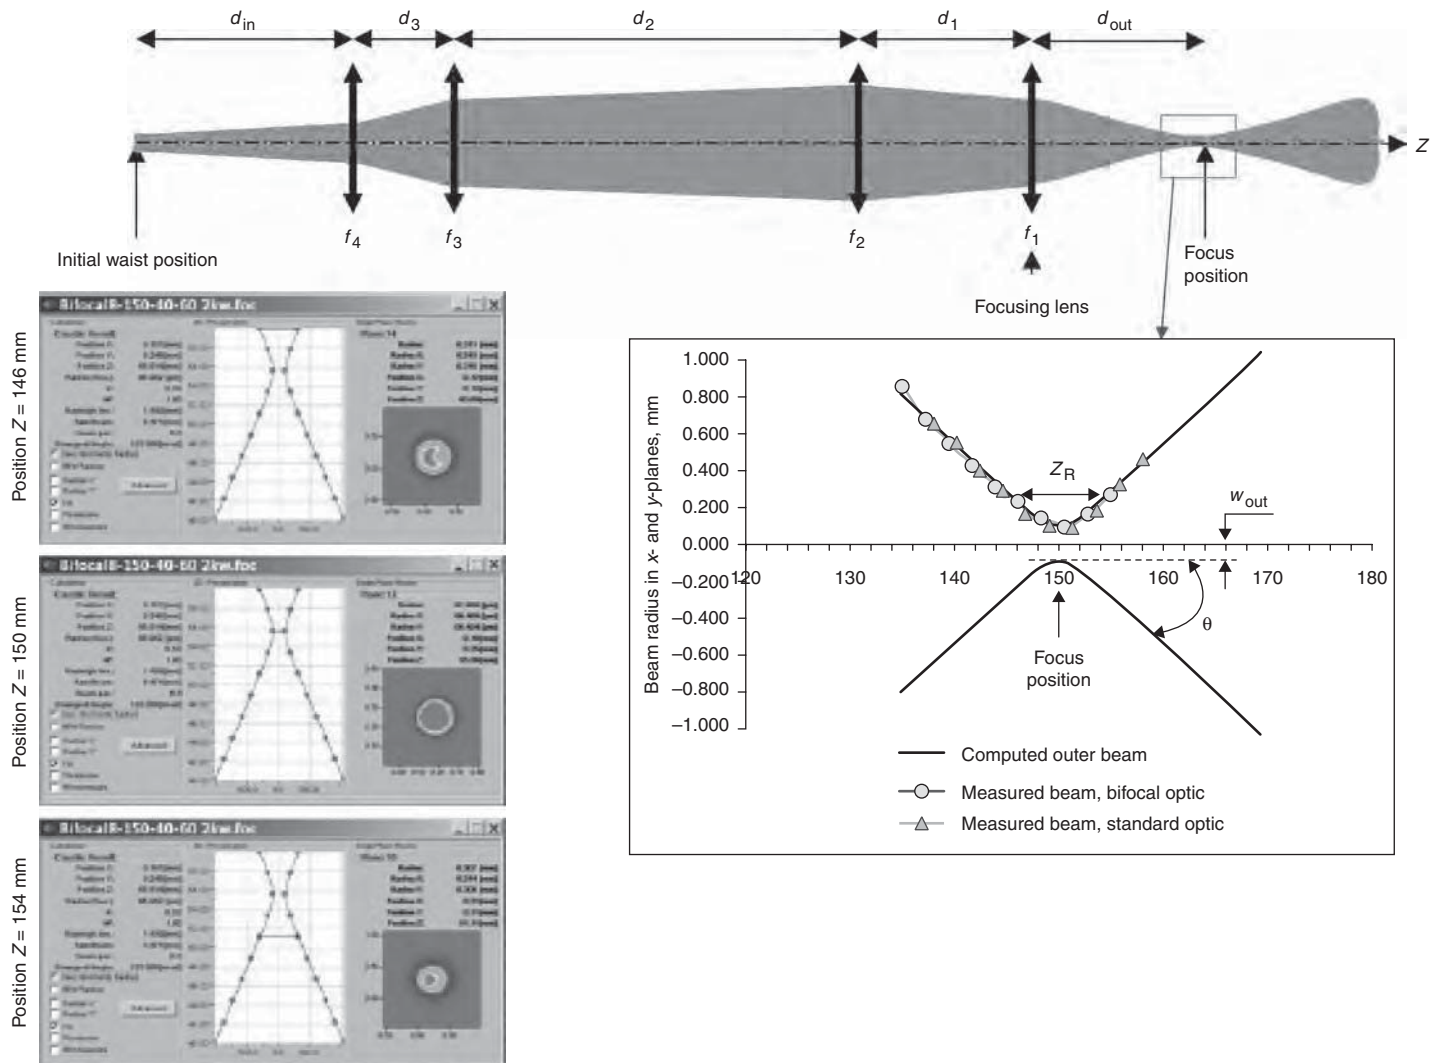

Fig. 8 Beam propagation caustics of diameter versus distance from the focusing lens. The top view represents the same generic beam-delivery system as in Fig. 7, with the optical path unfolded. The calculations with the analytical Eq 1 are in near-perfect agreement with measurements performed with a digital beam scanning analyzer (samples in left illustration) on bifocal and ordinary focusing lenses with focal length of 150 mm (6 in.), collimator lens of 120 mm (4 3/4 in.) focal length, and delivery fiber diameter of 150 mm (6 in.). The 5 kW fiber laser yielded a beam parameter product $= w \cdot \theta = 5 \text{ mm} \cdot \text{mrad}$ at the end of the delivery fiber.

to CO₂ lasers for cutting materials such as copper and brass.

Focus Position

Focus position (fp), defined in Fig. 3 and illustrated in Fig. 11, can be controlled by adjustment of the lens standoff distance between the focusing lens and the workpiece surface. This lens standoff can be adjusted manually during set-up or automatically by the power of a servo or stepping motor integrated inside the focusing head torch, without necessarily altering the nozzle standoff (Fig. 3); certain laser machines also use adaptive mirrors upstream from the focusing lens to dynamically control focus position. Such adaptive mirrors have curvature that can be altered by water pressure change or with piezoelectric actuators, which can change the focal length and thus change the diameter and divergence of the beam incident on the focusing lens and therefore change the characteristics d_{out} , W_{out} , and Z_R of the focus (Eq 1). For thin-gage cutting, the focus position is generally placed on the workpiece surface. For thick gage with O₂ assist gas, focus position may be placed above the workpiece surface for best edge quality in mild steel. For stainless steel and aluminum, cutting with N₂ assist gas and positioning the focus spot at least half way of the thickness below the surface are advantageous to reduce dross formation.

Assist Gas Types

There are four families of assist gas used for cutting purposes: pure reactive gases such

as oxygen; pure inert gases such as argon or helium; neutral gases such as nitrogen, which is not chemically reactive with a majority of metals and is a low-cost alternative to inert, rarer gases; and any combination of the first three kinds, such as air (20.9% O₂ + 78% N₂ + 1% Ar + traces of other elements). In some applications, additional mist or even a water shower assists laser cutting by cooling the workpiece. Table 5 summarizes the most common assist gas usages in industrial laser-cutting applications.

Gas Supply

Assist gases are supplied in three main modes adapted to the consumption rate of the manufacturing operation (Fig. 12):

- For low consumption rates, compressed gas cylinders that can be brought individually or in sets of 6 to 16 inside a plant are sufficient. A typical bank of 12 cylinders with nearly 3600 standard cubic feet (scf) total capacity of N₂ gas can supply between 3 and 4 hours of stainless steel cutting operation at 1000 standard cubic foot per hour (SCFH) flow rate if operating at approximately 50% duty; that is, actual cutting occurs only during 50% of the time, resulting in just under 1.8 h of cutting time. If a bank of cylinders contains the same volume of O₂, for low-pressure cutting of, for example, mild steel, it can supply approximately 32 hours of cutting operation at 100 SCFH if operating at approximately 50% duty.

- For high consumption rates of assist gas, bulk tanks are more suitable for high-volume storage of N₂, O₂, Ar, and H₂ in cryogenic liquid form rather than compressed gas. Table 6 gives liquid temperature and equivalent standard volumes of gas for 1 gal cryogenic liquid of the aforementioned molecules. Bulk tanks are generally stored outside the facility on a special foundation pad, with a vaporizer needed to transform the liquid into gas at pressure up to approximately 225 psi (15 bar) with ordinary bulk tanks and possibly up to 600 psi (40 bar) with more expensive bulk tanks designed for the higher-rated pressure. An optional boost pump or, as an alternative, a pumpless pressure booster system can help build up to 500 psi (35 bar) of supply pressure from an ordinary bulk tank. Although adding initial installation cost, bulk tanks enable much less cost per scft of gas than packs of compressed gas cylinders.
- Intermediate consumption rates can use transportable insulated cylinders containing cryogenic liquid gas, which can be installed inside a facility. As an alternative, an expanded-capacity pack of compressed gas cylinders at higher pressure (4500 psi, or 310 bar) can be used; each such 16-cylinder pack allows almost 9000 scft total capacity of N₂ gas.

Lasing gases are required only for gas lasers such as CO₂ lasers. Industrial CO₂ lasers can have either of two kinds of high-global-purity lasing gas supply requirements:

- The first kind requires individual cylinders of helium, nitrogen, and CO₂. These three gases are subsequently mixed in a proprietary mixture composition by a mixer internal to the laser machine. A turboblower internal to the laser machine circulates the lasing gas inside the cavity. To maintain high performance of the laser, the lasing gas that has degraded inside the cavity due to various chemical reactions is evacuated by a vacuum

Table 4 Typical values for equivalent beam parameter product $w \cdot \theta$ at the workpiece for industrial multikilowatt laser-cutting systems used in job shops and production environments

Diameters of delivery fiber are generally in the range of 100 μm for disk and fiber lasers and 600 μm for yttrium-aluminum-garnet (YAG) lasers.

	CO ₂ laser, mm · mrad	YAG laser lamp-pumped, mm · mrad	Fiber laser multimode, mm · mrad	Disk laser multimode, mm · mrad

Fig. 9 Comparative scale between CO₂ laser and 1 μm laser-cutting systems. (a) Comparing 3 kW disk laser cutting with the 100% baseline of a 5 kW CO₂ laser for N₂-assisted fusion cutting of stainless steel. The disk laser yields superior speed performance up to approximately 4 mm (0.160 in.) thickness. Beyond 4 mm, CO₂ lasers are superior, in part because the edge quality of solid-state laser cutting degrades much more quickly than that of CO₂ laser cutting when thickness increases. Data courtesy of Trumpf Inc. (b) and (c) Comparing 2 kW fiber laser cutting with 3 and 4 kW CO₂ laser cutting. “Q” indicates dross-free cutting mode, whereas “HS” indicates high-speed cutting mode with the presence of plasma at the zone around the point of incidence of the beam on the workpiece, which may result in slight dross. (b) is with O₂ assist gas; (c) is with N₂ assist gas. Data courtesy of Bystronic Inc.

pump, and fresh, clean lasing gas is reinjected to compensate. This lasing gas refreshing can occur either continuously or by batched sequences.

- The second kind requires cylinders or cartridges filled with a specified premix of these same three gases, sometimes with added traces of CO and/or xenon and/or O₂, depending on the laser manufacturer. In some laser designs, the cartridge can last almost a year before needing a refill.

Gas Purity

Assist Gas Purity. Industrial-grade global purity of liquid oxygen assist gas is at least 99.5% at the tank or cylinder supply. The main impurities present in gaseous oxygen vaporized from liquid oxygen are nitrogen, water, and argon. Due to the closeness of the boiling temperatures of argon and oxygen (Table 6), argon is the most abundant impurity in industrial-grade liquid oxygen. Liquid oxygen can be further purified to reach the global-purity grade of 99.95% and above, by which one can expect substantial performance improvement to achieve a 10 to 40% increase in cutting speed, as reported in Ref 9 and 10 and represented in the experimental data of Fig.13.

Such significant range of performance improvement makes room available to share some of it between increasing cutting speed, increasing tolerance to focus position, and even improving the resulting cut-edge roughness quality.

The higher-purity oxygen at the supply source must be matched by an upgrade of the assist gas delivery system such that it preserves the higher purity all the way from the supply tank to the workpiece.

Industrial-grade global purity of liquid nitrogen exceeds 99.997%, which is largely sufficient for optimal laser-cutting performance.

Lasing Gas Purity. For industrial laser cutting of metals, CO₂ lasers are the only ones that consume lasing gases. The global purity of lasing gases is usually specified higher than industrial-grade gases. They yield a more efficient lasing mechanism and an appreciably longer life of consumables and nonconsumable components in the laser cavity. Higher-global-purity gas also yields higher peak power, better beam stability, and mode structure. Research aimed at ranking the relative impact of specific impurities on the laser performance found, for example, that addition of small quantities of carbon monoxide (CO) enhances the life of optics consumables by reducing the decomposition of CO₂ into CO and O₂. Some laser manufacturers specify a small, controllable quantity of CO in their CO₂ lasing mix. However, moisture and certain specific hydrocarbon molecules have unwelcome consequences and are also part of typical lasing gas specifications. For example, 10 ppm of

acetylene (C₂H₂) has as much negative effect on the laser efficiency as 10,000 ppm of methane (CH₄) (Ref 11). Water moisture (H₂O) is known to destabilize direct current and radio frequency discharges and accelerate degradation of the optical properties of cavity mirrors and lenses. Controlling specific impurities is more critical than controlling global purity. Laser gases are stored in specially segregated and dedi-

cated cylinders that should not be used even for the same molecules with lesser purity specifications, let alone other molecules. This is to prevent even residual ppm quantities of certain hydrocarbons from contaminating the high-global-purity lasing gas when the cylinder is filled. With some gas suppliers, the cylinders undergo special surface treatment aimed at limiting adsorption of any gas in the inside walls.

Fig. 10 Cutting speeds for tubes of various materials, with O₂ as well as N₂ assist gas and with CO₂ laser and fiber laser-cutting systems. F3 indicates 3 kW fiber laser, and C3.5 indicates 3.5 kW CO₂ laser; MS, mild steel; SS, stainless steel; and AL, aluminum. Courtesy of BLM Group

Fig. 11 Focus position comparison between multispectral with O₂ assist gas and stainless steel (SS) or aluminum (AL) with N₂ assist gas. Focus position when cutting with N₂ assist gas is preferably about halfway or more below the workpiece surface to yield a dross-free, fine-cut quality edge. With oxygen-assisted cutting, best cut-edge quality is obtained with the focus position at approximately 0.5 to 2 mm (0.02 to 0.08 in.) above the workpiece top surface.

Assist Gas Flow Rates

Flow dynamic through an orifice can be either in subsonic regime or supersonic regime. The transition from subsonic regime to supersonic regime occurs as soon as the following condition is realized:

$$\frac{P_0}{P_a} \geq \left(\frac{\gamma + 1}{2}\right)^{\frac{\gamma}{\gamma - 1}} \tag{Eq 5}$$

where P_0/P_a represents the ratio of stagnation absolute pressure, P_0 , in the cutting torch over the ambient atmospheric pressure, P_a , and γ is the ratio of specific heat coefficients for the flowing gas. At sea level, atmospheric pressure, P_a , is generally approximately 1 bar = 14.7 psi = 10^5 Pa. For O_2 and N_2 , $\gamma = 1.4$, and this condition means $P_0 > 0.89$ bar (13 psi, or 9×10^4 Pa) above atmospheric pressure.

The following “standard” volume flow rates of gas flowing through a nozzle circular orifice are derived analytically in appendix C of Ref 1. Here “standard” signifies that the volumes of gas are as if at atmospheric pressure and 273 K temperature, where one mole of any gas always occupies the same universal volume of 22.4 L:

$$\text{Subsonic volume flow rate} = \alpha \frac{P_0 D^2}{\sqrt{T_0}} \sqrt{\left(\frac{P_a}{P_0}\right)^{\frac{2}{\gamma}} - \left(\frac{P_a}{P_0}\right)^{\frac{\gamma+1}{\gamma}}}$$

$$\text{where } \alpha = \frac{\pi}{4} \sqrt{\frac{2\gamma}{Rm(\gamma-1)}} * CF \tag{Eq 6}$$

$$\text{Supersonic volume flow rate} = \beta \frac{P_0 D^2}{\sqrt{T_0}}$$

$$\text{where } \beta = \frac{\pi}{4} \sqrt{\frac{\gamma}{Rm} \left(\frac{2}{\gamma+1}\right)^{\frac{\gamma+1}{\gamma}}} * CF \tag{Eq 7}$$

where the molar mass, m , is in kilograms of the assist gas; $R = 8.314$ J/K · mol is the ideal gas constant; T_0 represents the temperature in Kelvin of the assist gas inside the cutting torch; D is the nozzle throat diameter in meters; and pressures P_a and P_0 are expressed in Pascals. With all variables and parameters expressed in International System (SI) units, CF is a unit conversion factor for the resulting volume flow rate; if the volume flow rate is expressed in SI units m^3/s , then $CF = 0.0224$; if in L/min, then $CF = 1344$; and if in standard cubic feet per hour (SCFH), then $CF = 2849.47$.

For a mixture of gas, such as air composed of approximately 21% O_2 + 78% N_2 + 1% Ar, γ and m are given theoretically by the following formulas in which x_i represents the molar fraction of gas i , and γ_i and m_i are the specific heat ratio and the molar mass, respectively, of gas i . Table 7 lists values for m and γ for various gases:

Table 5 Typical assist gas types used in industrial laser cutting of metals

Material	Assist gas	Applications
Mild steel	Low-pressure O_2	Most common for 2.67 mm (0.105 in.) and thicker
Mild steel	High-pressure N_2 , 5 to 20 bar	Mostly for high-speed cutting of thin sheets and to avoid oxide scales on steel cut edges
Stainless steel	High-pressure N_2 , 5 to 20 bar	Most common for stainless steel
Aluminum alloys	High-pressure N_2 , 5 to 20 bar	For special nonoxidized cut edge and/or thick plate requirement
Aluminum alloys	High-pressure air, 5 to 20 bar	Lower cost than pure N_2 but increases dross
Copper alloys	Low- to high-pressure O_2 , 1.5 to 12 bar	More efficient than air
Brass	Low- to high-pressure O_2 or N_2 , up to 20 bar	High-speed cutting of thin workpieces
Titanium alloys	High-pressure Ar, 3 to 10 bar	For aerospace applications, reactive O_2 and N_2 are avoided.
Nickel alloys	High-pressure N_2 , 3 to 10 bar	For aerospace and energy industries applications: slower cutting speed than with O_2 assist, but less dross and no edge oxidation

Fig. 12 Assist gases can be supplied in a bulk tank containing liquid cryogenic molecules or in transportable cylinders containing either compressed gases or liquid cryogenic molecules. Courtesy of Air Liquide

Table 6 Conversion data from 1 gal of cryogenic liquid molecules

A full, ordinary 1500 gal bulk tank can contain 5 U.S. tons (4590 kg) of liquid nitrogen, which is the equivalent of 139,000 scft of the same when vaporized in gas form at standard atmospheric pressure and temperature.

Molecules (1 gal of liquid = 3.785 L)	Boiling point at atmospheric pressure		Gas volume equivalent		Weight	
	°C	°F	nm ³ (a)	scft(a)	kg	lb
N_2	-196	-320	2.447	93.11	3.06	6.745
O_2	-183	-297	3.025	115.1	4.322	9.527
Ar	-185	-302	2.957	112.5	5.276	11.63
H_2	-252	-423	2.981	113.41	0.2679	0.5906
CO_2	-78	-109	1.9431	74.04	3.842	8.470
He	-269	-452	2.649	100.8	0.4728	1.042

(a) nm³ represents a normal cubic meter volume, and scft represents a standard cubic foot volume. In this context, the terms *standard* and *normal* are interchangeable because they equally refer to temperature condition of approximately 300 K and pressure of 1 bar for the gas volume considered. Source: Ref 8

$$\frac{1}{\gamma - 1} = \sum \frac{x_i}{\gamma_i - 1} \text{ and } m = \sum x_i * m_i \tag{Eq 8}$$

Example 1: Cutting Mild Steel. A 4 kW CO_2 laser cutting of 6.4 mm (¼ in.) mild steel uses a 190 mm (7.5 in.) focal length lens and O_2 assist gas at a cutting speed of 100 inches per minute (ipm) (255 cm/min), with a nozzle diameter of 2 mm (0.08 in.) and oxygen pressure of 0.7 bar (70 kPa) above atmospheric

pressure. The absolute pressure of 1.7 bar (170 kPa) is in the subsonic regime. The resultant consumption flow rate of oxygen is 116 SCFH. If the operator switches to a 3 mm (0.12 in.) nozzle at the same pressure, the flow rate would jump to 260 SCFH.

Example 2: Cutting Stainless Steel. A 4 kW CO_2 laser cutting of 1.5 mm (0.060 in.) stainless steel uses N_2 assist gas at a cutting speed of 400 ipm (10 m/min), with a nozzle diameter of 1.5

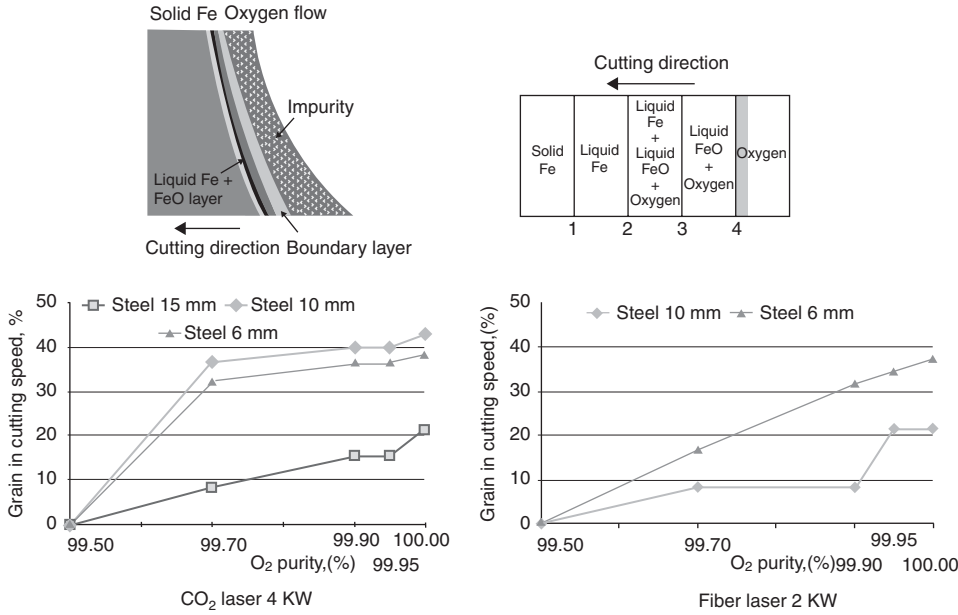

Fig. 13 Influence of oxygen assist gas purity on laser-cutting speed for CO₂ laser and fiber laser cutting of mild steel. Source: Air Liquide-CTAS Cutting and Welding R&D Laboratory

mm (0.060 in.) and nitrogen pressure of 13 bar (130 kPa) above atmospheric pressure. The absolute pressure of 14 bar (140 kPa) is in the supersonic regime. The resultant consumption flow rate of nitrogen is 577 SCFH. If the operator switches to a 3 mm (0.12 in.) nozzle at the same pressure, the flow rate would jump to 2308 SCFH.

Table 8 gives volume flow rates as a function of nozzle diameter and pressure for O₂ and N₂ assist gases. Yet another powerful piece of information that can be derived from these analytical formulas is the flow rate sensitivity to variations in pressure, temperature, and nozzle diameter by mathematically calculating the differentials. It allows for better understanding of repeatability and reproducibility challenges and can save some troubleshooting time: For the supersonic regime:

$$\frac{\Delta(\text{Flow rate})}{\text{Flow rate}} = \frac{\Delta P_0}{P_0} - \frac{1}{2} \frac{\Delta T_0}{T_0} + 2 \frac{\Delta D}{D} \quad (\text{Eq 9})$$

For the subsonic regime:

$$\frac{\Delta(\text{Flow rate})}{\text{Flow rate}} = F_0 * \frac{\Delta P_0}{P_0} - \frac{1}{2} \frac{\Delta T_0}{T_0} + 2 \frac{\Delta D}{D} + F_a * \frac{\Delta P_a}{P_a} \quad (\text{Eq 10})$$

where $F_0 + F_a = 1$ and F_0 varies from 1 at the limit of transition to the supersonic regime (Eq 5) to $+\infty$ at the no-flow limit when $P_0 = P_a$ (Ref 1). For most O₂-assisted laser cutting of mild steel, F_0 is typically of the order of 1.15. Generally, one assumes that P_a remains fairly constant, so $F_a * \Delta P_a \approx 0$.

Consequently, Eq 9 and 10 reveal that a 10% variation in nozzle diameter results in a 20%

variation in flow rate that will be noticed in the cutting performance. A typical nozzle size is 1 mm (0.040 in.); thus, a ± 0.1 mm (0.004 in.) variation in diameter, which is common and may appear negligible, has a substantial $\pm 20\%$ impact in flow rate equivalent to a 20% change in pressure. The way these nozzles are manufactured, whether their throat orifice is maintained clean and free of debris or residues, the dewpoint or the viscosity of the gas are factors that can impact the effective diameter, D , value and thus greatly influence the repeatability and reproducibility (R&R), particularly for smaller nozzle diameters.

Similarly, a temperature variation from -1 °C (30 °F, or 272 K) on a January morning to 38 °C (100 °F, or 311 K) on an August afternoon yields a 14% temperature difference and thus a 7% difference in flow rate. The key is to set up the system such that the process is tolerant enough so that a 7% variation will not affect R&R. It is also interesting to note that for O₂-assisted cutting occurring in the subsonic regime, the temperature of the kerf can be transferred to the gas inside the nozzle by radiation but also by conduction and convection when given the time. This may substantially increase the temperature of the gas in the nozzle after some duration of uninterrupted cutting time with subsonic assist gas flow; the impact on the cutting performance may be much more troublesome. However, when operating in the supersonic regime, conduction and convection heat cannot be transferred upstream in a supersonic flow; the only upstream heat-transfer mechanism in that case is limited to radiative heat transfer from the kerf to the nozzle.

Finally a 10% change in pressure could result in a 10% flow rate change in the supersonic

Table 7 Specific heat ratio of various potential elements of assist gases

Assist gas elements	γ	m , g

regime and slightly more than 10% in the subsonic regime.

Material Considerations

The majority of laser-cutting applications involve cutting of metals, which are mainly uncoated and coated mild steels, stainless steels, and aluminum alloys. Many steel makers, such as ArcelorMittal and US Steel in North America and Chubu Steel in Japan, have studied the effect of different alloying grades of steels on laser cut-edge quality (Ref 13). Penn et al. (Ref 14) compare in great detail the ability of various aluminum alloys, namely 6111-, 5754-, and 5182-series alloys, to be laser cut. The study recommends laser cutting of these automotive-grade aluminum alloy sheet metals instead of die blanking them for volume production of aluminum sheet blanking.

The following sections describe metallurgies and other key material considerations that impact laser-cutting performances and introduce examples of laser cutting of nonmetal materials.

Mild steels consist predominantly of iron with some small quantities of alloying elements, primarily carbon, manganese, silicon, phosphorus, sulfur, aluminum, and copper. From appliance panels and automobile body parts made with deep-drawable-quality mild steels to structural members made from high-strength steels, most steels used in consumer goods are low-carbon steels of commercial grade, drawing quality, or structural quality. Their compositions are between 0.05 and 0.40% C; manganese content is maintained between 0.25 and 0.50%, while phosphorus is kept under 0.035%, sulfur under 0.04%, and silicon under approximately 0.25%.

Generally speaking, steels on the low end of carbon content enable cutting at speeds up to 20% higher and of maximum thickness up to 20% thicker than steels on the high-end range of carbon content. Structural-quality steel with carbon content close to or higher than 0.40% is prone to microcracking along the cut edge. Under fatigue, those cracks can develop into full-fledged part failure in service. Heat treatment after cutting could be one way of fixing microcracking. It is interesting to note that such microcracking problems are actually more acute when using traditional mechanical cutting

Table 8 Flow rates in units of standard cubic feet per hour (SCFH) as a function of pressure and nozzle diameter for N₂ and O₂ assist gases (1 SCFH ≈ 0.47 L/min)

Gage reading			Flow rates, SCFH

means such as die blanking; for that reason, cutting of some advanced-strength steel hydroformed, closed-section products is preferably done with robotic laser cutting rather than with die trimming.

Electrical steels with higher levels of approximately 0.4% Si can be found in components such as transformer frames because of their increased electrical resistivity and higher thermal oxidation threshold. Such high levels of silicon result in approximately 20% reduction in cutting speed and the generation of more severe dross.

Manganese content as high as 0.5% and sulfur content as high as 0.04% also disrupt a laser-cutting process sufficiently to reduce cutting speed and worsen dross growth; such contents can be found in tool steels.

In the case of oxygen-assisted laser cutting of mild steel, an exothermic reaction between iron and oxygen occurs at approximately 1500 K (1225 °C, or 2240 °F) before metal melting starts:

This exothermic reaction can be equivalent in heat input to a CO₂ laser power of approximately

500 W added to a laser-material interaction zone the size of a typical focused laser beam spot, that is, approximately 250 μm in diameter for laser cutting. This heat input advantage enables a tremendous boost in cutting speed compared to cutting the same material with N₂ assist gas (Fig. 14). This advantage with O₂ gas is more prevalent with low laser power or with thicker gage. At high power and with thinner gages, faster speeds are achieved with N₂ assist gas than with O₂. Figures 15 and 16 illustrate the gas dynamic associated with O₂ and N₂ assist gases and their impact on the cutting process. When cutting with a 1 μm laser such as YAG, fiber, and disk lasers, the absorptivity of the 1 μm wavelength by a metal is several fold larger than that of a 10.6 μm wavelength of the CO₂ laser (Fig. 17). Consequently, with 1 μm laser cutting, the advantage of using oxygen assist becomes more modest than with oxygen-assisted CO₂ laser cutting.

One disadvantage of O₂-assisted laser cutting is that it generates iron oxide flakes that stick along the cut edge (Fig. 18). These flakes are composed of FeO in the core

and harder Fe₂O₃ on the outer layer. They are unwelcome contaminants for subsequent welding operations. These iron oxide flakes are also brittle and very easily crumble away from the cut edge into sand-sized particles and wear against tools and dies. The flaking-away action is obviously detrimental to most painting and stamping processes. One way to prevent formation of oxide flakes is to laser cut mild steel with N₂ assist gas. In particular, galvanized steels coated with either zinc- or aluminum-base coating are predominantly laser cut with N₂ assist gas. Because of the low-melting-temperature coating, dross forms when cutting coated steels; this dross can be minimized by slowing down the cutting speed. Typically, there is approximately a 20% difference in “production” cutting speed between bare steel less than 2 mm (0.08 in.) thickness and the same with a coating weight greater than approximately 80 g/m². Generally, no substantial difference is observed between the different galvanizing coating processes, that is, electrogalvanizing, hot dipped galvanizing, and galvannealing.

Stainless steels can contain up to approximately 18% Cr and 8% Ni by weight. They are highly resistant to corrosion due to a protective Cr₂O₃ film that naturally forms on its surface when exposed to free atmosphere. This Cr₂O₃ oxidation film also reduces the exothermic oxidation of iron with O₂, thus lowering the benefit of using O₂ assist gas compared to N₂. The Cr₂O₃ has a much higher melting temperature than iron, and during cutting, the same protective film of Cr₂O₃ solidifies around droplets of molten metal and sticks to the bottom edge of the kerf, thus creating stalactites called dross. Oxidation of nickel creates a black film coated on the dross ends (Fig. 19). To reduce dross, stainless steel is often laser cut with N₂ assist gas. The high pressure of N₂ assist gas requires large consumption of nitrogen and therefore increases processing costs. At equal laser power and equivalent cut-edge quality, the maximum thickness that can be cut dross-free for stainless steel is a little under half of that for mild steel. This has an impact on the cost of operation, as illustrated in Fig. 20.

Aluminum Alloys. After steels, aluminum and aluminum alloys are most significant in terms of industrial laser-cutting applications. Just as with stainless steel, aluminum is quickly oxidized when exposed to free atmosphere and forms an Al₂O₃ autoprotective surface film that prevents further corrosion penetration. This thin Al₂O₃ film oxidation also limits the benefit of oxidation with O₂-assisted laser cutting. Similarly, the same film is also responsible for dross formation because of the much higher melting temperature of 2300 K (2025 °C, or 3680 °F) for Al₂O₃ compared to only 950 K (675 °C, or 1250 °F) for aluminum. For these reasons, aluminum is mostly laser cut with compressed air or, most often, with N₂ assist gas for optimal quality.

Titanium and Nickel Alloys. The aerospace and energy industries represent some of the largest users of titanium alloys and nickel alloys, because these metals exhibit high toughness and high strength-to-weight ratio advantages over more common metals, including aluminum and steel. Nickel alloys such as Monel (66% Ni, 30% Cu), Inconel 600 (76% Ni, 15% Cr, 8% Fe), and Hastelloy (57% Ni, 16% Cr, 15% Mo, 6% Fe) are known for their high corrosion resistance under acid chemical environments and high temperature.

During oxygen-assisted thermal cutting, titanium reacts with O₂ in a highly exothermic reaction, and even with neutral gases such as N₂ in an environment at elevated temperatures above approximately 480 °C (895 °F). This highly reactive reaction of titanium can generate vigorous-to-explosive flame plumes detrimental to fine, intricate feature cutting. Cutting titanium alloys with an inert assist gas such as argon yields cutting speeds several fold slower than cutting with O₂ assist gas. Nickel alloys can be cut with N₂ assist gas for dross-free cut quality.

Copper Alloys. Lasers can cut copper in pure form or in alloy form, such as brass with zinc as the main alloying element of approximately 33%, or bronze with tin as the main alloying element of approximately 10% content. Copper alloys are difficult to laser cut because of a combination of high thermal conductivity (Table 9) and a high reflectivity to laser beams, particularly the higher wavelength (Fig. 17). Even though oxidation of copper by oxygen is moderately exothermic compared to steel oxidation, O₂ is still preferred over N₂ assist gas when laser cutting copper alloys because it yields significantly higher cutting speed. Figure 21 illustrates laser cutting of various metals, including copper

tubes with solid-state laser sources, thanks to better absorptivity of copper to the 1 μm wavelength.

Table 10 compares the heat energies needed to melt and vaporize a reference volume element of three materials: steel, aluminum, and stainless steel. These energies represent only a fraction of the laser beam energy needed, because most of it is wasted by reflection, transmission, conduction, convection, and radiation. In addition, other quality restrictions, such as edge smoothness and dross, or material properties, such as optical reflectivity, elevate the requirements for quality cutting beyond the plain heat energies input.

Fig. 14 Typical cutting speeds for N₂ versus O₂ at CO₂ laser powers of 4 kW versus 2 kW. The lower the power, the more O₂ contributes to speed. At high power, the higher the thickness, the larger the relative contribution of O₂ to speed; at thin gages, faster speeds are achieved with N₂ than with O₂.

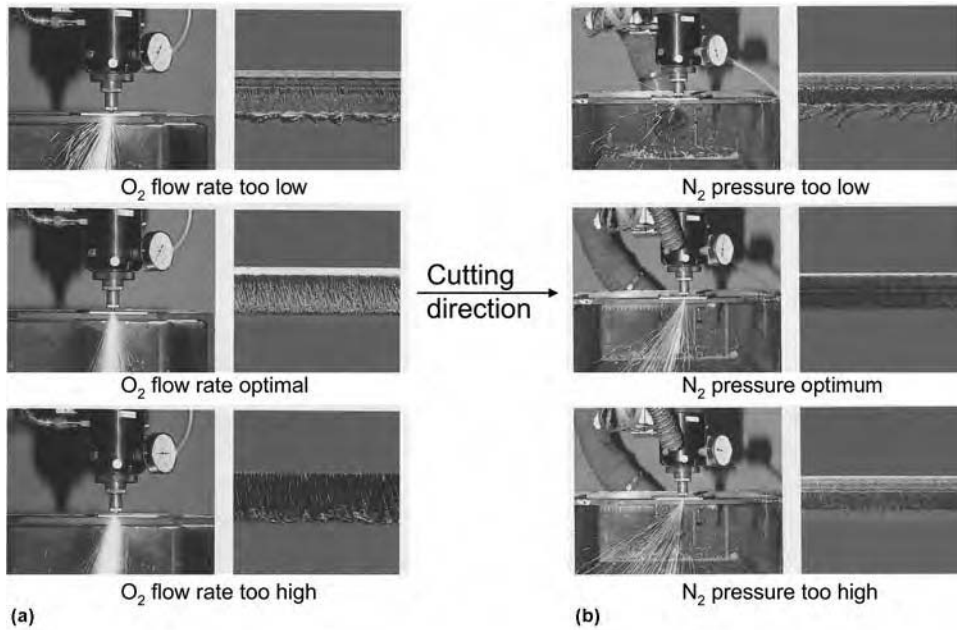

Fig. 16 Influence of gas pressure set-up on laser-cutting performance. (a) O₂ assist gas with mild steel. (b) N₂ assist gas with stainless steel. Courtesy of Air Liquide-CTAS Cutting and Welding R&D Laboratory

Fig. 18 Oxide scales cut with O₂ assist gas have a shiny, dark-blue appearance and flake off from the cut edge. They are detrimental to downstream painting and welding operations. Gouging leaves deep crevices that flare in the direction of the assist gas flow; they usually indicate excess heat from too much laser power or too much O₂ flow rate.

Fig. 19 (a) Features of edge quality for laser cutting. The striations observed on the cut-edge surface are indicative of a cut front line with three zones: a smoother cut area at the top, a rougher break area at the bottom, and a hanging dross area. For a high-quality cut, the break and the dross should be minimized or eliminated. (b) Dross-free, smooth cut edges for aluminum (cut with N₂ assist gas), stainless steel (cut with N₂ assist gas), and mild steel (cut with O₂ assist gas)

Fig. 17 Dependence of metal surface reflectivity on laser light wavelength. YAG, yttrium-aluminum-garnet. Data extracted from Ref 15

Wood, Plastics, and Synthetic Materials. Lasers can cut wood very effectively with O₂ assist gas. The die board industry is very vibrant, with over 5000 members in North America alone. Die boards are thick wood tools with narrow kerf cuts through which metal blades are inserted. These tools are used to cut cartons and papers, such as for the packaging used for pizza delivery and beer pack boxes (Fig. 22). Most die board cutting is still being done with routers. However, to enable more sophisticated three-dimensional blade inserts, laser cutting has become the manufacturing tool of choice, gaining market share versus all other wood-cutting technologies at a phenomenal growth rate. With a 2200 W CO₂ laser, 12.7 mm (½ in.) thick plywood material can be cut at a feed rate of 62 ipm (158 cm/min) using bifocal technology (Ref 19).

Lasers cut plastics, acrylic plastic sheets, synthetic materials, and even clothing fabrics in industrial applications. Just as for wood, adequate air filter systems are recommended to keep the atmosphere safe for operators. Because polyvinyl chloride can produce toxic chlorine vapors when cut with a thermal process, it is highly recommended that no thermal process be used to cut it.

Surface Conditions

Some metals coming out of hot rolled mills exhibit oxidation in the form of corrosion or, even worse, have oxide scale inclusions on their surfaces. These oxide inclusions have hardness and melting temperatures much higher than the base material; such differences in properties yield cutting defects, and set-up parameters must be readjusted. For these reasons, mill scales and corrosion are generally undesirable for laser cutting. Some steel materials are specified to be pickled and oiled to remove these and other surface contaminants; they yield a higher

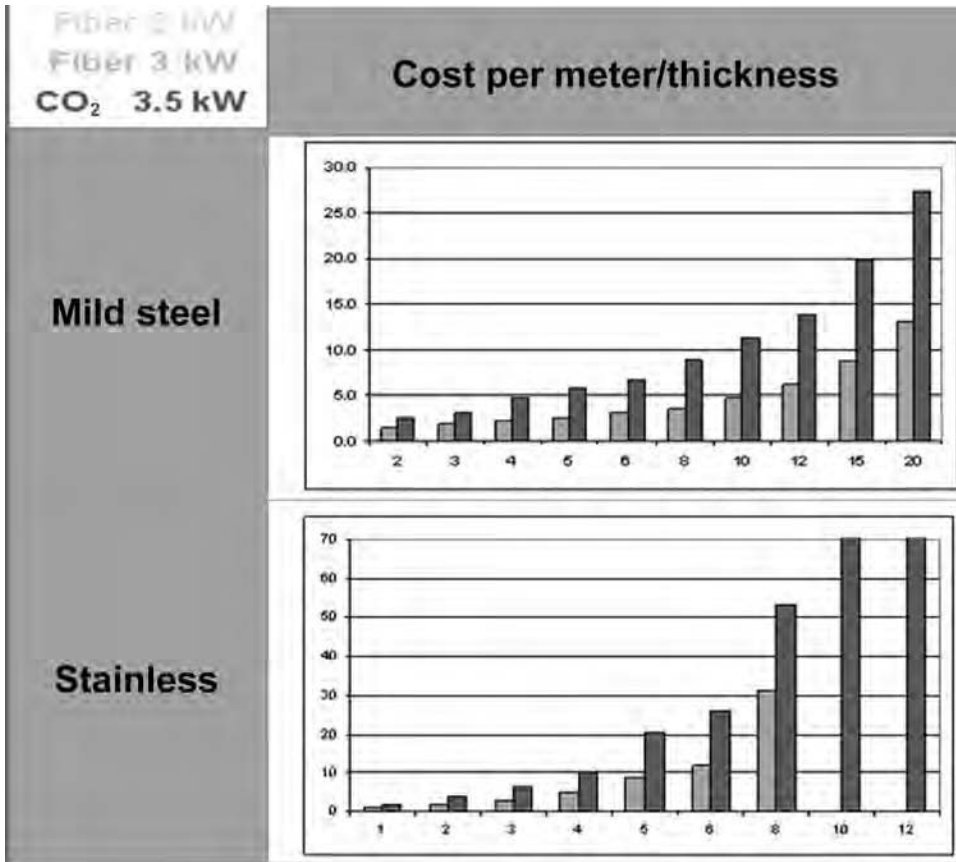

Fig. 20 Cost comparison for cutting of stainless steel and mild steel. Because high-pressure N₂ assist gas is required for cutting stainless steel, the cutting costs are approximately double those for cutting mild steel. Adapted from data courtesy of BLM Group

feed rate, more stable and repeatable cutting process, and better edge quality. Mill scales can also be shot blasted away with ceramic dust particles. However, the hard ceramic particles must be brushed away from the surface after shot blasting is completed.

Comparison between Laser and Traditional Cutting Processes

The various cutting technologies differ by their range of applications, process tolerances,

as well as variable and fixed costs (Ref 20). Table 11 summarizes the differences between three material-removal cutting technologies: laser cutting, water-jet cutting, and plasma cutting.

Principles of Laser-Drilling Processes

Laser drilling has been used in production for decades in the aerospace industry to drill

cooling-channel holes in aircraft engine turbine blades (Ref 18) (Fig. 23). In a typical nickel alloy aircraft engine turbine blade, laser-drilled cooling channels have diameters approximately 0.5 mm (0.02 in.) wide and can run as deep as 5 to 25 mm (0.2 to 1 in.). The cooling air from these holes is used to create a cold air-film layer across the surface of the turbine and to prevent combustion gases that are hotter than the melting temperature of the turbine material from directly contacting the turbine (Ref 21). Laser drilling also has applications in micromanufacturing, such as for drilling microholes of 0.1 mm (0.004 in.) diameter to depths exceeding 0.5 mm (0.02 in.) in surgical needles in the medical industry, and also in the semiconductor industry, such as for photovoltaic cells. The production of photovoltaic silicon film with thickness under 200 μm requires lasers to drill holes of diameter as small as 30 μm (Ref 22) at a rate of 20,000 holes per second. Galvano-scanner mirrors enable the synchronization of high-speed, high-acceleration positioning of the laser beam with high-frequency beam pulsing.

Drilling holes with lasers is done with two main techniques: percussion drilling and trepanning. Figure 24 illustrates examples of four drilling practices that derive from these two main techniques: single- and multiple-pulse percussion drilling, trepanning, and helical trepanning.

Percussion drilling is similar to the piercing process described to initiate laser cutting in that laser pulses of high energy create enough power density to almost instantaneously vaporize a certain volume of material. The amount of energy per volume of material to be vaporized can be written as:

$$E = \rho \left[\overbrace{C_{p-solid} (T_f - T) + L_f}^{Melt} + \overbrace{C_{p-molten} (T_v - T_f) + L_v}^{Vaporize} \right] \quad (Eq 12)$$

where ρ is the density of the material; C_p represents the specific heat for the solid and molten materials, respectively; L represents the latent heat for fusion and vaporization in accordance with the subscript; T_f and T_v are the fusion and vaporization temperatures, respectively; and T is the starting room temperature of the workpiece. It is known that C_p varies with temperature; for approximation purposes, Eq 12 includes the first-order approximation that C_{p-solid} is constant from room temperature, T, to T_f and that C_{p-molten} remains constant from melting point, T_f, to vaporization point, T_v. Table 10 lists comparative values of these parameters for steel, aluminum, titanium, and Inconel alloys; some variations are to be expected, depending on the nature and relative quantity of alloying elements and heat history.

Source: Ref 16–18

For the single-pulse mode, a single pulse suffices to achieve the drilling depth required. In the multiple-pulse mode, each pulse digs progressively deeper into the material until the desired drilling depth is produced. If the workpiece is not drilled all the way through, the hole is called a “blind hole.” At each pulse, vaporized material is ejected out of the hole by recoil pressure (Fig. 25). The vapor ejection occurs at high speed under the recoil pressure from the

bottom of the hole in formation. Thanks to a Venturi effect, the vapor plume drains with it some molten metal droplets along the walls of the hole. These droplets resolidify into slag deposited on the workpiece surface and could potentially damage it.

With the percussion technique, the laser beam is kept in a stationary position relative to the workpiece. For the trepanning techniques, the laser beam is maneuvered by a numerically

controlled mechanism into a motion relative to the workpiece during the drilling process. The shape of this motion determines the shape of the drilled hole. Generally, the trepanning technique is used to drill holes that are larger than the laser beam spot diameter (Eq 1–3).

Typical lasers used for drilling are transverse excited atmospheric CO₂ lasers and Q-switched CO₂ lasers (10.6 μ m wavelength) (Ref 23), YAG lasers (1.064 μ m), fiber lasers (1.07 μ m), copper vapor lasers (0.511 and 0.578 μ m), and even excimer lasers (0.193 to 0.308 μ m) that can achieve drilling by ablation, used predominantly in nonmetals due to their short ultraviolet wavelength.

Table 12 illustrates examples of set-up parameters representative of drilling of various metals with a solid-state 1 μ m laser such as a YAG laser.

Hole Quality

When piercing to initiate laser cutting, the quality of the pierced hole is not very important. For most drilling applications, however, specific quality factors are generally imposed. For example, in applications where the drilled holes are channels for fluid dynamics, such as for turbine blades, or when they determine electrical efficiency, such as for solar cells, the following quality criteria may have to be kept under control for the laser-drilling process to be validated for production:

- Parallelism or taper of the walls of the drilled holes
- Variations in inside diameter or inside dimensions when not cylindrical along the depth of the hole
- Surface roughness inside the hole
- Presence of slag inside the walls of the hole
- Depth of a recast layer; the presence of microcracks developing from the recast layer
- Presence of resolidified metal droplets or other slag particles on the workpiece surface
- Degree of oxidation that can potentially be promoted at high temperature

In general, imposing quality factors negatively affects the throughput capability and quality process capability, C_{pk} , of a laser-drilling operation.

Ultrashort High-Energy Pulses for Laser Drilling

One method to increase the hole quality in terms of reducing or eliminating recast layers and slag projections is to use ultrashort pulsed laser beam output with high energy per pulse. Some of these lasers reach several Joules of energy per pulse, with pulse duration as low as a few femtoseconds. Consequently, under each pulse of several terawatt/cm² of power density, a volume of material instantaneously evaporates without giving time for conduction to heat the

Fig. 22 (a) Cylindrical die board being laser-cut. (b) Ready-to-ship die board with steel rule blades inserted, and gray rubber pads with pressure-sensitive adhesives to prevent cardboard from sticking to the die after the cut. (c) Examples of corrugated boxes for pizza delivery cut with die board steel rule dies. (d) Acrylic plastic sheets can also be cut with lasers.

surrounding material. It generally results in the elimination of slag projections when laser drilling most materials and, in the case of drilling metals, the elimination of recast layers (Fig. 23). Such high irradiance could nevertheless damage the optical elements used in the beam-delivery system; indeed, the fused silica material used, for example, for lenses for solid-state lasers has a reported damage threshold of approximately the terawatt/cm² level.

Principles of Laser Shock-Peening Processes

Laser shock peening is a mechanical process intended to increase the fatigue and fretting resistance of a workpiece by producing a compressive residual stress within the material. A pulsed laser beam capable of being focused into high energy density per pulse creates a high-amplitude shock wave that propagates from the surface into the workpiece, to the point of plastically deforming layers of material and thereby inducing a residual compressive stress (Ref 25). In the laser shock process, the workpiece is generally coated or covered with a compound such as tape or paint; this compound

Table 11 Comparison between laser cutting, water-jet cutting, and plasma cutting

All values are approximate.

Parameter	Laser cutting	Water-jet cutting	Plasma/fine plasma cutting
Cutting process	High-power density light absorption heats up the material beyond its melting and vaporization points. Pressurized assist gas flushes molten and vaporized material through the kerf.	High-pressure water beam, with or without abrasive, "files" the material away. No or negligible heat is generated.	An electrical arc between electrode and workpiece ionizes a beam of pressurized gas to extreme temperatures (>15,000 K), which heats up the material beyond its melting point and flushes molten metal through the kerf.
Three-dimensional processing	No problems	Difficult and not recommended	No problems
Processed materials	All materials	All materials	Electrically conductive metals
Practical range of application metal thickness in the field	Metal thickness up to approximately 32 mm (1.25 in.). High-pressure assist gas can cut as thin as 0.8 mm (0.030 in.). Cutting of any nonmetal	Cutting of stone, ceramics, and up to 25 mm (1 in.) thick metals. Gages thinner than approximately 32 mm (0.125 in.) are difficult to process.	Preferable for metal thickness between 32 and 50 mm (0.125 and 2 in.)
Hardware consumables	Focusing lens, intra- and extracavity mirrors, nozzle tips	Nozzle and all high-pressure components, such as valves, hoses, and seals	All torch components (nozzles, electrodes)
Specialty consumables	Lasing gases: 10 L/h (for CO ₂ lasers only)	Abrasive: 36 kg/h (79 lb/h)	None
Fluid consumables	Assist gases: 15 bar N ₂ : 1000 SCFH(a) 1.5 bar O ₂ : 100 SCFH	Water: 60 L/h	Assist gases: 80 psi N ₂ = 500 SCFH(a) 80 psi O ₂ = 500 SCFH
Kerf width relative to laser-cut kerf width	1:1	3:1	4:1
Cut-edge quality	Cut surface will show a striated structure.	Sand-blasting appearance	Cut surface will show a striated structure; bevel-cut edges.
Metallurgical change in heat-affected zone (HAZ)	Deformation, tempering, and significant hardness changes may occur in the HAZ.	None	Deformation, tempering, and significant hardness changes may occur in the HAZ. Large-width HAZ
Eye safety	CO ₂ laser: laser safety glasses; 1 μm laser: total enclosure preferred	Standard safety glasses and protection against contact with high-pressure water jet are needed.	Safety glasses for electric arc processes
Noise safety	Low-decibel (dB) noise level	Above 85 dB, hearing protection required	Above 85 dB, hearing protection required
Waste	Cutting waste is mainly in the form of dust, requiring vacuum extraction and filtering.	Large quantities of cutting waste occur due to mixing water with cut material and abrasives.	Cutting waste is mainly in the form of dust, requiring vacuum extraction and filtering.

Fig. 25 Laser percussion drilling process. (a) Medium-energy, long pulses generate wide recast layers that can be a source of microcracks initiation sites in the Heat Affected Zone, HAZ. (b) High-energy, short pulses minimize and, in some cases, eliminate the recast layers and slag projections. Smaller-diameter holes can be produced than in (a).

becomes vaporized instantaneously by each laser pulse, resulting in high-temperature plasma and a shock wave (Fig. 26). A film of water flowing over the surface reflects the shock wave back into the workpiece to produce the compressive residual stress (Ref 26).

Figure 27 compares typical results of laser shock peening with traditional shot peening. Although the magnitude of the residual compressive stress is of the same order, the compressive stress generated by laser shock peening extends much deeper below the surface of the material, thus yielding greater fatigue resistance and even local strain hardening.

Typical lasers used are solid-state lasers, such as 1.05 μm wavelength neodymium-glass lasers with pulses as short as 15 to 30 ns and 50 J/pulse energy. Generally, the beam-delivery system of choice consists of mirrors and lenses rather than a fiber optic, so as to yield the maximum focusability possible.

Microjoining with Laser and Electron Beams

Gerald A. Knorovsky, Sandia National Laboratories

MICROJOINING with high energy density beams is both an old and a new subject. It is old, because some of the original work in both laser and electron beam welding was done with relatively low-power systems, and hence, the welds made were small. It is new in that the progress of miniaturization in industry has made the desire to make microjoints rapidly and reliably a current and exciting topic. In this article, the current state of microjoining with both electron and laser beams is summarized. Both techniques are still immature, so this article is somewhat forward-looking. Because both macroscale laser and electron beam welding are treated elsewhere in this Volume, differences are emphasized to minimize repetition. The reader is directed to those articles to obtain a basic understanding of each process at the macroscale.

Definition—What Is a Microweld?

For the purposes of this Volume, a microweld is defined as any weld that has at least one measured dimension (usually the thickness or diameter) less than 1 mm (0.04 in). Even though this value is a generous upper limit on weld size, it starts to distinguish between what has been known as microwelding for the past several decades, and which may more properly be called “milliwelding.” A stricter definition would reduce this upper limit by an order of magnitude to approximately 100 μm . Where possible in this article, examples are provided that adhere to the stricter definition. This definition goes a long way toward explaining the compelling attraction of the laser and electron beam processes for microscale welding. Simply put, it is their unique ability to precisely and controllably provide highly focused, high-power heat sources.

Microscale Physical Phenomena

To introduce the reader to phenomena that affect the melting, coalescence, and solidification needed for a successful microweld, this

section considers elementary physical processes such as heat and fluid flow. (The reader is directed to the lecture by Nobel Laureate E.M. Purcell, “Life at Low Reynolds Number,” for another, and unique, perspective of fluid dynamics and its consequences for microscopic life, Ref 1).

Transport

Energetics. To melt material either in a spot weld or along the path of a seam weld, a sufficient amount of energy must be deposited during the time that the beam dwells at each location. Assuming a fusion-zone volume approximated by a cube of 100 μm on a side for simplicity ($1 \times 10^{-3} \text{ mm}^3$) and noting that on the order of 10 J/mm^3 are required to melt typical metals (Ref 2), the input energy required (at 100% melting efficiency) is approximately 10 mJ. The local beam dwell period for a continuous or modulated beam seam weld can be approximated by the impinging beam diameter divided by the travel speed. At a dwell time of ~ 1 ms, equivalent to a typical small laser spotweld or one pulse of an overlapping spot laser seam weld at a travel speed of 50 $\mu\text{m}/1\text{ms}$ ($\sim 50 \text{ mm/s}$) (successive spots typically overlap by at least 50% in such welds), the beam power required would be 10 mJ/1 ms ($\sim 10 \text{ W}$).

Because highly focusable beam power sources (single-mode fiber lasers and small electron beam welders) of up to ~ 1 kW are presently available, quite fast travel speeds should be energetically possible. At 1 kW, still assuming a cubic fusion zone 100 μm on a side and its energy requirement of 10 mJ, the dwell time necessary is reduced to 10 mJ/1 kW = 10 μs , corresponding to a travel speed of 100 $\mu\text{m}/10 \mu\text{s}$ = 10 m/s (32.8 ft/s). Such speeds are not compatible with computer numerical control (CNC) table translation speeds, suggesting that laser scanner heads or magnetic lens electron beam rastering will be necessary to take advantage of the available power.

Diffusion Distances. The thermal diffusion distance (δ_t) corresponding to the beam dwell

time can be used to estimate the heat-affected zone (HAZ) size. The thermal diffusivity (α) of metals varies between 0.1 and $11 \times 10^{-5} \text{ m}^2/\text{s}$ (Ref 3), which gives the range of thermal diffusion distance in 10 μs , $\delta_t \sim (4 \cdot \alpha \cdot t)^{1/2}$ as 6 to 70 μm (Ref 4). In contrast, at the 5 ms dwell time typical for a small macroweld, the thermal diffusion range is 140 to 1500 μm . These time and size scales are important to consider when fixturing geometry and material choices are being made, and when HAZ thermal effects in microparts are being evaluated.

Thermal diffusion in the fusion zone is often overwhelmed by convective heat transfer. In simplified conduction-only models, the large effect of convection is often simulated by an “enhanced” thermal diffusivity, typically taken as 2 to 5 times greater than that of the solid state. This enhancement may be different in different directions (e.g., greater in the depth direction than the in-plane direction), to better simulate actual fusion-zone geometry depth-to-width ratios.

The mass diffusion coefficient for metals in the liquid state (Ref 5) is often approximated as $\sim 10^{-9} \text{ m}^2/\text{s}$, which is approximately 4 orders of magnitude less than the thermal diffusivity. Applying the same equation (using D_L rather than α and dwell times as given previously, the mass diffusion distance (δ_m) is calculated as $\sim 200 \text{ nm}$ for a 10 μs dwell time and $\sim 4 \mu\text{m}$ for 5 ms. This distance is useful when considering the expected distances over which compositional microsegregation may exist. Another factor influencing compositional homogenization in a dissimilar-metal fusion zone is convection, discussed in the following section.

Forces Acting on Microwelds

In the previous section, fluid convection was noted as providing enhanced thermal transport and affecting segregation in weld fusion zones. Because of these major effects, the various forces driving (and resisting) fluid flow are analyzed in more detail. After discussing each force, a summary tabulation is given,

highlighting which forces have enhanced importance in microwelds.

Driving Forces. Fluid flow in welds is driven by the force of gravity, viscous aerodynamic drag, the magnetohydrodynamic (Lorentz) force, surface-tension-driven forces (Marangoni flow), and the reaction force from rapid evaporation (Newton's second law).

Clearly, shielding-gas-driven viscous aerodynamic surface drag does not apply in the vacuum of an electron beam chamber, and because laser shielding gas flow is not driven by an arc plasma jet, nor does it apply for the laser beam case. (A more quantitative discussion of viscous shear forces in liquids, that is, a condensed fluid, is given in a later section, "Resisting Forces," in this article).

Current-driven magnetohydrodynamics (MHD) clearly does not apply in laser welding, because no electric current is present. Because the current density of an electron beam microwelder is low (even though its power density can be quite high, due to the few tens of kiloelectron volts, or keV accelerating voltage), MHD effects do not apply to electron beam microwelds either. (In gas tungsten arc welding, MHD effects start to predominate at currents beyond approximately 150 A, Ref 6, with an arc diameter of ~ 1 mm, corresponding to an order of magnitude estimate current density of ~ 150 A/mm². In the case of an electron beam microweld, the beam current is ~ 100 μ A, and the beam diameter is ~ 50 μ m, resulting in a current density of $\sim 100 \times 10^{-6}$ A/(50×10^{-3})² mm² = 0.04 A/mm², more than 3 orders of magnitude lower. For a more quantitative discussion of MHD effects, see Ref 7.)

Gravity generates two types of force in the fusion zone. The first is the buoyancy force on a submerged object (e.g., an inclusion, or bubble). Archimedes' principle states that this force is equal to the weight of the fluid displaced. The net force on the object must take into account that it may have weight also. Thus, the net force is given by $F_{\text{net}} = g\Delta\rho V$, where g is the gravitational acceleration, $\Delta\rho$ is the difference in density between the object of interest and the fluid it is immersed in, and V is the volume of the object. The buoyancy force is usually minor; however, it factors in when materials of significantly different densities are being welded, or when porosity is generated. Changes in fluid density are also created by either temperature gradients or by compositional gradients in an otherwise homogeneous fluid (i.e., local inhomogeneity, rather than a discrete object). The buoyancy force generated is proportional to volume. However, so is the mass of the volume of interest; thus, the acceleration is volume-independent.

The second gravity-induced force is the metallostatic head pressure, given by $p_m = g\rho h$, where h is the height and ρ is the density of the fluid column above the location of interest. This force scales with the vertical extent of the fusion zone. Given a concurrent relative increase in the effect of surface tension (see the next section), gravity-induced out-of-

position effects on the weld pool shape are expected to be minimal in beam microwelds.

Marangoni flow originates from the change in surface tension with temperature. It is a shear force and only acts at surfaces, although its consequences can dramatically influence fluid flow in a weld fusion zone (Ref 8). This driving force is calculated as:

$$\tau_M = d\sigma/dr = (d\sigma/dT)(dT/dr)$$

where σ is the liquid/vapor surface tension, T is the temperature, and r is the distance. Typical values for $d\sigma/dT$ range from approximately -0.3×10^{-3} N/m-K for a pure metal or 0.36×10^{-3} N/m-K (note the sign change) when a surface-active element is adsorbed on the surface (Ref 9). The flow is driven from the area of low surface tension toward that of high surface tension regardless of the sign of $d\sigma/dT$.

Estimating the magnitude of dT/dr in a macroweld as $dT/dr \sim 1200^\circ/0.005$ m (dT is approximated as the difference in boiling and melting temperatures, Ref 10), then $d\sigma/dr \sim \pm 70$ Pa (0.01 psi). Again, this is a shear stress and not a pressure, as in the normal case of capillarity. The magnitude of the shear stress, although small when the temperature gradient extends over centimeters, increases by 4 orders of magnitude and becomes quite appreciable when it extends over micrometers. Finally, because the surface tension temperature coefficient can be either positive or negative, the flow can be up or down the temperature gradient, causing significant changes in metal flow.

The last driving force to be considered is evaporative recoil-driven flow (Ref 11). Intense surface heating causes a high local evaporation rate, and the momentum of the evaporated metal atoms creates a reaction force that depresses the surface of the melt and may be sufficient to cause the formation of a cavity, or keyhole. With the formation of this cavity, the displaced liquid must flow elsewhere, often resulting in a raised crown around the molten-zone periphery and, in extreme cases, ejection of molten metal from the pool. This force is important for both laser and electron beam processes. For a given recoil pressure (evaporative force/unit area), the net overall effect with respect to size will depend on the resisting forces (the topic of the next section). Because the major resisting force will be surface tension, which increases at small size scales, the tendency to keyhole should be reduced or, alternatively, will need higher-intensity beams to achieve an equivalent (geometrically similar) behavior.

Resisting Forces. The previous section discussed driving forces; in this section, resisting forces are examined, of which the two most important are viscosity and capillary surface tension. They are also known as restoring, retarding, or dissipative forces.

The force due to viscosity is due to the inherent tendency of a fluid to resist being sheared and is given by:

$$\tau_{yx} = -\mu du_x/dy \quad (\text{Eq 1})$$

where τ_{yx} is the shear stress due to viscosity, u_x is the velocity in the x -direction (assumed to be the direction in which the shearing motion is occurring), and y is the other direction in the shear plane, normal to the shearing direction. (This same equation applies for the case of the aerodynamic viscous drag force mentioned in the previous section, "Driving Forces," except the viscosity coefficient scales with density and is thus several orders of magnitude smaller when viscous force due to a gaseous fluid is calculated, all other factors being constant.) This simple linear equation describes so-called Newtonian flow; other types of flow will raise the differential term to a power other than 1. Typical values of μ (the absolute viscosity) for molten metals are ~ 5 to 7×10^{-3} Ns/m² for molten iron and $\sim 1 \times 10^{-3}$ Ns/m² for molten aluminum (Ref 12). As an example, for fluid flow in the unmixed layer next to the solid HAZ of a steel macroscale weld, $du_x \sim 0.1$ m/s (0.3 ft/s) and $dy \sim 0.1$ mm (0.004 in.), resulting in $\tau_{yx} \sim 6$ Pa (0.0009 psi). In a microweld, the entire fusion zone may be smaller than the boundary-layer thickness noted previously. This implies that any flow in such a pool is close enough to a boundary to be strongly affected by it, implying that viscosity has an increased importance. Indeed, for microscale fusion zones, calculation of the Reynolds number ($\rho u_x D/\mu$), which gives the ratio of inertial to viscous force terms, shows it to be quite small, because it is proportional to the characteristic size D . For the aforementioned macroweld example, using data for steel, the Reynolds number is ~ 1000 ; by simply changing D to 0.1 mm, it drops to 10. With a decrease in velocity, it will decrease even more. Among other implications, low Reynolds number flows tend to exhibit little turbulence and do not mix very well (Ref 12); thus, dissimilar-material microwelds may be more inhomogeneous than a similar geometry but larger macroweld.

Surface tension (more correctly, the liquid/vapor surface energy) acts as a restraining force by attempting to minimize the surface area of a liquid/vapor interface. For a fluid with mean surface curvature κ , the surface tension generates an internal hydrostatic pressure p (also called the capillary pressure), given by:

$$p = \sigma\kappa \quad (\text{Eq 2})$$

Values of $\sigma \sim 0.5$ to 2 N/m (or N-m/m² = J/m²) are typical for liquid metals (Ref 13). The curvature, κ , of a surface is given by:

$$\kappa = (1/r_1 + 1/r_2) \quad (\text{Eq 3})$$

The two terms in the right side of the equation are the principal curvatures, that is, the curvatures of lines in the surface at the point of interest with the largest and smallest values. The curvature of a line is given by the inverse

of the radius of the circle that best approximates the line at the point of interest. (For a cylinder of radius r , the principal curvatures are $1/r$ and $1/\infty$; thus, the mean curvature is $1/r$. For a sphere of radius r , both principal curvatures are the same, $1/r$; thus, the mean curvature is $2/r$.) In a macroweld with a mean surface curvature equivalent to a surface radius of ~ 5 mm, the pressure created is ~ 400 Pa (~ 0.06 psi). Surface tension forces are increasingly important for microwelds because their magnitude increases linearly with surface curvature. Assuming that the applicable radii of liquid shapes on the fusion-zone surface scale with the overall size (i.e., geometrical similarity), surface tension effects will increase as the fusion-zone size decreases. If, instead of a 5 mm surface radius as mentioned previously, the surface radius is 5 μm , the capillary pressure will be 400 kPa (~ 4 atm). Because of the increased effect of surface tension relative to other forces in microwelds, one may expect that the surfaces of microwelds will be (relatively) smoother than macrowelds.

Other Forces. Thermal expansion and contraction act on the solid material surrounding the fusion zone and can produce sufficient force to create buckling or tearing, depending on whether the force is in compression or tension. Because the beam processes generally have a free liquid surface, the molten zone by itself can support relatively little stress. However, if contact between the parts being welded exists, and certainly after solidification, thermal stress/strain can be generated. The thermal expansion-induced stresses and strains created by melting are calculated in two steps (the constants used subsequently are for steel). First the linear expansion strain (per unit length of material) from ambient to the melting temperature is calculated from:

$$\epsilon_m = \alpha \Delta T_m$$

(This neglects the additional expansion upon melting.) Then, the stress needed to recompress back to the original length is calculated from:

$$\sigma_m = E \epsilon_m$$

where α is the average linear coefficient of thermal expansion, $\sim 10^{-5}$; ΔT is the temperature difference from ambient to melting, ~ 1500 °C (2730 °F); and E is Young's modulus, ~ 210 GPa (Ref 3). Substituting, $\epsilon_m \sim 0.015$ and $\sigma_m \sim 3$ GPa. Clearly, the linear elastic assumptions made are violated by this enormous stress, and plasticity and/or fracture will intervene. Further, none of the aforementioned factors are dependent on the size scale.

Even if the parts are not fully restrained and large forces are not generated, just the motion of parts expanding and contracting becomes of interest. Let a micropart be held a distance of 1 mm (0.04 in.) from the beam aim point, assumed to be at its edge. For simplicity, assume a linear temperature gradient from

ambient to the melting temperature is established from the clamping point to the edge where the beam impinges. The edge of the workpiece will move $\sim \epsilon_m/2 = 7.5$ μm , which is comparable to the beam diameter and which must be allowed for when programming the beam aim point.

Momentum effects can be due to pool sloshing, workpiece acceleration/deceleration, and impingement of material into the pool. In most instances, microbeam welds will be autogenous, so one can neglect this last source. The force due to pool sloshing can be estimated from:

$$f = dP/dt = d(mv)/dt \\ \sim 2 (\text{Pool mass} \times \text{Pool velocity}) \\ / (\text{Slosh period}/2)$$

where P is the momentum vector, m is the mass of the pool, v is the pool maximum velocity, and t is time. The factor of 2 comes from the reversal of motion, and the pool velocity is estimated from:

$$v \sim \text{Surface displacement (Peak-to-valley)} \\ / (\text{Slosh period}/2)$$

A hemispherical volume of steel of radius 1 mm (0.04 in.) has a pool mass of 0.3 g (0.01 oz.). With a surface displacement of ~ 0.2 mm (0.008 in.) and a period of 5 ms (Ref 14), the magnitude of f is calculated as ~ 20 mN. It has been found that the natural period of molten pools varies as the square root of the pool mass (Ref 14), and because the pool mass varies with the cube of the radius, the period should vary with the size to the $3/2$ power. It is assumed that the surface displacement exhibits geometric similitude with size. Combining, the aforementioned force equation is expressed in terms of size dependencies as:

$$f \sim \text{Mass} (\propto \text{Size}^3) \\ \times [\text{Displacement} (\propto \text{Size}^1)/\text{Period} (\propto \text{Size}^{3/2})] \\ / \text{Period} (\propto \text{Size}^{3/2}) \sim \text{Size}$$

While geometrical similitude predicts a linear size dependence for the surface displacement, elsewhere it is argued that surface tension will have a larger retarding effect at small size scales. Thus, a less-than-linear surface displacement dependence on size may be expected, in which case the size to the first power dependence predicted for sloshing force may be an overprediction. Data comparing surface velocities of millimeter-sized laser welds versus centimeter-sized gas tungsten arc welds seem to confirm a weak dependence on size, at least in macrowelds (Ref 15–17).

Forces due to external motion (i.e., a CNC stage accelerating the part through a sharp corner) are again given by $F = dP/dt$. For the case of a part accelerating around a corner, this transforms to:

$$f = mv^2/r$$

Assuming a 1 mm (0.04 in.) hemisphere fusion zone, a velocity of 25 mm/s (0.08 ft/s), and a radius of 0.1 mm (0.004 in.), the force on the pool calculates to be ~ 2 mN. For a 100 μm hemisphere microweld (keeping the same velocity and radius), the value decreases to 2 μN .

A compilation (Ref 18) of representative values for the forces/stresses described previously, contrasting macro and micro situations, is given in Table 1. Equivalency between stress/pressure and force assumes a 1 mm \times 1 mm area or 1 mm \times 1 mm \times 1 mm cube for macro forces and 10 μm \times 10 μm square or 10 μm \times 10 μm \times 10 μm cube for micro forces. The last column highlights the fact that surface-related stresses are extremely important in the microworld, and mass- or momentum-related stresses are more important in the macroworld.

Beam-Material Interactions

Typical welding laser photons and electron beam welder electrons interact differently with materials, losing their energy by way of differing physical mechanisms. Photons produced by a welding laser are ~ 1 eV energy (Ref 19) and react with the valence electrons of the workpiece, which are of comparable energy (Ref 20). This energy transfer is quantized (massless photons travel at only the speed of light, unlike electrons that can have variable velocity); hence, the photon loses all or none of its energy to a prospective target valence electron. The excited electrons in turn can give a part of their energy to other electrons or can emit a lower-energy photon. The net effect of these interactions results in a high metallic reflectivity for typical laser wavelength photons. Because the valence electrons are delocalized in metals and form a continuous layer at the surface, this interaction happens at the surface in the first atom layer or two; thus, the energy deposition is highly localized to the surface.

In contrast, the multi-keV electron beam welder electrons interact with the fields of the atom inner electrons (Ref 20). These scattering locations are more widely spaced; hence, the electrons can penetrate much deeper than photons into the lattice before interacting (micrometers of penetration instead of nanometers). Thus, the heating effect is more volumetric, although the surface heating is still quite appreciable. X-rays, back-scattered electrons, and secondary electrons that are also produced reduce the net energy input (especially for higher-atomic-number elements), but the energy-transfer efficiency for the electron beam is considerably higher than for a laser beam of comparable intensity.

With a sufficiently energetic beam (laser or electron), a keyhole may develop in the weld fusion zone; in macrowelds, the laser beam may reflect within the keyhole several times, multiplying the single-event absorption

Table 1 Macro versus micro comparison of forces acting on the weld pool

Force origin	Macro example magnitude: pressure/stress force	Micro example magnitude: pressure/stress force	Ratio of pressure/stress magnitudes: micro/macro
Driving forces			
Gravity metallostatic head	0.8 kPa (0.12 psi) 0.8 mN (0.0002 lb)	20 Pa (0.003 psi) 0.002 μN (5 × 10 ⁻¹⁰ lb)	0.025
Gravity buoyancy force (Δρg):			~1
Autogenous(a)	2 kN/m ³ , 20 mN (0.005 lb)	2 kN/m ³ , 2 μN (5 × 10 ⁻⁷ lb)	
Dissimilar(b)	50 kN/m ³ , 50 mN (0.01 lb)	50 kN/m ³ , 5 μN (1 × 10 ⁻⁶ lb)	
Aerodynamic shear stress	70–400 Pa (0.01–0.06 psi) 70–400 μN (0.00002–0.00009 lb)	70–400 Pa (0.01–0.06 psi) 7–40 pN (2 × 10 ⁻¹² to 9 × 10 ⁻¹² lb)	~1
Marangoni shear stress	70 Pa (0.01 psi) 70 μN (0.00002 lb)	0.7 MPa (101 psi) 70 μN (0.00002 lb)	10,000
Laser or electron beam driven evaporation	1.5–7 kPa (0.2–1.0 psi) 1.5–7 mN (0.0003–0.002 lb)	1.5–7 kPa (0.2–1.0 psi) 0.15–0.7 μN (3 × 10 ⁻⁸ to 2 × 10 ⁻⁷ lb)	~1
Resisting forces			
Liquid viscosity shear stress	6 Pa (0.0009 psi) 6 μN (1 × 10 ⁻⁶ lb)	6 Pa (0.0009 psi) 0.6 pN (1 × 10 ⁻¹³ lb)	~1
Surface tension pressure	2 kPa (0.3 psi) 2 mN (0.0004 lb)	200 kPa (30 psi) 20 μN (4 × 10 ⁻⁶ lb)	100
Other forces			
Thermal expansion (linear)	3 GPa (435 ksi) (ambient-to-molten) 3 kN (670 lb)	3 GPa (435 ksi) (ambient-to-molten) 0.3 N (0.07 lb)	~1
Pool sloshing	200 mN (0.04 lb)	20 μN (4 × 10 ⁻⁷ lb)	0.0001
Stage motion, centrifugal	40 mN (0.009 lb)	40 nN (9 × 10 ⁻⁹ lb)	0.000001

efficiency by the number of reflections (Ref 21). This situation is not likely to occur in microjoining, where the limited part thickness will generally imply that if a keyhole is achieved, it will go all the way through the thickness, reducing the opportunity for multiple reflections. Thus, laser microwelds will probably exhibit lower energy-transfer efficiency than macrowelds.

Stability of the Keyhole. Because microwelds usually take place in parts that are thin, the typical microfusion zone is full penetration, and a simple surface energy analysis (Ref 22) of such a keyhole will yield some interesting conclusions relative to its stability. Assume that a cylindrical keyhole of radius r exists in a cylindrical spot weld fusion zone of radius R and depth h . The negative pressure created by surface tension on the cylindrical keyhole surface is given by σ/r , where σ is the liquid/vapor surface tension of the liquid. The evaporative recoil pressure generated by beam heating of the keyhole surface balances the surface tension force and keeps the keyhole open. The liquid/vapor surface area S of the fusion zone with keyhole is approximated by $S = 2\pi(R^2 - r^2 + rh)$. The change in surface area versus the keyhole radius is $dS/dr = 2\pi(h - 2r)$. The rate of change of dS/dr shifts from positive to negative when $h = 2r$. If $h > 2r$, equivalent to a relatively deep, small-diameter cavity, $dS/dr > 0$, which implies that a decrease in keyhole radius will result in a decrease in surface and hence surface energy. To preserve this keyhole, the evaporative recoil pressure must be present, or it will close up. On the other hand, if $h < 2r$, corresponding to a wider keyhole, dS/dr is negative, and the keyhole will decrease its energy by expanding, even without an

increase in recoil pressure, suggesting that it will not close up when the beam is shut off. This latter condition suggests that a lack of coalescence will occur, or that a drilling condition rather than a welding condition exists. Because only the depth-to-width ratio is critical, this stability analysis is independent of size scale.

In a previous paragraph, it was noted qualitatively that surface tension effects tend to decrease the tendency to keyhole as the size scale decreases. The aforementioned stability analysis shows in a more quantitative manner that the evaporative pressure needed to keep a keyhole open will increase inversely as the keyhole radius shrinks. The energy input/unit area of the keyhole surface will similarly need to increase to obtain a higher evaporation rate and hence recoil pressure.

Humping. When taking advantage of the high travel speeds afforded by the intense beams available from both laser and electron beam welders, the problem of weld bead surface morphology instability known as humping is likely to take place, as pictured in Fig. 1(b) (Ref 23). This is a result of rapid convective fluid flow created by the beam, together with convergent flow channels imposed by the solid/liquid (edge of fusion zone) and solid/vapor (keyhole interior surface) interfaces in the weld pool. For a given-sized weld pool, a smaller beam diameter creates a smaller keyhole, which in turn affords larger fluid channels, reducing the maximum flow velocity attained in the pool ($V \approx vd/(D - d)$, where V is the fluid flow velocity, v is the pool travel speed, and D and d are as pictured) and reducing the humping tendency, as shown in Fig. 1 (a) and (c).

Process Description

Suitable Equipment

As of this writing (2011), microjoining electron beam welders are just becoming commercially available. Most work to date has been done with converted scanning electron microscopes (SEMs), with the modifications ranging from simple substitution of the filament to a higher-current-capacity one (e.g., thoriated tungsten versus pure tungsten) and removal of the objective aperture, to actual modifications of the column, where beam-shaping apertures are modified to allow more current down the column. Small electron beam welders are commercially available, but they tend to be most useful at the less strict submillimeter definition of microscale rather than the strict sub-100 μm definition.

Minimally modified SEMs can produce ~1 W of beam power at beam diameters of ~10 μm, moderately modified SEMs can produce ~5 W at ~20 μm beam diameter, and small electron beam welders are capable of several hundred watts at ~100 μm beam diameter. The moderately modified SEMs and small electron beam welders also have much better beam and/or part motion controls, which are capable of producing actual seam welds, rather than being restricted to spot welds.

The situation with respect to laser micro-welding is much better, because the ability to produce diffraction-limited beams with sufficiently excellent optical elements and apertured beams has always been available, if expensive and inefficient. With the advent of kilowatt-power single-mode fiber lasers, obtaining diffraction-limited Gaussian beams has become almost routine, even employing conventional optics.

Fig. 1 (a) Schematic of fluid flow that encourages humping. (b) Example of a humped laser bead. (c) Velocity ratio calculated as a function of keyhole diameter, weld speed of 1 m/s (3.3 ft/s), and 40 μm thick stainless steel foil. Source: Ref 23

Spot Sizes. The optical diffraction limit and various lens aberrations set the smallest easily achievable beam diameter for visible and near-infrared wavelength lasers at $\sim 10 \mu\text{m}$ (Ref 24). In the case of electron beams, high-quality SEM or electron probe microanalysis instruments routinely focus their probe beams to a diameter $< 1 \text{ nm}$. The several-watt electron beams needed for microwelding cannot be focused as sharply as those used in electron microscopes (Ref 25); however, even for extremely sharply focused beams, electron absorption effects increase the beam/material interaction volume to a few-micrometer radius, which limits their effective minimum size, rather than the free-space focused beam diameter. Figure 2 shows a Monte Carlo calculation (Ref 26, 27) that simulates the path of electrons impinging on a solid. Thus, an effective minimum diameter of $\sim 10 \mu\text{m}$ is appropriate for electron microwelder beams as well as lasers, although this can be decreased if low accelerating voltages are used. (For comparison purposes, high-power electron beam or

multimode laser macrowelders typically employ beam diameters of ~ 0.5 to 1 mm, or 0.02 to 0.04 in., although they are capable of much smaller diameters, $< 0.1 \text{ mm}$, or 0.004 in.)

Beam Monitoring. Measurement of the beam size and current for microjoining electron beam systems is done with a Faraday cup, in the same manner as for large electron beam welders. (The Faraday cup is a standard piece of equipment for every SEM and transmission electron microscope, or TEM, as well.) The beam current is measured by directing the entire beam into the cup, and the size is measured by rastering it across either the edge of the Faraday cup aperture or across an electron-opaque element held above the cup, which may be a straight edge such as a razor blade. The time dependence of the energy reaching the cup may be used to imply the distribution of energy in the beam versus the position, although the assumption of radial symmetry is made. More sophisticated techniques involve traversing the beam in a circular path across a series of slits arranged in a radial

array. Computed tomography (CT) techniques can then be applied to reconstitute the beam-intensity distribution, without making any symmetry assumptions (Ref 28). The major difference between the micro-CT technique and the macro is that the slits used in the macrobeam technique are small with respect to the beam diameter, and this is not practical when the beam size is only 10 to 50 μm in diameter. An added differentiation of the beam energy versus time is thus required, which adds some experimental uncertainty, as does the decreased signal-to-noise levels when dealing with very small current beams.

For microlaser beams, as for the electron beam case, the techniques employed for macrolaser beams are still applicable, with some adaptation. Again, more care will be required to deal with ambient electrical noise, and more sensitive photon detectors may be required. Laser beam analysis systems with photodiode arrays of sufficient dimensional resolution are not yet available for focused beam use, so a defocused condition must be measured; however, with the advent of commercial high-resolution digital photography, higher-resolution arrays will undoubtedly become available in the near future, should demand arise. The simplest technique for macrolaser beam spot size determination—drilling a hole in a thin polymer film (typically 0.05 mm, or 0.002 in., thick Kapton polyimide, E.I. du Pont de Nemours and Company)—can be emulated at the microscale by using a thin graphite layer physically deposited onto a glass microscope slide. Fused silica may be necessary to avoid cracking of the glass if the laser beam is sufficiently energetic.

Both fiber laser and electron microbeams have excellent depth of focus. This capability will broaden the tolerance of both processes with respect to beam focus position.

Metallurgical Consequences

Effect on Cooling/Solidification Rates. The combination of fixturing needed to align and clamp microparts into intimate contact, plus the fact that melting temperatures do not scale with size, will tend to increase the temperature gradients seen by microparts during welding. This in turn will result in increased cooling rates compared to macrowelds. It is well known that rapid solidification can change the microstructures obtained when compared with those resulting from more sedate cooling rates. Examples include the changeover from ferritic to austenitic primary solidification in stainless steels (Ref 29), to more extreme cases where amorphous solids are formed rather than crystalline (Ref 30). In the case of stainless steels, the change to austenitic solidification can have negative weldability consequences relative to hot crack formation (Ref 31).

When cooling rates are increased, so are solidification rates. The ratio of gradient to

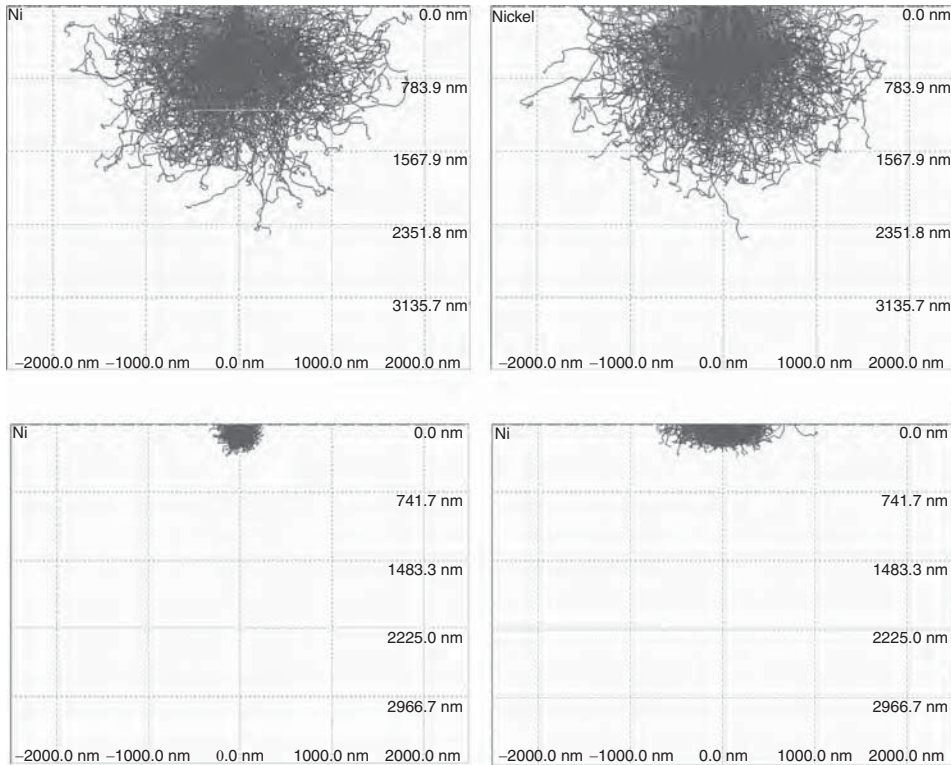

Fig. 2 Monte Carlo simulations of primary (blue, or gray in grayscale image) and backscattered (red, or black in grayscale image) electron beam paths for 30 keV (top) and 10 keV (bottom) beams of 100 nm (left) and 1 μm (right) diameter in pure nickel. Five hundred electron trajectories have been plotted. Source: Ref 26, 27

liquid/solid interface velocity, G/v , must be determined to predict whether plane front, cellular, or dendritic solidification will be favored in alloys being microwelded. Calculations (Ref 32) indicate that for both spot and seam laser microwelds, the G/v ratio decreases with size. The breakdown from a planar to a dendritic solidification interface occurs by the mechanism of constitutional undercooling, which involves solute partitioning at the interface, atomic diffusion of the solute, and convection in the molten pool. The condition for plane-front breakdown is given as $G/v < \Delta T_0/D$, where ΔT_0 is the temperature difference between the liquidus and solidus at the nominal composition of the material solidifying, and D is the diffusion rate of the alloy element in the liquid phase. For 304 stainless steel, calculations indicate that plane-front instability should be expected to occur in microwelds (Ref 33).

Because of solute partitioning between the liquid and solid, in alloy solidification a steady-state composition profile develops after an initial solidification transient, and a final transient often results in multiphase (eutectic or eutectic-like) terminal solidification. The initial transient length is given by $\delta_{tr} \sim 4D/vk$, where k is the partition coefficient (characteristic ratio of solidus to liquidus compositions over the solidification temperature interval). Using physical parameters appropriate to 304

stainless steel, the initial transient distance calculated is small, $<1 \mu\text{m}$. The terminal transient can be approximated by twice the excess composition buildup boundary layer ($\sim 4D/v$) (Ref 34) in front of a solidifying interface, $\sim 4(7.5 \times 10^{-9} \text{ m}^2/\text{s}/0.1 \text{ m/s}) = 3 \times 10^{-7} \text{ m}$, assuming a travel speed of 100 mm/s (0.3 ft/s). With faster travel speeds, the terminal transient will continue to decrease.

In cases of extremely rapid travel speed welds (several meters per second) using rastering/scanning techniques, it is conceivable to apply the absolute stability criterion posed by Mullins and Sekerka (Ref 35) and given by:

$$\lambda_i \sim 2\pi[(D\Gamma/v\Delta T_0)]^{1/2}$$

where λ_i is the critical wavelength below which perturbations will decay rather than grow because of surface energy, Γ is the Gibbs-Thomson coefficient ($= \sigma/\Delta s_f =$ surface tension/entropy of fusion per unit volume), and the other terms are as defined previously. While the value for λ_i is quite small ($\sim 0.025 \mu\text{m}$), it has been calculated that the limit will occur at solidification rates of $\sim 1 \text{ m/s}$ (3.3 ft/s) (Ref 34). At yet faster speeds, partition-less solidification may become possible. Models suggest that a velocity of $> 7.5 \text{ m/s}$ (24.6 ft/s) would be required in stainless steel alloys (Ref 36). No experimental evidence of either of these

phenomena are presently available. One speculates that the latter limit could be more easily achieved by microwelding of bulk metallic glasses, which tend to solidify to the amorphous state at more moderate cooling rates.

Diffusion-Limited Kinetics. A consequence of the extremely short dwell times/rapid cooling rates possible in microwelding is that diffusion-limited phase transformations may be suppressed, especially for those transformations that have incubation periods that are longer than the thermal cycle available. In particular, recrystallization and grain growth in the HAZ will probably not occur. If phase transformations do occur, the likelihood is that either short-range diffusion (massive) or diffusion-less (martensitic) mechanisms will be responsible.

Unmixed Zone. When etched metallographic sections of dissimilar-metal macroscale laser and electron beam welds are examined, fusion zones typically exhibit incomplete mixing as evidenced by a marbled structure. It is also very common to see dendritic solidification structures, and further, one often sees an unmixed resolidified layer at the boundary with the unmelted HAZ. The thickness of this unmixed zone varies with the welding process and is controlled by the viscosity of the fusion zone and the fluid flow conditions obtained at the solid/liquid interface. A typical thickness for this stagnant layer in a macroscopic arc weld can be on the order of a few tens of micrometers (Ref 37), that is, equivalent in size to the entire fusion zone of a microweld!

Ripples. Macro- and milliscale welds often exhibit a finely rippled (and sometimes surprisingly regular) surface topography, caused by solidification of waves of material “sloshing” back and forth due to the liquid pool resonant modes of motion. In microwelds, these effects are modified by the magnified effect of surface tension and the relative sizes of the mass and thermal diffusion distances. Smaller fusion zones have been determined to have higher resonant frequencies by several investigators.

For an object exhibiting sinusoidal motion given by $d = d_0 \sin(\omega t)$, where d is the instantaneous displacement, d_0 is the amplitude of the displacement, ω is the angular frequency ($2\pi f$, where f is frequency), and t is time, the velocity is given by the derivative of the displacement, and the acceleration (proportional to force, by way of $f = ma$) by the second derivative. The velocity is thus $v = \omega d_0 \cos(\omega t)$, and the acceleration is $a = -\omega^2 d_0 \sin(\omega t)$. The power expended is given by the product of the force and velocity, $P = -m\omega^3 d_0^2 \sin(\omega t) \cos(\omega t)$. Thus, for a given vibrational power level, P , $\omega^{3/2} d_0$ will be a constant, implying that higher-frequency vibrations will tend toward lower displacements, resulting in a less rippled surface, even without taking into account surface tension.

Surface Contamination. The most likely routes for contamination to enter a fusion zone are by way of pre-existing contaminated surfaces and gaseous contamination from inadequate shielding by inert gas or insufficient

vacuum. The latter will tend to be proportional to the instantaneous melted surface area exposed (contamination by adsorption of the HAZ and diffusion into the fusion zone may also occur but will be neglected). In a lap weld completely across two thin sheets of total thickness t , the surface area melted by a completely penetrated weld of uniform width w and length l is given by $A = 4lw + 2tw$. The volume of the weld is given by $V = ltw$. The surface-to-volume ratio is thus given by $A/V = (4lw + 2tw)/ltw$. Assuming that the length of the weld is greater than either the thickness or width, $A/V \sim 4lw/ltw = 4/t$. Thus, the surface-to-volume ratio will be inversely proportional to the weld thickness.

A form of self-contamination may occur from redeposition of vapors created by the high-intensity beam. In macrowelds, this layer is often removed with an alcohol swab; however, this will not be possible with microparts. Avoidance of keyhole formation may be necessary, and this will restrict the maximum power that may be employed. Indeed, given this restriction, the heat sinking applied by part fixturing may need to be carefully evaluated, or the acceptable window of power/travel speed may become quite small.

In addition to the development of pre- and postweld cleaning techniques, there will be an equal need to keep cleaned parts free from recontamination before (and after) welding. This will require attention to packaging and transport containers and processes. Laminar-flow clean benches or rooms will probably be necessary, as will be suitable training of personnel to use only clean utensils to handle microparts.

Fixturing and Process Controls

Fixtures. To produce reproducible microwelds, extreme emphasis must be placed on suitable fixturing. The two-dimensional nature of most microwelds implies that the thermal fields are laterally much more extensive than those typical of three-dimensional welds; thus, the relative length of material that may expand due to thermal effects is greater than for typical macrowelds. Furthermore, thin sheet materials are extremely sensitive to buckling when placed in compression; thus, the macroscopic tendency to clamp everything securely in place may not be sufficient to ensure a good microweld. It is already clear from pioneering work in Germany (Ref 38–40) that butt welds are extremely difficult to achieve, and lap, fillet, and edge welds will be much more practical. Such geometries inherently allow for some slippage of one part face-to-face with the other, reducing buckling tendencies. Similarly, cross-wire welds are more practical than in-line welds. Investigators have found that it is desirable to incorporate spring-loaded restraints, which allow for some motion of the parts being welded while keeping them in good thermal

contact. One advantage of laser welding over electron beam welding is that photon-transparent materials exist that may be used to physically clamp together the two parts being welded, while the laser beam is transmitted through the clamp material to the joint location. Fused silica has been successfully used as such a clamp (Ref 41).

Unfortunately, fixturing necessary to restrain parts and maintain intimate contact between them also impacts the thermal field and acts as a severe heat sink. Calculations show that such heat sinks may increase the heat-input requirement manyfold over that needed to just melt the materials of interest (Ref 18). Conversely, if no heat sinking is present, it may be very easy to overheat the parts being joined, because thermal diffusion to nearby boundaries does not take long for microscale parts (Ref 18). Methods of ensuring reproducible thermal contact will need to be developed.

Finally, for very small parts, it may become useful to employ heat-flow calculations that take into account the wave nature of heat flow, rather than the usual Fourier conduction equation (Ref 42).

Parameter Control Requirements. Another important factor in reproducible microwelds will be in precisely controlling the beam energy, travel speed, travel path, beam focus (spot size), and any pulsing or modulation applied to the beam.

Closed-loop process controls will need to employ high-bandwidth methods, because the characteristic times for microjoining processes will be quite short. Because it is likely that beam rastering will be employed rather than part motion, techniques to evaluate and correct pincushion/barrel distortion and astigmatism, when the beam is rapidly bent through large angles, will need to be instituted.

Another reason to employ closed-loop controls of beam energy is that heat sinking to part fixtures is generally not very reproducible and can have a major effect on the thermal history of the parts being welded. Electron beam microjoining may have an advantage over laser, simply because the feedback control methods will probably employ visual recognition techniques, and good imaging is inherent with the electron beam microprocess.

Beam Scanning versus Part Motion. One of the problems with microwelding is that, compared with photolithographic chemical methods used for microchip production (or even processes such as vapor-phase reflow soldering), it tends to be a serial process with relatively low productivity. The ability to rapidly scan/raster the beam offers at least a partial parallel processing option. It is possible to move both laser and electron beams with great rapidity (both are essentially momentum-less) and excellent reproducibility. Examples of such applications abound in the entertainment industry. Cathode ray tube devices have been around for many decades, and the ability to project rapidly changing images by way of micromirror

arrays is also a well-developed technology. Existing laser scanners generally employ dual-perpendicular-axis galvo-driven mirrors to provide beam scanning across an area, but because these are relatively high-momentum devices, they will no doubt give way to microelectromechanical systems (MEMS) or entirely solid-state methods in the future. Some examples of rapid-scan scenarios are given in a later section.

For the electron beam microwelder, the accelerating voltage can be readily controlled. This affords the possibility of controlling the relative penetration of the electrons and, consequently, the distribution of heat in extremely thin workpieces. When welding extremely thin materials in a lap weld configuration, if the penetration can be controlled to provide heating of both layers rather than just the top layer, improved coalescence may be promoted. Calculations (Ref 43) show that this effect is feasible with accelerating voltages in the range of 10 to 40 keV. The thickness where this effect operates ranges from just a few micrometers for nickel to $\sim 10 \mu\text{m}$ for silicon.

Postweld Metrology/Inspection

Visualizing and Measuring Microwelds. Microwelds can be difficult to see, let alone examine for conformance with requirements, simply because of their diminutive size. After all, $10 \mu\text{m}$ is only approximately 3 times the diameter of a human hair. For this reason, electron beam microwelding has a distinct advantage over laser microwelding, simply because SEM-like capability can be easily integrated into the welding system (assuming the welder is not a converted SEM to begin with). Otherwise, high-quality light optical or separate SEMs will be needed. Metrological calibration of such scopes will be needed to verify correct sizes. (Calibration of digitally-reconstituted images with high depth of field is still an active area of development as of this writing in 2011.)

Nondestructive Evaluation Micro-methods. Other nondestructive examination approaches similar to those employed for maintaining the quality control of microcircuits and MEMS devices are plausible. These could include hermeticity testing (although microvolumes being tested will need careful consideration of fine/gross leak testing time windows and care to not overpressurize and collapse them), ultrasonic probing (immersion C-mode scanning acoustic microscopy), and, of course, functional testing.

Handling. A remarkable feature of micropart handling is that it is sometimes difficult to release them once they have been picked up, due to residual magnetic, electrostatic, or stiction forces. Thus, handling tools will need to be provided that are capable of precise motion and positive, yet gentle holding, followed by an equally positive release. Alternatively, it may be necessary to hand off the parts from the manipulation tool to an active holding

device in the part holder. “Sticky” surfaces may suffice for part holders, but they must avoid transfer of deleterious contamination to clean surfaces to be welded.

Techniques and Applications

In the following section, examples of developmental welds employing laser and electron beam microwelding techniques are described.

Stationary Beam/Moving Workpieces

Moving the parts to be welded under a stationary beam is the conventional way in which laser and electron beam welds have been made. (Slight motion of the beam about its mean position, as in a circle, bar, or other geometrical shape pattern-generation positional modulation schemes, is allowed within this classification.)

The following examples of electron beam microspot and seam welds were accomplished with a moderately modified SEM (Ref 39). Another example, shown in Fig. 3, shows laser microwelding of stainless steel foil with a high-brightness fiber laser of moderate power. Thin stainless steel foils that ranged in thickness from 10 to 30 μm were welded successfully with 25 W at a travel speed of 1 m/s (3.3 ft/s). The beam was focused to $\sim 10 \mu\text{m}$ diameter (Ref 44, 45).

Particularly noted by the authors was that, while contact between the foils was needed to ensure coalescence of the two foils (Fig. 3b shows decoalescence when a gap is present and also shows humping in the top view of the two foils after disassembly, third panel from the left), heroic fixturing was not needed, because the condition for $dS/dr > 0$ was obtained.

Rapid Beam Rastering/Scanning

An alternative approach to holding the beam stationary while moving the workpieces is to reverse the roles. Both laser beams and electron beams are directed sources of energy and can be readily and rapidly steered by mirrors or magnetic lenses. Figure 4 shows schematically how a rapidly rastered electron beam (up to 800 m/s, or 2625 ft/s) can provide both productivity and quality enhancements (Ref 46). The two left figures schematically illustrate making multiple welds essentially simultaneously to

Fig. 3 Single-mode fiber laser lap welds in stainless steel foils of 10, 20, and 30 μm thicknesses. Source: Ref 44, 45

improve productivity. The right figure shows a gear being welded to a shaft with three simultaneous spots trisecting the weld circle, to simultaneously reduce distortion and improve productivity.

Figure 5 shows the results of combining either a local rotation or a transverse excursion with a larger circular travel path on a 30 μm foil of grade 1.4301 material (equivalent to grade 304 stainless steel) (Ref 46), a technique often used with electron beam macrowelders to reduce root spiking and surface roughness. In this case, the alternating step-function transverse excursion simulated generating three concentric traces, rather than just acting to broaden the beam. These bead-on-foil melt runs took several seconds and correspond to many retraces of the travel path, except for the trial on the far left, which corresponds to a conventional procedure where the heat source is localized and traces the weld path once, albeit with circular beam “weaving.” The second column of panels keeps the same relative speed of the two motions (100 to 1) but increases the overall rate tenfold, thus tracing the circle 10 times. The middle column takes a different approach, where the weaving is much slower than the large-diameter circular path travel speed ($\sim 1.6 \text{ m/s}$, or 5.2 ft/s), effectively presenting a 0.5 mm (0.02 in.) narrow circular heat source that is slowly changing its overall diameter. The next two columns adjust the ratio of the motions, with the fourth column slowing the circular path travel speed to 160 mm/s (0.5 ft/s) while increasing the diameter change rate tenfold, while the fifth column returns to the 1.6 m/s (5.2 ft/s) path velocity but increases the weave frequency in a manner to approximate a circular heat source but with significant width. The oscilloscope traces, taken at a constant beam persistence, show the temporal behavior of the beam for a time period of $\sim 30 \text{ ms}$. Highly retraced fusion pathways appear to accentuate grain-boundary grooving of the fused area and may not be useful.

Laser Spike Welding

Laser spike welding (Ref 47) is an attempt to deal with the difficulty of ensuring intimate contact in lap welds. In this technique, the initial laser power setting creates, by way of conduction-mode heating, a fully penetrated fusion zone in the upper layer; then, its power

is increased to a level that generates sufficient recoil force to drive the diaphragm-like pool into contact with the bottom layer. This recoil-force-driven contact must last for sufficient time for the upper pool to adhere to the bottom layer, either by causing superficial surface melting or by way of a brazelike adhesive bond. While the gap that may be bridged is only limited by the ability of the upper pool to extend without becoming unstable, the technique is limited by the bondability of the lower layer. If, for example, the lower layer is highly conductive, it may be difficult to heat it sufficiently to cause bonding via either melting or adhesion. Certainly, for the second mechanism, surface cleanliness will be critical. If the brazelike bonding approach can be made to work, this technique may be useful for joints between incompatible (intermetallic-compound-forming) dissimilar-metal pairs.

An example of the technique successfully applied to 250 μm thick X8CrNi1812 stainless steel foils is shown in Fig. 6. Gaps of up to 100% of the individual foil thickness were successfully bridged. With large gaps, the conical depression of the top surface may become objectionable; if so, a second cosmetic pass can be applied.

While developed as a spot welding technique, the approach may conceivably be applied to generate overlapping spot seam welds. The pulse profile duration of $\sim 20 \text{ ms}$ is not excessively long, so productivity should not suffer.

Because of the nonstandard pulse profile, which incorporates a delayed power spike, a laser with flexibly programmable pulse profiles will be required.

While not reported, an electron beam version of this technique should also be possible.

SHADOW Technique

SHADOW welding refers to a stepless, high-speed, accurate, and discrete one-pulse welding technique (Ref 48) that was developed to adapt laser macrowelding machines to the microweld. In this technique, a single pulse from a pulsed welding laser is translated rapidly along the parting surface of the parts to be joined, in effect tracing the entire weld seam path during the single pulse. Pulses retracing

Fig. 4 Rapid beam rastering for productivity and quality improvement

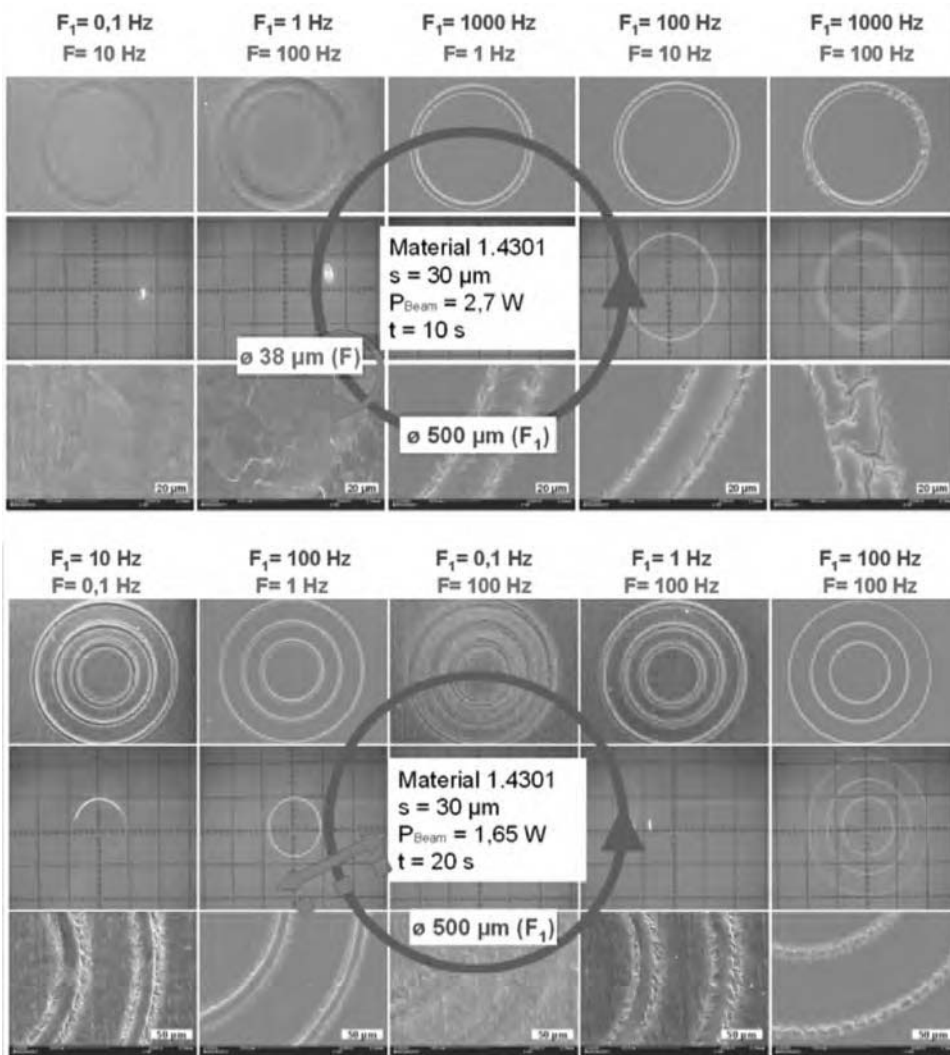

Fig. 5 Effect of relative frequency of modulation for circular (top) and alternating sign step-function bar-type (bottom) beam positional modulation relative to the overall path. Source: 46

the original pulse may also be added subsequently, perhaps using less power to stress relieve or heat treat the weld zone. Either the beam or the parts to be joined may be translated. For welds with circular symmetry, spinning the workpieces at a sufficient rotational speed is easy, although if the weld path is not circular, a galvo-directed beam scanner will be necessary. An early example of the technique in the production of mechanical time-piece parts is shown in Fig. 7. Advantages to the SHADOW technique over ordinary pulsed neodymium: yttrium-aluminum-garnet laser welding include a significant reduction in heat input (the rapid travel speed and single pulse have much higher melting efficiency than an overlapping pulse seam weld), less vapor re-deposition on the part, a smooth, ripple-free weld surface, and less angular distortion of the shaft, because the weld solidifies more or less simultaneously around the circumference, balancing the residual stresses.

Another example of the SHADOW technique in the production of miniature ball bearings is shown in Fig. 8.

In both of these examples, the laser beam was scanned on the part. In the example in Fig. 9, the part was rapidly rotated under the laser beam. The SEM image shows the exceptional weld surface smoothness achievable with this technique. The continuous seam also was found to aid in avoiding cracking by the high-strength steel pins used to pin the disks together.

Laser Droplet Welding

One of the major difficulties associated with microjoining is the inability to add filler material in a convenient manner. Generally, the only way to add filler is to incorporate a preplaced shim into the joint, and this is highly inconvenient when the parts are very small to start with. Thus, metallurgical incompatibilities that can

be solved with the addition of the appropriate filler prevent dissimilar pairings that are of industrial interest and importance. Laser droplet welding (Ref 51–54) is an approach that allows controlled addition of filler metal to micro-joints. Laser droplet welding has some similarities to laser spike welding described earlier. The process is described schematically in Fig. 10. An initial low laser power, P1, creates a molten droplet at the tip of an advancing wire. After a brief period of even lower power, P2, during which the droplet translates across the multilaser beam focus point, a high-power pulse, P3, vaporizes the wire behind the droplet, detaching and propelling the droplet by vapor-recoil force across a gap to the target location, where the droplet wets, spreads, and resolidifies. An example where droplets of pure nickel are used to join thin sheets of stainless steel is shown in Fig. 11, and an example where silver droplets are used to join a silver foil onto a silver-coated silicon substrate is shown in Fig. 12.

Electron Beam Microwelding Fixtures

Many issues of both fixturing and weld parameter choices are still to be resolved for microjoining. Research is being actively pursued to determine whether rapid beam rastering relative to a single microweld (e.g., breaking the beam path into segments and retracing the entire path rapidly, as in Fig. 5, etc.) may affect its development and reproducibility.

If beam microwelding processes are to successfully evolve from the development laboratory to the production floor, it is clear that much work remains. Some partial solutions to fixturing issues are given in examples in Ref 38 that are representative of electron beam microwelding scenarios (and they would be expected to be of equal use for laser microwelding). These examples were accomplished with a modified SEM capable of providing up to 6 W of power in a beam of $\sim 20 \mu\text{m}$ diameter.

One example describes fixturing for an in-line wire weld. As previously noted, cross-wire welds of small-diameter wires are much easier to accomplish than in-line geometry. However, when such an in-line geometry is necessary, it has been found useful to hold the wires together under a moderate axial pressure provided by spring loading of the clamping fixture (Ref 38). In the case of fillet seam welds, similar concerns with consistent thermal contact and foil buckling due to beam heating must also be addressed. It has been found useful to apply a lateral tensile preload to the substrate foil when fillet welding two foils together (Ref 38).

Attempts at making butt welds have been successful (Ref 38) with fixtures that employ an aluminum substrate support plate, a spring-loaded cover plate, and lateral spring-loaded clamps butting the two workpieces together. Thus, the adjustable fixturing restrains the workpieces against both in-plane

and out-of-plane motion, as well as provides thermal heat sinking.

Future Trends

In the previous sections, it has mostly been assumed that the beam microwelding processes are used as heat sources for autogenous welds. However, it is also possible that either the laser beam or the electron beam can be used to cause deposition of material from a vapor cloud directed in the vicinity of the gap to be joined (a quite rarefied cloud in the case of the nonlaser techniques). These techniques, laser-enhanced chemical vapor deposition and focused electron beam deposition by “cracking” of organometallic gases, have been demonstrated to effect repairs in microelectronic circuits (Ref 56).

Furthermore, the possibility of using ions, in addition to electrons and photons, also exists. (Ions are more effective at cracking the organometallic gases employed, although they alloy into the material deposited.) Focused ion beam (FIB) and focused electron beam (FEB) instruments available to the analytical community are being used regularly to cut and manipulate thin foils for examination by TEM instruments (Ref 57). As part of this technique, the FIB is used to cut thin specimens that are still attached by a narrow bridge of material, then a manipulation wand is spot welded to the foil by the FIB or FEB technique, and finally the thin bridges are cut away. Other investigators have shown that this technique can be used to create shapes and bonds in other geometries (Ref 58). The downside to the FIB/FEB technique is that it provides a very low deposition rate, and it can be difficult to bridge relatively wide gaps. Nevertheless, because the beams used can be very low current, they retain their extremely small-diameter focusing capability, such that nanometer-sized structures can be created. An example of such a deposit used to seal over etch holes left in a MEMS device is given in Fig. 13 (Ref 46).

As a concluding note, the difficulty of handling microparts has been noted repeatedly. It is interesting to speculate that processes such as laser shaping (and its electron beam analog) may be used to fold portions of lithographically-produced foil structures into proper alignment, which would then be welded together and finally cut away from the substrate to yield a final composite structure without ever having been handled, other than by the processing beam (Ref 59).

Procedure Development and Practice Considerations for Inertia and Direct-Drive Rotary Friction Welding*

Revised by Tim Stotler, Edison Welding Institute

ROTARY FRICTION WELDING is a solid-state welding process that uses the compressive force of the workpieces that are rotating or moving relative to one another, producing heat and plastically displacing material from the faying surfaces, thereby creating a weld. Process variations include inertia, direct-drive, linear, and radial friction welding, as well as friction surfacing. This article provides information about practice considerations for the two most common variations: inertia and direct-drive friction welding.

Inertia welding obtains the heat needed for welding from stored rotational kinetic energy. Figure 1 depicts the parameter characteristics of the process. The inertia of the system is changed by either adding or removing flywheels from the rotating spindle that provides rotary motion and/or by changing the spindle speed.

After the inertial mass is set, the parts are loaded in the machine (one in the spindle and one in the fixture/tailstock). The spindle speed and welding forces are set to predetermined levels. The spindle is then accelerated to the set speed. After this speed is attained, the drive system is disengaged, allowing the flywheel (and the part in the spindle) to effectively coast. The stationary part is then brought into contact with the rotating part, under a preset applied force, causing frictional heating to begin. The flywheel is stopped by the transition of its kinetic energy into thermal energy (frictional heating) at the welding interface. This energy heats the part and allows forging to occur, displacing material at the interface. A second-stage force can also be used with inertia welding. This force is often referred to as an upset force and can be programmed to occur at any

point in the deceleration of the spindle speed or after the spindle has stopped.

Direct-drive friction welding differs from inertia welding, primarily in how the energy is delivered to the joint. Figure 2 depicts the characteristics of this process. Direct-drive friction welding, like inertia welding, has one of the parts loaded into a rotating spindle while the other is held stationary. However, the spindle has a fixed mass. To start the process, the spindle is set into motion at a constant speed. The

parts are then brought into contact under a low force (termed first friction force, or preheat force) and allowed to heat for a preset time or distance. In most applications, a higher welding force (termed second friction force, or welding force) is then applied, which increases the rate and amount of material extruded from the joint. The second friction force is also controlled through a preset time or distance. After the preset time or distance has been reached for the first two friction stages, the rotating spindle is

Fig. 1 Inertia welding parameter characteristics. Source: ANSI/AWS C6.1-89

* Revised from T. Stotler, Procedure Development and Practice Considerations for Inertia and Direct-Drive Friction Welding, *Welding, Brazing and Soldering*, Vol 6, ASM Handbook, ASM International, 1993, p 888-892

Fig. 2 Direct-drive friction welding parameter characteristics. Source: ANSI/AWS C6.1-89

brought to a stop using some type of braking mechanism. Braking is typically done via mechanical means (caliper-type brake) and/or an electric-type brake in the spindle drive motor. In most cases, a third increase in the welding force (usually referred to as the upset force) is applied at the start of or after braking has completed. This upset force acts to consolidate the joint. In contrast to inertia welding, where the microstructure at the interface reflects a rotational-type forging, direct-drive friction welding produces an axially forged microstructure in the weld. However, if braking times are increased, allowing the upset force to be applied while the spindle may still be rotating, some rotational-type forging can be obtained.

All friction welding processes induce a torque into the parts to be welded. This reaction torque induces work into the microstructure at the weld area and often has a distinct benefit to the strength of the joint. Typically, two torque peaks are induced on the workpiece: an initial peak when the parts are first brought into contact, and a final peak when the spindle decelerates to a stop. The first peak is related to developing a steady-state thermomechanical condition at the bondline. The final torque peak is associated with mechanical work as the part begins to cool. For inertia welds, this final torque peak induces a twisting-type feature to the microstructure that effectively refines the structure. For direct-drive friction welds, there is less of a twisting action to the microstructure. The level of this final torque peak is directly related to the rotating inertia of the spindle and the applied forces as the spindle decelerates. As a result, the final torque peak is

typically higher, and related refinements in microstructures are more commonly associated with inertia welding. Conversely, direct-drive systems typically both brake the spindle (removing energy from the system) and apply an upset force after the spindle has nominally stopped. As a result, the final torque peak is reduced compared to inertia welding. This lower final torque peak behavior often produces a microstructure that is more similar to that of a forged part, with little twisting to the structure.

While this second torque peak can be advantageous for improving local microstructures, a reduction in these values can be beneficial in certain applications. Such applications include those where the workpieces themselves are susceptible to damage with higher torque loads. For example, a thin-walled tube may buckle under a high final torque peak. Selection of a specific variant of friction welding, and the processing conditions used, must be based on the desired application, including component materials and resultant stiffness.

Tooling

Part of defining a set of welding parameters and then qualifying a procedure is careful consideration to the tooling design. Tooling includes all the items needed to safely counter the welding forces and torque loads imposed on the part, as well as the tooling needed to provide proper alignment between the parts to be welded. Misalignment of the two parts to be welded, caused by poor tooling design, is often found to be the cause of most friction weld defects. Misalignment of a tube-to-tube joint

can cause a reduction in the effective weld area. Tooling that is not sufficient to react the welding force(s) can prevent the weldment from reaching the desired level of force, also leading to a reduction in weld properties.

Tooling also refers to the items considered as consumables, although these items have very long lives. Tooling that makes contact with the parts to be welded has a finite life due to wear as the parts are loaded and unloaded from the machine. An environment where the volume of welds to be made causes the tooling to retain heat from part to part can also cause wear. Each particular joint design and welding rate will determine the frequency at which the tooling must be replaced. However, the frequency at which tooling changes occur should not be high enough to adversely affect the cost of the process. Wear of the tooling that contacts the part can also cause misalignment or other defects.

Procedure Qualifications

The following sections on welding parameter design and welding of different material family classes is intended to provide a baseline for initial development of a welding parameter set. Once a parameter set has been developed, along with the other necessary tooling and preweld and postweld processing needs related to the friction welding process, a welding procedure specification (WPS) is developed. American Welding Society (AWS) Document C6.2, "Specifications for Friction Welding of Metals," provides a guideline for development of a WPS. Included are guidelines for the three classes of welds and the type of testing necessary. Testing methods are also typically covered by AWS B4.0, "Standard Methods for Testing of Welds," unless otherwise indicated by the design needs of the weldment.

As part of the WPS, a process robustness testing procedure is also conducted. The process robustness defines the tolerance of the process to manufacturing variability that often occurs. Items included in the robustness definition could be each of the welding process variables, misalignment of the parts, part cleanliness, tooling wear, and so on. The levels at which each variable is tested are usually selected at the extreme upper and lower ends of each variable or at levels considered to be the allowable engineering design limits.

Welding Parameters

Inertia Welding Parameter Design. Differences in part geometry (bar-to-bar, tube-to-tube, bar-to-plate, and so on) affect the welding parameters. The calculation procedures described here are based on carbon steel. For a given alloy system, inertia welding spindle speeds are set within a specified range of surface velocities. Surface velocities for welding

carbon steels in all geometries typically range from 90 to 610 m/min (300 to 2000 ft/min). The actual spindle speed (rev/min) is calculated by:

$$\text{rev/min} = \frac{\chi S}{\pi \text{OD}} \tag{Eq 1}$$

where χ , the conversion factor, is 12 for the U.S. customary unit and 1000 for the metric SI unit, S is the surface velocity (m/min or ft/min), and OD is the outside diameter of the part (mm or in.).

For solid bars and a fixed welding force, lower surface velocities tend to reduce center heating. Center heating is not an issue for tube-type geometries, meaning there is greater flexibility in the surface velocities used. The effect of surface velocity on the heat pattern in a solid bar is shown in Fig. 3.

As mentioned previously, rotating flywheels are the source of energy for the inertia welding process. During the friction welding force stage where spindle deceleration occurs (Fig. 1), the process is characterized by a loss of material from the interface to the flash. Larger inertias prolong the welding cycle. The calculation of the flywheel energy that is needed to produce a weld depends on the surface velocity, material type, and joint geometry. As shown in Table 1 for a solid bar of low-carbon steel, the moment of inertia (expressed as wK^2 in mass units) is $0.18 \text{ kg} \cdot \text{m}^2$ ($4.2 \text{ lb} \cdot \text{ft}^2$). This is found by using Eq 2 and the approximate flywheel energy (E_T) of $63 \text{ N} \cdot \text{m/mm}^2$ ($30,000 \text{ ft} \cdot \text{lbf}$

in.²) for the inertia welding of low-carbon steels:

$$wK^2 = \frac{E_T C}{(\text{rev/min})^2} \tag{Eq 2}$$

where the value of C is 5873 for the U.S. customary unit and 182.4 for the SI unit, E_T is the total flywheel energy, and the (rev/min)² value is that for the spindle, which was calculated in Eq 1.

As mentioned previously, inertia welding has flexibility in how the welding force can be applied. Typically, a single force is used, but a second-stage force can be implemented (Fig. 1). The typical pressures for welding carbon steels range from 96.5 to 207 MPa (14 to 30 ksi). The second-stage force (forging force), which can vary from 1.5 to nearly 4 times the welding force, is usually determined through experimentation. The effect of the welding force on the size of the heat-affected zone is inverse to that of surface velocity. That is, welds made at low welding forces have heat-affected areas resembling those produced with high surface velocities (Fig. 3).

When designing an initial set of inertia welding parameters, the normal order of selection can be summarized as:

- Choose the desired spindle speed (rev/min)
- Calculate the total moment of inertia (wK^2) that is needed for the required energy level, E_T
- Choose the nearest available total moment of inertia (wK^2) level on the welding machine

- Recalculate the necessary spindle speed using the selected total moment of inertia (wK^2) that is available on the machine
- Calculate the necessary welding force (and upset force, if used)

Direct-Drive Friction Welding Parameter Calculations.

Similar to inertia welding, the same equation (Eq 1) is used for calculating the spindle rev/min value. Surface velocities for the direct-drive friction welding of carbon steels range from 76 to 182 m/min (250 to 600 ft/min), with tube joints requiring slightly higher surface velocities than joints using bars. Typical welding pressure values for carbon steels range from 83 to 166 MPa (12 to 24 ksi) for the second friction force and from 166 to 332 MPa (24 to 48 ksi) for the upset force. Although first friction forces vary, they are typically 10 to 20% of the second friction force. Examples of welding parameters for bar-to-bar and tube-to-tube direct-drive welds are shown in Table 2.

Table 1 Typical inertia welding conditions for low-carbon steel

Parameter	Value
Bar-to-bar	
Diameter, mm (in.)	25.4 (1)
Weld area, mm ² (in. ²)	506 (0.78)
Total moment of inertia, wK^2 , kg · m ² (lb · ft ²)	0.18 (4.2)

Steels

Carbon Steels. Generally, most metals that can be hot forged can readily be friction welded with either process variant. Carbon steels, which fall into this category, have been the fundamental basis of welding-parameter calculations for both inertia and direct-drive friction welding. Low- and medium-carbon steels are the easiest to weld and generally require no postweld heat treatments. Higher-carbon and alloyed steels can also be joined; however, a narrower welding-parameter window is often evident than for low-carbon steels. This is primarily due to the reduced forging characteristics of the higher-carbon steels. Steels that contain significant amounts of free-machining elements, such as lead, also can be friction welded. However, these free-machining elements can cause undesirable directional properties near the bondline and may also act as dry lubricants that reduce frictional heating. Heat treatable steels also can be friction welded. The rapid quenching of the weld area can present hardenability concerns, and a subsequent tempering or annealing procedure may be required. Hardenable steels such as these should be welded with parameters that increase the welding time in order to reduce the cooling rate.

Stainless steels are also commonly joined using either friction welding process. Austenitic and ferritic stainless steels are easily joined to each other and to themselves. Because the heat treatable stainless steels are sensitive to temperature and pressure, a postweld thermal treatment may be necessary to achieve the desired weld properties. Precipitation-hardenable stainless steels are often solution heat treated and aged after welding.

Welding parameters for stainless steels are similar to those used with carbon steels. Surface velocities for both bars and tubes fall within the same range as for carbon steels for both process variants. The flywheel energies, E_T , and welding forces for the inertia welding of stainless steels are typically 30 to 50% higher than those for carbon steels. The welding forces for both process variants are often 30 to 40% higher. Another factor relevant to the friction welding of stainless steel is the location of the weld when subjected to a corrosive environment. If possible, it should be located outside of the corrosive environment. In some instances, an increased corrosion rate occurs near the weld.

Nonferrous

Aluminum-Base Alloys. Aluminum alloys are commonly joined by friction welding. For inertia welding, rotational forging will form flow lines with radial patterns, as opposed to the straight flow patterns produced with direct-drive friction welding or flash welding. An advantage for direct-drive friction welding is that thin-walled aluminum tubes are somewhat easier to join. This result is from the ability to stop the rotation of the spindle before a forge force is applied, effectively reducing the final

torque peak. Because severe hot working of the two materials will occur, the heat-affected regions of aluminum friction welds are very narrow and have a fine-grained structure. In addition, the severe hot working leads to dynamic recrystallization at the interface.

Parameters for the inertia welding of aluminum alloys differ somewhat from those used for carbon steel. The differences are due to the higher thermal conductivity of these materials. The surface velocities used for welding aluminum alloys are approximately 30 to 50% higher than those used for carbon steel. Pressures for inertia welding are significantly lower than they are for carbon steels, ranging from 20 to 50% of those used for a similar-sized carbon steel part. The flywheel energy is from 20 to 50% of that for carbon steel. For direct-drive friction welding, the surface velocities are 10 to 50% higher than they are for carbon steel, depending on the type of aluminum alloy. Welding and upset pressures are typically 30 to 50% of those used for carbon steel.

Reactive and Refractory Metals. Of these classes of materials, the titanium alloys have been joined by friction welding the most frequently. For the inertia welding process, titanium alloys have flywheel energies that are similar to or slightly lower than those of steel. Surface velocities are typically at the higher end of the carbon steel scale, ranging from values that are equivalent to those used for carbon steel to values that are 40% greater. However, welding forces are lower, typically ranging from 30 to 40% of those used for welding carbon steel. This difference is attributed primarily to the lower thermal conductivity of titanium.

Work has been done using direct-drive friction welding for titanium, although to a lesser degree than inertia welding. The welding parameters for the direct-drive friction welding of titanium are similar to those of steel, with a slight reduction in the welding forces. Most friction-welded joints in titanium can be used in the as-welded condition. However, somewhat better tensile and fatigue properties are obtained if stress relieving or solution annealing and aging procedures are used.

Zirconium has properties that are very similar to those of titanium. Therefore, initial welding parameters should be based on the parameters for titanium.

Both friction welding processes can be used to join molybdenum and tungsten. Current applications include the friction welding of molybdenum and tungsten wires in drawing operations for the lighting industry. There is not a significant amount of friction welding information available for niobium and tantalum; however, it is expected that these alloys can be successfully welded.

Copper-, Nickel-, and Cobalt-Base Materials. Copper- and nickel-base alloys are commonly friction welded. Copper alloys are also typically used in a dissimilar-metal welding application with aluminum. For inertia welding, surface velocities are nearly twice those of carbon steel, because of the high thermal conductivity of

copper. Flywheel energies and welding forces are approximately 50% of those used for carbon steel.

For direct-drive friction welding, higher surface velocities would be required for copper, given its high thermal conductivity. Welding forces would also be lower, as they are for inertia welding.

Nickel-base alloys are routinely joined using the inertia welding process, specifically in the aerospace industry. Surface velocities are lower than those of steel, typically no higher than 50% of that for carbon steel. However, because of increased elevated-temperature properties, flywheel energies and welding forces are nearly double those required for carbon steels. After inertia welding, the joint in heat treatable nickel-base alloys is often subjected to a solution and aging treatment. This is needed to precipitate second-phase particles (that is, γ' and γ'') that have been taken back into solution by the thermal cycle of the weld.

For direct-drive friction welding, the surface velocities are approximately half those used for carbon steel, whereas welding forces are nearly double those used for carbon steel. The welding procedures for cobalt-base alloys are similar to those for nickel-base alloys.

Dissimilar Metals

In terms of process requirements for inertia or direct-drive friction welding of dissimilar-material combinations, the welding parameters typically tend to be closer to those used for the higher-strength material in the dissimilar combination. This results in a larger amount of upset from the lower-strength material. The higher-strength material may have little or no upset. As in any other joining process, the strength of the bond can be no higher than that of the lower-strength material. The combinations of metals that have been joined using the friction welding processes are shown in Fig. 4. Other combinations may be possible, with additional procedure development.

Two of the most common dissimilar joints produced using the friction welding processes are:

- Copper to aluminum
- Aluminum to steel or stainless steel

In such applications, some surface preparation may be required prior to joining. This preparation is to clean the surface just before welding and/or to prepare the interface with a specific joint geometry. In most cases where aluminum is used in a joint, a dry machining or chemical etching of the aluminum is preferred. As mentioned previously, a majority of the forging (material loss) will occur in the aluminum.

The joining of aluminum to ceramics can be done with friction welding. Steel has also been attached to ceramics using an aluminum interlayer. This is performed by first welding the steel to the aluminum, followed by welding the bimetal joint to the ceramic. Using an interlayer for applications such as this is common

Fig. 4 Material combinations that are weldable by friction welding processes. List of alloys was compiled from available friction welding literature. Source: ANSI/AWS C6.1-89

when two incompatible materials are to be joined. The interlayer material must be selected on the basis of its ability to be forged and its compatibility with the two parent materials.

Process Monitoring and Control of Rotary Friction Welding

Daniel A. Hartman, Manufacturing Behavioral Science
Thomas J. Lienert, Los Alamos National Laboratory

THERE ARE A VARIETY of friction welding processes. Usually, they are characterized by the type of relative motion that is applied between the two components, including radial, orbital, angular reciprocating, linear reciprocating, or rotary. Two important variations of friction welding are friction surfacing and friction stir welding. These processes are sufficiently different from other traditional friction welding variants, that is, where two parts are rubbed together to achieve coalescence, and therefore are not discussed in this article. The most common method of friction welding uses rotary motion, in which one axially symmetric component, a stud, tube, or bar, is rotated with respect to a stationary component. Upon reaching a setpoint speed, the parts are brought together under pressure.

For a very short period after contact of the two parts, relative motion is accommodated by rubbing friction, which in turn causes heat generation. However, seizure occurs almost immediately at a radial position of 1/2 to 2/3 of the sample radius. In the seized region, relative motion is locally accommodated by high-strain-rate viscoplastic deformation of the material. This process results in the formation of a volume of deforming material shaped like a flat ring surrounding the seized region (Ref 1), and heat generation in this volume is then driven by viscoplastic deformation at high strain rates. At the time of initial seizure and formation of the deforming volume of material, rubbing of the interface continues for regions outside of the ring of material undergoing deformation. Subsequently, the ring of deforming material spreads radially inward and outward until the entire interface is replaced by a volume of deforming material (Ref 1). After this time, identification of a distinct interface between the two parts is not possible. If sufficient amounts of heat and pressure are applied, then the components will be forge-welded together by the time motion is arrested.

There are many advantages of friction welding as a production method. Generally speaking, friction welding is a highly robust and repeatable process. The process is capable of producing consistently identical welds and tolerates minor dimensional irregularities in the faying surfaces. The process parameters are easily controlled and well suited for automation and mass production. Welding cycles are measured in seconds as

compared to minutes for other more conventional methods, such as fusion welding. Because friction welding is a solid-state process, it is generally free from defects associated with solidification phenomena, including gas porosity and segregation. Filler metals, fluxes, and shielding gas are not required, which greatly simplifies the process. Finally, unlike fusion welding processes, friction welding is generally amenable to joining dissimilar metals.

This article reviews recent process monitoring and control developments in rotary friction welding. While the review focuses on rotary friction welding processes, the concepts outlined here are certainly applicable to other friction welding processes. The American Welding Society categorizes two basic variations of rotary friction welding as direct-drive friction welding (also commonly referred to as continuous-drive friction welding) and inertia friction welding (also commonly referred to as stored energy friction welding). Both methods employ high-velocity rotation and pressure to develop friction and heat at the faying surfaces to weld a rotatable part to a fixed part.

Background

Friction welding is a solid-state joining process that achieves coalescence of materials through compressive force and workpiece movement. During processing, heat generated by friction and high-strain-rate deformation softens the material surrounding the original faying surfaces, and the pressure causes displacement of this material in the radial direction as flash. The objective is to generate sufficient heat, soften the material around the interface, and plastically displace material and surface contaminants to form a solid-state weld. An important criterion to achieving a high-integrity metallurgical bond is to break up and expel the contaminated surface layers (oxides, lubricant, and adsorbed species). This process can be challenging with dissimilar materials when there is a substantial difference in material hardness.

Direct-drive friction welding employs a motor for continuously rotating one component. The system also includes a clutch and a brake. The brake is applied to control the deceleration phase.

Figure 1 illustrates the process parameter relationships during the evolution of a conventional direct-drive friction weld. The rotatable component to be welded is brought up to a setpoint speed while the other component is held stationary. (The technically correct term for speed is *angular velocity*, but the term *speed* is commonly used as standard terminology for friction welding parameters.) Upon reaching the required speed, the two components are brought together under moderate interface pressure. This action causes a rapid generation of heat and softening of material at the interface. Plasticized material and surface contaminants are expelled from the interface as flash. When the forging range of the material is reached, the motion is arrested by applying the brake. This is usually complemented with an increase in axial pressure (known as forge force) to forge the parts together.

Inertia friction welding (IFW) is a rotary friction welding process that employs a finite amount of stored energy in the form of a rotating flywheel. Figure 2 illustrates the process parameter relationships during the evolution of a conventional inertia friction weld. During processing, the rotating flywheel is accelerated to a spindle disengage speed. Upon reaching this speed, the drive motor is released by either disengaging from the spindle or applying zero torque to the spindle. The spindle decelerates naturally to the setpoint spindle speed, at which time the parts are brought together under an axial compressive force. (Speed control in inertia welding is difficult due to the massive flywheel and resulting inertia. Therefore, the common approach is to overshoot the preprogrammed speed and allow the spindle rotation to naturally decelerate to the desired setpoint.) As with direct-drive friction welding, heat generated by friction and high-strain-rate deformation softens the material surrounding the original faying surfaces, and the pressure causes displacement of this material in the radial direction as flash. The spindle rotationally decelerates at a rate dependent on the inertia, the energy losses inherent in the weld system, and the countervailing frictional weld torque due to the surface contact between the two workpieces. Upon reaching zero velocity, the weld controller initiates a cooling dwell period where weld pressure (or upset pressure) is maintained for a

predetermined period of time. An increase in force (forge force) is sometimes used to help improve the integrity of the weld (commonly referred to as a two-stage inertia friction weld). Generally, however, inertia friction welding uses a single weld pressure.

Unlike a typical direct-drive friction welding process where the rotational speed can be regulated, inertia friction welding is carried out at variable speed. The final upset is determined at the end of the cooling dwell period (and when the slide movement toward the spindle ceases). The

total upset can be calculated based on the difference between the upset zero position (at initial contact) and the upset final position. During inertia friction welding, the spindle is not under direct control of the motor drive, and upset is therefore determined by the process parameters and the natural characteristics of the weld itself, such as material properties, geometry, and surface finish. The upset that forms during the deceleration phase of a traditional inertia weld is uncontrolled, that is, the final upset is the response from an open-loop control process, and is therefore

subject to some inherent variability due to minor variability in the process parameters, surface irregularities of the two components, or minor variability in the material properties.

Table 1 lists the minimum required process parameters for controlling an inertia and direct-drive friction welding process. Referring to Fig. 1, at least seven parameters are required to control a conventional direct-drive friction welding process. In contrast, a conventional inertia friction welding process requires at least four parameters to accomplish the process (Fig. 2). The smaller number of parameters for the inertia welding process facilitates a simpler process development and optimization effort as compared to direct-drive friction welding (Ref 2).

The equipment for direct-drive and inertia machine tools is primarily the same. In general, a rotary friction welding machine tool consists of a drive motor for rotating a workpiece at high speed, a tailstock assembly for holding a stationary workpiece, a hydraulic ram for pressing the workpieces together, a hydraulic control system for controlling the force exerted by the ram, and an electrical control system for controlling the different phases of the weld process. Additionally, an inertia friction welding machine requires a flywheel for storing the rotational kinetic energy prior to engaging the rotating and nonrotating workpieces. The ability to store energy in the flywheel and thereby avoid using a continuous-drive motor during the friction weld phase makes the power requirements of inertia welding lower than the direct-drive process.

Fig. 1 Direct-drive friction welding relies on a continuous-drive motor and axial pressure to transfer energy to the common interface. First, the rotatable component to be welded is brought up to a setpoint speed while the other is held stationary. Upon reaching the required speed, the two components are brought together under moderate interface pressure. This causes a rapid generation of heat and softening of material at the interface. Plasticized material and surface contaminants are expelled from the interface as flash. When the forging range of the material is reached, the motion is arrested by applying the brake. This is usually complemented with an increase in axial pressure (known as forge force) to forge the parts together.

Fig. 2 Inertia friction welding relies on a finite amount of stored energy and axial pressure to transfer energy to the common interface. First, one workpiece is rotated while the other is held stationary. The inertial mass is accelerated to a preselected speed. The two workpieces are brought together under an axial compressive force. Rubbing of the faying surfaces generates local heating and softening of material at the interface. Plasticized material and surface contaminants are expelled as flash. The spindle rotationally decelerates at a rate dependent on the inertia, the frictional losses inherent in the weld system, and the countervailing frictional weld torque due to the surface contact between the two workpieces. Upon reaching zero velocity, the weld controller initiates a colling dwell period where weld pressure (or upset pressure) is maintained for a predetermined period of time.

System Parameters

The friction welding process is a tightly coupled system that is composed of the following:

- One rotating component
- One nonrotating component
- Electric motor and flywheel (for inertia) or electric motor and continuous-drive characteristics (for direct drive)
- Axial load and hydraulic response characteristics
- Dynamically evolving material response characteristics at the common interface

Decoupling such a complicated system is extremely difficult. However, mapping the

Table 1 Process parameters

Inertia	Direct drive
Speed	Speed
Welding force	Friction welding force
Inertia mass	Friction heating time, t_1
Dwell time	Delay time, t_3
	Deceleration time, t_2
	Forge force
	Forging time, t_4

The inertia friction welding process requires the selection of four independent parameters to accomplish the process, while the direct-drive friction welding process requires at least seven parameters to carry out the process.

friction welding process as a parameter space can help identify aspects of the process that must be explored in terms of process variability that can adversely affect product quality.

Figure 3 illustrates how the friction welding process can be separated into process and product attributes and follows the guidance provided in Ref 3. Process attributes are those aspects of the process that the welding engineer has control over. They include the indirect weld parameters (IWP), preselected parameters, workpiece parameters, and other influential aspects of the process. The product attributes, or direct weld parameters (DWP), represent the characteristics of the postwelded product.

The weld quality is characterized by the direct weld parameters and is affected to varying degrees by the coupled effects of the process attributes. Indirect weld parameters are parameters that can be modified in-process as part of an open- or closed-loop control procedure, while the preselected parameters remain fixed during the process, for example, the inertial mass. Finally, other factors that can affect weld quality include fixturing and workpiece alignment, machine maintenance and condition, hydraulic temperature, and the operator.

Once the preselected parameters are properly chosen, the quality of the weld can be controlled through proper selection and modification of the IWP. In general, the welding process presents the control engineer with two principal problems:

- In most cases, the relationship between the IWP and the DWP are non linear.
- The variables are highly coupled.

The job of the welding engineer is to determine a set of IWP that will produce the desired DWP. If the production floor conditions do not differ too much from the development environment, and the process and environmental variability is kept to a minimum, then the welding

operation can be expected to satisfy the post-process quality inspection procedures. Otherwise, human or computer intervention must provide the necessary feedback to make corrective actions in the welding equipment settings.

Monitoring and control of a manufacturing process falls within one of four categories:

- *Machine monitoring:* Machine monitoring involves measuring an indirect weld parameter before, during, and/or after the process and comparing the measured value to a setpoint. In general, if the measured value falls outside of some predetermined tolerance, then a machine fault is signaled.
- *Process monitoring:* Process monitoring involves measuring either direct weld parameters or key in-process physical behaviors. Comparing a measured direct weld parameter to a desired setpoint is usually straightforward. For example, a good first-order indicator of weld quality and process repeatability is the final upset. Most manufacturers use the final upset as a cursory indicator of process health and product quality. Extending this further, some machine tool manufacturers monitor the axial displacement rate, (the rate of change in length with respect to time) to gain a deeper understanding into the process performance. In general, however, in situ measurement of the direct weld parameters is difficult due to accessibility and instrumentation limitations. Consequently, in-process physical behaviors such as torque, strain, acceleration, audio, or acoustic emission are used to infer various direct weld parameters. Several examples are discussed in detail in the section “Monitoring” in this article.
- *Machine control:* Machine control extends machine monitoring by implementing a closed-loop control system on one or more indirect weld parameters. Two of the more common closed-loop controllers in rotary

friction welding are spindle speed control (particularly for direct-drive machine tools) and axial load control (controlling the thrust of the ram in response to a pressure control signal).

- *Process control:* Process control extends process monitoring by implementing a closed-loop control system on one or more direct weld parameters. For example, most modern inertia friction welding machine tools can now control the final upset, and recently friction welding machine tool manufacturers have demonstrated control of the axial shortening rate (or upset profile) by modulating pressure and/or drive torque.

Ideally, closed-loop control of the heat generated at the weld interface is of great interest and importance to controlling friction weld quality and joint strength. The peak joint temperature and the temperature profile within the weld region have a significant impact on material movement, flash formation, heat and deformation zones, and joint strength. Closely related to the temperature profile is the cooling rate, which directly influences the residual-stress state developed in the weld.

Monitoring the temperature at the weld interface is both difficult and impractical for a production welding environment. However, in-process physical behaviors, such as the rate of axial shortening, can be used to infer weld quality and have been used to control weld quality in certain friction welding machine tools. Other in-process physical behaviors, such as the stick-slip phenomenon, can be used to infer heat and material flow at the weld interface. Monitoring the torque, strain, or acceleration during friction welding can yield insight into the heat and material flow at the weld interface. It can also provide feedback to anomalous processing conditions, such as fixturing inconsistencies, workpiece misalignment, material chemistry variability, or surface irregularities or contamination.

Recent process monitoring and control advances are presented in the following two sections.

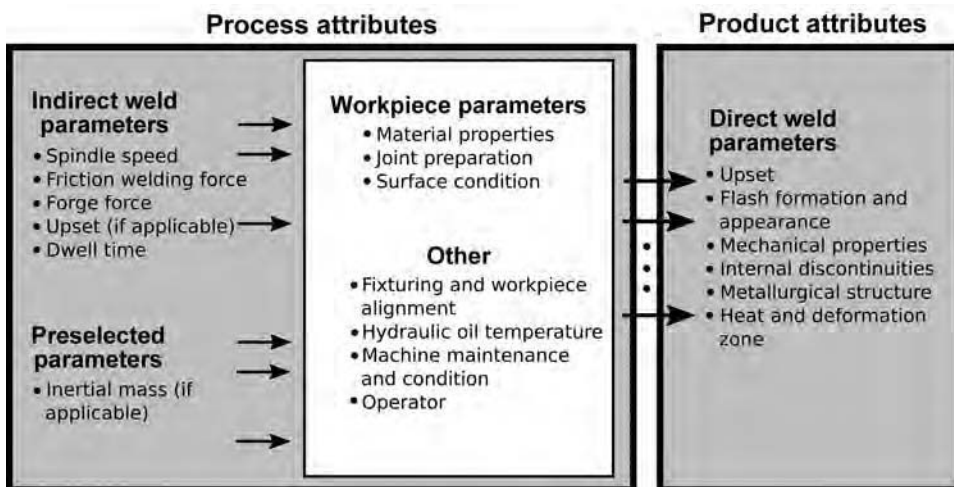

Fig. 3 The friction welding process can be separated into process and product attributes. The process attributes include those aspects of the process that the engineer has control over. The product attributes represent characteristics of the postwelded product.

Monitoring

Although friction welding is considered a highly robust and repeatable process, like all manufacturing processes, variability within the process can manifest itself as manufacturing flaws and product defects. Issues such as incoming material quality, workpiece surface finish and cleanliness, machine drift, and operator error can have a deleterious impact on the coalescence of the materials. In general, variability in the friction welding process is difficult to detect due to the inherent robustness of the process. Often, simple visual inspection or cursory examination of the process parameters reveals little information of the anomalous behavior or manufacturing flaw. In most cases, only large departures from the optimal process parameters or manufacturing conditions yield sufficient indications that there

is a problem with the process. Consequently, manufacturing flaws can potentially go undetected.

The application of postprocess destructive and nondestructive test methods is usually dictated by the standards required for the satisfactory service performance of the product. Destructive and nondestructive tests are an important part of the quality-control process that ensures products are safe. Traditionally, friction-welded parts tend to be difficult to inspect for the following reasons:

- Nondestructive test (NDT) methods normally detect gross disbands, leaving more subtle discontinuities, which could have a significant effect on fatigue life or joint fracture toughness. However, characterization of certain subtle aspects of discontinuities and macrostructures has been demonstrated for friction welds (Ref 4–7).
- The NDT methods are manually intensive, and the interpretation of their results is occasionally subjective and can be contradictory when viewed by different weld inspectors (Ref 8).
- Destructive postprocess inspection is time-consuming and costly. While the process provides reliable and quantitative assessment of the test weld, it imparts very little information about the process as a whole or any production welds in particular.

References in the open literature to nondestructive, in-process inspection date back over 50 years. The concept is not new, but the transition from research and development to commercialization has been slow up until

recently. The following sections present some of the more salient research efforts into nondestructive, in-process monitoring techniques for friction welding.

Weld Strength of Ferrous Alloys

A vein of noteworthy research into in-process quality control of friction welds was pursued by Wang and Oh. In Ref 9, Wang et al. demonstrated the feasibility of using acoustical emission (AE) as an in-process quality metric for inertia friction welding of ferrous metals. The authors correlated AE counts with joint strength for bar-to-bar (AISI 4140 to 1117 and 12L14) and tube-to-tube (AISI 1020 to 304SS) welds. The AE sensing was accomplished with a piezoelectric transducer attached directly to either the stationary chuck or the workpiece. For mild steels, the authors found two distinctive regions of AE: one during the welding process (A-zone) and the other during the cool-down portion of the weld cycle (B-zone).

The first burst of AE activity is due primarily to the plastic deformation of the material during the weld, whereas the second burst of AE activity is suspected to be a result of martensitic transformation. The authors showed relatively good correlation between the cumulative B-zone AE counts and the tensile breaking force (i.e., strength) for ferrous metals. However, their nonferrous (aluminum and copper) metal experiments resulted in no detectable B-zone AE activities, and hence, they were unable to determine weld strength.

In Ref 10 and 11, Oh et al. extended the data analysis portion of the experimental work conducted by Wang. The authors used the total

cumulative AE counts (A-zone counts + B-zone counts) as an in-process quality metric. In particular, they correlated weld strength with total cumulative AE counts and initial energy, total cumulative AE counts and total upset, and total cumulative AE counts and welding time (for direct-drive friction welding). The authors empirically derived an equation for tensile strength that can be used for in-process monitoring of friction weld strength. In Ref 12, Oh et al. correlated weld strength with IFW parameters (rotational speed, pressure, and inertia) and total cumulative AE counts. Oh et al. presented their final report (Ref 13) that correlates zone-A AE counts with weld strength.

Metallurgical Integrity of Dissimilar Metals

Friction-welded components made by joining aluminum to copper and stainless steel to copper are widely used in the electrical industry. In addition to a proper joint design and the selection of optimal welding parameters, surface preparation, including the surface finish and cleanliness prior to welding, can be critical for adequate metallurgical joint integrity. In Ref 14, Hartman et al. explored the feasibility of detecting inadequate surface preparation during IFW of stainless steel to copper.

The technique monitored the airborne audio data from the welding process using a novel, noncontact audio sensor. Four off-the-shelf electret microphones were mounted in an aluminum ring that surrounded the weld interface. The acoustic ring and an unwelded part are illustrated in Fig. 4.

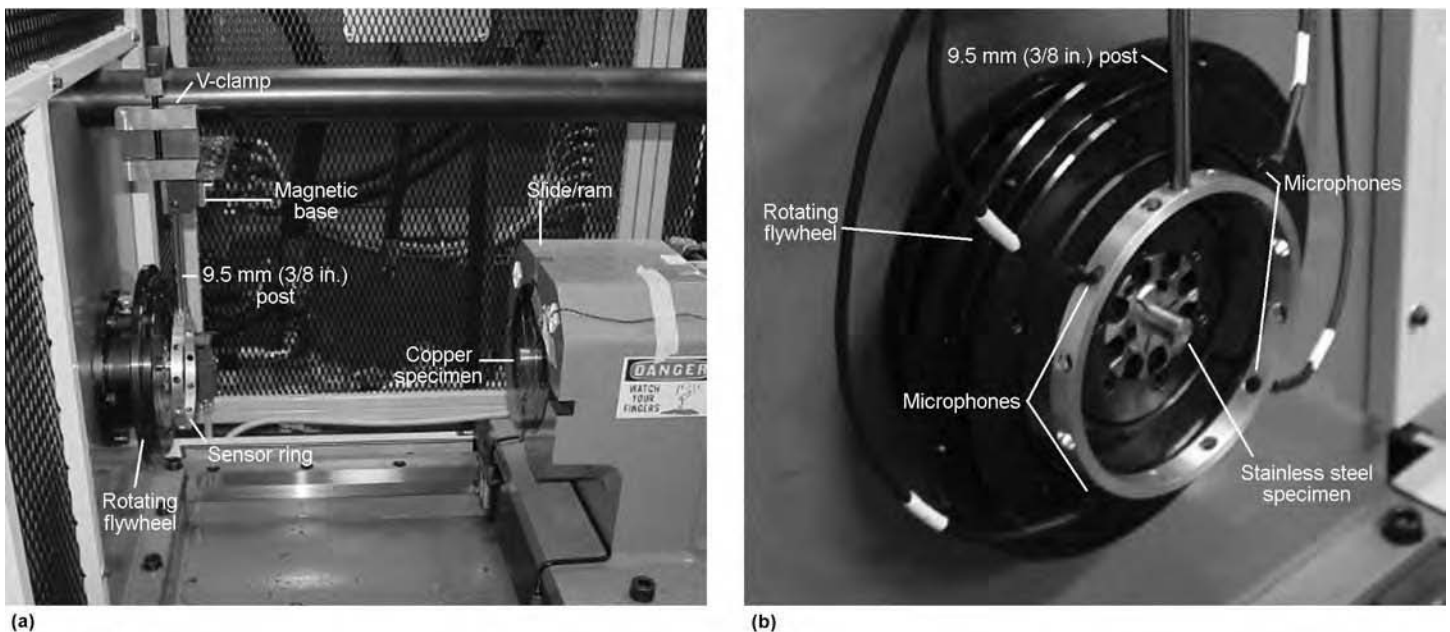

Fig. 4 The free-standing acoustic-ring assembly contains four equally-spaced microphones that surround the weld interface. For reference, a 12.7 mm (0.5 in.) diameter type 304L stainless steel bar is located in the rotating fixture of the inertia welding machine.

An experimental matrix was devised in which the resulting welds would fall into one of two bond integrity categories: acceptable or unacceptable. An acceptable weld is defined as one in which the majority of the interfacing surfaces are bonded. An unacceptable weld is defined as one in which no or little bonding at the surfaces exists.

The study welded 2.54 cm (1.0 in.) diameter oxygen-free high-conductivity copper bar to 1.27 cm (0.5 in.) diameter annealed type 304L stainless steel bar. Approximately three weeks before welding, each specimen was given a

preliminary finish cut to ensure a faying surface finish of 0.81 μm (32 $\mu\text{in.}$). The welding parameters remained constant throughout the investigation.

During the experimental welding portion of the investigation, the faying surfaces of selected copper specimens were machined immediately before welding while bathed in isopropyl alcohol. Others were welded as-is, that is, without further machining to remove surface oxidation that may have occurred while at ambient temperature and pressure for up to five weeks prior to welding. In all cases, the stainless steel was

rotated during the weld cycle, while the copper remained fixed.

Destructive testing of each weld was accomplished using an unguided bend test. The as-welded, full-sized specimens were tested. Following the fracturing of each specimen, image analysis was used to quantify the percent of bonded area. A total of 23 welds were considered in this study.

Although the experimental matrix was designed with only one variable in mind (surface preparation of the copper), three different bond integrity categories were generated:

- *Acceptable*: Bonded area is approximately 100%.
- *Conditional*: Bonded area is less than 100% but greater than 5%.
- *Unacceptable*: Bonded area is less than 5%.

Table 2 Unguided bend test results

Weld No.	Surface condition before welding	Bond quality	Bonded area, %
1–12	Freshly machined	Acceptable	100
13	Freshly machined	Conditional	80
14	Freshly machined	Conditional	70
15	Freshly machined	Conditional	69
16	Freshly machined	Conditional	67
17	Freshly machined	Conditional	54
18	Freshly machined	Conditional	26
19–23	Freshly machined	Unacceptable	0

Although the experimental matrix was designed with only one variable in mind (surface preparation of the copper), three different bond integrity categories were generated: acceptable, conditional, and unacceptable. The conditional welds were prepared in the same manner as the acceptable welds, which demonstrates the difficult and sensitive nature of joining these two materials. The weld numbers are ordered in the table for illustrative purposes, while the experimental matrix was conducted in a random order.

The conditional welds were prepared in the same manner as the acceptable welds, which demonstrates the difficult and sensitive nature of joining these two materials. Table 2 shows the results from the experimental matrix.

Figure 5 illustrates the typical flash and fracture surface for each category of weld. All specimens exhibited a symmetric flash with a light-golden color. The amount of upset (or reduction in length) was approximately

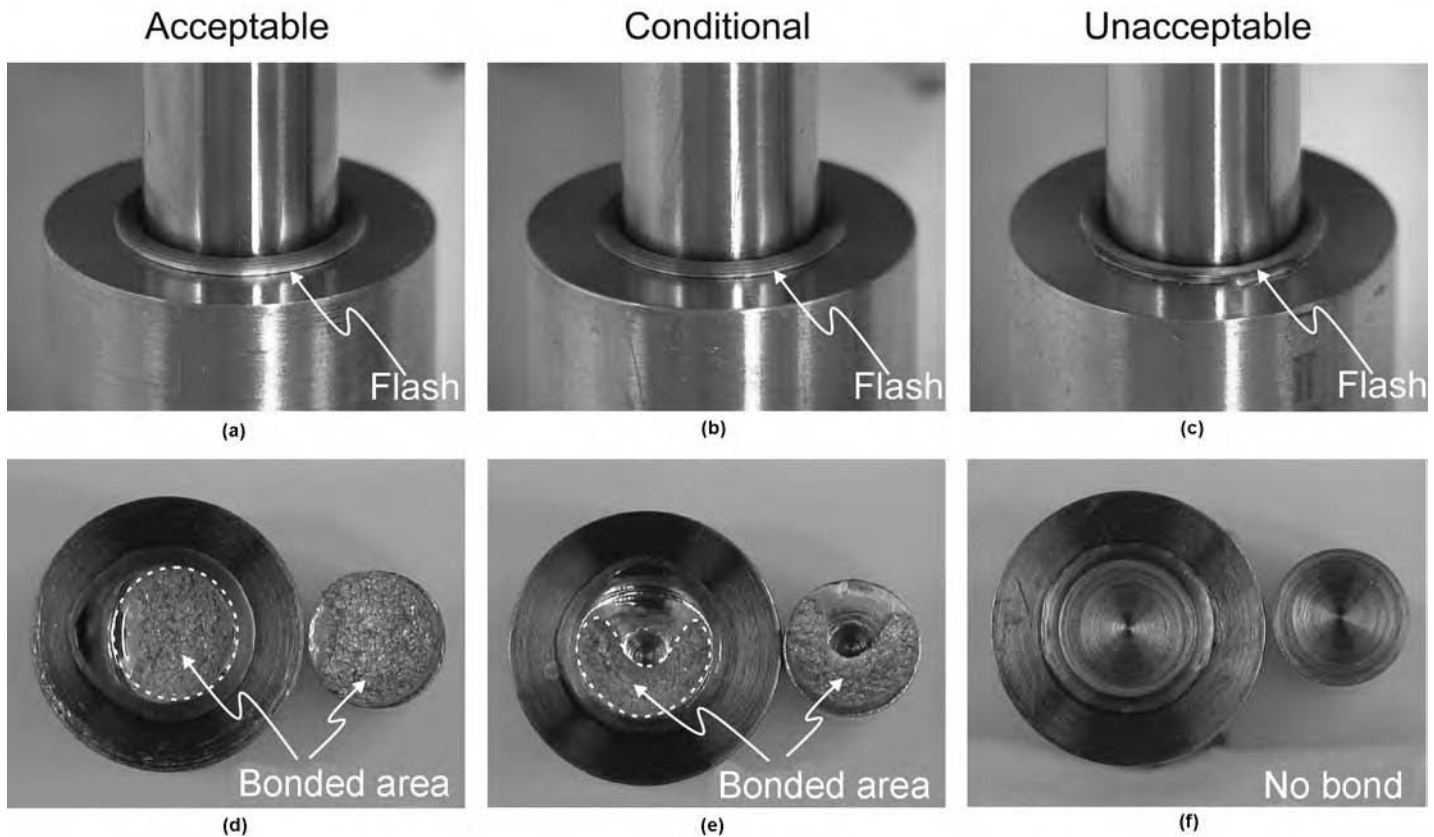

Fig. 5 The surface cleanliness of the copper was the only variable in the 23-weld experimental matrix, yet three different categories of bond quality were produced. All specimens exhibited a symmetric flash with a light-golden color. The amount of upset was approximately the same across all three categories. A total of 18 welds were freshly machined, while 5 welds were purposely left oxidized. All 5 oxidized welds yielded unacceptable bond quality, and 6 of the 18 freshly machined welds produced conditional bond quality. A conditional weld occurred intermittently even though the surface preparation was the same as an acceptable weld. The intermittent conditional bond quality demonstrates the difficult and sensitive nature of joining these two materials.

equal across all specimens and predominantly occurred in the copper. Moreover, the fact that the upsets were approximately equal, yet yielding acceptable, conditional, and unacceptable welds, suggests that upset alone is an insufficient measure of bond quality for this particular material combination.

A neural network was used to explore and discover structure within the audio data frequency content that may correlate with bond integrity. Due to the small experimental set, a single hold-out method was used to train and test the learning and classification capabilities of the neural network over a wide range of temporal and spatial aspects of the data. The results indicate that differences in the surface finish of the copper can be seen in the audio data.

Ferrite Formation of Stainless Steel Alloys

Austenitic stainless steels (γ -SSs) are widely used in chemical processing and petroleum refining applications due to their corrosion-resistance properties. Inertia friction welding is a solid-state joining process that can be used for welding a wide variety of components, and it generally works well for stainless steel alloys. The thermomechanical cycle experienced during IFW of some γ -SSs can lead to the formation of the body-centered cubic ferrite phase along the bondline. The presence of ferrite along the bondline can create concern regarding the mechanical and corrosion properties of the resulting weldment. In Ref 15 and 16, Hartman and Lienert investigate the feasibility of detecting the presence of ferrite during the microstructural evolution of IFW of three austenitic stainless steels.

Three stainless steels were chosen for this study: 310, 304, and 255. The 310 and 304 alloys are considered to be austenitic stainless steels, while the 255 alloy is a duplex (50% austenite and 50% ferrite) alloy. Five inertia friction welds were produced on 2.54 cm (1.0 in.) outside diameter tube samples (3.175 mm, or $\frac{1}{8}$ in., wall thickness) of each alloy using a Manufacturing Technology, Inc. model 90B machine. All welds used the same initial energy of approximately 15.3 kJ. Welds were made at three levels of forge pressure and three combinations of $\langle I \rangle$ (moment of inertia) and (revolutions per minute) to give the same initial energy.

A noncontact, audio-based, free-field microphone Brüel & Kjør-type 4939 was mounted several inches away from the weld zone and recorded the acoustic energy (in the form of sound pressure) that emanates from the friction welding process. The audio data were sampled at 50 kHz to account for potential signal content above a human's nominal audible sound sensitivity. The sensor sensitivity and the amplifier gain settings remained constant throughout the experimental effort. High-speed video was also collected synchronously with

the audio data in an attempt to correlate the audio data with the physical mechanisms of the IFW process.

The three alloys exhibited distinct acoustic signatures versus time. Examples of representative signatures are shown in Fig. 6 to 8. The audio data for the 255 alloy showed an initial small acoustic burst at the beginning of the weld cycle and remained relatively quiet thereafter. For the 304 alloy, acoustic bursts were found at the start and finish of each weld, with a quiet period in between. The 310 alloy exhibited the most energy of the three alloys, with acoustic content throughout the entire weld cycle and higher amplitude spikes at the start and finish.

For all three alloys, the amplitude and duration of the bursts and quiet periods varied

slightly with changes in welding parameters. For example, the amplitude and duration of the bursts increased with increasing pressure. The majority of the frequency content was found to be predominantly in the 20 to 25 kHz range.

In summary, the three alloys exhibit distinct acoustic signatures versus time that varied slightly with changes in welding parameters. The bursts appear to correlate temporally with features of the torque curve. The differences in acoustic signatures for welds made on the different alloys using identical welding conditions likely stem from differences in the acoustic, thermophysical, and thermomechanical properties between the alloys. This technique may prove useful for determining the phase balance of the weld region after welding and for predicting weld quality in situ.

Fig. 6 The acoustic signature and machine data from a 255 dual-phase stainless steel alloy inertia friction weld. Most of the acoustic energy occurred during initial contact. The weld was relatively quiet thereafter.

Fig. 7 The acoustic signature and machine data from a 304 stainless steel alloy inertia friction weld. The majority of the acoustic energy occurred at the beginning and end of the weld, with a quiet portion in between.

Fig. 8 The acoustic signature and machine data from a 310 stainless steel alloy inertia friction weld. The 310 stainless steel alloy generated the most acoustic energy of the three alloys. Unlike the 304 stainless steel alloy, this material exhibited a relatively loud burst of energy in the middle portion of the weld and was generally “noisy” throughout the entire process.

Control

Over the past 50 years, friction welding machine tools have seen an increase in precision and an overall improvement in machine control due to the introduction of high-performance embedded computers and micro-controllers for closed-loop feedback control and improvements in electric motors, servos, and encoders. The basic premise behind a friction welding machine control algorithm is to monitor and control the speed, pressure, and upset to provide assurance of the quality of the weld. Most machine tool controllers provide a fault indication should any of these values stray outside of some predetermined range within which a good quality weld can be assured.

Shortcomings that were once considered limitations of the friction welding process, such as control of the final rotational position of a rotating component with respect to the stationary workpiece or excessive tolerance in the final upset length, are now possible with high-precision sensing, fast-acting actuators, and closed-loop control algorithms. Yet, much of the work in machine and process control is proprietary. The specific details are closely guarded as secret intellectual property, which enables the machine tool manufacturers and certain end-users to maintain an advantage in a competitive market. Consequently, very little work is disclosed in the open literature.

Nevertheless, research and development in the area of process control is on-going by machine tool manufacturers and friction welding end-users (primarily aerospace companies). Improved control of the final upset length and rate-dependent control of the upset trajectory are now possible because of sophisticated

machine tool controllers that can manipulate a multiaxis machine element along a complex three-dimensional path at constant velocity. Research is also being performed in improving the weldability of dissimilar alloys by matching ductilities during welding through heating and/or cooling one component and/or the other.

In-Process Quality Control

The friction welding process usually lasts no more than a couple of seconds. During this time, a seasoned operator is listening to the process. After many years of experience, a knowledgeable operator can distinguish a “good” from a “bad” weld based strictly on the sound produced. The terms *good* and *bad* are commonly used on the production floor by the operator. In particular, the operator may say, “That was a good weld” or “That weld did not sound right.” From a manufacturing behavioral perspective, the operator is suggesting that the process did not generate the typical sounds to which he/she has grown accustomed. The terms *good* and *bad* are used loosely here to convey anomalous behavior and not to imply that the part is defective. Although the operator may be unable to articulate why the weld is different, he or she instinctively knows when the process sounds different. Unfortunately, these anecdotal observations carry little clout with process engineers and production floor managers.

The welding operator’s years of experience and intuitive knowledge about the process represents an undeveloped and largely overlooked aspect of manufacturing quality control. While time and resources are devoted to training and qualifying operators, calibrating and

qualifying machines, developing qualified procedures, and implementing sophisticated destructive and nondestructive test methods, in-process quality control remains absent from mainstream quality-control practices and exists only in isolated research and development activities. Generalizing upon and automating a human’s innate ability to sense, store, recall, and distinguish anomalous weld behavior can provide a significant leap forward in current manufacturing quality-control practices.

In-process quality control is based on the premise that most in-process physical behaviors of a manufacturing process can and should be regarded as process quality feedback. In-process monitoring relies on the systematic analysis and investigation of manufacturing behavior through controlled and naturalistic experimental observations and rigorous formulations. The end result is a nondestructive, in-process monitoring solution for manufacturing quality control. The in-process monitoring solution embodies a decision process and communication strategy for real-time, nondestructive, in-process manufacturing quality feedback.

The in-process monitoring research that was presented in the section “Monitoring” in this article was conducted with a narrow focus on a single process or product attribute:

- Correlate AE with joint strength
- Correlate audio with surface cleanliness and infer bond integrity
- Correlate audio with ferrite formation

The well-focused approach makes for a strong technical paper, but it overlooks the broader implications that in-process quality control can have on the current manufacturing quality-assurance and quality-control paradigm. From a more general perspective, monitoring the manufacturing behavior complements the current quality-control approaches that have already been engineered into a manufacturing process.

Traditional manufacturing quality-assurance and quality-control strategies prevent flaws from becoming defects by tightening tolerances and/or increasing postprocess destructive and nondestructive testing. However, the danger of experiencing a defect in-service can never be argued or strategized away. Machine tool manufacturers are continually improving machine control and tightening process tolerances in an effort to minimize process variability and to ensure high-quality product. In-process monitoring is a developing capability that has the potential to offset an overreliance on postprocess destructive and nondestructive testing. As in-process monitoring gains wider acceptance, the logical next step is for the machine tool manufacturer to implement closed-loop control on key in-process variables. Closed-loop control of key in-process variables will enhance the friction welding process robustness by sensing minor process variabilities and adjusting certain IWP to ensure compliance with the desired DWP.

Development of Welding Procedures for Friction Stir Welding

Kevin J. Colligan, Concurrent Technologies Corporation

THE DEVELOPMENT of a welding procedure is one of the most important steps in implementation of a welding process in a production application. Procedure development can be systematically achieved by clearly defining the requirements of the procedure and the test plan, by executing the required testing and analyzing the results, and by fully documenting the testing performed and the results obtained. Successful procedures in similar materials can suggest a starting place for developing the welding tools and key process parameters for new procedures. By thoroughly testing and documenting procedures for friction stir welding (FSW), problems during production use of the process can be minimized by determining the robustness limits of the process, the properties of the welded joint, the required equipment capabilities, and the tool and fixture designs.

In its simplest form, the development of a welding procedure is simply a matter of determining the technical parameters that produce a sound weld in a given material. However, this is most often an insufficient basis for defining a procedure for production of commercial products. More commonly, development of a welding procedure involves establishing the robustness of the welding process, the properties of the welded joint, the required equipment capabilities, the tool and fixture designs, and the economic justification for using the procedure. The complexity of procedure development can also be increased by the requirements of applicable specifications or regulations based on the end use of the procedure, which may have special rules for testing and record keeping. The development of a welding procedure includes the process of discovering the technical parameters for consistently producing a sound weld, as well as the development and analysis of all of the necessary supporting data to satisfy the applicable requirements and to ensure the reliability of the procedure.

The route to commercial production for products involving a welding process can take many paths, but commonly it involves development of a preliminary product design, iteration between detail design and procedure development,

procedure qualification, work instruction development, and operator training and qualification. This article mainly concentrates on the development of procedures for FSW and touches on procedure qualification but does not address joint or product design and does not discuss the development of work instructions or other production qualification activities. It is also assumed that the reader has a working knowledge of FSW technology.

Procedure development is best viewed as an evolutionary process, where the welding process is initially demonstrated, evaluated, improved, tested further, and finally qualified for use. Iteration through these steps is common, as results of testing suggest new approaches. The development process may include the following steps:

- *Preliminary welding trials:* Show that a sound weld can be made
- *Systematic welding trials:* Explore the range of key process parameters
- *Robustness testing:* Evaluate welding performance subjected to procedure variability

These three sets of welding experiments are intended to optimize the welding process in an orderly way, minimizing the cost of procedure development by essentially learning to “crawl before walking.” This process also will help the introduction of a new welding process to the production environment by establishing reasonable expectations for each step of procedure development. The preliminary welding trials are not intended to yield optimum results, just a sound weld of any kind. Having done that, work can move on to systematically exploring key process parameters to find a combination of parameters that gives maximum joint performance. This can then be followed by tests to evaluate performance with some degree of production variability, such as joint misalignment. It should be noted that as these steps progress, there may be test results that indicate returning to an earlier step and making changes to the tool design or process parameters. For example, if the procedure is found to have very low

tolerance to joint-tracking errors (lateral offset of the joint relative to the tool), then the pin diameter may need to be increased and the preliminary and systematic welding trials repeated. More details on the overall process of procedure development are presented in Fig. 1 and in the paragraphs that follow.

The development of a welding procedure, starting with no prior experience with welding a given material, can be very challenging. Although FSW is a comparatively simple welding process, even a small number of process variables can quickly lead to a multitude of potential welding procedures. One objective of this article is to equip the reader with a summary of published procedures to suggest a starting point for new work. With this information in hand, the welding engineer may minimize the trial-and-error effort often associated with development of an FSW procedure. Preliminary welding trials are intended to simply demonstrate that sound welds can be produced. At this stage of the development, there may be a number of candidate welding tool designs that are evaluated, and one or more may yield acceptable results and be selected for follow-on testing.

Once a preliminary welding procedure has been demonstrated, the next phase of welding procedure development should be a process of systematically exploring the range of welding parameters to see their effect on basic joint properties appropriate to the end usage of the welded component. A detailed plan should be written, describing all of the detailed activities needed for optimizing the welded joint properties. Most often, these properties include tensile strength, yield strength, and ductility. Metallographic analysis is also useful for examination of the internal structure of the weld. Postweld aging or other treatments may also require development. After analyzing all of these various data, the welding engineer can select a welding procedure for producing test articles for more extensive testing, the results of which may influence the final detail design of the product.

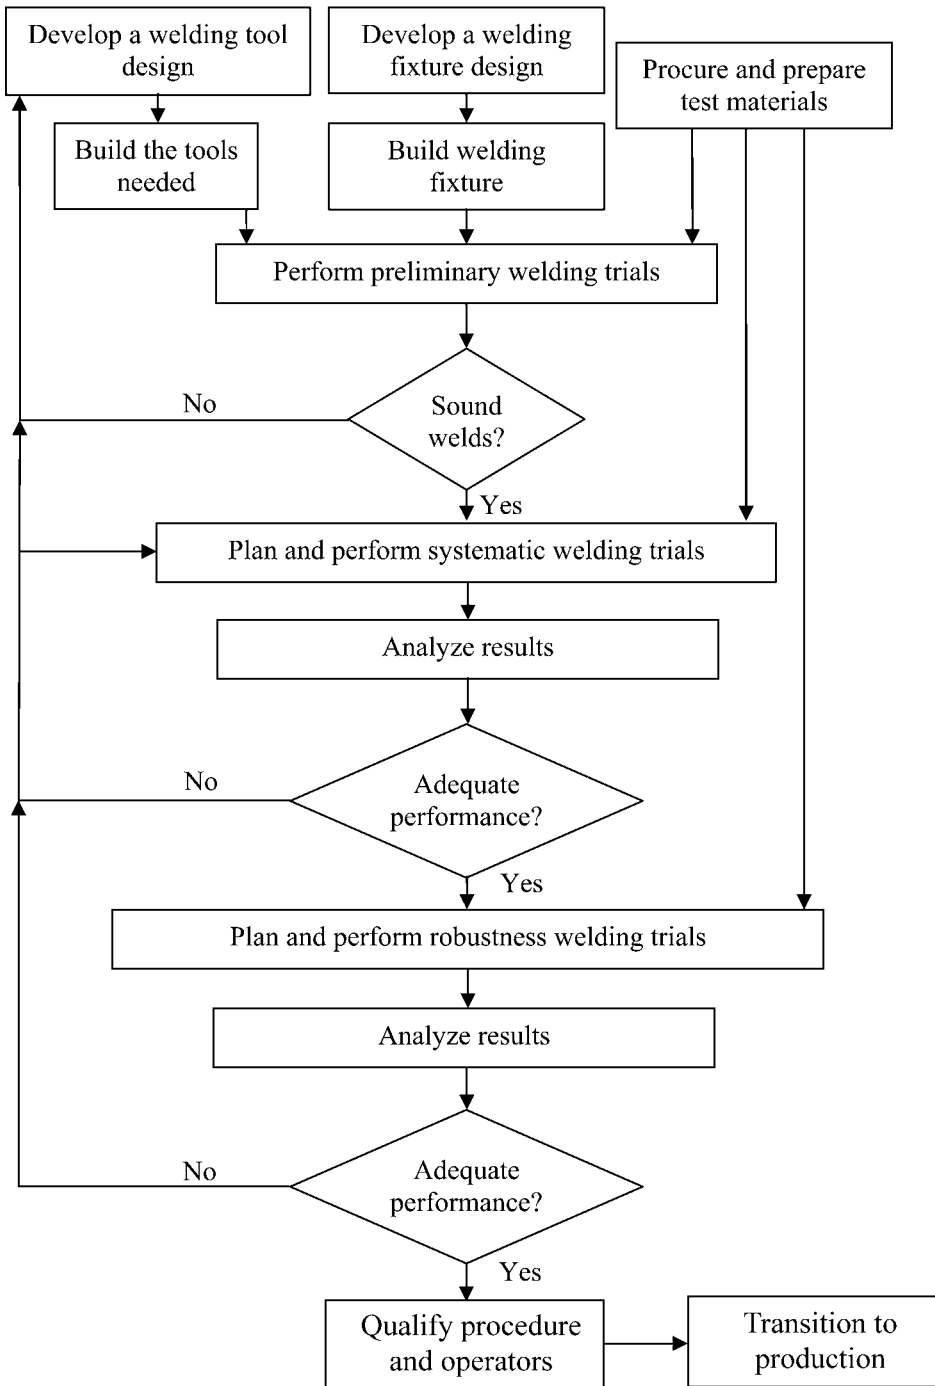

Fig. 1 Flowchart of welding procedure development steps

Robustness testing is intended to assess performance of the welding procedure when subjected to the process variability that inevitably occurs during production. The welding procedure parameters that are most subject to in-process variability are tested at the limits of their expected variation, confirming that the welding procedure is sufficiently robust. If any of these tests fail, the decision can be made to

improve the welding process, improve in-process controls, or both.

Prior to being finalized in many applications, such as safety- or mission-critical applications, the procedure will require formal qualification testing. Here, the weld procedure is used to produce welded materials and/or representative production parts and tested according to the rules established in published specifications

(Ref 1–5). Data from this testing provide assurance of the viability of the procedure for the associated application relative to accepted specifications. Assuming that these requirements are met, the procedure becomes accepted as a qualified procedure for use in production of the part.

This article details the development of a welding procedure, including the process of defining a preliminary procedure, the optimization of parameters, the development of supporting data, and other key features to ensure a successful procedure. The process of welding procedure qualification is also described, although this discussion must necessarily be generalized based on the variety of requirements for qualification from industry to industry and, over time, within an industry.

Procedure and Procedure Development Requirements

Clearly defining the associated requirements is an important first step in developing a welding procedure. For example, a welding procedure developed for an aerospace application, where safety of flight may be an issue, requires more testing than procedures developed for less demanding applications. By first defining the requirements for procedure development, adequate testing can be planned and efficiently executed, and the associated cost can be estimated in advance.

Important questions to ask during procedure development planning include the following:

- What is the alloy and its product form, temper, and thickness?
- What is the joint design? What is the geometry of the production part?
- What will be the condition of the workpiece material presented for welding? Will pre-weld processing be required, such as cleaning, oxide removal, edge trimming, and so on?
- Is there a required production rate for economic justification? Is there a known maximum acceptable cost per unit length of weld?
- What are the performance requirements for the joint? This should be broadly interpreted to include strength, ductility, fatigue performance, corrosion, toughness, and stress-corrosion cracking.
- What are the cosmetic requirements for the joint? Is it necessary to have a specific final surface condition?
- Is there a required welding tool life? Is there a known limitation on the cost of the welding tool?
- Will postweld aging or other treatment be required?
- Will formal qualification of the procedure be required? What are the requirements for the qualification? Will it be necessary to qualify using a production-representative

workpiece, or can test panels be used in the qualification?

- Will production welding be done on a known fixture, or will the fixture be designed later? Will it be possible to simulate the production welding fixture during procedure development?
- What style of FSW will be employed? Will it be conventional FSW, on a welding fixture with an anvil, or bobbin FSW, on a fixture with no anvil?
- What are the capabilities and limitations of the FSW equipment to be used for production?

A second step in developing a welding procedure is establishing what information is needed to completely define the procedure. The goal is to specify all of the important variables related to the process so that the qualified procedure can be replicated in production. Some specifications for welding refer to this list as essential elements (Ref 1). The following list provides a starting point for developing the essential elements for an FSW procedure, although the details of each procedure may require modification of this list:

- Base-metal specification (alloy, temper, product form)
- Base-metal thickness (nominal and range)
- Base-metal orientation relative to prior processing of the workpiece (for example, rolling direction)
- Joint design (joint type, allowable mismatch, allowable gap)
- Welding tool design (including material)
- Joint preparation (cleaning procedure, oxide removal procedure)
- Welding equipment (make and model of welding machine)
- Fixture design (anvil cross section and material, clamping arrangement and parameters)
- Welding parameters (spindle speed, travel speed, rotation direction, tool tilt angle, etc.)
- Welding tool pin length or length range for adjustable pin tools
- Tool axial position control method (load control or position control)
- Tool axial position relative to workpiece or anvil (such as the heel plunge depth or pin/anvil gap)
- Tool axial force (for axial load control method)
- Auxiliary heating or cooling method and parameters, if used
- Postweld processing (surface modification, heat treatment, etc.), if used

In developing a welding procedure, it is important to keep a record of all of the essential elements used for each weld, along with other suitable notes, so that the procedure can be reliably repeated. An example welding procedure record is shown in Table 1. The weld identification number can be used to refer to the welding procedure record. Using this type of form for each weld produced during process development should ensure

complete definition of the welding conditions and make procedure qualification and transition to production much easier.

Procedure Development

In this section, critical features of FSW tool design, initial process parameters, systematic welding trials, and robustness testing are discussed.

One of the most challenging aspects of FSW is the control of the welding tool depth in the workpiece. There are two aspects to this requirement. First, the welding tool shoulder contact with the workpiece surface must be regulated to give consistent heat generation and weld consolidation. Second, the welding tool pin depth must be controlled to maintain close proximity to the anvil,

a requirement for full penetration of the weld. Of course, this does not apply to bobbin-style FSW, in which the pin passes completely through the workpiece. For conventional, single-sided FSW, the maximum pin-to-anvil gap may be from 0.25 to 1.0 mm (0.010 to 0.040 in.), depending on the design of the pin and its ability to project plastic deformation beyond its end. The base-metal properties and other process conditions may also influence weld penetration. These tight tolerances on the pin-to-anvil gap make it clear that the relationship between the welding tool pin length and the workpiece thickness is a very important one.

The variables related to welding tool pin length and workpiece thickness are listed as follows and are shown schematically in Fig. 2 and 3:

Table 1 Example welding procedure record

Welding Procedure Record

Fig. 2 Schematic of friction stir welding tool, anvil, and workpiece for spherical-tipped pin and tilted tool axis, side view. See text for an explanation of the variables.

Fig. 3 Schematic of friction stir welding tool, anvil, and workpiece for flat-tipped pin and tilted tool axis, side view. See text for an explanation of the variables.

- A = tool tilt angle
- G = pin/anvil gap
- H = heel plunge depth
- L = pin length
- P = pin diameter
- R = pin tip radius
- S = shoulder diameter
- T = workpiece thickness

The equations for calculating the pin length, given the other variables, are presented as follows. For welding tools with a spherical tip, the pin length is calculated as:

$$L = R + \frac{T - G - H - R + \frac{S}{2} \sin A}{\cos A}$$

For a welding tool with an essentially flat tip, the pin length is calculated as:

$$L = \frac{T - G - H + (\frac{S}{2} - \frac{P}{2}) \sin A}{\cos A}$$

It should be noted that the radius for the spherical-tipped pin can be greater than half the diameter of the pin, as long as the lowest point of the pin tip is on the radius portion, not on the corner of the pin. In the latter case, which occurs when A is greater than $\sin^{-1}(P/2R)$, use the equations for the flat-tipped pin, counting the pin length as the distance from the shoulder to the corner of the pin, which does not include the length of the radius at the pin tip.

It should also be noted that in the equations for calculating the pin length, the heel plunge distance is a factor. However, the appropriate heel plunge depth for optimum weld performance is difficult to know without some preliminary welding experiments. A good starting point may be:

$$H = 0.7 * S * \sin A$$

For welding tools that are operated with the welding tool axis normal to the plane of the workpiece, the calculation of pin length is greatly simplified. These tools are operated with the shoulder surface flush to the workpiece surface, so the pin length is simply the workpiece thickness (T) minus the pin/anvil gap (G).

During procedure development, it is easiest to start with a known welding procedure in an alloy/thickness combination that is similar to the workpiece of interest. The list of welding procedures presented in Table 2 is the result of an analysis of published reports in which sound welds were described for aluminum alloys. Although the procedures may or may not be optimized, they were at least reported to produce sound welds. It is rare to find complete details related to welding procedures in the literature, so this summary covers publications where sufficient detail was given to afford a reasonable indication of how the welds were produced. The data in Table 2 can be used to learn about the design of welding tools. Dubourg and Dacheux (Ref 6) analyzed the literature and compiled welding procedures for FSW of aluminum materials between 1 and 8 mm (0.04 and 0.32 in.) in thickness. They reported statistical relations between workpiece thickness and shoulder diameter and between workpiece thickness and pin diameter. Following their approach, the data from Table 2 can be used in a similar way, as shown in Fig. 4 and 5. It is interesting that the relationship between workpiece thickness and shoulder diameters shows that when a broad range of workpiece thickness is analyzed, a bilinear relationship emerges, with the transition point being at approximately 8 mm (0.32 in.) thickness. This reflects the way in which heat generation by the shoulder plays a lesser role in thick-section FSW, because its ability to influence heating through the full material thickness diminishes with increasing workpiece thickness. These charts can be used to determine a starting point for the welding tool shoulder and pin diameters for a given workpiece thickness.

Once the welding tool shoulder and pin diameters are selected, other tool design features must be established (Ref 40). Welding tools for aluminum alloys typically include thread-shaped features that are designed to drive workpiece material away from the shoulder, toward the anvil, during welding. The pin design may also include flats or other reentrant features cut into the threaded profile, typically for the purpose of increasing transport of workpiece

Fig. 4 Shoulder diameter as a function of workpiece thickness, from the literature

material around the pin and reducing in-plane resistance force against the pin. Welding tool shoulders may be essentially smooth and cupped inward slightly, or they may be flat, with spiral grooves designed to pull softened workpiece material toward the pin. The welding tool shoulder may also protrude in a tapered profile, which is embedded in the workpiece surface during welding (Ref 41).

Once the initial welding tool design is selected, it is necessary to choose starting

welding conditions for preliminary welding trials. Experience in adapting FSW procedures to untested workpieces has indicated that one way to extrapolate the spindle speed from an established procedure to one with a different welding pin diameter is to calculate the pin surface speed from a known procedure in a similar alloy, and then apply that pin surface speed to the present welding tool design. The data in Table 2 can be used to choose a similar alloy type, calculate the pin surface speed, and then

calculate a spindle speed for the tool design chosen. A reasonable travel speed can then be estimated by calculating the advance per revolution (travel speed divided by the spindle speed) for a similar welding procedure, and then multiplying this by the spindle speed calculated previously. This will give a good starting point for preliminary welding trials.

Procedure development often begins with a series of preliminary welds that are made for the purpose of exploring new tool designs and the reaction of the workpiece to the welding process. This is especially true for a completely new welding procedure, where there is limited experience with the material or tool design being used. Preliminary welds must be made in this case just to establish that a weld can be produced, before detailed plans can be developed.

Systematic welding trials are best carried out after a detailed plan is developed. The test plan should define the specific test welds to be made, the postweld testing to be performed, and all documentation requirements. The test plan should contain all of the details needed by welding engineers and technicians, including specific welding procedures, sketches of weld geometry, inspection requirements and procedures, cut plans for welded plates, specimen geometries, mechanical test procedures, and metallographic preparation details. Also, it is often useful to produce successive revisions of the test plan as results are obtained and new test requirements emerge. It may be helpful to use outline numbering in the various sections and paragraphs of the test plan, so that work instructions distributed to the various work areas can reference specific test plan paragraphs.

Systematic welding trials usually consist of making welds with different welding speeds and spindle speeds, at a minimum, and may

include evaluation of other process variables. Each test panel is then tested to characterize the weld produced. This testing may include nondestructive testing and should, at a minimum, include a detailed visual inspection. Test panels are then typically cut to produce a variety of test specimens, according to the test plan. Mechanical property tests could include root, face, or side bend testing and transverse tensile testing. Several specimens for each test type are normally tested to develop mean values for each weld. These specimens may be distributed along the length of a long weld or clustered at some region on the test panel. These specimens are often interspersed with specimens for metallographic preparation and inspection.

During systematic welding trials, it is helpful to consider each specific aluminum alloy as being able to tolerate increasing spindle speed only up to some maximum value, beyond which the transverse tensile strength begins to decrease. Increasing the spindle speed further will lead to volumetric defects internal to the weld, and still further increases in the spindle speed will lead to gross, surface-breaking defects and will be accompanied by an increasing in-plane force (resistance to travel) against the welding tool. The spindle speed yielding the maximum tensile strength can then be used to calculate the maximum pin surface speed that the alloy will tolerate. This surface speed can then be used to calculate the maximum spindle speed for other pin diameters.

Once the maximum spindle speed is determined for a given alloy, trials with different travel speeds can be tested. In non-heat-treatable alloys, such as the 5xxx-series aluminum alloys, tensile strength is not typically influenced by travel speed to a great extent, but in heat treatable aluminum alloys, strength often increases with increasing travel speed. This increase in strength continues to a maximum value, and then the strength begins to decrease with further increase in travel speed. As with the spindle speed trials, further increasing travel speed will ultimately lead to internal defects, then to gross, surface-breaking defects and to increasing in-plane force against the welding tool. The maximum travel speed with high tensile strength and good weld formation may then be further tested in follow-on trials.

The data analysis that accompanies systematic welding trials involves generating a summary of the information collected, looking for trends in the data, seeking explanations for observations, and developing conclusions about the best procedure to use in follow-on tests. Even if the systematic welding trials produced a procedure that is a clear “winner,” it is important to go through the data analysis to confirm and support preliminary conclusions formed during testing and to document the results of the trials.

If the welding system used for welding trials has a data collection package, it is often useful to plot the data from each weld in a systematic way so that the data from each weld can be

studied and compared to data from other welds in the series. This process may include producing charts that show travel speed and spindle speed as a function of time or position on the weld, and a chart that shows in-plane force, plunge force, and spindle torque as a function of time or position on the weld. Plotting as a function of position on the weld is helpful for isolating data generated at the locations where tensile specimens were cut for testing. It is also possible to plot weld power (heat generated per unit time) and specific energy (heat generated per unit length), using the following equations. See Table 3 for details of the associated units.

$$\text{Power} = 2 * \pi * \text{Torque} * \text{Spindle speed}$$

* Power units conversion

$$\text{Specific energy} = \frac{2 * \pi * \text{Torque} * \text{Spindle speed}}{\text{Travel speed}}$$

* Specific energy units conversion

Tensile test results should also be analyzed. It is a good idea to look at the fractured specimens from each weld and note the general failure location, the point of failure initiation, the appearance of the fracture surface, and any indications of defects that may have caused or influenced the fracture. The goal here is to determine if each tensile specimen represents the true transverse strength of a sound weld or if fracture was the result of some defect. Average values for tensile strength, yield strength, and elongation should also be calculated, along with the standard deviation of the test lot. For sound welds in aluminum alloys, the standard deviation should be very low; for example, it is common to see standard deviations for tensile and yield strength to be less than 7 MPa (1 ksi), and for elongation, less than 1%. These values may be slightly higher for 5xxx-series alloys. If fractures in any of the specimens are the result of a defect that can be attributed to incorrectly following the welding procedure, the weld should be repeated and retested. Tensile

Fig. 5 Pin diameter as a function of shoulder diameter, from the literature

Table 3 Power and specific energy units conversion

Torque	Travel speed	Spindle speed	Units conversion	Energy units
ft-lb	in./min	rev/min	Power: 1 Specific energy: 1 Power: 0.00128 Specific energy: 0.00128 Power: 0.0226 Power: 0.0000303	Power: ft-lb/min Specific energy: ft-lb/in. Power: Btu/min Specific energy: Btu/in. Power: W Power: hp Power: J/min Specific energy: J/mm Power: W
N-m	mm/min	rev/min	Power: 1 Specific energy: 1 Power: 0.0167	Power: W Power: J/min Specific energy: J/mm Power: W

results should then be plotted as a function of the welding process parameters that were evaluated.

After completing systematic welding trials and establishing the preliminary welding procedure, it is often necessary to perform robustness testing, where the welding procedure is tested to evaluate materials produced with some degree of intentional variability in welding conditions. The goal is to determine how sensitive the welding procedure will be when encountering the inevitable in-process variation, discussed in the previous section. This testing may, for example, indicate that a lower travel speed, and hence production rate, is necessary to ensure reliable joint properties, given the anticipated variations in workpiece features and process execution. This testing may also include more detailed characterization of basic weld properties, such as toughness, corrosion, fatigue, and stress-corrosion cracking tests, as required by operational or performance specifications. The welding process parameters most likely to vary in-process are:

- Travel speed
- Spindle speed
- Workpiece thickness
- Plunge depth
- Plunge force
- Joint offset
- Joint gap
- Joint mismatch
- Tool geometry (wear)

Travel speed and spindle speed are two very important variables in FSW, and they typically experience a degree of normal variation in practice. However, most welding systems are capable of controlling these variables well enough that weld quality is not adversely affected. In spite of this, it is usually a good idea to implement a data collection system to log these values during production welding, as confirmation that the correct weld parameters were used and that machine performance was adequate throughout the weld.

Workpiece thickness is usually not subject to a significant amount of in-process variation when the workpiece is a machined component, but when rolled plate or extruded products are used in the as-received condition, thickness variation within a workpiece or between workpieces can be significant and can lead to poor FSW quality. As a result, careful attention must be paid to workpiece thickness variation in FSW. Typically, mill-produced aluminum materials are controlled by one or more specifications. One common specification that regulates geometry of aluminum mill products is ANSI H35.2 (Ref 42). This specification gives the allowable thickness variation for rolled and extruded products. Based on this or other applicable specifications, one can test the ability of the welding tool to produce sound welds at the limits of thickness variation. When the potential thickness variation is greater than the

welding tool design can handle, such as when the strength or ductility of the joint is reduced at the maximum material thickness condition, thickness measurement procedures can be specified, and welding tool pin length adjustment can be employed.

Welding tool plunge depth is also critical to producing a sound friction stir weld. The welding tool plunge depth can be expressed in terms of the heel plunge depth, the pin/anvil gap, or the depth of the tip of the welding tool relative to the workpiece surface, depending on the details of the control system used. Some welding systems employ absolute position control, relative to a fixed coordinate system. Others use relative position control, either relative to the anvil or relative to the workpiece surface, and still other systems may operate with no active axial position control, such as a system where the axis is set and locked during welding. Other welding systems may only operate in load control, where the plunge force is controlled and the welding tool depth varies in response to variation in local conditions. In any case, the depth of the welding tool in the workpiece is critical to ensure complete weld penetration and to ensure adequate surface forging by the shoulder. As a result, plunge depth must be monitored during welding. As with the travel speed and spindle speed, this variable should be recorded in a log file during production welding for the purpose of confirming that the welding tool tip was sufficiently close to the anvil at all times to achieve complete weld penetration.

In an FSW implementation that uses plunge force as the primary axial position control variable, plunge force variation is typically low enough that sound welds can be reliably produced. The larger issue is the variation in plunge depth that occurs as the welding system actuates the axial position to maintain constant plunge force, as discussed previously. In a process where the axial position is the primary control variable, the plunge force should be monitored to ensure that adequate consolidation of the crown surface of the weld is maintained. Review of the weld log file can give an indication of possible areas of the weld that may have defects from being insufficiently consolidated at the crown surface during welding due to low plunge force.

During welding, joint gap, offset, and mismatch errors can occur, either due to improper setup in advance of welding or due to shrinkage stress and welding forces during welding. It is often wise to evaluate the effect of these alignment errors on joint strength in order to know the limits of variability that can be tolerated. Gap tolerance can be evaluated by completing a weld or series of welds in specially designed test panels that have short, shallow notches cut into one side of the joint, as shown in Fig. 6. By testing several gap settings, joint strength as a function of gap can be determined. If the gap tolerance is too low, additional welds at a lower travel speed may provide a more robust

procedure. Similar tests can be done for offset errors and mismatch errors. Based on the results of these tests, an in-process monitoring scheme can be implemented to confirm joint alignment and joint gap, thus ensuring that these errors never result in excessive joint strength variation.

Finally, welding tool wear over time can result in variation in the welding process. The best way to account for tool wear is to complete life testing of the welding tool in production or in simulated production welds. Tool life can be determined by the point at which wear of the welding tool results in sufficient alteration of the tool that joint strength or other critical joint properties are adversely affected, or by catastrophic tool failure due to accumulated fatigue damage. In either case, a life test can indicate the practical life of a given welding tool design.

The results from the systematic welding trials and the robustness testing should then be collected and summarized for future reference and reported when formal qualification is required. Formal weld procedures can then be prepared for use in each application.

Procedure Qualification

Procedure qualification is the process by which a regulatory authority evaluates a welding procedure, performed by a contractor, and approves the use of the procedure in production of some deliverable item. Similarly, operator qualification is the process by which an individual is approved to execute a qualified welding procedure. Further, in some cases, regulatory authorities have set requirements for how production welding operations are to be carried out, such as requirements for detailed work instructions, in-process monitoring, and post-weld inspections and testing. In this section, some of the common features of procedure qualification are presented.

Typically, procedure qualification consists of the steps listed as follows, although there may be some variability in the process between specifications (Ref 1–5, 43):

1. Develop and document a welding procedure, with all supporting tests and evaluations

Fig. 6 Joint gap test panel schematic

2. Submit the procedure and supporting data for review
3. Demonstrate the procedure(s) being proposed and record all variables used
4. Test weldments(s) produced and collect test data
5. Present procedure and qualification test data for approval
6. Release the procedure for production use

In qualifying a welding procedure for FSW, given the relative newness of the process, it is important to communicate with the approval authority early in the planning process and to be well prepared for the qualification process. As the test plans for systematic welding trials and robustness testing are developed, they should be submitted to the approval authority to solicit their comments on the planned testing. This will help ensure that all appropriate tests are completed in advance of requesting formal procedure approval. After preparatory tests are completed, the test data should be submitted to the approval authority in advance or concurrently with a request to witness qualification welds.

Friction Stir Welding Tool Designs

Carl D. Sorensen, Brigham Young University

A KEY DIFFERENTIATOR between friction stir welding (FSW) and other friction welding processes is the presence of a nonconsumable tool in FSW, often referred to as a pin tool to differentiate it from other tooling associated with the process. The pin tool used in FSW influences virtually every aspect of the process. Pin tool design affects the process loads, material flow, process-zone temperature, and weld quality. Tool design also has significant effects on tool life and tool cost. Historically, tool design has been a combination between art and science. As the understanding of the process matures, tool design has been coupled more closely with process behavior, and tool performance has increased correspondingly.

This article discusses materials for FSW pin tools, various tool geometries that have been used, designs for specific applications, predicting and measuring tool performance, and other considerations in FSW pin tool design.

Friction Stir Welding Tool Materials

Friction stir welding has been performed with a variety of pin tool materials. When welding materials with low softening temperatures (under approximately 600 °C, or 1110 °F), the range of materials that can be used is relatively large. However, when welding materials with higher softening temperatures, it can be a challenge to find appropriate tool materials. This section discusses the requirements for tool materials along with materials that have been successfully used in various FSW applications.

Tool Material Requirements

Friction stir welding is a challenging material application. The pin tool is surrounded by workpiece material at the softening temperature, which is typically between 80 and 95% of the absolute melting temperature of the workpiece (Ref 1). Friction stir welding tools also see significant process loads; on the order of 10,000 Newtons (N) of force along the tool axis and several thousand Newtons perpendicular to the tool axis are common (Ref 2, 3).

Table 1 summarizes the relationships between the classes of tool materials and the desired tool material characteristics.

Strength at Room Temperature and Process Temperature. Friction stir welding tools must be strong enough to support the process loads. This strength must exist both at room temperature (for the start of the weld) and at elevated temperature (for the major portion of the weld). For welding alloys such as 6061 in thicknesses under approximately 16 mm (0.6 in.), strength is typically not a major problem. For higher-strength alloys and thicker plates, strength can be a significant factor in the choice of FSW pin tool material.

Chemical Inertness at Elevated Temperature. Chemical interactions with the material to be welded can cause significant detrimental effects. Strong chemical adhesion of the workpiece and the tool can lead to reduced flow. Chemical wear can reduce the strength of tools. Tool material can contaminate the weld material. In some cases, incipient melting at the tool-workpiece interface is thought to lead to liquid metal embrittlement of the tool (Ref 4). To avoid all of these problems, tool materials that do not chemically react with the workpiece should be chosen.

Wear Resistance. Over an extended period of time, wear can change the shape of the tool and adversely affect the properties of the weld. In some cases, wear can lead to tool failure in a relatively short time. In other cases, wear particles of the tool material left behind in the weld can greatly reduce the properties of the weld, especially in fatigue (Ref 5). Therefore, tool materials should have a strong resistance to wear.

Fracture Toughness. Friction stir welding tools operate in a cyclic environment under high loads. To avoid failure, fracture toughness should be high. Fracture toughness has been a particular problem in tools for welding high-softening-temperature materials such as steels. Pure tungsten tools have low fracture toughness at room temperature, leading to failure on plunge (Ref 6). Ceramic and superabrasive tools tend to fail by fracture, rather than by wear. Higher fracture toughness is always a desirable characteristic for FSW tools.

Manufacturability. Many FSW tools have complex geometries, so manufacturability is a key aspect of tool material choice. Tools that can be worked with standard machines and processes are generally preferred over those that require special processing (e.g., grinding with superabrasive wheels). Nevertheless, if the performance of a difficult-to-manufacture material justifies the increased cost, such materials can be used for FSW tools in demanding applications.

Availability. To be feasible for a production process, the availability of the material should be high. Materials whose availability is limited will tend to have high cost or may be unavailable at any cost. For example, iridium was tried as a tool material for FSW of titanium alloys (Ref 7). Although it had most of the characteristics required for a tool material, availability of iridium is so limited that it could not be used as a commercially feasible tool material.

Cost. Friction stir welding tools are generally considered to be consumables. Therefore, the cost should be commensurate with this application (Ref 8). For some high-performance materials, the cost of a tool can exceed several

Table 1 Characteristics of typical friction stir welding tool materials

Material characteristic	Tool material class				
	Tool steels	Superalloys	Refractory metals	Carbides, cermets, and ceramics	Superabrasives
Room-temperature strength	Good	Excellent	Excellent	Excellent	Excellent
Process-temperature strength	Good	Very good	Excellent	Good	Excellent
Chemical inertness	Good	Very good	Good	Good	Excellent
Wear resistance	Good	Good	Very good	Good	Excellent
Fracture toughness	Very good	Very good	Very good	Good	Poor to good
Availability	Excellent	Very good	Very good	Very good	Very good
Cost	Excellent	Very good	Poor to acceptable	Good	Poor to acceptable

thousand dollars. Such expensive tools will have only limited applicability, where the value of the joint to be made is sufficiently high to support the tool cost.

Classes of Tool Materials

Various tool material classes have been used to perform FSW and processing. This section describes the general properties of each of the classes of tool materials.

Tool steels have been used for the large majority of FSW. The most commonly cited tool steel is H13 (Ref 9–26), which is used to weld most aluminum alloys, magnesium, lead, and other low-softening-temperature materials. H13 is an air-hardening, high-hot-strength tool steel with good thermal fatigue resistance and wear resistance (Ref 27). Other tool steels used include O1, D2, SKD61, Orvar Supreme, and Divar (Ref 28–33). The maximum-use temperature for oil- and water-hardening tool steels is approximately 500 °C (930 °F). Secondary-hardened tool steels can be used up to approximately 600 °C (1110 °F) (Ref 27).

Superalloys. Cobalt- and nickel-base superalloys have been used as materials for FSW tools in high-strength aluminum, copper, and thin steels. These alloys typically have excellent high-temperature deformation resistance. They are relatively available, serving as commercial alloys for aircraft engine components, and have moderate costs. Nimonic 105 has probably had the most use in welding copper (Ref 34). MP159 (a cobalt-base superalloy) has been used for welding high-strength aluminum alloys such as 7075 and 7050 (Ref 4, 35, 36). Some researchers have reported premature tool failure when used at high temperatures in these alloys, which was thought to be related to liquid metal embrittlement (Ref 4).

A custom cobalt-base alloy strengthened by $\text{Co}_3(\text{Al,W})$ precipitates has been tested for use in welding carbon steel and titanium alloys (Ref 37). It was tested with a relatively short probe (1.4 mm, or 0.06 in., in length) but was able to survive over 45 m (148 ft) in mild steel.

Limited reactivity was found with either steel or titanium. Its relatively low cost and high manufacturability make it a promising tool material for future testing.

Refractory metals are promising FSW tool materials for high-softening-temperature alloys because of their very high hot strength. Niobium and tantalum have high oxygen solubility at elevated temperatures, so they cannot be used for FSW in atmosphere (Ref 38). Molybdenum and tungsten have both been used for FSW of steel and titanium. Pure tungsten suffers from low room-temperature toughness (Ref 4, 39). W-25%Re, W-1%LaO₂, and Densimet have all been used for FSW of steel, titanium, and copper (Ref 40–48).

With the exception of tungsten-rhenium alloys, refractory metals have an acceptable price and availability. Due to a limited supply of rhenium, tungsten-rhenium alloys are extremely expensive. Refractory metals are limited in the geometries that can be used, because small features tend to wear away rapidly (Ref 49). The most common refractory metal tools have either no surface features or very gentle surface features.

Carbides and Ceramics. A variety of ceramics and carbides have been explored for use in FSW tools. Al₂O₃ and Si₃N₄ have outstanding strength, but their toughness is too low for successful use in FSW of steels. Cemented tungsten carbide (WC-Co) has been used for welding metal-matrix composites due to its high abrasion resistance (Ref 50). Cemented carbide has also been used for welding of steels (Ref 51). The use of cemented carbide for steels is limited by its relatively low hot strength.

Superabrasives are ceramic materials that have been processed in high-temperature, ultra-high-pressure (HT-UHP) presses. The most widely known superabrasive is synthetic diamond. It is used for FSW tools in the form of a sintered compact called polycrystalline diamond (PCD). The superabrasive most widely used in FSW is polycrystalline cubic boron nitride (PCBN). Because they must undergo an HT-UHP process, superabrasive materials

are fairly expensive. Manufacturability of superabrasive tools can be a challenge, because the primary method of machining is grinding with diamond abrasive wheels. Availability of the raw materials for superabrasives is excellent.

Polycrystalline diamond has been used in FSW of aluminum metal-matrix composites, where its superb hardness and wear resistance allow for extremely long tool life (Ref 52). It is also a candidate shoulder material for FSW of titanium. Polycrystalline diamond is not usable for FSW of steels because of its high reactivity with iron at elevated temperatures (Ref 53).

Polycrystalline cubic boron nitride has been used for FSW of a variety of high-softening-temperature materials. It has the lowest wear rate of all materials used for FSW in these alloys. However, the relatively low fracture toughness of PCBN generally leads to failure by fracture rather than by wear (Ref 39).

FSW Tool Material Applications

A variety of FSW tool materials have been used for welding various materials. Because the tool requirements vary with the material welded, the tool materials for each alloy class are discussed separately. Table 2 summarizes the tool materials used for each alloy class.

Aluminum Alloys. The bulk of FSW in aluminum alloys is performed with H13 steel tools, at least up to a thickness of 13 mm (0.5 in.). Other tool steels have been used, but H13 appears to be the workhorse of the aluminum FSW industry in moderate and low thicknesses (Ref 11–26). In greater thicknesses and with higher-strength 7xxx-series alloys, H13 probes can fail prematurely. In such applications, the cobalt-base alloy MP-159 is the most widely used tool material (Ref 4, 35, 36). For aluminum alloys, tool materials are generally considered to meet the primary needs, with tools often lasting for 1000 m (3300 ft) or more of welding.

Table 2 Tool materials used for welding various alloy classes

Material welded	Tool material class				
	Tool steels	Superalloys	Refractory metals	Carbides, cermets, and ceramics	Superabrasives (a)
Aluminum alloys	Most commonly used, typically H13	MP159 used for probes in 7xxx alloys	...	WC-Co	...
Magnesium alloys	Generally H13	WC-Co	...
Copper alloys	...	Nimonic 105 for probe, Inconel 718, Waspalloy	Densimet for shoulder, Mo, W-25Re	WC-Co	PCBN
Titanium alloys	Mo, W, W-Re, W-LaO ₂ , Mo-Re-HfC	WC-Co, but limited tool life	...
Stainless steels	W-Re (ferritic)	...	PCBN
Low-alloy steels	...	Co(Al,W) ₃	W-Re, W, Mo, W-Re-HfC	WC-Co	PCBN
Nickel alloys	WC-Co	PCBN
Metal-matrix composites	WC-Co	PCD
Thermoplastics	H13

(a) PCBN, polycrystalline cubic boron nitride; PCD, polycrystalline diamond

Magnesium alloys have been welded with both tool steel (H13) and WC-Co (Ref 54). The mechanical and thermal loads on the tool in welding magnesium are generally quite small, so the lower-strength tool materials work well. Perhaps the largest concern in FSW of magnesium is the tendency of the alloy to stick to the tool (Ref 55). Careful attention to tool surface finish helps provide successful results in FSW of magnesium alloys.

Copper and Copper Alloys. Copper has been tested with perhaps the widest range of tool materials of any alloy. Because FSW has been chosen as a joining technology for 50 mm (2.0 in.) thick welds in sealing canisters to contain nuclear waste in Sweden, a significant research program on FSW of thick-section copper has been carried out for several years. Seventeen different probe materials, including metals, cermets, ceramics, and superabrasives, were tested (Ref 56). Of these materials, Nimonic 90, Inconel 718, and Waspalloy were able to produce 3.3 m (11 ft) long welds. Nimonic 105 was able to produce welds 20 m (66 ft) in length with no visible damage. For these canister welds, Densimet was chosen as the shoulder material (Fig. 1). The PCBN tools have also been demonstrated to produce sound welds with good life in copper, aluminum bronze, and nickel-aluminum bronze (Ref 56, 57).

Titanium Alloys. Titanium and its alloys are particularly challenging to weld because of the high softening temperature, low thermal conductivity, and high reactivity of these alloys. Polycrystalline cubic boron nitride was tested and found to react with the titanium (Ref 58). Various tungsten alloys have been used to weld titanium alloys. W-1%LaO₂ has been shown to provide excellent results in welding beta and alpha-beta titanium alloys (Ref 59–62). A proprietary refractory metal alloy produced by General Electric and Edison Welding Institute has also shown promise in FSW of titanium. Although molybdenum alloys and W-25%Re survive the FSW process in titanium, the welds

made with these materials were of lower quality than those made with W-1%LaO₂ (Ref 63).

Stainless Steels. Ferritic stainless steels have been welded with both PCBN and refractory metal alloys (Ref 64–66). Both materials produce sound welds. Refractory metal tools currently have a higher thickness capability (approximately 18 mm, or 0.8 in.) than PCBN tools (approximately 8 mm, or 0.3 in.).

Austenitic stainless steels are much more challenging to weld than ferritic steels. Tool wear is a challenge in these alloys. Tools containing tungsten wear quite rapidly (Ref 67, 68). The PCBN tools wear less rapidly but still experience some wear. Smooth PCBN tools (Fig. 2) can sometimes lead to sigma-phase formation in FSW of 304L (Ref 69, 70). The PCBN tools with a convex scrolled shoulder and a stepped-spiral pin (Fig. 3) have been shown to eliminate sigma-phase formation (Ref 71). Thus, it appears that thread features may be necessary to achieve optimum properties in FSW of 304L. Polycrystalline cubic boron nitride has also been used to weld 316L and 2507 superduplex (Ref 39, 72). No tool materials have been found that successfully join AL-6XN superaustenitic stainless steel (Ref 73).

Low-Alloy Steel. Tungsten- and molybdenum-base tools have been used to successfully weld low-alloy steels, including W, W-25%Re, and W/Mo-Re-HfC alloys (Ref 74–78). Tools made from these alloys are typically hemispherical or truncated-cone probes with very small shoulders and smooth surfaces (Ref 79). Periodic redressing of the tool allows for an extended tool life.

A cobalt-base alloy containing Co₃(Al,W) precipitates has been shown to weld both low- and high-carbon steels (Ref 37). Although the alloy is only demonstrated for thin sheets (the probe length was 1.4 mm, or 0.06 in.), the

material looks promising due to its high availability, high manufacturability, and low cost.

Polycrystalline cubic boron nitride has been used to weld a variety of low- and high-alloy steels (Ref 80–83). Welds are generally of high quality, with good ductility and joint efficiencies greater than 90%. Tool wear is generally quite low in these alloys. Tool failure is generally due to fracture.

Nickel Alloys. Finding tool materials for welding of nickel alloys has been a significant challenge. WC-Co has been used to make welds in alloy 600 (Ref 84). Polycrystalline cubic boron nitride has been used to weld a variety of nickel alloys, including alloys 600, 718, 201, and 22 (Ref 39). Surface finish and mechanical properties are excellent, although tool life remains an issue in strengthened alloys.

Metal-Matrix Composites. The ceramic particles found in metal-matrix composites lead to excessive wear in FSW of these materials with tool-steel tools (Ref 85–87). More wear-resistant materials are needed. WC-Co has been demonstrated to allow FSW aluminum-base metal-matrix composite with 30 vol% SiC particles, with acceptable wear rates. A composite tool with a PCD shoulder and a WC-Co + PCD probe was demonstrated to weld aluminum metal-matrix composites with both SiC and B₄C, with no measurable wear (Ref 52).

Thermoplastics. The mechanical requirements for FSW of thermoplastics are similar to those for aluminum, although the temperatures are lower. H13 is generally used as a tool material for these applications. Friction stir welding of thermoplastics requires a stationary shoulder (Ref 88, 89) and has yet to find wide commercial application.

Friction Stir Welding Tool Geometry

Friction stir welding tools consist of a shoulder and a probe (or pin). The shoulder is larger in diameter than the probe and rides along the joint at or near the surface of the workpiece. The probe extends below the surface to approximately the maximum depth of the weld. It can

Fig. 1 Friction stir welding tool with convex scrolled shoulder of Densimet and MX Triflute probe of Nimonic 105. Source: Ref 34

Fig. 2 Conventional geometry (smooth concave shoulder, cylindrical pin, three flats) used for welding ferrous alloys

Fig. 3 Convex scrolled shoulder and stepped-spiral pin geometry used for welding ferrous alloys

be convenient to consider the designs of each component of the tool separately.

Shoulder Designs

The shoulder of the pin tool has the primary function of containing the deformed material within the weld zone. It has a secondary function of generating frictional heat to soften the material ahead of the probe. However, the heat generated by the shoulder increases the top-to-bottom asymmetry of the through-thickness thermal profile. Therefore, current research is exploring the value of minimizing shoulder heating.

Shoulders have three fundamental geometries: concave, flat, and tapered or convex.

Concave Shoulder. The concave shoulder was the original shoulder used in FSW (Ref 90) (Fig. 4). The concave shoulder has the cross section of a hollow cone, with a cone angle of approximately 6 to 10° from the horizontal. The hollow cone provides a reservoir for material displaced by the probe during the plunge phase of FSW and serves to bring material back toward the probe to achieve full consolidation. The shoulders of concave shoulder pin tools are typically smooth, with no surface features of any kind.

Pin tools with concave shoulders must be operated with the tool axis tilted (typically between 2 and 5°) from the vertical, such that the trailing edge of the shoulder is lower than the leading edge. This facilitates consolidation of the weld, but making nonlinear welds with tilted tools requires a machine with at least four axes of motion in order to maintain the appropriate orientation of the tool.

Flat Shoulder. A major advantage of a pin tool with a flat shoulder is that the tool does not need to be tilted to complete the weld. The disadvantage of such a tool is that there is no inherent ability to move material from the edge of the shoulder toward the probe. Therefore, flat shoulders typically have scrolls or

other features designed to draw weld material toward the tool axis (Ref 91).

Scrolls can have a variety of shapes, but the most common shape used in flat-shoulder tools is a rectangular cross section, spiral scroll projecting from the flat surface of the shoulder (Fig. 5). The tools are typically run with the scrolls 0.3 to 0.8 mm (0.01 to 0.03 in.) below the surface of the workpiece. If the scrolls are deeper, excessive flash results. If the scrolls are shallower, there is typically insufficient consolidation.

Tools with narrow flat shoulders and no scrolls have been recently used to weld materials with high softening temperatures (Ref 92) (Fig. 6). However, in this application the tool must be tilted like a standard concave shoulder tool.

Tapered and Convex Shoulder. Flat-shoulder tools and, to a lesser extent, concave-shoulder tools must operate within a very narrow depth range. If the tool is too shallow, insufficient consolidation occurs. If the tool is too deep, excessive flash is generated. This means that the tool must follow the profile of the top surface of the workpiece.

In contrast, the end of the probe should remain a fixed distance from the anvil to assure a full-penetration weld. Therefore, for a fixed probe length, it is desirable to maintain a fixed

tool position regardless of the workpiece surface profile.

To solve this fundamental conflict, tapered- and convex-shoulder pin tools were developed (Ref 93, 94). In such tools, the outer radius of the shoulder is farther from the end of the probe than the inner radius of the shoulder. This allows the tool to create a successful weld over a range of thicknesses nearly equal to the taper in the shoulder (Fig. 7).

To keep the material properly constrained within the stir zone, tapered- and convex-shoulder tools need scrolls. In contrast with the scrolls on flat shoulders, scrolls on tapered and convex shoulders are typically much shallower.

Like flat-shouldered tools, convex- and tapered-shoulder tools can be run at zero tilt angles. However, unlike flat-shouldered tools, convex- and tapered-shoulder tools can be successfully run at a large range of plunge depths (Ref 94).

Tapered-shoulder tools were the initial tools in this class, and they work well. By allowing the cross section of the shoulder surface to have geometry other than a straight line, the performance of the tool can be tailored to a particular application. For example, a convex-shoulder tool can be designed that will have less variation in top surface width with plunge depth than a tapered-shoulder tool.

Tapered shoulders allowed the creation of fixed-gap bobbin tools, where two tapered shoulders were separated by a fixed-length probe (Fig. 8). The fixed-gap bobbin tool allows symmetric welding of plates with relatively inexpensive equipment, even in the presence of typical plate thickness variation.

Stationary Shoulder. If the shoulder is being used for only the primary purpose of containing material, there is no need to have the shoulder rotate with the probe. In such cases, a nonrotating or stationary shoulder can be used.

Stationary shoulders (Fig. 9) were first used in FSW of thermoplastics, where the rotating shoulder tended to fling material out of the stir zone. By moving to a stationary shoulder with

a heating cartridge embedded, the material was able to be both heated and contained (Ref 89). Stationary shoulders have also been applied in the welding of aluminum and titanium alloys. These shoulders have been used in butt

welding and fillet welding (Ref 96). Through proper design of the stationary shoulder, coupled with the addition of a feed wire, the surface profile of the weld can be controlled. For example, reinforcement can be added to a butt weld, or a radius can be added to a fillet weld. A stationary-shoulder weld can often be made with an exceptionally high-quality surface finish (Fig. 10).

One of the challenges in stationary-shoulder welding is preventing the weld material from entering the gap between the stationary shoulder and the rotating probe. This is typically accomplished through the use of very small clearances between the shoulder and the probe.

Probe Geometries

The purpose of the probe is to generate deformation and resultant heat and to facilitate the flow of the material in the stir zone. Various probe geometries and features have been used to accomplish these objectives.

Cylindrical. Probes used in the initial FSW experiments were typically cylinders with ends having a spherical radius (Ref 90) (Fig. 4). Later designs had a flat rather than round end.

Cylindrical probes have been used with various features. Smooth probes having no features have been used for experimental work (Ref 3), but their use in production work has been limited. The most common feature on cylindrical probes has been threads. Threads are generally constant-pitch, 60°, V-form threads.

When tool materials are difficult to thread, small flats have been used on a cylindrical probe to increase the heat generation in the stir zone (Ref 81). This is generally done with a symmetric series of flats at an angle to the tool axis. Three flats is a common number to use (Fig. 11).

Flutes have also been used in conjunction with threads on cylindrical pins, particularly for use in swept-spot welding. Such tools are discussed in the section on tools for specific processes.

Conical. Cylindrical tools perform well in relatively thin plate, but as plate thickness increases, the strength of a cylinder is insufficient, so tools with more strength at the top surface of the weld are desirable. The most common geometry used to accomplish this is a truncated cone or frustrum geometry. This geometry has a relatively narrow probe end to keep forces low and a relatively large probe base to keep probe strength high. Conical probes can be smooth or can use various features to improve metal flow and increase heat generation. The commonly-used features include threads, flats, and flutes, alone or in combination.

Smooth conical probes have been used for welding materials with high softening temperatures, particularly for tools made out of refractory metals (Ref 79).

Other. Some researchers have noticed that tools used to weld difficult materials, such as

materials with high softening temperatures or metal-matrix composites, deform rapidly in the early stages of welding. However, at later stages of welding, the tool deformation rate decreases. This has led these researchers to propose that the deformed probe geometries are optimal for the particular welding process.

In welding silica-reinforced aluminum with a threaded cylindrical steel probe (Ref 28–30), the probe wore near the root to greatly increase the root radius while slightly decreasing the probe radius (Fig. 12). The large radius was thought to contribute to the low wear rate.

In processing nickel-aluminum bronze with a stepped-spiral probe, the end of the probe was observed to shorten, leading to a beehive-shaped probe. It was thought that this probe shape provided an optimal trade-off between strength and slenderness.

Noncircular Cross Sections. Most FSW probes have generally circular cross sections. However, other geometries have sometimes been used. Probes with a generally polygonal cross section have been used in both butt and spot welding.

Perhaps the most widely used noncircular probe geometry is the Trivex (The Welding Institute) probe (Fig. 13). The Trivex probe is roughly triangular in shape (Ref 95, 97–99). Each of the triangular sides is a circular arc whose center is located at the opposite vertex.

The Trivex tool has a dynamic volume ratio of approximately 1.3, even without additional features being added. The Trivex tool has been found to reduce both axial and path-direction forces by approximately 20% compared to a cylindrical tool.

Probe Features

Probe features can generally be classified as threads, flats, or flutes. They serve to increase heat generation and to control the flow of the material around the pin. Flats and flutes interrupt the threads on the probe and may provide for better mixing of the weld material.

It has been proposed that a major purpose for probe features is to facilitate the transfer of weld metal from the leading edge of the weld to the trailing edge of the weld. The swept volume of the probe gives the minimum volume of the stir zone. The actual volume of the probe is the volume of the material that must be displaced. The dynamic volume ratio is the ratio of these two volumes. A smooth probe with a circular cross section has a dynamic volume ratio of 1.0. A typical cylindrical threaded probe has a dynamic volume ratio of 1.1. A probe with aggressive threads and flutes, such as the MX-Triflute (The Welding Institute), has a dynamic volume ratio of 2.6. High values of the dynamic volume ratio have been found to

lead to high weld travel speeds, particularly in thick-section welding (Ref 56).

Threads. Threaded conical pins have been reported with three different thread forms: V-threads, stepped-spiral threads, and threads with semicircular or other well-radiused root cross sections. The threads on the probe have two major purposes. First, they generate heat through forcing the deformation of the parent material. Second, they control the flow of the parent material in the vertical direction. For butt welds, the material is typically forced downward by the threads to achieve full-penetration welds. For lap and spot welds, the flow is adjusted to minimize the sheet-thinning defect.

Many of the threads used in FSW are standard V-form machine threads. These threads can be easily made from existing tools and provide the benefits of threads as mentioned previously. However, the sharp angle in the root of the thread provides a stress concentration that can lead to probe failure at high loads. They primarily load the material in shear parallel to the probe surface, so they provide less material deformation than other thread profiles.

To avoid the problems with stress concentrations at the root, threads with MX-type features have been designed (Fig. 14). These threads often have much steeper faces than the standard 60° V-thread (Ref 99). They also have generous radii at the root of the threads. This serves to

Fig. 13 Trivex tools with and without threads. Courtesy of The Welding Institute

extend tool life while increasing the dynamic volume ratio of the probe.

Stepped-spiral threads (Fig. 15) are often used on FSW probes, particularly for applications in higher-softening-temperature materials. Stepped-spiral threads have a cross section similar to a staircase, with a thrust surface parallel to the tool axis. Because the thrust surface is completely exposed to the workpiece material throughout the length of the probe, the volume of material effectively loaded by the probe is higher than for V-threads and MX threads. The dynamic volume ratio of stepped-spiral-threaded conical probes is between that for V-threaded and MX-threaded probes.

Flats are the least aggressive of the thread-interruption features. They slightly increase the dynamic volume ratio compared with threads alone. They also increase the heat-generation rate. The flat surfaces provide the equivalent of a machining tool with a large negative rake, which is inefficient for cutting but generates heat quite well.

To maximize strength, flats are generally produced in odd numbers (Ref 99). This allows the full radius of the probe to be available directly opposite the flat, thus providing the strongest possible probe for a given geometry.

Flats have not been demonstrated to have a major effect on facilitating vertical mixing of the material, but they do provide an increased rate of material flow from the advancing side to the trailing side. For a typical conical pin

with a standard V-thread form and three flats, the dynamic volume ratio is approximately 2.

In applications for aluminum and other alloys with low softening temperatures, flats are seldom used, because flutes give a higher dynamic volume ratio. However, in applications for steel and other high-softening-temperature alloys, flats are used because they can be readily made in hard tool materials and show reduced wear compared to flutes (Ref 81).

On conical probes, flats typically run parallel to the conical edge and extend the entire length of the probe. On cylindrical probes, flats are generally inclined with respect to the tool axis and cover only part of the probe length (Fig. 16).

Flutes are the most aggressive features that are typically created on FSW probes. They give the highest dynamic volume ratios, typically in the range of 2.6 (Ref 99). They are most often combined with threads when used for butt welding but have been used without threads for spot welding and lap welding.

To maximize probe strength, an odd number of flutes is generally used. Virtually all of the fluted tools described in the literature use three flutes.

The most common fluted tool described in the literature is the MX-Triflute tool, invented by The Welding Institute. This tool contains three flutes and MX threads and has been used in welding of aluminum alloys as well as copper (Ref 100).

In addition to their effect on dynamic volume ratio, which affects transport of material from the leading edge of the probe to the trailing edge, flutes can also affect the axial transport of material from the root of the probe to the end of the probe. Flutes can have any of the following characteristics (Ref 101) (Fig. 17):

- Additive, meaning that they move material in the same direction as the threads
- Neutral, meaning that they are aligned with the tool axis and have no effect on the axial material transport
- Subtractive, meaning that they move material in the opposite direction of the threads

For butt welding, an additive configuration is generally used. For lap and spot welding, a subtractive configuration is sometimes used to minimize sheet-thinning defects. Although neutral flutes have been tested, they do not appear to be in wide use.

Designs for Specific FSW Processes

Most FSW currently performed is butt welding using a pin tool with fixed geometry, as has been described previously. However, a number of processes vary from this typical practice. These processes require tool designs specific to the process.

Adjustable Probe Length. To accommodate workpieces with variable thickness, pin tools

Fig. 14 Typical friction stir welding tool with an MX-Triflute probe. Source: Ref 38

Fig. 16 Representative variations of the Whorl tool (The Welding Institute), including both flats and square threads. Source: Ref 38

Fig. 17 Probe designs with various flute actions. Threads move material away from the shoulder; flutes have variable directions. Courtesy of Dwight Burford, National Institute for Aviation Research

with adjustable probe lengths have been developed (Ref 102, 103). These tools can also be used to eliminate the probe exit hole by gradually reducing the probe length to zero (Fig. 18). The main drawback to adjustable-probe welding is the necessity for more complex FSW machines to provide separate axes for the probe and the shoulder.

Welding with adjustable probe length requires a cylindrical probe geometry. Threads have been used with adjustable probes, as have flats, but flutes have not been reported in the literature.

Self-reacting welding (sometimes called bobbin tool) is an FSW process with no anvil. Instead, a rotating tool carries shoulders on both sides of the workpiece, with a probe that connects the two shoulders. This process minimizes the external forces required for FSW, because the two shoulders on opposite sides of the plate support the compressive loads required to forge the material in the stir zone. It also provides a way to weld without leaving a probe exit hole, because the tool can be run right off the edge of the parent metal.

Two versions of self-reacting welding have been implemented: adjustable gap and fixed gap. In adjustable-gap self-reacting FSW (Fig. 19), the lower shoulder is connected to

an adjustable probe while the upper shoulder is fixed to the machine spindle (Ref 104). By adjusting the probe length, the gap between the shoulders can be adjusted to compensate for part-thickness variations. Adjustable-gap self-reacting FSW requires machine capabilities equivalent to those for adjustable-probe FSW.

In fixed-gap self-reacting FSW, the gap between the upper and lower shoulders is fixed (Ref 105). Some form of convex or tapered shoulder is used to compensate for variations in part thickness. Any FSW machine is capable of fixed-gap self-reacting FSW. In fact, The Welding Institute has demonstrated fixed-gap self-reacting FSW on a computer numerical control milling machine (Ref 106).

Both forms of self-reacting FSW run at zero tool tilt and therefore require scrolled shoulders. Both forms carry the compressive load of the shoulders on the probe, so stresses in the probe are high. Both require cylindrical probes. In both cases, the probes are generally threaded and without flats or flutes, although flats have been used occasionally. The probe often contains left-hand threads on one end and right-hand threads on the other, to drive material flow toward the centerline of the workpiece.

Fig. 18 Schematic showing how an adjustable probe can be extracted to eliminate an exit hole. Source: Ref 39

Fig. 19 Adjustable self-reacting (bobbin) pin tool used in friction stir welding of aluminum extrusions. Source: Ref 39

Fig. 20 Flared Triflute tool used for lap welding of aluminum. Source: Ref 39

Due to the high loads in the probe, self-reacting FSW has been demonstrated only on aluminum alloys.

Lap Welding. In lap welding, the original joint line is perpendicular to the tool axis. Standard FSW tool designs induce significant material flow parallel to the tool axis. For butt welding, this flow is vital because it allows the formation of full-penetration welds. In lap welding, this axial flow is problematic because it can create a displacement of the original joint into either the top or bottom workpiece. This displacement, known as a hooking defect or plate thinning, greatly reduces the strength of the lap joint (Ref 107).

To avoid the hooking defect, it is desirable to minimize the flow of material across the original joint. At the same time, to eliminate the original joint, it is necessary to have significant flow in the plane of the joint. This requires design of special probes for effective lap welding.

One very effective probe for lap welding is the flared probe. Flared probes are frustrums of cones that have a radius that is larger at the end of the probe than at the probe root. These tools, generally in the form of a Flared-Triflute tool (The Welding Institute) (Fig. 20), have been used effectively in lap welds for relatively thick aluminum (Ref 108). Flared-Triflute tools have been demonstrated to reduce process forces and reduce upper plate thinning by a factor of 4.

Refill Spot Welding. Refill friction stir spot welding (RFSSW) (Fig. 21) was developed by GKSS (Ref 109).

In RFSSW, a tool with three coaxial pieces having relative motion is used. The outer piece is a stationary clamp. The intermediate piece is a rotating shoulder that can also move axially relative to the clamp. The inner piece is a rotating probe that moves axially relative to the clamp and the shoulder. In RFSSW, the clamp is brought to the surface of the parts to be welded. The rotating probe is then extended into the cavity formed by the shoulder, the probe, and the clamp. Finally, the shoulder is extended

Fig. 21 Schematic diagram of refill friction stir spot welding process. Source: Ref 109

to the surface of the workpiece while the probe is retracted to the surface of the workpiece, leaving the final weld surface flush with the original surface of the workpiece.

Because of the need for axial motion while constraining the weld material, the probe geometry for RFSSW must be cylindrical. As with adjustable-probe FSW, threads have been used in RFSSW tools, but no flats or flutes have been reported in the literature.

Swept Spot Welding. Swept spot friction stir welding (SSFSW) is used to join thin sheets in a lap configuration. In SSFSW, a fixed-probe FSW tool is displaced into the upper sheet. The tool is then transformed through a relatively localized path to create a localized lap weld. The path can have various geometries, such as stitch welding, swing welding (Fig. 22), and Octaspot welding (Wichita State University) (Fig. 23) (Ref 101, 110, 111).

In each of these welding processes, the objective is to eliminate the oxide layer between the sheets to enable a metallurgical bond. A potential failure mode in SSFSW is the sheet-thinning or hooking defect, where the remnant oxide layer is displaced upward or downward from its original location, leading to reduced strength due to reduced sheet thickness.

Fig. 22 Tool movement and view of finished spot for three variants of friction stir welding (FSW) spot welds. (a) Friction stir spot welding (sometimes called poke welding). (b) Stitch FSW. (c) Swing FSW. Source: Ref 110

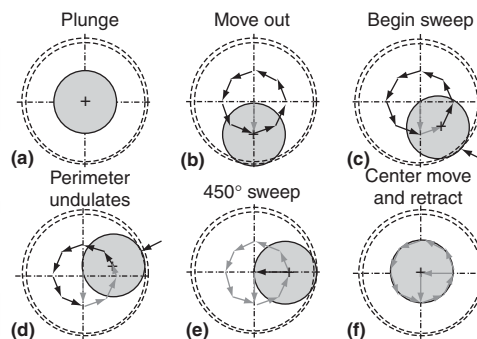

Fig. 23 Path moved by the tool in an Octaspot weld. Source: Ref 101

Control of vertical flow is important in SSFSW to minimize the sheet-thinning defect. Tools with cylindrical probes, threads, flats, and flutes have been used in SSFSW. Trivex tools have been found to provide improved spot weld strength.

Predicting and Measuring Tool Performance

At the present time (2011), design of pin tools for friction stir processing is as much art as science. Hypotheses concerning the effects of tool features on tool performance are difficult to prove, and tool design is accomplished more by judgment than by calculations. Efforts to improve this situation are proceeding through numerical modeling as well as through experimental investigations.

Modeling of Tool Features

Numerical modeling of the FSW process is a challenging task. It is a coupled thermomechanical process, with large gradients in both temperature and deformation. Furthermore, large plastic deformations are observed in the process. Thus, models are often used more to gain insight into the appropriate physics than to obtain an exact answer about the process.

Of particular challenge when modeling tool features is the fact that the threads are generally quite small compared to the dimensions of the probe, shoulder, and workpiece. A mesh that accurately captures the threads would be very large and lead to extremely long solution times. Thus, in most numerical models of FSW, the threads are not explicitly modeled. Instead, a boundary condition representing the effect of the threads is applied to the probe surface.

While this simplification makes sense from a modeling point of view, it makes it difficult to model the effects of the threads, because the boundary condition is an input to the model rather than an output.

Perhaps the most thorough numerical investigation of the effects of tool features has been carried out by Colegrove and Shercliff (Ref 95, 97). Using two- and three-dimensional computational fluid dynamics models, they explored a variety of probe profiles to examine the effects on material flow and probe-boundary conditions. To enable calculations in a reasonable time, they decoupled the thermal model from the flow model. The flow model was restricted to the region near the probe, and fine features on the tool, such as the threads on the probe, were ignored. It was expected that these were second-order effects.

The Colegrove and Shercliff model was effective in predicting the potential for defect formation with the Trivex tool and demonstrated increased axial flow in the Triflute tool (Fig. 24). Predicted force trends for both the Triflute and Trivex tools matched the experimental data, even though the absolute numerical values were significantly different.

Buffa et al. propose a method for designing optimal FSW tools through the application of a numerical model of the FSW process (Ref 113). Although the process seems sound, and the parametric exploration of the tool design space is appropriate, it appears that the model is too simple to provide reliable results.

The scientific design of FSW tools through predictive modeling is currently not technically feasible.

Experimental Observation of Tool Features

Experimental observation of the effects of features on tool performance is generally limited to single-point observations. For example, Colegrove and Shercliff compared the performance of Trivex and Triflute tools at various operating parameters. However, they compared only one version of the Trivex tool and one version of the Triflute tool.

The parametric exploration of FSW tools is a relatively new experimental technique. Yang et al. explored eight different tools in a parametric study of lap welding of magnesium (Ref 114). They identified that a triangular-shaped probe (Fig. 25) was superior to a round or pie-shaped probe, and that a small-diameter shoulder was superior to a large-diameter shoulder.

Sorensen and Nielsen completed a parametric exploration of convex scrolled-shoulder, stepped-spiral probe tools (Fig. 26) in FSW of AA7075 (Ref 94). They explored the effects of all the parameters used to design the tool in a screening design to identify the parameters that had a significant effect on process forces, spindle torque, and tool temperature. They identified probe angle, shoulder length, scroll radius, and scroll pressure angle as the most significant variables affecting the performance of the tool (Table 3). A follow-on response-surface study by Nielsen identified correlation functions to predict the process loads, torque, temperature, and defect formation as a function of tool design and operating parameters (Ref 115).

Although experimental studies such as these are time-consuming, at present they provide the best opportunity for quantifying the effects of tool design on the FSW process.

Summary

Much is known about the design of FSW tools. The design process is still somewhat empirical, but tool design can proceed on a rational basis. Tool materials can be chosen to be compatible with the material to be welded. Tool geometry and tool features can be chosen to achieve the desired weld characteristics. Modeling and experimentation have demonstrated the ability to assist in the selection of specific values for tool and operating parameters. Tools should be carefully designed to achieve the desired properties in the completed weld.

Friction Surfacing*

FRICION WELDING, a solid-state (non-melting) joining process, relies on the presence of relative motion between the parts while they are being pressed together under an applied axial force to generate the thermomechanical conditions for welding. The process, in its simplest form, makes use of rotary motion. A modification of conventional friction welding makes it possible to deposit layers of metal onto a substrate, a metal-transfer method that is called friction surfacing.

Although surfacing by friction can be regarded as novel, the original concept was reported, and a patent application filed, in 1941 (Ref 1). The technology was dormant until the late 1950s, when the process was rediscovered by Russian workers (Ref 2) with a wide variety of applications that used the process at that time:

- Shaft reclamation (Ref 3)
- Hardfacing of agricultural parts (Ref 4)
- Reconditioning bushings of sliding friction bearings and roll trunnions (Ref 5–9)
- Hardfacing (Ref 10) and improving wear resistance in gas and oil equipment (Ref 11)

Currently, friction surfacing has been successfully developed and commercialized over the past decade. The process is used for corrosion- and wear-resistant coatings and for reclamation of worn engineering components. Friction surfacing can be considered as an alternative for fusion-based overlay coatings, such as coating stainless steel on low-carbon steel for corrosion protection, repair, or reclamation. The solid-state nature of the process retains or even improves the mechanical properties of the coating and eliminates alloy dilution associated with fusion.

Friction surfacing can deposit a wide variety of high-specification materials, with an ideal metallurgical bond, onto a range of metal substrates. Friction surfacing has been used to apply a metal coating onto a metal substrate, but the process is being explored for the deposition of metal coatings onto ceramic substrates (Fig. 1). This unique way of metallizing ceramics has potential uses in heat sinking applications on temperature-sensitive substrates and as tracks for providing electrical conductivity.

Friction surfacing can deposit a wide variety of dissimilar materials with a good metallurgical bond onto a range of substrates. Advantages include:

- Excellent bonding with no inclusions, porosity, or oxidation
- Dense, clean, and fine microstructures
- Deposition of nonweldable alloys
- No melting of materials, with negligible dilution and small localized heat-affected zone
- Automatic and highly repeatable process

Process Description

In the friction-surfacing process, a rotating consumable is brought into contact with a moving substrate, which results in a deposited layer on the substrate (Fig. 2). First, the consumable rod is rotated to the desired speed. Next, it is brought into contact, under an axial force, with the stationary substrate. An initial rubbing period is required to allow the generation of heat and a plasticized layer in the consumable (Fig. 3). Several seconds are required before this condition is achieved. Then, the substrate is traversed across the consumable, leav-

Fig. 1 Friction surfacing of an aluminum layer on an alumina substrate. Courtesy of The Welding Institute

ing a layer of deposited material. The deposit is characterized by a fine hot-worked microstructure, zero dilution, and a very strong bond with the substrate.

The width of the coating depends on the diameter of the consumable rod and is normally in the range of 0.9 times the rod diameter (Ref 12). The thickness of the deposited layer is influenced by the primary surfacing variables of rotational speed, axial force, substrate traverse rate, consumable diameter, and type of material. Generally, the fully bonded width of the deposit is approximately 1 to 3 mm (0.04 to 0.12 in.) less than the diameter of the consumable, with the extreme angles of the deposit being characterized by lack of bond. It is thought that this lack of bond is associated with nonuniform pressure distribution across the consumable, lack of restraint to the highly plasticized flowing material, and the reduced time in action seen at the outer edges as compared to the center of the consumable.

The deposit thickness in a single pass is considerably influenced by the type of consumable material. Materials that have good resistance to plastic deformation at elevated temperatures, such as the nickel-base alloys and the Stellite alloys, will only yield thicknesses of the order of 0.5 to 1 mm (0.02 to 0.04 in.). When austenitic stainless steel and carbon steels are used, the thickness increases to approximately 3 mm (0.12 in.). For materials with low strength at elevated temperature, such as aluminum and its alloys, thicknesses can approach 5 to 6 mm (0.20 to 0.24 in.).

Representative variables associated with friction-surfacing conditions are shown in Table 1. A typical deposit of austenitic stainless steel from a 25 mm (1 in.) diameter rod that has been laid down on mild steel by the friction-surfacing process is shown in Fig. 4(a). The layer is characterized by a uniformly rippled surface of consistent width and thickness. A transverse section reveals lack of bond at the edges and sound bond formation between the deposit and substrate, above the narrow, crescent-shaped, heat-affected zone in the latter (Fig. 4b). Figure 4(c) shows the microstructural features at the bond interface. It is important to remember that a uniform and smooth mushroom-shaped upset is continuously formed on

* Revised from E.D. Nicholas, Friction Surfacing, *Welding, Brazing, and Soldering*, Vol 6, *ASM Handbook*, ASM International, 1993, p 321–323.

Fig. 2 Basic technique for friction surfacing

Table 1 Friction-surfacing parameters for selected material combinations

Combination	Consumable diameter		Rotation speed, rev/min	Applied force		Traverse rate	
	mm	in.		kN	10 ³ lbf	mm/s	in./s
Austenitic stainless steel to mild steel	25	1.0	550	50	11.3	5	0.20
Stellite 6 to austenitic stainless steel	20	0.8	330	50	11.3	2.5	0.10
Al-4Cu to Al-4Cu	25	1.0	780	17	3.8	4	0.16

the consumable rod during the surfacing operation.

If it is necessary to clad larger surface areas, then multiple side-by-side layers can be laid down. If thicker deposits are needed, then layers one on top of another can be used. If both approaches are called for, then interpass machining may be required to ensure sound adhesion properties.

Selection of process parameters for new coating materials or substrate geometries is typically by experimental development work. Most of the earlier works on friction surfacing focused on feasibility aspects of the process (Ref 13–15). Mathematical models of the process may facilitate process optimization. Current development activities include optimization models (Ref 12, 16, 17), process modeling (Ref 18), and the performance of friction-surfaced coatings (Ref 19).

Equipment

The process uses equipment that is similar to a machine tool, for which the surfacing conditions are preset. Therefore, the process can provide good reproducibility and is not dependent on operator skill. The earliest feasibility studies were conducted on a modified, continuous-drive, friction-welding machine (Ref 20).

Practical use necessitated increased surfacing capacity.

The ability to use converted machine tools offers a low-cost option in the technology of friction surfacing. For example, a milling machine (Ref 21) designed for the heaviest class of milling was used for longer deposition runs and larger-diameter components. Machines (such as in Fig. 5) are built dedicated to friction surfacing. In this example, the machine is particularly suited for longitudinal deposition. The table moves with 1575 mm (65 in.) of longitudinal travel and 725 mm (30 in.) of transverse travel at a lateral rate between 0.5 and 17 mm/s (0.02 and 0.68 in./s). Capabilities of this example include:

- Put down runs of 3 m (10 ft)
- Use consumables up to 70 mm (3 in.) in diameter
- Provide a range of rotation speeds from 250 to 1800 rev/min
- Develop axial forces up to a maximum of 180 kN (40.5×10^3 lbf)

The machine frame is designed to minimize deflection. Rotary manipulators (Fig. 6) can be used for circumferential deposition onto curved surfaces. A rotary table can be used for annular deposits on disks and flanges.

Fig. 3 Friction surfacing process of metal deposition as the substrate is being moved to the left. Courtesy of Frictec Ltd.

Applications

Initially, potential applications for this solid-state technique were in the cladding of localized areas. Typical examples include the anticorrosion surfacing of slide valve plates, the surfacing of the annular contact face of composite pipe flanges, the inlay cladding by suitable strategic materials in positions that suit bearings and seal-contact areas on shafts, and the cladding of the exposed regions of shafts that are used in pernicious environments. Hardfacing applications on cutting edges and agricultural tools were the early applications (Ref 11).

The available methods, in terms of surfacing and surface-treatment technology, are still being developed, particularly in the reclamation of worn parts and reconditioning of worn shafts. The process may increasingly accompany other solid-state, large-overlay techniques, especially with respect to localized repair and the reclamation of explosively clad and roll-bonded composite materials.

Various substrate geometries that have interesting potential for friction cladding are shown in Fig. 7. Shell banding may be another application, where suitably soft material is friction surfaced to the bodies of artillery shells (Ref 22). Other possibilities include the manufacture of specialized wear tiles (for sinter plant and quarrying equipment) and the in situ reclamation of worn railway points. Turbine blades, guillotine and shear blades, disk brakes, machine-tipped tools, and press tool dies are also considered to be potential friction-surfacing applications.

Friction surfacing has now been applied to a wide range of monolithic deposit/substrate combinations. There has been considerable success in producing high-strength bonding, fine-grained forged microstructures, and full homogeneity. A lack of porosity has also been attained, as have desirable surface properties, such as corrosion and wear characteristics that

either equal or surpass the bar stock from which the deposit originated. Combinations include:

- Inco 625 to austenitic stainless steel
- Austenitic stainless steel to carbon steel
- Stellite 6 and 12 to austenitic stainless steel
- Hastelloy to austenitic stainless steel
- Ti-6Al-4V alloy to Ti-6Al-4V alloy
- Al-4Cu alloy to Al-4Cu alloy
- Hardfacing steels, such as D2 and H13, to medium-carbon steels

As noted, friction surfacing of metals on ceramic substrates is also a more recent area of development. For example, process research at The Welding Institute has used friction

surfacing to deposit aluminum with less than 50 μ m thickness onto an alumina substrate (Fig. 1). The technique also can be used to lay copper tracks on aluminum nitride and silicon carbide substrates.

Diffusion Bonding*

THE JOINING OF MATERIALS IN THE SOLID STATE can be an attractive alternative to fusion-welding processes. In fact, metals that are conventionally difficult to weld and combinations of dissimilar materials can only be welded using a solid-state process. The wide range of techniques that are available for solid-phase joining have various modes of heat and pressure application.

Diffusion welding represents one extreme within this range, in that it involves minimal pressurization but relatively high temperatures and long periods of time. In its simplest form, the process involves holding premachined and cleaned parts in intimate contact and then heating them in a protective atmosphere. As its name implies, diffusion has a major role in the joining of mating parts, although other mechanisms, such as microyielding and oxide dissolution, are also critical steps in successful welding.

The process of diffusion welding has been used for many years, although it did not attain industrial acceptance until the 1970s or 1980s, and then, only for specialized applications. A comprehensive, although somewhat dated, review of systems that have been successfully joined using diffusion welding is provided in Ref 1.

The specific advantages of the process include its ability to join most metals and some nonmetals in like or dissimilar combinations, the minimal amount of deformation that results, and the fact that the weld area is mostly independent of welding time. These advantages are offset by the need to machine parts to fairly tight tolerances on component fit-up, as well as on surface finish. However, the requirements that are generally specified can readily be achieved using standard machine shop practices.

Process Variants

Solid-Phase Process. The more-conventional form of diffusion welding uses uniaxial loading, which can be applied by dead weight, mechanical, pneumatic, or hydraulic means.

The applied load is such that macrodeformation of the parent material(s) does not have to be reached. Because deformation also depends on welding temperature, temperatures that range from 50 to 75% of the melting point are usually employed. Heat can be applied by radiant, induction, and either direct or indirect resistance heating. Most welding operations are performed in vacuum or inert gas atmospheres, although welding in air has been reported (Ref 2). When welding noble metals, the requirements for a clean atmosphere are less stringent, but protection can prevent parent-metal oxidation while maintaining a clean weld interface.

An examination of the proposed sequence of stages in diffusion welding (Ref 3, 4) emphasizes the importance of the original surface finish. In forming a bond, it is necessary for the two metal surfaces to come into atomic contact (Fig. 1). Hence, microasperities and surface contaminants must be removed from the bonding faces. The applied load first causes the plastic deformation of surface asperities, thereby reducing interfacial voids. Bond development then continues by diffusion-controlled mechanisms, including grain-boundary diffusion and power-law creep.

Premachined parts for uniaxial diffusion welding should have a surface finish of greater than $0.4 \mu\text{m}$ ($16 \mu\text{in.}$), roughness average (RA). Swabbing with acetone or petroleum ether, which should occur immediately prior to set-up in the welding machine, can suffice as a degreasing measure. Ultrasonic cleaning also has been used. Many researchers have examined the removal of oxide, prior to welding, by ion bombardment or other means. This can be applicable to certain metals if welding is to be carried out in the same vacuum chamber, or if the parts are in-vacuo coated with an oxide-resistant material. However, the additional cost and time involved in this procedure make it impractical for most industrial applications.

The liquid-phase process is applicable only to dissimilar-material combinations or to like materials in situations where a dissimilar-metal insert is used. Solid-state diffusional processes lead to the formation of a different phase at

the weld interface. The liquid-phase welding temperature is based on the temperature at which this phase (usually eutectic) melts. This thin layer of liquid spreads along the interface to form a joint at a lower temperature than the melting point of either of the parent metals. A reduction in welding temperature leads to the solidification of the melt. At the point where this phase is diffused into the parent metals, by holding at temperature, the process is known as

Fig. 1 Mechanism of diffusion welding. (a) Initial "point" contact and oxide contaminant layer. (b) After some "point" yielding and creep, a thinner oxide layer with large voids results. (c) After final yielding and creep, some voids remain with very thin oxide layer. (d) Continued vacancy diffusion eliminates oxide layer and leaves few small voids. (e) Completion of bonding

transient liquid-phase diffusion welding. The optimal welding time and temperature can be estimated by using the applicable phase diagram and solidification kinetics (Ref 5).

The **superplastic forming/diffusion welding** (SPF/DW) technique has been developed specifically within the aerospace industry. Its industrial importance is such that it is worthy of separate consideration. The process is used commercially for titanium and its alloys, specifically those that exhibit superplastic properties at elevated temperatures within defined strain-rate conditions (Ref 6–8). This process also has been successfully used for advanced aluminum alloys (Ref 9). Because the temperature and pressure conditions coincide with the conditions required for welding, the two processes have been combined into one manufacturing operation. See also the *ASM Handbook* articles “Superplastic Sheet Forming” (Ref 10) and “Forming of Titanium and Titanium Alloys” (Ref 11).

Hot Isostatic Pressing (HIP) is a solid-phase process that involves the application of a high-temperature, high-pressure gas to components. Isostatic pressurization allows the welding of more-complex geometries than the uniaxial welding process can handle.

A hot isostatic press consists of a furnace within a gas pressure vessel. Its size can range from a diameter of 100 mm (4 in.) to a diameter of 1.1 m (44 in.) and a height of 2.2 m (88 in.). Argon gas is typically used, and there is a need to encapsulate the bond interfaces to prevent the gas from entering the site of the bond. This is most often achieved by locating the specimen in an evacuated and sealed steel can, although various other means can be used as well.

The pressures associated with HIP welding are significantly higher than those used in uniaxial welding. However, because the pressure is isostatic, the level of deformation is extremely low. In addition, less premachining is required. Typical HIP cycles can last from 6 to 16 h, but because many components can be fitted into one furnace, the unit costs on large production runs can be low. Bryant (Ref 12) has developed a graphical procedure to determine the minimum pressure and temperature required for the HIP welding of several metals and alloys.

Diffusion Bonding of Metals

Steels

Diffusion Bonding of Carbon and Low-Alloy Steels. Although diffusion welding is applicable to this class of steels, industrial applications are limited. The process is used in situations where it is essential to avoid or minimize distortion and postweld machining, and for complicated geometries that involve internal features.

These steels are generally welded without the use of filler material (interlayer). The parts

themselves are machined to a good surface finish ($<0.4 \mu\text{m}$, or 16 $\mu\text{in.}$, RA surface roughness, and flat) and assembled in a heating unit such that force can be applied uniaxially or isostatically.

In terms of uniaxial diffusion welding, a wide range of bonding conditions have been shown to give sound joints, that is, temperatures of 900 to 1200 °C (1650 to 2190 °F), pressures of 5 to 14 MPa (0.7 to 2 ksi) and times of 5 to 120 min. Because the parameters are interdependent, as temperature increases, the load and/or time can be reduced and vice versa. Figure 2 depicts a typical cross section of a joint in 0.4% C steel, in which a layer of ferrite indicates the bond line of the sound bond that has formed.

Tensile strength develops as temperature/pressure/time increase. Parent-metal tensile strength is readily achieved; failure occurs away from the joint interface, even when welding is not complete. Work has shown that only 80% bonding is necessary to achieve the equivalent parent-metal strength (Ref 13). However, ductility and joint-line toughness require a greater level of bond integrity.

Joints made in 0.4% C steel and a 1Cr-0.25Mo alloy steel have shown low Charpy impact values, when compared with the parent steels (Ref 14, 15). With the 0.4% C steel, it is possible to improve the toughness properties by using a postweld normalizing heat treatment (equivalent to the thermally cycled and normalized parent material). However, although the chromium-molybdenum steel had an improved microstructure after a postweld quench and temper heat treatment, it still had low joint-line toughness. This indicates the greater difficulty in forming a sound joint as alloy content increases.

Therefore, when diffusion welding carbon and low-alloy steels, the final application and service requirements should be considered carefully. The process is useful in low-stress applications, but when impact toughness is required, the fitness of a particular steel for the specific purpose must be examined. For higher-carbon-content steels and low-alloy steels, a suitable postweld heat treatment is recommended to return the steel to its original

Fig. 2 Cross section of diffusion weld in 0.4% C steel. Original magnification: 50 \times

condition. However, it should be noted that some of the high temperatures referred to earlier ($\geq 1100 \text{ }^\circ\text{C}$, or 2010 °F) can cause significant grain coarsening.

The HIP welding of these steels also can be used when typical conditions involve a temperature of 1100 °C (2010 °F), a pressure of 100 MPa (14.5 ksi), and a bonding time of 4 h. Again, grain coarsening and the property considerations described previously must be reviewed.

Diffusion Bonding of High-Strength Steels. Although diffusion welding has not been widely applied to high-strength steels, it is a feasible process, and guidelines similar to those identified for carbon and low-alloy steels will apply. Because diffusion welding relies on microplastic yielding in the early stages of bonding, it is necessary to use parameters at the higher end of the ranges specified previously, that is, temperatures above 1000 °C (1830 °F) and pressures of 7 MPa (1 ksi) and above.

Although good tensile properties can be achieved, the as-bonded toughness will be low. In addition, a postweld heat treatment to restore the parent microstructure is recommended.

Diffusion Bonding of Stainless Steels. Stainless steels can be diffusion welded using conditions similar to those that are used for high-strength steels. These steels are normally covered by a thin adherent oxide (chromium oxide) that must be broken up and/or dissolved during the welding process. This is possible when higher temperatures and/or higher pressures are used. Alternatively, stainless steels can be welded in dry hydrogen, which will reduce the oxide film, or the oxide can be removed prior to welding. The latter measure has been accomplished by anodic cleaning of the steel surfaces, followed immediately by copper plating to protect the surfaces from reoxidation. Again, if a dry hydrogen atmosphere is used, then the copper oxide will be reduced during welding and a sound bond will be attained.

Although few property data are available on the diffusion welding of stainless steels, it is known that tensile strength is readily achieved, whereas toughness is more difficult. If high welding temperatures are employed, then it will generally be necessary to use a postweld heat treatment to restore properties.

Nonferrous Alloys

Diffusion Bonding of Aluminum-Base Alloys. Diffusion welding of aluminum alloys is difficult, because of the presence of a tenacious surface oxide film. The surface oxide can be disrupted by the use of large deformations and/or high temperatures in, for example, roll bonding. However, for low-deformation diffusion welding, interlayers of similar or dissimilar materials have been used. The specific

procedures to be followed for aluminum alloys vary, depending on the alloy system.

For Al-Mg-Si alloys (specifically, Al-0.6Mg-0.9Si-0.5Mn), diffusion welding without an interlayer has yielded tensile strengths of 145 MPa (21 ksi) for a welding temperature of 550 °C (1020 °F) (Ref 16). However, this does induce deformation of the components. It has been more attractive to use copper or silver interlayers, which can be applied as a coating or a foil. These interlayers can be used to provide a solid-state weld or a transient liquid-phase (eutectic) weld. Care must be taken to achieve the latter, to ensure that the heating rate is not so slow as to allow the interlayer to be diffused away before the eutectic temperature is reached. Solid-state diffusion welds made with either copper or silver have yielded joint strengths of 85 MPa (12 ksi) for bonding temperatures as low as 450 °C (840 °F).

More attention has been directed to the diffusion welding of alloys that are of interest to the aerospace industries, that is, 7010 (Ref 17), 7475 (Ref 18, 19), and 8090 (Ref 20–23). No clear guidelines exist as to the best practice for welding these alloys, because researchers have investigated many techniques and the results point in sometimes conflicting directions. Welding the alloys without an interlayer is possible, if disruption of the oxide can take place during welding. Some success has been achieved by welding the 7475 alloy with a “rough” surface (that is, brushed in air), by surface grinding the alloy in an argon atmosphere prior to welding, and by grit blasting with fine alumina particles followed by chemical cleaning in hot 30 wt% NaOH solution. Long welding times have been used for this material, and high strengths have been reported by welding at 515 °C (960 °F) under a load of 5 MPa (0.7 ksi) for 5 h, followed by a postweld heat treatment to T6 condition. In instances where interlayers have been used for this alloy system, the material that has shown the greatest promise is zinc.

Aluminum-lithium alloys are currently attracting great attention for applications in the aerospace industries. This is because lithium significantly increases the elastic modulus of aluminum, by approximately 6% for each wt% addition of lithium, and simultaneously decreases its density by 3%. For aerospace applications, improvements in specific modulus and strength can lead directly to weight savings. In addition, it has been shown that aluminum-lithium alloys can develop superplastic behavior after appropriate thermomechanical processing, which means that advantage can be taken of the SPF/DW procedures already established in this industry.

Superplastic forming after welding restricts the welding temperature that can be used. Ideally, the temperature should be lower than or equal to the superplastic temperature for the alloy. In addition, the welding time must be restricted to avoid grain growth in the parent

sheet, which could affect the superplastic-forming properties.

Aluminum-lithium alloys have been bonded with no interlayer and with interlayers of zinc, copper, zinc-copper, pure aluminum, and aluminum alloys. Surfaces have been prepared by a number of techniques, such as grinding with emery paper, shot peening, chemical etching, and degreasing. All techniques have shown some degree of success, but it is difficult to compare results, because the testing methods to achieve shear strength are varied. Generally, all of these welds require some form of post-weld heat treatment to restore properties (for example, solution treatment at 535 °C, or 995 °F, followed by quenching). A section through a diffusion weld containing a pure aluminum interlayer is shown in Fig. 3. The position of the original aluminum foil is discernible by the presence of spheroidal precipitates, similar in size and shape to those precipitated in the grain boundaries of the aluminum alloy.

To avoid surface contamination during heating to the welding temperature, greater care must be taken with the aluminum-lithium alloys, because of the reactivity of lithium. However, this reactivity is also claimed to make this alloy system somewhat easier to weld than other less-reactive aluminum alloys.

Diffusion Bonding of Reactive and Refractory Metals. The diffusion welding of titanium alloys is well documented, because of its commercial application and importance to the aerospace industry. Many titanium airframe structures are now manufactured using the SPF/DW process, which provides significant benefits through weight and cost savings. Typical examples include hot-air nozzles, landing-gear doors, intricately shaped housings, keel sections, and heat-exchanger ducts. Most of the detailed procedures for welding are commercially sensitive. The factors that are important are (Ref 24):

- Metallurgical condition of the starting material
- Characterization of the superplasticity of the material
- Surface cleanliness
- Tooling material and surface condition
- Welding atmosphere
- Forming and welding parameters
- Part geometry

The primary alloy that is used is Ti-6Al-4V. It has been established that commercially available sheet material containing an equiaxed, uniform, small grain size (preferably <10 μm, or 400 μin.) is suitable for superplastic forming. Conventional cutting processes are used for the preparation of sheet material, which is then subjected to an etching treatment prior to placement in the press. Although tooling is typically made of a 22Cr-4Ni-9Mn stainless steel with appropriate surface-parting compounds, ceramic-faced tooling has also been used. During the application of heat at

temperatures ranging from 900 to 930 °C (1650 to 1710 °F), argon gas provides a protective atmosphere that is also used, under pressure, to effect forming and diffusion welding. Tool-to-titanium sealing, to contain the forming/bonding pressure of 2 to 4 MPa (0.3 to 0.6 ksi), is of paramount importance to leakage prevention.

Multiple-sheet fabrication requires the application of a stop-off material (typically, yttria and a binder) after conventional titanium cleaning. The application of a stop-off material uses a silk-screen technique that allows complex patterns to be transferred to the sheet. The multiple-sheet pack is plumbed with stainless steel capillary tubes for internal gas pressurization (between the sheets), as opposed to single-sheet processing, where gas pressure access is achieved directly through tooling parts. The process allows formed titanium shapes that are far more complex than those produced by conventional forming methods. Parts can feature integral end flanges, deep beads, corner beads, and small-bend radii. In addition, compound contour; multiple, variable, hollow sections; and complex sandwich (including circular) structures with varying core configurations can be fabricated.

Fig. 3 Cross section of diffusion weld in aluminum-lithium alloy containing pure aluminum interlayer. Original magnification: 75×

Fig. 4 Effect of applied pressure (for two bonding times) on the tensile strength of solid-state welds of CaO-stabilized ZrO₂, joined to itself using an interlayer of 5052 aluminum alloy. Source: Ref 50

Zirconium and its alloys also have been joined by diffusion welding, as have the refractory metals of tungsten, tantalum, niobium, and molybdenum (Ref 25).

Diffusion Bonding of Other Nonferrous Alloys. Other alloy systems have been diffusion welded but with few industrial applications. Copper bonds to itself readily, if the surface oxide can be disrupted, and temperatures ranging from 850 to 950 °C (1560 to 1740 °F) have been employed. Alternatively, a liquid-phase procedure that uses silver as an interlayer has been adopted to reduce welding times. The nickel- and cobalt-base alloys are bondable, but some alloy systems exhibit good high-temperature strength that inhibits the microyielding required for diffusion welding. Beryllium alloys also can be bonded at low temperatures (Ref 26).

The noble metals, such as gold, bond readily because of their very thin surface oxide. Gold, in particular, is often used as an interlayer material when welding temperatures are restricted, because bonds can be achieved at temperatures as low as 250 to 350 °C (480 to 660 °F), if the surfaces and atmosphere are clean.

Dissimilar-Metal Combinations

Diffusion Bonding of Dissimilar Ferrous Alloys. Dissimilar steel joints have not been extensively investigated in diffusion-welding research, primarily because it was initially believed that the process would mostly be used to join material combinations that were difficult to join by other, more-conventional methods. However, this is not strictly true, and in situations where multiple joints can be formed in one welding operation, the process can be economically viable for dissimilar steel joints.

The literature on steel includes the bonding of high-speed steels to carbon steels for prismatic cutting tools (Ref 27) and the joining of pure iron to a range of carbon steels (Ref 28). In this latter work, the bond tensile strength was greater than 430 MPa (62 ksi), which exceeds that of the weaker parent metal. A slight increase in tensile strength occurred with a decrease in welding temperature from 1000 to 900 °C (1830 to 1650 °F).

Diffusion Bonding of Dissimilar Nonferrous Alloys. Many combinations have been studied within this category, but the most common one uses aluminum as one of the parent materials (Ref 29–31). The diffusion welding of aluminum to copper and titanium results in the formation of intermetallic compounds at the bond interface. With copper, it has been found that the aluminum/copper intermetallic can reach 15 µm (600 µin.) in thickness before a reduction in the joint strength occurs (Ref 32). Also described in this work is the fact that the parent aluminum strength was not achieved, even before the excessive growth of the intermetallic, which suggests that full bonding can

be achieved only after the time necessary for extensive intermetallic formation. However, aluminum-to-titanium diffusion bonds can reach a tensile strength that is equal to that of the parent aluminum, and it is claimed that intermetallic thicknesses of up to 10 µm (400 µin.) can be tolerated (Ref 33). Again, an interlayer of silver can be used to promote bonding between the aluminum and titanium, such that the parent aluminum strength can be achieved in shorter welding times.

The aerospace and nuclear industries have driven the development of a wide variety of special alloy and dissimilar-metal combinations. Examples of materials that have been successfully joined include nickel-stainless steel (Ref 34), uranium-stainless steel (Ref 35), beryllium-nickel (Ref 36), beryllium-stainless steel (Ref 36), thorium dioxide dispersion-strengthened-nickel alloys (Ref 37), zirconium-steel (Ref 38), and copper-Monel (Ref 39).

Diffusion Bonding of Ferrous-to-Nonferrous Alloys. The joining of aluminum to steel has received a great deal of interest. This subject has been reviewed by Elliot and Wallach (Ref 40), who recognized that the two major problems associated with this metal combination are:

- The tenacious oxide layer on the aluminum, which, being stoichiometric and highly stable, inhibits weld formation
- The formation of brittle intermetallics, such as the FeAl₃ and Fe₂Al₅ types, at the joint interface

These problems are generally overcome by using interlayers, both to promote welding and to prevent the formation of brittle intermetallic compounds. Silver has been successfully used as an interlayer, either as a foil interlayer or applied by electroplating (Ref 41, 42), vapor deposition (Ref 43, 44), or sputter deposition (Ref 45) on one or both surfaces. Both solid- and liquid-phase joints have been produced, the latter of which involves melting of the aluminum-silver eutectic.

Other interlayer materials that have been examined include nickel and a multilayer system of zinc and silver. However, both of these have disadvantages. The nickel also forms brittle intermetallics with iron that inhibit joint strength. In the multilayer system, the zinc was found to erode the silver, thereby removing the diffusion barrier. In addition, aluminum and steel alloys can be diffusion welded without any interlayer by a careful evaluation of the process parameters and with a higher amount of aluminum deformation.

The diffusion welding of refractory metals to steels has been another major research area. Molybdenum has been welded directly to steel, but the formation of brittle intermetallics limits the strength of the joints. Lison and Stelzer (Ref 27) have investigated the interlayers required to give good joint properties for

this metal combination, based on metallurgical compatibility and the coefficients of thermal expansion. A complex multilayer system was devised, in which tantalum, vanadium, nickel, and copper were positioned in the following order: Mo-Ta-Ni-Cu-steel. Initially, the Mo-Ta-V combination was bonded at 1500 °C (2730 °F) for 40 min, whereas the remaining bonds were formed at 850 °C (1560 °F) in 20 min. The mechanical properties of such a joint are not given, but metallographic examination revealed full bond formation.

Diffusion Bonding of Oxide Ceramics (Ref 46)

Developments in gas-turbine and ceramic-engine technology have created an interest in the diffusion welding of ceramics to steels, because the low temperatures used for joining minimize the residual stresses created by thermal mismatch. Silicon nitride and zirconium oxide are two examples that have been successfully welded to steel using the diffusion welding process. Both ceramic-ceramic and ceramic-metal joints have been fabricated using diffusion bonding. Most of the work has been on ceramic-metal joints in which the metal portion of the joint is either a bonding material added to the interface between two ceramic components or is the second member of a bimaterial joint. The more extensively studied ceramic-metal joint is discussed first and in more detail. Ceramic-ceramic diffusion welding and a variation on this process in which ceramic powder compacts are simultaneously sintered and bonded (sinter-bonding process) are discussed at the end of this section.

Ceramic-Metal Joints

Two types of interaction have been observed in diffusion welding of ceramic-metal joints. In the first type, bonding, is driven by a decrease in surface energy as a new interface is formed to replace the two original surfaces. This physical interaction is indicated by an abrupt transition in microstructure between metal and ceramic at the interface. Examples of this type of bond include those between alumina welded under high vacuum to the metals aluminum, copper, nickel, platinum, and niobium (Ref 47, 48). However, under certain conditions of temperature and excess oxygen activity, reaction products can form at some of these interfaces (Ref 49). In the case of the Al₂O₃-Nb couple, a model system that has been extensively studied, a reaction layer does not occur at the interface because Al₂O₃ dissolves in the niobium (Ref 48). The driving force for the formation of the physical-type bond is the change

in surface energy (ΔG_s) as given by the Dupre equation:

$$\Delta G_s = (\gamma_c + \gamma_m) - \gamma_{cm} \quad (\text{Eq 1})$$

where γ_c and γ_m are the surface energies of the ceramic and metal, respectively, and γ_{cm} is the surface energy of the interface formed during joining. The change in surface energy (ΔG_s) is the same as the thermodynamic work of adhesion (W_{ad}), the energy required to separate a unit area of the bonded interface.

In the second type of solid-state bond between ceramics and metals, chemical reaction further lowers the energy of the system and increases the strength of the bond. Chemical reaction product layers are observed in the joints after welding. These reaction products generally cause stronger bonds; however, weakening of the joint may occur if the reaction products grow to excessive thicknesses during welding or in service. Diffusion welds between oxide materials and metals that result in the formation of interfacial reaction products are alumina with aluminum (although it is suggested in Ref 50 that the reaction is between aluminum and the SiO_2 in the alumina and not with the Al_2O_3 itself); aluminum and magnesium with SiO_2 and ZrO_2 (Ref 51) nickel and titanium with Al_2O_3 (Ref 52).

The temperature required for diffusion welding to occur usually ranges from 0.5 to 0.8 of the absolute melting point of either the ceramic, the metal being bonded to the ceramic, or an interlayer that is added at the interface to promote bonding. A wide range of applied pressures has also been used, ranging from 15 kPa to 200 MPa (3 psi to 29 ksi) and higher. The surface finish of the mating materials is also a critical variable, because the success of the process depends on the attainment of intimate interfacial contact. If all other variables are equal, the surface finish and pressure are related because rough surfaces require greater pressures to force the surfaces into contact for bonding. The observed effects of each of these variables (applied pressure, temperature, and surface finish) are discussed as follows.

Applied Pressure. Diffusion welding is usually performed under conditions in which at least one component undergoes plastic deformation under the applied load. The material that deforms may be the ceramic, the metal portion of a ceramic-metal joint, or an intermediate material placed in the joint. Klomp suggests that applied pressure is critical in solid-state bonding of oxygen-active metals to oxide materials (Ref 50). The applied pressure creates an active metal surface by plastic deformation of the surface oxide layer that usually inhibits bonding, thereby allowing contact between clean metal and the ceramic during the bonding process. Such behavior was clearly observed in a study conducted by Arata and Ohmori on the solid-state bonding of CaO-stabilized ZrO_2 to itself in vacuum using 0.5 mm (0.02 in.) thick

inserts of 5052 aluminum alloy (2.2 to 2.8 wt % Mg) (Ref 51). The surfaces of the ZrO_2 to be joined were polished with 1500-grade emery paper and degreased with acetone prior to bonding. The effect of bonding pressure on the room-temperature tensile strength of the joints is clearly shown in Fig 4. The bonding mechanism was described as a sequential process in which the oxide film on the aluminum alloy is broken, the alloy is forced into the pores of the zirconia, and finally the aluminum and magnesium of the alloy react with the grain-boundary phases of the zirconia and with the zirconia.

Bonding Temperature. Temperature is the most significant variable affecting the strength of diffusion-welded joints, yet the mechanisms involved in ceramic-ceramic or ceramic-metal diffusion welding have not been modeled. Formation of metal-metal joints (Ref 53, 54) are considered to involve the processes associated with pressure sintering, that is, plastic flow, creep deformation, and diffusion along surfaces and grain boundaries or through the bulk of a grain. If similar behavior occurs in joints containing ceramics, it can be concluded that increased temperature increases contact between the materials being joined by reducing their yield strengths, and increases the diffusion rates that control pore closure, grain growth, and chemical interactions.

The effect of temperature on mechanical deformation at the joint can be illustrated by the previously cited work of Arata and Ohmori (Ref 51). As shown in Fig 5, a 25-fold increase occurred in the room-temperature tensile strength of ZrO_2 to ZrO_2 welds (using 0.5 mm, or 0.02 in., thick inserts of 5052 aluminum alloy) when the bonding temperature was raised from 450 to 550 °C (840 to 1020 °F).

Similar behavior was observed by Nicholas and Crispin (Ref 55) in diffusion welding an alumina (97.5% Al_2O_3) to type 321 stainless steel using an aluminum interlayer, as shown in Fig 6. The effects of variations in welding parameters were determined in a series of experiments using a steel insert between standard ASTM F 19 testpieces. Fixed variables were: a 0.5 mm (0.02 in.) thick interlayer of commercial-purity aluminum at both alumina-steel interfaces, an applied pressure of 50 MPa (7.25 ksi), a time at temperature of 30 min (2 to 3 h heat-up time), and a vacuum of a few mPa. The bonding surfaces of the alumina testpieces were in the as-received, fired condition. Increasing the welding temperature from 496 to 625 °C (925 to 1155 °F) resulted in progressively stronger joints. In room-temperature tensile testing, the welds made at 625 °C (1155 °F) failed at the stainless steel-aluminum interface, while all others failed at the alumina-aluminum interface. These authors concluded that the relationship between fabrication temperature and the strengths of the joints which failed at the alumina-aluminum interface could be expressed as follows:

Fig. 6 The effect of bonding temperature on the room-temperature tensile strength of diffusion welds between alumina and type 321 stainless steel (made using an aluminum interlayer). Source Ref 55

Fig. 7 The effect of the roughness of the surfaces of the materials being joined when alumina was diffusion welded to niobium. Source: Ref 59

$$\sigma = \sigma_0 \exp(-Q/RT) \quad (\text{Eq 2})$$

where σ is the failure stress, in MPa, of samples bonded for a fixed time, at a given applied pressure, over a range of temperatures. In this equation, σ_0 is a constant (3.14×10^6 MPa), Q is an apparent activation energy (83.3 kJ mol^{-1}) for the bonding process, R is the gas constant, and T is the absolute temperature. Derby (Ref 56) observed that the activation energy derived from the data in this study was approximately the same as the 80.3 kJ mol^{-1} reached in a similar study by Dawihl and Klinger (Ref 57). Derby compared these values with the activation energies for self-diffusion by lattice-, grain-boundary-, or surface-diffusion mechanisms and for vapor-phase transport in aluminum and alumina. Because of the close agreement with the published value for grain-boundary self-diffusion in aluminum (84 kJ mol^{-1}), Derby concluded that grain-boundary diffusion in the aluminum was the most probable bonding route in these welds.

Crispin and Nicholas also conducted a similar study on diffusion welding the same alumina (97.5% Al_2O_3) to itself using a 0.5 mm (0.02 in.) thick copper foil interlayer (Ref 52). Welding was conducted in vacuum (<10 mPa) at temperatures ranging from 600 to 950 °C (1110 to 1740 °F), a time at temperature of 30 min, and a pressure of 50 MPa (7.25 ksi), which was applied when the sample reached the bonding temperature. They concluded that the most obvious correlation in the experimental data was between average joint strength and fabrication temperature. The room-temperature tensile strengths of the ASTM F 19 alumina specimens increased from essentially no strength when welded at 600 °C (1110 °F) to a maximum of 54 MPa (7.8 ksi) when welded at 875 °C (1605 °F). Further increases in welding temperature led to decreases in joint strength. The samples welded at temperatures >700 °C (>1290 °F) failed within the alumina, but generally near to and influenced by the interface.

Surface Roughness. The effect of surface roughness on the strength of diffusion welds has been explored in several studies. In research by Derby (Ref 56), ASTM F 19 testpieces fabricated from alumina (99.5% Al_2O_3 , 0.5% MgO + CaO) were joined using a 0.5 mm (0.02 in.) thick interlayer of 99.99% aluminum, an applied pressure of 50 MPa (7.25 ksi), and a temperature of 600 °C (1110 °F). The atmosphere during bonding was not specified, but the bonding conditions were reported to be similar to those of Nicholas and Crispin, who used a vacuum of >10 mPa. Two surface conditions were investigated: a ground surface with an average surface roughness of 1.4 μm and average peak-to-valley height of 5 μm , and a polished surface with values of 0.4 μm and 1 μm , respectively. A postbonding heat treatment of 30 min at 400 °C (750 °F) in the bonding furnace was followed by a 4 h anneal at 200 °C (390 °F) in a furnace. The strength of the samples was negligible without these

thermal treatments. For both surface conditions the bond strength increased with time. However a maximum of only 20 MPa (2.9 ksi) after 40 min bonding time was reached in the ground specimens, while the strength of the lapped specimens reached an average strength of 32 MPa (4.6 ksi) after a 20 min bonding time. An interesting footnote to this study is that much stronger joints, with tensile strengths averaging 50 MPa (7.25 ksi), were achieved at bonding temperatures above the melting point of aluminum (660 °C, or 1110 °F).

Suganuma and co-workers investigated the solid-state bonding of an alumina (99.7 wt% Al_2O_3) to niobium (99.5 wt% pure) as a function of bond face grinding conditions (Ref 59). The bonding was done in a hot press under a vacuum of 2.7 mPa, at a temperature of 1500 °C (2730 °F) for 1 h, and an applied pressure of 20 MPa (2.9 ksi). The effects on room-temperature bond strength of three surface roughness conditions of both the alumina and the niobium were explored. The bonded specimens were ground to remove a 1.5 mm (0.06 in.) wide unbonded region that was sometimes present along the edges of the joint, and then cut into bars for four-point flexure testing. As in the study by Derby, these researchers concluded that significantly stronger joints resulted in welds made with the alumina having the smoothest surface (average surface roughness of 0.97 μm). However, as shown in Fig 7, the surface finish of the niobium had just the opposite effect; that is, the strongest bonds were produced with the roughest niobium (average surface roughness of 3.49 μm). In addition, the rough bond face on the niobium resulted in the elimination of the unjoined region at the edges of the original specimens. Both beneficial effects of niobium roughness were probably caused by plastic flow of the metal.

Ceramic-Ceramic Joints

As stated previously, diffusion welding is usually performed under conditions of temperature and pressure where at least one component plastically deforms under the applied load so that the surfaces to be joined are brought into intimate contact. Although the material that deforms in most cases is either the metal portion of a ceramic-metal joint, or an intermediate material placed in the joint, it may also be the ceramic. For example, Ellsner et al. reported weak joints when a coarse-grained alumina (grain size $\sim 18 \mu\text{m}$) was bonded to itself without an interlayer, because the ceramic was creep resistant and therefore resisted formation of an intimate interface (Ref 60). Conversely, bonds between the same coarse-grained alumina and an alumina with smaller grains ($\sim 1 \mu\text{m}$) were much easier to produce because the fine-grained material deformed much more readily. The flexure strength (test method not given) for joints between the two aluminas

reached a maximum value of 200 MPa (29 ksi) when welded at 1750 °C (3180 °F).

Scott and Tran studied the effect of the level of MgO sintering aid on diffusion welds in high-purity alumina (Ref 61). Dense, fine-grained alumina bodies (1 to 3 μm average grain size) were fabricated by pressureless sintering at 1500 °C (2730 °F), a series of compacts containing 0.0075, 0.075, or 0.75 wt% MgO. The sintered pellets were diffusion welded in a vacuum hot press at temperatures from 1200 to 1500 °C (2190 to 2730 °F) and applied pressures from 34 to 138 MPa (4.9 to 20 ksi). The bonded pellets were cooled to room temperature and then resintered in H_2 at 1875 °C (3405 °F) for 3 h for grain growth. As expected, the best results (as indicated by minimal interfacial porosity and grain growth across the original interface) were achieved at the higher temperatures and pressures. The study also showed that the level of MgO dopant in the alumina bodies had a significant effect on bond quality. Joints between samples with the highest level of MgO (0.75 wt%) had fewer interfacial voids and a much finer grain size. The lower dopant levels allowed exaggerated grain growth to occur, leaving porosity trapped in the large grains and at the interface.

The effect of the superplastic behavior of Y_2O_3 -stabilized tetragonal zirconia polycrystal ceramic (Y-TZP) on diffusion-bonded joints has been investigated by Nagano and coworkers (Ref 62). The materials included fine-grained alumina (99.9 wt% Al_2O_3 , 0.64 μm grain size), coarse-grained alumina (99.7 wt% Al_2O_3 , 5.87 μm grain size), Y-TZP (3 mol% Y_2O_3 , 0.59 μm grain size), and a series of Y-TZP/alumina composites with the alumina content ranging from 20 to 80 wt%, and grain sizes of approximately 1 μm . Bonding was conducted in air at temperatures ranging from 1450 to 1500 °C (2640 to 2730 °F) under an applied stress of

Fig. 8 Relationship between the degree of deformation and the strength of solid-state welds. A series of Y_2O_3 -stabilized tetragonal zirconia polycrystal ceramic/alumina composites containing 80 wt% ZrO_2 , 3 mol% Y_2O_3 , and 20 wt% Al_2O_3 were joined to each other at temperatures ranging from 1450 to 1500 °C (2640 to 2730 °F). Source: Ref 62

12.5 MPa (1.8 ksi). The welded samples were cut into bars that were tested in four-point bending at room temperature. They concluded that the strengths of the bonds increased with the degree of deformation during welding (Fig. 8), which resulted from higher bonding temperatures or increased amounts of the superplastic Y-TZP phase in at least one member of the joint. Flexural strengths greater than 1000 MPa (145 ksi) were achieved. Similar to Ellsner (Ref 60), they found that it was difficult to bond the coarse-grained alumina to itself, but that it was possible to bond the coarse-grained alumina to materials that were more readily deformed during welding, such as the 80% Al₂O₃-20% Y-TZP composite or the fine-grained alumina.

Explosion Welding

Stephen Liu, Colorado School of Mines
John Banker and Curtis Prothe, Dynamic Materials Corporation

EXPLOSION WELDING (EXW), also known as explosive cladding, is accomplished by creating a high-velocity collision between two metal surfaces. The explosive detonation causes shock loading of one of the metals, the flyer plate, accelerating it downward and causing an oblique impact with the other metal, or base plate. It is necessary that this impact have sufficient energy to cause the colliding metal surfaces to flow hydrodynamically. Upon impact, conservation of momentum results in a reentrant jetting action and hydrodynamic flow of the faying metal surfaces. The jet is ejected outward from the collision apex, producing clean surfaces, being that it is comprised of the metal that was the prior effacing metal surface layers. The residual virgin metal surfaces are then forced together under high pressure, resulting in welding.

This phenomenon was first observed during World War I, when fragments from bombs or shells were found to be welded to surrounding metal structures (Ref 1). The first publication to recognize the potential for generating metallic welding by using explosively driven plates appeared in 1944 (Ref 2). The first EXW patent was issued in 1962 (Ref 3).

The two most beneficial attributes of EXW are:

- Dissimilar-metal systems can be welded, even when conventional fusion welding techniques are metallurgically inappropriate due to brittle intermetallic compound formation
- Large-area clad plates of almost any metal combination can be manufactured economically.

Applications of EXW are diverse and include the production of sandwiched metal for coinage (Ref 4), the production of titanium-to-stainless steel transition joints in the Apollo spacecraft (Ref 5), and production of explosion clad plates for industrial applications. The most common application of EXW is production of clad plates used in construction for pressure vessels for environments requiring superior corrosion resistance combined with high temperatures and/or pressures, such as chemical processes (Ref 6).

Several very good reviews of the EXW process have been published (Ref 7–11). A fundamental understanding of EXW involves a large number

of highly interactive variables (explosive detonation dynamics, dynamic materials deformation, metallurgical bonding, and more). Many of these interactive variables are defined in this article, and the references cited offer additional detail and explanation. Reliable models and predictive algorithms using numerical methods have been established, but, to a large extent, EXW is an empirical industrial technology practiced by experienced technologists. As such, much of the available knowledge relating to EXW is still based on experimental observation.

Since its origin in the 1960s, the EXW process has been shown to be a highly robust and reliable industrial welding technology. By 2010, there were well over 50 companies producing explosion-welded products worldwide. Combined annual industrial production is estimated to be in the range of 300,000 metric tons.

Overview of Process Attributes

Metallurgical Attributes. Because of the absence of heating, EXW products do not exhibit many of the metallurgical characteristics of fusion-welded, brazed, or hot rolled/forged products. Unlike those processes, in EXW (Ref 12–15):

- The component metals remain in their wrought states; continuous cast structures are not created.
- The microstructures, mechanical properties, and corrosion properties of the wrought parent components are not significantly altered.
- There are no bulk heat-affected zones.
- There is virtually no diffusion of alloying elements between components.
- The EXW interface is typically stronger than the weaker of the two parent components.

Metals Combinations. Explosion welding is an effective joining method for virtually any combination of metals. The only metallurgical limitation is that the component metals must exhibit sufficient ductility and fracture impact toughness to undergo the rapid deformation of the process without fracture. Generally accepted

limits are 10% elongation and 30 J (22 ft lb) Charpy impact energy minimum, respectively. Explosion welding is suitable for joining metals of the same type, for example, steel to steel, as well as metals with substantially different densities, melting points, and/or yield strengths, for example, tantalum to titanium alloys. The process is extensively used to join corrosion-resistant alloys to carbon or alloy steels. Table 1 shows a broad range of metal combinations that have been successfully welded using EXW. Most of the unproven combinations are considered to be weldable but have not been evaluated due to a lack of industrial or commercial need.

Explosion Welding Interface Morphology. Explosion welding is traditionally known for its wavy bond zone morphology (Fig. 1). However, the interface morphology can range from flat to turbulently wavy depending on the features needed from the interface and the welding process variables selected. Bond morphology is discussed in greater detail in the section “Weld Interface Morphology” in this article.

Size and Configuration Limitations. Explosion welding is appropriate for use over a broad range of sizes. It has been used for joining electronic components of widths less than 0.5 mm (0.020 in.) and for cladding plates up to 5 × 12 m (16 × 40 ft). Cladding metal thicknesses can range from 0.025 to 100 mm (0.001 to 4 in.), and base-metal thickness can range from 0.025 mm (0.001 in.) to over 1 m (40 in.). The size limits are generally mandated by component metal manufacturability and transportation requirements.

Explosion welding is limited to the welding of flat surfaces or coaxial cylindrical surfaces. This limitation results from the interface jetting mechanism, which is discussed in detail in later sections of this article. Explosion welding is ideally suited for joining large, flat areas, as in clad plate manufacture. When more complex components are the objective, a bimetal preform is typically produced by explosion welding in the plate or tube configuration, followed by hot or cold working to the end-product configuration.

Performance Characteristics and Process Reliability. The physical and mechanical performance features required of the EXW bond zone are determined by the product application.

In most cases, a direct weld between the two desired metals will achieve the required interface performance. However, with some combinations of metals, the required bond zone performance characteristics are best achieved with an interlayer between the two primary metals. For example, a titanium interlayer can be used to increase the performance temperature of an aluminum/copper weld, and a silver interlayer can be used to improve the leak tightness of an aluminum/stainless steel weld.

When EXW is performed by experienced technologists using metals in the appropriate metallurgical conditions, the process reliability is exceptionally high. The loss of product due to EXW process failure by well-established manufacturers is typically well under 0.1%.

Procedure Development and Practice Considerations

Explosion welding, like all other welding or joining processes, has a well-defined set of input parameters or conditions that must fall within certain limits for the desired weld quality to be achieved. Contrary to other joining processes, however, the EXW process occurs so rapidly (completed within a few microseconds) that there

is no time for in-process adaptive control or modification of the welding parameters or conditions. Therefore, a total quality joining approach must be taken to ensure that proper process parameters are applied and controlled to consistently achieve high-quality welds. The quality must be built into the preparation stages of the process materials and setups before welding takes place. It is necessary to be thoroughly familiar with every aspect of the process and the quality level that must be applied in order to ensure the consistent quality of the end-product weld (Ref 17).

This section provides a general overview of the important mechanistic aspects of EXW, the process-material interactions, and the critical aspects or parameters that must be controlled. The procedure for ensuring control is also discussed. This type of approach to setting and controlling process parameters is particularly important when explosion welding dissimilar or metallurgically incompatible metals. Metallurgically incompatible combinations, such as titanium and steel, aluminum and steel, and zirconium and steel, will form brittle intermetallic compounds at the explosion weld interface if excessive energies are used during welding. The intermetallic compounds result in poor-quality welds. Setting and controlling process parameters is also important when welding some of the newer advanced materials, which have little tolerance for parametric variations. To fully understand EXW and its control, it is helpful to know the general characteristics of the process, particularly the rates, pressures, and energies involved. The following are the general process parameters:

Traversal rate, m/s (ft/s)	2000–3000 (6600–9800)
Pressure, GPa (10 ⁶ psi)	1.5–6.0 (0.22–0.88)
Pressure time duration, μ s	5–20
Energy deposition/unit area, J/cm ² (Btu/ft ²)	100–300 (90–260)
Energy deposition rate, MJ/s (Btu/h)	20–90 (70 \times 10 ⁶ to 310 \times 10 ⁶)

By comparison, standard fusion welding processes will typically have traversal rates of a

fraction of a meter/second and energy depositions/unit area in the range of 10,000 to 30,000 J/cm² (9000 to 26,000 Btu/ft²). The low-energy input of EXW and the high interface propagation rate along the weld interface allow the weld to be made with an absolute minimum of thermal excursion and very limited heat-affected zone (HAZ).

To better explain the EXW process, some fundamental understanding of the several components of the process is discussed in the following sections. It is important to understand that these parameters are affected by the general geometric positioning relationship between the components to be welded. Two basic geometric configurations of the EXW process are commonly used: angle welding and parallel-plate welding. In the angle-welding configuration, the cladder plate is positioned at an angle relative to the base plate. Angle welding is limited to relatively small weld areas (weld length < 20 times cladder plate thickness), such as for seam welding or welding very small components. The parallel-plate geometry is much more commonly used. It is applicable for production of very large weld areas, typical of clad plate. Figure 2 presents a schematic of the parallel-plate EXW configuration.

Explosives and Explosive Detonation

The explosive is the energy source for the process. It releases its energy in a very specific manner during detonation. It is therefore necessary to first recognize how explosives detonate and how their energy is delivered to the flyer or cladder component. In almost all instances, the explosives used for EXW can be classified as nonideal. They do not detonate in a manner that can be easily defined by the physics equations-of-state typically used for extremely-high-velocity military or weapons explosives. This behavior results from the fact that these explosives are almost always granular in nature, with the primary ingredient typically being ammonium nitrate (NH₄NO₃). Other ingredients (for example, sensitizers,

Fig. 2 Schematic showing mechanics of explosion welding. (a) Alignment of components to be joined before detonation. (b) Motion of components at detonation. (c) Close-up view of jet and wavy interface characteristic of explosion welding process

density control agents, and diluents) are then blended to produce an explosive that yields the desired detonation velocity, pressure, and duration of pressure.

The detonation characteristics of the explosive are controlled by its composition, particle size distribution, pour or packing density, layer thickness, confinement, moisture content, and, in some instances, age. The detonation performance of the explosive should be tailored to match the metals or alloy combinations being welded with respect to the density, thickness, and sonic or shock wave velocity of the flyer component, as well as the sonic velocity of the base component (if it is different from that of the flyer component).

Detonation is a progressive event that starts at the detonator and progresses into the undetonated explosive at a rate known as the detonation velocity. Within the detonation region (Fig. 3), the detonation front consists of an

Fig. 3 Schematic showing detonation regions in a nonideal explosive and the associated acceleration of the flyer component

initial high-pressure shock wave intense enough to trigger the high-pressure chemical reaction that follows in the reaction zone. In an ideal explosive, the reaction goes almost instantaneously to completion; therefore, the reaction zone is extremely short (usually <1 mm, or 0.04 in.). In a nonideal explosive, however, the reaction zone is much longer (5 to 25 mm, or 0.2 to 1 in.) because the reaction takes longer to complete. While the pressure in the reaction zone of a nonideal explosive is much lower than that in the initial shock wave, it has a much longer duration in which the high-pressure gases in the zone can deliver their impulse to accelerate the flyer component. Behind the reaction zone is the third and final region of relatively low-pressure expanding gases, which contribute little, if any, to the impulse delivered to the acceleration of the flyer component. Each type of explosive has its characteristic detonation velocity, pressure, and duration factors that can be applied to predict the specific velocity, pressure, and duration for a given thickness and density of that explosive. For welding, it is usually desirable for nonideal explosives to detonate in the range of 2000 to 3000 m/s (6600 to 9800 ft/s). When the explosive is manufactured to exacting specifications, it is possible to control the detonation velocity within $\pm 2\%$ of the target terminal velocity. With nonideal explosives, however, such factors as start-up regions near the initiation point and predetonation compression due to the precursor shock wave in the flyer component ahead of the EXW collision front can cause nonsteady-state detonation conditions, which in turn can result in non-uniform weld quality.

Several important concepts pertaining to the explosive parameters, hydrodynamic flow, jetting, and metal properties were discussed earlier. The following discussion summarizes the criteria used to model the explosive bonding process.

Shock Effects and Explosive Parameters. Even though many different types of explosives have been used for EXW, those that have a broad range of low-detonation velocities are

the most appropriate, because of the deleterious effects of shock rarefaction. Shock fronts are described by a sharp discontinuity in pressure on one side of the transmitting medium where the violent motion that is due to high pressure is separated from a near-quiet state in the unaffected material. This condition can produce tensile stresses of sufficient magnitude to fracture the explosive weld. Shock waves are not pronounced unless the velocity of the shock front exceeds the sonic velocity of the transmitting medium. Sonic velocity is defined as:

$$U_s = \sqrt{\frac{E'}{\rho}} \quad (\text{Eq 1})$$

where U_s is the sonic velocity, E' is the appropriate elastic modulus, and ρ is the material density. If the shock wave propagation does not exceed the sonic velocity, then a broadening of the shock front occurs, and the magnitude of resultant stress and stress gradients is greatly reduced. Because most metals have a characteristic sonic velocity that ranges from 2000 to 6000 m/s (6600 to 20,000 ft/s), it is desirable to use explosives with detonation velocities within this range. Carpenter et al. (Ref 18) indicate that explosives with detonation velocities greater than 120% of the sonic velocity of the metal should not be used (Ref 19).

Detonation velocity is a characteristic of the type of explosive and has been shown to be directly proportional to the explosive density. This proportionality is shown in Eq 2, as derived empirically for nitroguanidine explosive (Ref 20):

$$V_d = 1440 + 4020\rho_e \quad (\text{Eq 2})$$

where V_d equals the detonation velocity, and ρ_e is the explosive density. The typical operating range for nitroguanidine is from 2000 to 5000 m/s (6600 to 16,000 ft/s), which corresponds to explosive densities that range from 0.14 to 0.9 g/cm³ (0.0051 to 0.033 lb/in.³).

The explosive pressure, P , is also proportional to the explosive density, ρ_e , as shown by the Bernoulli equation:

$$P \propto V_d^2 \rho_e \quad (\text{Eq 3})$$

Flyer plate velocities can be calculated from models similar to that presented by Gurney (Ref 21), who assumed that the driven metal was accelerated perpendicular to the direction of the detonation propagation and used a specific energy with a characteristic value for each explosive (the Gurney energy). Kennedy (Ref 22) gives a very good explanation of the Gurney model, along with several reconstructions of the Gurney equation, to account for changes in geometry. The equation that is applicable to the parallel gap explosive bonding technique is:

$$V_p^2 = 2E' \frac{3}{[1 + 5(\frac{m}{c}) + 4(\frac{m^2}{c^2})]} \quad (\text{Eq 4})$$

where V_p is the flyer plate velocity, E' is the Gurney energy, m is the flyer plate mass, c is the explosive mass, and m/c is the explosive load factor.

Once the flyer plate and detonation velocities are known, it is a simple matter to define the dynamic nature of the flyer plate bend angle through geometry. The following equation holds for the parallel gap geometry:

$$V_p = 2V_d \sin\left(\frac{\beta}{2}\right) \quad (\text{Eq 5})$$

where V_p and V_d are the velocities defined in Eq 4 and 5, respectively, and β is the flyer plate dynamic bend angle.

Equations 1 through 5, as well as an understanding of the metal physical-mechanical properties, are the basis for most models developed for EXW. These models are discussed as follows in general terms, beginning with a description of component acceleration, component collision, and jetting phenomena, followed by a description of welding and the methods used to define explosive parameter boundaries that will produce acceptable welds.

Component Acceleration

For EXW, the explosive is distributed over the top or exposed surface of the flyer component and is detonated such that the detonation front progresses in a grazing or tangential manner over the length of the flyer component. In doing so, the explosive delivers a specific level of impulse to the flyer component that causes it to be accelerated to a terminal bend angle, θ , and velocity, v_p , as shown in Fig. 2. For EXW, the acceleration region before terminal conditions are reached is the important region.

The acceleration of the flyer component actually results from the two separate zones of the detonation region in the explosive. First is the contribution of the high-pressure shock front

in the explosive. This imparts a high-pressure shock wave into the flyer component. The shock wave traverses back and forth, or rattles, between the opposite surfaces of the component, causing it to accelerate quickly in its early stages. The effects of this contribution diminish quickly and cause the component to reach only approximately 80% of the full-potential bend angle (Fig. 3) and velocity. As the effects of the shock component begin to diminish, the expanding high-pressure gas from the trailing reaction zone takes over and continues the acceleration more gradually until the terminal angle and velocity are obtained when the reaction is completed. This contribution (Fig. 4) plus the shock contribution yields the total impulse delivered to the flyer component. In an ideal explosive, nearly all of the acceleration comes from the extremely high pressure of the shock wave and very little from the trailing reaction zone; therefore, the primary (flyer) component reaches terminal conditions much more quickly with an ideal or near-ideal explosive.

The flyer component acceleration depends on the following parameters:

- Explosive pressure (shock and gas)
- Duration of the explosive pressure pulse
- Sonic or shock wave velocity of the flyer component
- Thickness of the flyer component
- Density of the component material

With the aforementioned variables, the acceleration characteristics of the flyer component can be calculated. In addition, techniques exist to directly measure the acceleration of a flyer component (Ref 23). Precise knowledge of the acceleration achieved for a specific flyer component/explosive combination is extremely important. It allows the exact standoff or separation distance to be set between the flyer and base components to obtain the required

collision angle and flyer component velocity in the next step of EXW (that is, the collision and welding step).

Component Collision. Once the accelerated flyer component crosses the standoff gap, it collides with the stationary base component. The exact collision angle and flyer component velocity achieved at the time of the collision will, of course, depend on the combination of the acceleration characteristics of the flyer component and the standoff distance selected for the system. The standoff distance is usually specified to ensure that the collision occurs while the flyer component is still undergoing acceleration, usually in its final stages.

The collision is characterized by:

$$v_p = 2v_c \sin\left(\frac{\theta}{2}\right) \quad (\text{Eq 6})$$

where v_p is the velocity of the flyer component or the relative velocity of the flyer and base components; v_c is the collision point velocity of the welding front, which also equals the detonation velocity, v_d , of the explosive; and θ is the collision angle. If any two of the aforementioned variables are known, it is then easy to calculate the third variable. The relative component velocity, v_p , at the time of the collision is very important in that it determines the equation-of-state pressure generated at the collision point. This pressure, which must be sufficient to generate hydrodynamic flow of both materials at the collision point, can be determined from the characteristic pressure versus plate (or particle) velocity for the material or materials being welded. Figure 5 shows a high pressure versus particle velocity plot for a similar material collision. Initially, the pressure required for dynamic yielding of the two materials being welded is calculated. This pressure is then located on the curve, and a mirror image of the curve is drawn through the selected pressure. The point at which the mirror-image curve

Fig. 4 Plot of flyer plate component bend angle versus distance to show contribution of shock wave and gas pressure to acceleration

intersects the zero pressure line or abscissa is the minimum flyer plate velocity necessary to obtain the desired pressure and accompanying dynamic flow and jetting necessary for welding to occur.

Jet Formation. During World War II, it was discovered that a hollowed explosive charge lined with metal could be used to produce a high-energy jet to perforate armor plate. Several investigators (Ref 24–26) have described the limiting conditions for the formation of jets in high-velocity collisions. Walsh et al. (Ref 25) indicated that a critical impact angle must be exceeded before jetting will occur. On the other hand, Cowan and Holtzman (Ref 26) indicated that for subsonic collisions, the elastic strength of the metal must be exceeded before jetting will occur. In both cases, jetting is described by a hydrodynamic flow of the metal surfaces. Walsh et al. presented equations based on this principle and the equations of state, which enable a calculation of the critical angle for jetting.

When the required minimum collision pressure, a minimum duration of the pressure pulse, and a minimum collision angle are obtained, the surfaces of the two materials being joined locally flow in the immediate region of the collision point. Because of the angular geometry of the collision, these surfaces at the collision point are forced to reverse their flow direction with severe shearing flow and to be ejected out ahead of the advancing collision point in the form of a fine fingerlike mist (that is, a jet) (Fig. 2). Under the extremely high hydrodynamic pressures involved, this jet, which consists of a combination of both parent materials, has an extremely high temperature. When the collision conditions of the weld are within an appropriate range (as discussed in a following section, “Parametric Limits for Welding”), most of the jet, with its attendant heat, is ejected out of the weld interface with little or no effect on the remaining weld zone. Of

greatest importance, however, is that the surface-scarfing action of the jet removes the surface layers containing the oxides and other contaminants that typically inhibit solid-state atom-atom contact. These clean surfaces allow the two metals to directly weld under the substantial residual pressure of the collision, which continues to act from some period of time on the two metals at the weld interface. This residual pressure on the interface after the collision also counteracts any reflected stress waves from separating the weld while it is forming.

Kowalick and Hay (Ref 27) reported an experimental technique to evaluate both the critical angle for jetting and the morphological changes in explosion welds resulting from changes in collision angle. The experimental setup consisted of the normal flyer plate arrangement used in the parallel gap technique, but with the base plate replaced by a half cylinder. Each welding trial produced continuously changing flyer plate collision angles that resulted in surface deformation and interface morphology variations. This analysis expanded upon the work of previous researchers by evaluating the geometry of fluid flow, jetting, and their effects on bond morphology.

Laminar fluid flow (low collision-point velocity and low Reynolds numbers) was correlated with direct bonding and a very flat bond interface. Turbulent fluid flow was separated into two regimes:

- At intermediate collision-point velocities, the flow was described by vortice formation into a von Karman vortex street and the production of a wavy bond interface.
- At high collision-point velocities, the flow was disturbed by a disordering of the jet wake, which led to a molten layer bond interface.

The micrographs on the right side of Fig. 6 show the relationship between detonation

velocity and wave morphology. The images on the left side show the similarity to fluid flow over a protuberance.

Selection of EXW Parameters

The preceding discussion introduced the primary variables used to predict EXW parameters. The following four conditions are used to define a window of acceptable welding parameters:

- Critical angle for jetting (Ref 28)
- Critical flow transition velocity (Ref 26, 27)
- Minimum flyer plate impact for jetting, based on analysis of the stress required to cause flow
- Maximum flyer plate impact for the limitation of weld defects, based on jet entrapment (Ref 26)

The critical angle for jetting is used to define the upper boundary for collision-point velocities. The lower limit in collision velocity is determined by the transition from laminar to turbulent flow, where turbulent flow is preferred (Ref 27). The other two limiting conditions are specified by using the physical and mechanical properties of the material to determine the maximum amount of energy required to either produce hydrodynamic flow (that is, overcome a critical shear stress) or avoid extensive melting. Once the correct set of explosive parameters has been determined by using either predictive models or an empirical approach, the production of explosively welded metal is a relatively simple task.

Fig. 5 Plot of high pressure versus particle velocity typically used to determine the flyer component velocity necessary to achieve dynamic yielding and welding

Fig. 6 Explosion welding interface exhibits patterns similar to flowing fluid, even though metals remain as solids. Right side shows explosion welding interface patterns; left side shows pattern of fluid flow around a pin. Velocity increases from top to bottom in both cases.

Parametric Limits for Welding. All the aforementioned considerations and an understanding of EXW and its controlling parameters can be assembled to produce a parametric envelope or window of parameters within which a high-quality explosion weld can be consistently produced. The basic concept of the boundaries defining the envelope has been advanced by several researchers (Ref 29–31).

A typical parametric envelope is defined by four distinct boundary segments (Fig. 7). The lower boundary (1) is controlled by the collision pressure and dwell time of the pressure pulse. The left boundary (2), although somewhat complicated, is primarily controlled by the sonic velocities of the two materials being welded. The right boundary (3) is controlled by the upper sonic-velocity limit at which a jet will form. It is almost never of concern because EXW is typically conducted at collision velocities significantly below this limit. The upper limit (4 or 4A) is primarily controlled by the kinetic-energy release generated at the collision point. In similar or metallurgically compatible combinations of metals or alloys, increasingly higher amounts of energy in this area of the envelope result in increasingly greater amounts of residual heat effects (for example, large melt pockets, interface voids, and a general degradation of the weld quality and properties). Therefore, this boundary (4) cannot be sharply defined in this instance. In metallurgically incompatible systems, however, this upper boundary (4A) becomes very sharply defined because it corresponds to the energy level at which a brittle intermetallic compound begins to form. Welding at or above this limit produces a weld that is typically brittle and can fail in service. Typically, this boundary is relatively close to the lower boundary (1), thus leaving a relatively small amount of latitude in collision parameters permissible to obtain a high-quality weld.

Each of the aforementioned boundaries can be calculated with relative accuracy for almost

all material combinations and thicknesses to be explosion welded. With these limits defined, the collision conditions must then be maintained to fall within the boundaries sufficiently away from the edges to allow for minor variations in the collision conditions during EXW. If this is accomplished, then a reproducible, high-quality explosion weld can always be expected and produced.

Weld Characteristics

Of particular importance is the nature or characteristics of the explosion weld itself. When properly made, it is, in essence, a solid-state bond or weld without any HAZ to degrade its strength, as is typical of all other heat-dependent welding or joining processes.

Weld Interface Morphology. Most EXW products exhibit the characteristic wavy interface shown in Fig. 1. However the morphology of an explosion weld can range from a flat interface to a highly turbulent wavy interface, depending on the explosive detonation rate and energy. Figure 6 shows the effect of increasing explosive detonation velocity on wave characteristics.

The flat or straight-line interface occurs only when the collision conditions are at or near the lower limits for jetting and welding. These conditions typically require very slow explosive detonation rates that are challenging to control to the precision needed for EXW; thus, weld reliability can be compromised. Although rarely used in production EXW, a flat interface exhibits features that can be beneficial in some specific unique applications.

Wave Formation. Abrahamson (Ref 32) examined the formation of surface deformations that were caused by a traveling jet using projectiles shot at thin metal targets, resulting in oblique impact. Two primary conclusions

drawn from this work were that the target metal deformation was a horizontal shear in the direction of impact and that the resultant wave peaks were deformed in such a pattern that they turned back in the direction opposite to impact. When the angle of impact was varied, two important responses occurred. First, below an impact angle of approximately 5° , no wave formation was observed. Second, as the angle of impact was increased above 5° , the amplitude and wavelength increased. The proposed mechanism for wave formation in high-velocity oblique impacts was based on subsonic or supersonic metal flow. Bahrani et al. (Ref 33) and Hunt (Ref 34) drew upon this hypothesis and proposed a physical description of wave formation in EXW, which included the following sequence of events:

- *Step 1:* Impact produces shear deformation in the stationary base plate, which results in a depression.
- *Step 2:* Conservation of volume criteria produces an upheaval of metal (a hump) ahead of the impact apex.
- *Step 3:* Hump interferes with the jet flow and produces an eddy in the jet, which traps molten material in the rear vortex.
- *Step 4:* Allowing for collision-point velocity causes a forward deformation of the hump and further jet turbulence, which again causes jet entrapment in the front vortex.

This wave formation, which has been the subject of considerable investigation (Ref 33, 34), results from the localized dynamic compression of the two metals in the region immediately adjacent to the collision point and weld interface. The compression causes localized bulk flow of the metals, which become unstable and make the weld interface oscillate above and below the theoretical plane of the interface. The size of the wave pattern is the one postwelding characteristic that can be used to determine the collision conditions used to make the weld and to allow for adjustments in subsequent welds of the same material type and thickness.

Wavelength. The wavelengths or frequency of the interfacial wave in an explosion weld is directly related to the thickness of the flyer or cladding plate and its angle of collision with the base plate (Ref 35), as shown in Fig. 8. For practical purposes, this relationship is relatively independent of the types or combinations of metals or alloys being welded. It also shows that the wave formation ceases at collision angles of 4° or less.

Wave Amplitude. The amplitude of the waves, on the other hand, is more difficult to predict. It depends on several factors, including the relative flow characteristics of the two metals being joined and the collision-point velocity of the EXW process. Control of the wave size, particularly the wavelength, is an important part of controlling several aspects of the explosion weld because:

Fig. 7 Plot of collision angle versus collision velocity to obtain a typical explosion welding process parametric envelope for both similar- and dissimilar-metal combinations. See text for details.

- Wave size determines the amount of localized flow and work hardening in and adjacent to the explosion weld interface.
- Excessive collision energies and wave sizes can result in the formation of larger melt pockets on the front and back slopes of the waves, along with residual heat effects on the region in and adjacent to the weld interface, which will affect the mechanical properties of the weld (Fig. 6).

Interface Microstructure. As shown in Fig. 1, optical microscopy indicates no evidence of significant heating at the interface:

- No significant melt layers can be observed.
- There is significant cold work in the waves, and no recrystallization is evident.
- When examined by scanning electron microscopy, there is no evidence of diffusion of one metal into the other on either side of the interface.

Consequently, EXW is considered to be a cold welding process. Early researchers referred to it as a “solid-state electron-sharing bond” (Ref 26). Some researchers considered the interface to be similar in nature to a high-energy grain boundary.

Microstructural analysis of explosive bond zones has revealed several interesting results. Numerous metallurgical reactions have been reported:

- Extensive grain elongation in the direction of bonding, within several hundreds of micrometers of the bond interface, and measured elongations of several thousand percent (Ref 36)
- Residual dislocation densities on the order of 10^{11} cm^{-2} near the bond interface (Ref 36)
- Microtwinning has been observed (Ref 36, 37) in low-stacking-fault-energy metals (for example, copper).
- Recrystallization and recovery have been observed in bands on both sides of high-dislocation-density regions (Ref 38).
- Very little diffusion occurs across the bond interface (Ref 38).

These observations support the hypothesis, commonly held in the early years of the technology, that wave formation is a result of extreme metal deformation, and that bonding is a result of solid-state processes with very little diffusion.

Although the interface wave pattern can have significant effect on the EXW weld properties, it becomes increasingly apparent that the complex microstructures associated with the wave formation, not the wave pattern itself, determine the mechanical properties of the interface. In more recent years, transmission electron microscopy (TEM) studies have provided better insight into the nature of the interface and the bonding mechanism. These TEM studies indicate that very significant heating is occurring at the interface, but on a scale barely observable

with optical microscopy (Ref 39–41). These TEM studies indicate the presence of a thin interface reaction layer, 0.1 to 0.2 μm (3.9 to 7.9 $\mu\text{in.}$) thick. This layer appears to have been liquid at the time of formation, similar to the weld. Further, the studies report indications of an amorphous-like structure of the resolidified weld metal. This finding suggests that the time at elevated temperature is extremely short and the cooling rates are extremely fast. Other research data indicate that the metals are heated to the welding conditions and returned to well below the melting point in less than 20 μs . The result is a metastable metallurgical condition at the interface. The stable and deleterious phases that occur in most dissimilar-metal systems under equilibrium transformation conditions do not have time to form in explosion welds.

A comprehensive analysis of the characteristic features of the microstructures on the nanometer scale of explosive-welded components does not yet exist. The number of studies of this type has been severely limited by the high cost of TEM work and the relatively small budgets of the explosion cladding companies and research groups. It is estimated that less than twenty specimens were extensively analyzed

by TEM prior to 2008. Considering the area analyzed in a single TEM specimen, this is an extremely small sampling ratio. Modern nanoscale analytical capabilities are beginning to provide further knowledge of the interface. Figure 9 presents TEM data from work performed by Song and others at Max-Planck Institute in 2008 and 2009 (Ref 42).

Song et al. (Ref 43) has extensively analyzed a titanium-steel interface from the macrolevel to the nanometer level. They observed that the microstructure of the interface of an explosion weld can be characterized by four successive microstructures (Fig. 10). Figure 10 presents the hierarchical structure levels at the interface region of a titanium-to-steel interface. The macro-, meso-, and microlevels show structures that are similar to those that have been extensively investigated by others using optical microscopy. In discussion of the TEM analysis of the nanoscale interface, Song noted that “the extreme thermodynamic conditions associated with EXW cause formation of new, highly metastable crystal structures which, so far, were not reported in the crystallographic data bases. The very thin interface reaction layer (~ 100 to 300 nm) is the main, dominating component along the interface length that

Fig. 9 (a) Transmission electron microscopy image of titanium/steel interface. Titanium and steel both exhibit wrought grain structures on either side of a narrow interface region (~ 200 nm wide). (b) Titanium and steel compositions across the interface region

ensures good macroscopic bonding between the joined components. Its formation is very complex and involves both mechanical alloying and solid-state reaction processes occurring at very high pressure, high local heating, and subsequent rapid cooling.” Today (2011), the explosion clad interface is frequently referred to as a very thin, hypercooled fusion weld.

Ongoing studies at Max-Planck Institute, Oak Ridge National Laboratory, Colorado School of Mines, and others are beginning to provide significantly more insight and understanding of the product and process.

Explosion Welding Interface Mechanical Properties. The interface strength is typically measured using the shear strength test of A264 and similar specifications. The shear strength of an EXW weld is typically greater than the strength of the weaker of the two parent metals (Fig. 11a). When through-thickness tensile strength is important, interface tensile strength is measured using either a ram tensile (in accordance with MIL-J-24445A specification) or a modified round tensile specimen (Fig. 11b). The work by Prothe et al. (Ref 44) measured the through-thickness tensile strength of the EXW interface and compared it with the shear strength of the same material. The test data demonstrated that the tensile strength of the interface was consistently greater than the shear strength. Because most EXW product is clad plate with a thin cladding layer, interface tensile strength cannot be easily measured. These data are significant from the design perspective, in that the shear strength, which can easily be measured, is an indicator of minimum interface tensile strength. The minimum interface permitted in ASTM International/American Society of Mechanical Engineers (ASME) specifications for stainless steel, nickel, titanium, and zirconium clad is 137 MPa (20,000 psi).

Manufacturing Process and Practice

Because of the unique safety and noise-vibration considerations, EXW is generally performed in relatively isolated facilities by companies specializing in explosives operations.

Safety and Regulations

Safety is of critical importance in the practice of EXW. Guidelines and regulations for the safe handling and transport of explosives are provided by the U.S. Bureau of Alcohol, Tobacco, and Firearms (Ref 45), the U.S. Department of Transportation in its Federal Motor Carrier Safety Regulations (Ref 46), and the Institute of Makers of Explosives Safety Library Publications (Ref 47). Licensing and regulations for the purchase, transport, manufacture, and use of explosives may vary significantly among states and municipalities. Depending on the types of explosives used, the detonation by-products may be subject

to environmental regulation. Potential practitioners of EXW operations should understand the safety standards and regulations before proceeding.

Noise and Vibration Abatement. The sound and ground vibration generated during EXW can be considerable. Common methods for noise abatement include performing the operation in a highly remote geographic location, in a mine or bunker, or in a specially designed blast chamber or vacuum chamber. Safety considerations vary among these options. Precautions must be taken to ensure that personnel are protected from shrapnel and facility deterioration.

Clad Plate Production

The following discussion describes the process for welding a two-component flat plate product (Fig. 12). Bimetal flat plate products are commonly produced to internationally accepted clad metal specifications:

- *ASME SA-263/A263*: Martensitic and ferritic stainless steel clad to carbon or alloy steel

- *ASME SA-264/A264*: Austenitic stainless steel clad to carbon or alloy steel
- *ASME SA-265/A265*: Nickel and nickel alloy clad to carbon or alloy steel
- *ASTM B 432*: Copper and copper alloy clad to steel
- *ASTM B 898*: Reactive and refractory metal clad plate (titanium, zirconium, tantalum)

Sizing Considerations. It is common practice to start with materials that are wider, longer, and thicker than required in the finished product to compensate for thinning and edge effects. In most situations, metals cannot be reliably bonded fully to the edges. Typically, allowances for edge nonbond are four to eight times the flyer plate thickness, depending on the combination of metals. Additionally, an area of nonbond is typical near the explosive initiator. The thickness of the component metals is reduced during surface preparation and bonding. Surface conditioning removes up to 0.75 mm (0.030 in.) from the thickness. During the bonding operation, the force vector parallel to the detonation causes a 1 to 2% increase in plate lateral dimensions; this change is

Scale	Macro	Meso	Micro	Nano
Microstructure				
Schematic				
Hierarchical structure unit	Plastically deformed base materials: different degree of accumulated strain in Ti and elongated steel grains	Wavy interface: wavelength of 540 μm and amplitude of 100 μm	Wave crest: different intermetallic phases, presence of microcracks	Thin interface reaction layer: two nanosize-grained components

accomplished by a corresponding reduction in thickness. The jetting of the metal surfaces during the bonding process causes only a thin layer to be removed, usually less than 0.05 mm (0.002 in.).

Surface Preparation and Assembly. The faying surfaces of the components are ground to achieve a smooth, pit-free finish of 1 to 3 μm (50 to 100 $\mu\text{in.}$). The plates are fixtured parallel while separated by a standoff gap. Methods for determining the standoff gap were presented in earlier sections of this article. Small standoff devices are required to bear the weight of the flyer plate and the explosive. Edge standoff devices are easily ejected from the system during bonding; therefore, material of construction is rarely critical. Internal standoff devices must be of sufficiently low mass to be removed by the jet, or must be located in trim regions. Some commonly used internal standoff materials are thin metal ribbons and foam blocks.

Explosive Loading and Welding. The explosive is placed on top of the flyer plate. The most commonly used explosives are granular or liquid and are typically contained within a simple box structure fabricated around the perimeter of the flyer plate. Initiating explosives are positioned in a suitable location on the plate surface. The required detonation range of EXW is below that of most commercially manufactured explosives. Consequently, most practitioners of EXW use proprietary explosive blends. Appropriate detonation characteristics can be achieved by specialized blending of commercial explosives such as Amatol, Dynamite, or ANFO.

The main explosive layer is initiated by a sequence of an electric blasting cap and a

high-explosive booster, causing a progressive detonation of the explosive, which creates the actions. The energy of welding typically creates sufficient deformation that flattening occurs (Fig. 2) and welds the plates together.

Postweld Processing. Most metal systems do not require postweld heat treatment to achieve the specified properties; however, some combinations provide superior properties if they are given a stress relief after bonding. For example, titanium/steel and zirconium/steel exhibit improved bond toughness after stress relief, and ferritic stainless steels exhibit an improvement in ductile-to-brittle transition temperature after stress relief.

Straightening is required prior to further processing. Flattening is performed with equipment of the same design used in plate and sheet manufacture.

Testing and inspection are performed as mandated by the product specifications. Ultrasonic inspection, typically performed using standard procedures such as ASTM A 578, is the most commonly accepted method for inspecting the bond continuity. Bond shear strength is normally measured using the test defined in ASTM A 264.

Because of the process edge effects, it is common practice to cut the product from a larger plate after bonding. The process options vary with the metal combinations and include oxyfuel gas cutting, plasma cutting, waterjet cutting, sawing, and machining. Finished plates are typically polished on the cladding side for cosmetic quality. Figure 13 shows typical clad plates after final processing.

Process Variants

Essentially the same approach can be used for producing multilayer products or cylindrical shapes:

- Multiple layers can be welded sequentially in a single operation; as many as 50 individual thin layers have been welded in a single event.
- Two-sided clad plates, with a heavy core metal, can be produced by simultaneously welding both sides using a vertical assembly.
- Two or more cylinders can be welded concentrically. The explosive is placed either inside of the cylinder or outside of the outer cylinder, depending on diameter and wall thickness.

Shop Welding Applications. Small, specialty EXW devices have been developed for a few unique shop applications. Explosion welding is used in heat exchanger shops for joining tubes to tubesheets and tube plugging. Explosion spot welding devices have also been used in limited commercial applications (Ref 48, 49).

Products and Applications

The largest industrial application of EXW is manufacture of large clad plates that are used in pressure vessels (Fig. 14), heat exchangers (Fig. 15), and electrochemical process applications (Ref 5, 42, 50, 51).

The dissimilar-metal welding features of EXW are made available to a broader industrial base through the concept of welding transition joints. Transition joint components are produced by explosion welders at their production facilities and then provided in the form of blocks, strips, or tubular couplings to equipment fabricators for use in the conventional welding of dissimilar metals (Fig. 16). Common applications are aluminum/steel (Ref 52), titanium/steel, aluminum/titanium (Ref 53), and aluminum/copper-nickel for shipboard construction; aluminum/copper and aluminum/steel for electrical contacts and buss systems (Ref 54); aluminum/stainless steel for cryogenic pipe couplings; titanium/stainless steel for aerospace and aircraft applications; and

Forge and Coextrusion Welding

Revised by Paul S. Korinko, Savannah River National Laboratory

FORGE WELDING is a solid-state joining process in which the workpieces are heated to the welding temperature and then sufficient blows or force are applied to cause permanent deformation and bonding at the faying surfaces. It is most commonly applied to the butt welding of steels but is also used to laminate steels together, as in the manufacture of Damascus blades. It is an ancient process and has been dated as early as 2000 B.C. (Ref 1, 2).

Coextrusion welding is a solid-state process that produces a weld by heating two or more workpieces to the welding temperature and forcing them through an extrusion die. The process typically is conducted at elevated temperatures not only to improve welding but also to lower extrusion pressures. Some cold coextrusion welding of aluminum and copper has been performed. For hot coextrusion, the parts to be welded are often assembled in a can or retort that is designed with the appropriate leading taper and wall thickness to promote initiation of extrusion. For reactive metals, such as zirconium, titanium, and tantalum, the retort may be evacuated and sealed. Both forward and back coextrusion have been employed, but forward coextrusion is the usual mode. A principal advantage of coextrusion welding is that the high isostatic pressures associated with the process are favorable to the deformation welding of low-ductility alloys.

Forge Welding

Forge welding of ferrous materials is accomplished at very high homologous temperatures on the order of 0.8 to 0.9 of the melting temperature, which contrasts with hot pressure (thermocompression) welding of ductile face-centered cubic metals, which is normally performed at temperatures of less than one-half the melting temperature. The forge welding temperature is generally selected to be as high as possible with due consideration to avoiding such metallurgical problems as hot shortness, embrittlement, sensitization, and excessive grain coarsening. This limitation implies an understanding of the unique metallurgical problems of the alloy to be welded.

Forge welding can be completed either manually or automatically. For manual forge welds,

the process is as follows. The pieces to be joined are heated and forged into common joints (Fig. 1). The joint surfaces in Fig. 1 are slightly rounded or crowned to ensure that the centerline region of the components joined will be welded first to force any contaminants (for example, slag, dirt, or oxide) present on the surfaces out of the joint. The two pieces are fluxed with a material that will remove oxides and prevent further oxidation, and heated using a furnace, an oxyacetylene torch, or perhaps a clean-burning, slightly reducing fire of the type a blacksmith would use. The parts are heated to the desired temperature, that is, near white hot, and then hammered to the target thickness and thus joined. It is desirable to achieve the final dimensions in one or two heat cycles. If the joint has not been thinned sufficiently, then the joint is reheated and forged again. If the pieces have been overthinned, additional work is needed to bring the minimum dimension back.

Typical joint configurations used for automatic forge welding operations are shown in Fig. 2 (Ref 1). Hydraulic presses are typically employed to apply pressure. Presses are often highly automated, featuring microprocessor control of pressure and temperature cycles. Heat is applied locally to the joint area by multiple-tip oxyacetylene torches, resistance heating, or induction heating. Often, the oxyacetylene torches are oscillated to ensure uniformity of heating. In a closely related process, magnetically induced arc butt welding, the surfaces to be welded are heated by a rapidly rotating arc plasma. Generally, the process is conducted in the open air, with oxygen

partially occluded from the joint area by the initial contact of the faying surfaces. When employing oxyacetylene torches, a slightly reducing flame affords some atmospheric protection. Vacuum, inert, and reducing atmospheres have been used.

The normal welding sequence is:

1. Apply sufficient pressure to firmly seat the faying surfaces against one another.
2. Heat the joint to welding temperature.
3. Rapidly apply additional pressure to mechanically upset the weld zone.

Typical weld durations are 1 to 2 min. A less common procedure is to initially apply high pressure and permit deformation to occur during the heating cycle. Most forge welding employs sufficient pressure to upset the surface until the increase in the surface area is 125% or more. However, such high deformation tends to cause flow lines to bend toward the surface during upsetting. Consequently, alloys that contain significant stringers and inclusions may exhibit poor impact or fatigue properties when welded with high amounts of upset. This effect may be minimized by reducing the upset, which normally requires increasing welding temperature and/or time to ensure complete elimination of voids and surface oxide.

Forge welding is most commonly applied to carbon and low-alloy steels, with typical welding temperatures of approximately 1125 °C (2060 °F). Low-carbon steels can be used in the as-welded condition, but medium-carbon steels and low-alloy steels normally are given full heat treatments following welding. In those cases where full heat treatment is impractical

Fig. 1 Typical joint configurations used for manual forge welding applications. Source: Ref 1

Fig. 2 Recommended joint configurations used in automatic forge welding applications. Source: Ref 1

but hardening due to rapid cooling has occurred, induction heating may be used to temper the weld zone. Other metals welded by forge welding include high-alloy steels, nickel-base alloys, cobalt-base alloys, aluminum alloys, titanium alloys, and tungsten. Applications of this process include welding rods, bars, tubes, rails, aircraft landing gear, chains, and cans. The forge welding process is competitive with flash welding and friction welding.

The primary variables for forge welding are temperature, total deformation, and deformation rate (for automated forge welding). Of these parameters, temperature is usually the most important.

Forge welding can be used to weld high- and low-carbon steels together, as is done for decorative swords. The forging process allows uniform carbon distribution profiles to be generated while having the steel exhibit a patterned weld (Ref 3). In addition to the same base-metal weldments being made via forge welding, dissimilar metals such as aluminum and iron have also been joined. Control of the variables is important, and, as suggested previously, weld temperature is the critical variable for creating a successful weld joint (Ref 4).

Flux must be added when forge welding certain metals to prevent the formation of oxide scale. The flux and the oxides present combine to form a protective coating on the heated surfaces of the metal that prevents the formation of additional oxide and lowers the melting point of the existing oxide. The flux removes the native oxide and allows metallurgical bonding of these clean surfaces.

Silica sand and borax are two fluxes commonly used on steels. Silica sand can be used as a flux in the forge welding of low-carbon steel. The oxides of very-low-carbon steels (ingot irons) and wrought irons do not require fluxes because their oxides have low melting points. Borax, sprinkled on the workpiece while it is in the process of being heated, is commonly used in the forge welding of high-carbon steels because of its low fusion point (Ref 1).

Weld durations for resistance welding are very short (seconds) compared to those for forge welding where gas torches are employed. This is because heat is generated internally in resistance welding but externally with gas torches. Terms that are sometimes used synonymously with forge welding include pressure welding, upset welding, and solid-state resistance upset welding.

Coextrusion Welding

Coextrusion can be used to join materials from the same alloy family. A corrosion-resistant alloy can be joined with a less-expensive base alloy to provide the required chemical properties where needed without using monoliths of the typically more expensive corrosion-resistant alloy. Coextrusion welding can also replace

other fusion processes such as overlay welding for surface property enhancement.

In a similar process, extrusion welding has been used to butt weld tubes. The ends of the tubes are prepared for extrusion by beveling at a 45 to 60° angle to produce an overlapping joint (Fig. 3). The leading tube contains the female portion of the beveled joint and is the stronger of the two metals in dissimilar-metal joints. Extrusion press die angles of 30 to 35° are common. An advantage of extrusion welding over other methods of deformation butt welding of tubes is that there is no flash or upset to remove following extrusion.

Common Metals Welded. The most common metals welded by the coextrusion process include low-carbon steel, aluminum, aluminum alloys, copper, and copper alloys. Additional applicable materials include nickel, nickel-base alloys, zirconium, titanium, tantalum, and niobium.

Common coextrusion behaviors are illustrated in Fig. 4. The quality of the coextruded material can be affected by the arrangement of the materials being welded. In coextrusion of 304 stainless steel and carbon steel, having the core be 8 to 20% shorter than the sleeve for a coextruded pipe resulted in a more uniform extrudant with less material loss (Ref 6).

Magnetic Pulse Welding

Sachin D. Kore, Indian Institute of Technology, Guwahati, India
J. Imbert, Y. Zhou, and M. Worswick, University of Waterloo, Canada

WEIGHT-REDUCTION EFFORTS for automobiles require the joining of various light-weight metals, such as aluminum and magnesium alloys. Although welding is a well-known and widely accepted joining process, the welding of dissimilar and difficult-to-weld metals is a major challenge faced by the automobile and aerospace industries. Welding of dissimilar metals is difficult to perform by a fusion welding process, because of the differences in their melting temperatures as well as the intermetallic compounds formed in the weld, which result in unacceptable mechanical properties (Ref 1). Additional difficulties in welding aluminum arise from the high affinity of aluminum for oxygen and the resulting formation of aluminum oxide (Al_2O_3) layers on the surface, which in turn result in poor-quality welds. Solid-state techniques based on generating extremely high pressures to create welds between dissimilar metals have been developed, with explosive welding being the most studied. Solid-state welds require clean surfaces; in explosive welding, the impact of the materials achieves this by removing the surface oxide layers. Explosive welding is well suited for welding dissimilar and difficult-to-weld metals; however, because of cost and safety concerns, it has remained applicable mainly for low-production-volume applications. Magnetic pulse welding (MPW) is a solid-state welding technique that is potentially well suited for high-volume welding of dissimilar and hard-to-weld metals. A fast-emerging impact welding method similar to explosive welding, MPW produces a solid-state weld by creating contact at extremely high pressures and by removing the oxide layers through the velocity and angle of impact. Complete metallurgical bonding can be obtained by pressing the two nascent surfaces together at very high pressure to obtain a weld between the metals.

In this process, the sudden discharge of a capacitor bank through a coil of relatively few turns produces a strong transient magnetic field. If this field is coupled with a metal workpiece, an intense impulsive force acts on the material and accelerates it to a velocity of the order of 10^2 m/s (225 mph) in a few microseconds. Magnetic pulse welding is safer and more amenable to mass production than explosive welding,

because a capacitor bank replaces explosives as the energy source, making the process safer, more repeatable, and suitable for use with standard power grids.

Fundamental Theory

Two current-carrying conductors, when placed in close proximity, exert force on each other. If the current directions are the same on each conductor, an attractive force is induced on the conductors; if the current directions are opposite to each other, a repulsive force is induced. If the currents are of high intensity and high frequency, they will generate high forces. These intense repulsive forces are used to accelerate the materials for MPW.

The energy for the process is provided by a capacitor bank that is connected to a standard industrial power outlet. The capacitor bank is initially charged with a direct current power supply. To generate the forces required for welding, the charged capacitor bank is discharged through a coil, generating a high-frequency current with a damped sinusoidal profile. The current produces a transient magnetic field that interacts with the metal sheets that are to be welded, inducing eddy currents in them in the opposite direction of the ones in the coil. Finally, the interaction of the eddy currents with the magnetic field generates Lorentz forces (\mathbf{F}) on the work sheets that drive them away from the coil and toward each other. The Lorentz force (\mathbf{F}) is given by (Ref 2):

$$\mathbf{F} = \mathbf{J} \times \mathbf{B} \quad (\text{Eq 1})$$

where \mathbf{J} is the current density, and \mathbf{B} is the magnetic flux density.

Because the Lorentz forces depend on the current density, the higher the conductivity of the material, the higher the current density and thus the higher the induced forces. This makes materials with high conductivity better suited for the MPW process. Steels, for example, have relatively low conductivity, which, combined with their higher mass and strength, makes them less suitable for MPW. To weld low-electrical-

conductivity materials, a highly conductive and low-strength material, called the “driver,” is placed between the workpiece and the coil. The driver is accelerated by the Lorentz forces and, in turn, accelerates the workpiece.

The magnitudes of the induced Lorentz forces depend on the magnetic field acting on the workpiece. Ideally, all of the magnetic field is used to generate Lorentz forces. However, transient magnetic fields can penetrate conductors, and, if the conductor is thin enough, part of the magnetic field can “leak.” Alternating electric current flow mainly at the skin of the conductor, at an average depth called the ‘skin depth.’ It is defined as follows (Ref 2):

$$\delta = \sqrt{\frac{\rho}{\pi \mu_0 \mu_r f}} \quad (\text{Eq 2})$$

where ρ is the electrical resistivity of the workpiece, μ_0 is the permeability of the freespace = $4\pi \times 10^{-7}$, μ_r is the relative permeability, and f is the frequency.

In the case of sheet metal, the skin depth can be greater than the thickness, a condition that will cause “leaking” of the magnetic field and lower the efficiency of the process. It is desirable for MPW operations that the value of the frequency should be selected in such a way that the skin depth of the induced currents in the workpiece is less than its thickness. Under this condition, an appreciable amount of the magnetic field is confined within the thickness of the workpiece, and the diffusion of the field beyond it is reduced to a minimum value, thus increasing the efficiency of the welding process.

Magnetic pulse welding and techniques for performing it have been studied in detail by many researchers. Most of this research is performed using the forming and welding of tubes, because it is relatively easy to control the magnetic field for axisymmetric components such as tubes (Ref 3, 4). The parameters that determine weld quality in MPW are similar to those in explosive welding: critical impact angle, impact speed, and the presence of a wavy interface after welding (Ref 5–10). Magnetic pulse welding has been explored for welding similar- and dissimilar-metal tubes for structural applications (Ref 11–19).

Thus far, the MPW technique has been mainly studied and applied to tubular structures and has been much less studied for welding of flat sheets, because of the difficulties in designing coils and controlling the magnetic fields in flat sheet welding operations. However, Aizawa et al. (Ref 20–22), Kore et al. (Ref 23–28), and Zhang et al. (Ref 29) have reported the feasibility of MPW of flat sheets. Kore et al. (Ref 24, 25), in particular, have reported a detailed study of the effects of process parameters on the strength and width of magnetic pulse welds of aluminum-to-aluminum and aluminum-to-stainless steel sheets. Kore et al. (Ref 30) have also reported the feasibility of MPW of magnesium (AZ31) to aluminum (AA3003) flat sheets.

Equipment

An electromagnetic (EM) welding system comprises the equipment shown in Fig. 1, connected electrically to form a resistance (R), inductance (L), and capacitance (C), or RLC, circuit.

Because the current and frequency requirements are high for MPW, low inductance and resistance must be used in the power supply system, high-voltage switches, and transmission cables.

Work Coil

The work coil converts the electrical energy in the capacitors into magnetic energy, which is finally transformed to mechanical energy on the workpiece. It is the part of the RLC circuit through which a damped sinusoidal current of high magnitude is passed, producing the transient magnetic field necessary for the performance of the welding operation. Coils are an essential part of any EM welding process.

Depending on the EM metal-processing technique, such different types of coils as solenoidal, flat pancake, and bar coils can be used, as described subsequently (Ref 31, 32).

Solenoid Coils. A solenoidal coil is shaped like a helix and is used for processing axisymmetric components. These coils, depending on their operation, are further classified into two types:

- *Expansion coils:* These coils are used inside axisymmetric workpieces (i.e., tubes) to expand the workpiece, as shown in Fig. 2.
- *Compression coils:* When a solenoid coil is placed outside the axisymmetric workpiece (tube) to compress the tube, it is termed a compression coil, as shown in Fig. 3.

Flat Pancake Coil. A spirally wound coil, such as the one shown in Fig. 4, is often called a pancake coil. Such coils are used for material processing of flat sheets. These coils do not produce uniform magnetic fields and often have dead spots where the magnetic field and thus the induced forces are zero. These nonuniform magnetic fields lead to nonuniform force distributions that can cause significant problems when forming sheet metal; these nonuniform distributions must be taken into account in process design. Uniform pressure coils (or actuators, as they are called by their developers) have been proposed to solve these problems in some applications (Ref 33).

Bar coils are of simple design (Fig. 5) and are used to concentrate the current (and thus increase the current density) on specific areas of a workpiece. The increase in current density is achieved by reducing the cross-sectional area of the coils. The smaller cross-sectional area produces a more intense magnetic field and thus induces higher Lorentz forces on the workpiece area that is directly facing the coil. This type of coil is mainly used for concentrating the

repulsive force onto a localized area of the workpiece, to obtain high levels of deformation for welds in a particular area of the workpiece.

Capacitor Bank

Capacitor banks are energy-storage devices that are used to store electric energy and produce from it a high-frequency and high-intensity current pulse. The energy (E) stored in a capacitor bank is given by:

Fig. 2 Expansion coil

Fig. 3 Compression coil

Fig. 4 Flat pancake coil

Fig. 5 Flat coil (bar)

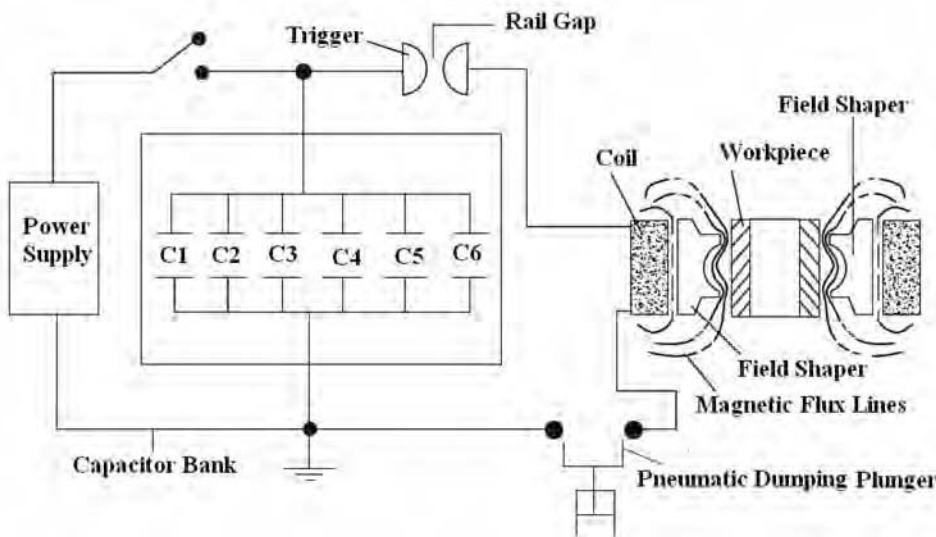

Fig. 1 Schematic of magnetic pulse welding equipment

$$E = \frac{1}{2} CV_0^2 \quad (\text{Eq 3})$$

where V_0 is the charging voltage, and C is the capacitance. The current pulse produced is in the form of a damped sinusoid (Fig. 6) (Ref 34).

The peak current produced by a capacitor bank is proportional to the charging voltage and the square root of the capacitance and inversely proportional to the square root of the inductance, as given by the following equation:

$$I_{\max} = V_0 \sqrt{\frac{C}{L_a}} \quad (\text{Eq 4})$$

where L_a is the inductance of the capacitor bank. The frequency of the current pulse produced is critical to the MPW process and is inversely proportional to the square root of the product of the capacitance and the inductance. The frequency is given by:

$$\omega = \sqrt{\frac{1}{L_a C}} = 2\pi f \quad (\text{Eq 5})$$

where f is the frequency. To determine the current pulse characteristics of a complete MPW, the inductance and capacitance of the system with the coil and workpiece included must be used. The capacitors can be connected in parallel, depending on the energy requirement for the material-processing operation.

High-Voltage Power Supply

Capacitors cannot be charged directly from a regular industrial alternating current power source, because direct current is required. The capacitor

bank must be charged from a variable-voltage power supply. Such a power supply consists of three basic elements: a step-up transformer, a rectifier, and a current-limiting device. It charges the capacitor by using a rectified current. The capacity of the power supply will depend on the requirements of the specific MPW operation.

High-Voltage Switches

Very high-speed switches, capable of withstanding high voltages, are required for MPW operations. Ignitrons, spark gap switches, or rail gap switches can be used to close the RLC circuit and produce the high-current pulse in the work coil. Ignitrons contain mercury and must be handled with care to meet all pertinent safety and environmental regulations.

Field Shapers

Field shapers are used to concentrate pressure at a specific location on the workpiece. They are also used to adapt large-diameter compression coils to smaller-diameter workpieces. Field shapers are essentially single-turn coils. They are inserted between the work coil and the workpiece; they receive their energy from the work coil and transfer it to the workpiece by induction (Ref 35). Thus, by using different sizes of field shapers, the same work coil can be used for job pieces of different diameters. However, field shapers must be electrically insulated from both the work coil and the workpiece. The use of field shapers increases the life of the coil by reducing the force acting on the coil.

The field shaper is inductively, rather than directly, coupled to a forming coil. Hence, the

efficiency of an EM welding or forming process that uses field shapers is lower than that in which only a forming coil is used. It is difficult to design a strong coil that can sustain the mechanical stress arising from Lorentz forces. By introducing a field shaper, the Lorentz forces can be shifted toward the region of greater mechanical strength of the coil (Ref 36, 37).

Additional Equipment

Other equipment that is helpful for MPW includes Rogowski coils (Ref 38) (to measure the current), accelerometers, load cells, and data-acquisition systems (to capture and analyze the signals obtained). High-speed cameras can be very useful, especially in the process development stage, in determining the deformation history of the workpieces and the location of arcing in the process.

Magnetic Pulse Welding Process

This section describes the MPW process and the critical parameters needed to obtain acceptable welds. Welding of axisymmetric sections is described first, followed by welding of flat sheet. Magnetic pulse welding of a tube to a solid core is shown in Fig. 7. In this case, a tube and a core that are to be welded are placed inside a coil. The outer tube is accelerated by the Lorentz forces induced on it by the coil, and it impacts the inner core (Ref 39–41). The impact pressure removes the oxides and surface contaminants and creates an atomic bond between the metals. Given the relative simplicity of the geometry, it is possible to estimate by both analytical and numerical methods the system inductance and EM pressure acting on the workpiece (Ref 5, 40).

Welding of sheet metal is substantially more difficult. A three-dimensional, flat rectangular, one-turn copper coil, such as the one shown in Fig. 8, can be used for MPW of similar- and dissimilar-metal sheets. The two sheets to be welded

Fig. 6 Current waveform for an electromagnetic welding operation. Source: Ref 34

Fig. 7 Cross section of tubes with coil and core for magnetic impulse welding

are placed between the upper and lower halves of the coil. When the transient current flows through the coil, it produces a transient magnetic field that induces Lorentz forces on the sheets and thereby accelerates them toward each other at very high speeds. The sheets will then impact one another, producing the desired weld.

The web of the I-shaped cross section of the coil concentrates the current, increasing the current density, J , and thus resulting in increased Lorentz forces. The reduction of the cross-sectional area is limited by the strength of the coil, which is also subjected to induced forces. If the area is too narrow, it could deform or even break.

Process Parameters

The impact energy and hence the formation of a weld in MPW depend on equipment and workpiece parameters. Equipment parameters such as the inductance, capacitance, and resistance of the circuit and the energy storage capacity of the capacitor bank are critical to achieving a proper weld. They directly influence the amount of energy transferred to the sheet and the time in which this transfer occurs—factors that in turn determine the acceleration of the sheet and its velocity at impact. Increasing the discharge energy increases the magnetic field generated and thus increases the shearing strength and the width of the EM weld of aluminum-aluminum and aluminum-stainless steel sheets for a given standoff distance.

Most researchers have found that MPW has many similarities to explosive welding in the workpiece parameters, for example, the critical impact angle, the impact velocity needed for joining, and the wavy interface created after welding (Ref 9). The velocity acquired by the sheets prior to impact depends on the energy input, as discussed earlier, and on the distance between the workpieces, or standoff distance. If the standoff distance is too small, then the workpiece does not accelerate to the required speed; if it is too large, the sheet will start to decelerate prior to impact. The impact velocity is crucial, because the kinetic energy achieved by the sheets is converted into impact energy. For example, in MPW of aluminum-aluminum and aluminum-stainless steel sheets, for a given set of process parameters, the standoff distance has one optimal value that gives the maximum shearing strength and width of the weld (Ref 24, 25). For lower values of standoff distance, collision takes place before the sheets attain the maximum velocity, whereas for higher values, the velocity attained drops at the time of collision (Ref 24, 25). The conductivity, mass, and strength of the material will affect the workpiece velocity and will also have an effect on the weld.

Researchers have studied the MPW process experimentally, although continued work is required in the welding of flat sheets. Masumoto et al. (Ref 6) studied EM welding of similar- (aluminum-aluminum) and dissimilar-metal cores and tubes. Kojima et al. (Ref 10) also studied the effect of flow stress, collision velocity, and collision acceleration in EM welding. They

found that, like collision velocity, collision acceleration also affects the quality of electromagnetically welded joints. Kore et al. reported the effect of such process parameters as discharge energy, standoff distance, and coil shape on the strength and width of magnetic-pulsed welds of aluminum-to-aluminum and aluminum-to-steel sheets (Ref 24, 25).

Mechanical Testing of Magnetic-Pulsed Welds

Magnetic pulse welding samples that have been mechanically tested in tensile shear tests show two types of failures: failure at the weld interface and failure away from the weld in the base metal. The MPW samples prepared with a lower value of discharge energy or a nonoptimal standoff distance fail at the weld interface. Welds obtained at optimal values of discharge energy and standoff distance fail away from the weld in the base metal, exhibiting welds that are stronger than the base metal (Ref 24–26). Hardness testing of the weld interface has shown higher hardness values near the weld interface compared to the base metal (Ref 26). This phenomenon is due to the compression of grains at the weld interface. The testpieces cut from the center of the welds (along the length of the weld) of aluminum-aluminum and aluminum-stainless steel sheets exhibit greater shearing strength than the pieces cut from the edges (Ref 24, 25). This behavior is attributed to higher penetration of the magnetic field at the center and a change of current direction in the sheets at their edges, a circumstance that weakens the magnetic field developed at the edges and hence the impulse acting on the sheets.

Metallurgical Characterization of Magnetic-Pulsed Welds

The microstructure of the aluminum-aluminum weld obtained by MPW (Fig. 9) shows two weld zones: one with complete metal continuity and one with a no-weld zone at the center. Complete metal continuity without any waves, as shown in Fig. 9, is characteristic of a sound weld. Kore et al. (Ref 24) reported that the wavy pattern at the weld interface is due to interfacial instability at lower energy values or nonoptimal standoff distance. The weld shown was obtained at a discharge energy of 5.184 kJ, a voltage of 7.2 kV,

Fig. 8 Magnetic pulse welding of flat sheets. Source: Ref 34

a standoff distance of 2.5 mm (0.10 in.), and a weld width of 1.1 mm (0.04 in.). The effect of process parameters, including standoff distance, coil geometry, and energy, on width and shear strength of the weld is reported in the literature (Ref 24, 25).

The defect at the center of the weld, shown in Fig. 9, was caused by entrapped oxide at the center and rebounding of the sheet at the center. The complex deformation state at the interface is also a contributing factor to the existence of the defect.

Magnetic pulse welding of aluminum-iron and Al-SUS304 steel sheets has been reported in the literature (Ref 22, 25). The effect of process parameters such as standoff distance, coil geometry, and energy on the strength and width of the weld is reported by Kore et al. (Ref 25). For joining dissimilar sheets, researchers have driven aluminum sheet by using EM force, with the iron sheet kept stationary rather than driven (Ref 22). Kore et al. used an aluminum driver sheet to drive the electrically-poor-conductor stainless steel sheet. This approach doubled the energy of impact (Ref 25) and led to stronger magnetic-pulsed welds.

An image from the microstructure of aluminum that is pulse welded to stainless steel sheet (Fig. 10) shows a continuous weld from an area exactly under the coil area. The void observed

Fig. 10 Magnified view of an aluminum and stainless steel (SS) weld zone from magnetic pulse welding. Source: Ref 34

in the weld is at the edges, where the sheet is not directly under the coil.

A micrograph of the weld between two copper sheets joined by MPW is shown in Fig. 11. Metallographic study and scanning electron microscopy analysis of the EM weld has confirmed metal continuity between the two sheets. Copper is an ideal candidate for MPW because of its high electrical conductivity and relatively low strength.

Aluminum-lithium alloys can be welded using MPW without the aid of drivers; however, specific heat treatment cycles must be used to reduce their yield strength. A magnetic-pulsed weld of aluminum-lithium is shown in Fig. 12; the presence of a wavy interface is notable. This interface is due to surface irregularities present on the sheets and also due to insufficient impact energy to crush the irregularities and obtain a sound weld. Pulse welding of copper to stainless steel (Fig. 13, Ref 42) was done by using an aluminum driver to accelerate both the copper and stainless steel work sheets, with a capacitor discharge energy of 8.46 kJ. Pulse welding of aluminum to magnesium AZ31 sheets (Fig. 14) produced welds with no intermetallics at the weld interface (Ref 30), a condition that is very difficult to obtain by using conventional welding methods.

Applications

Magnetic pulse welding can be relatively easily applied to mass production, especially when compared to explosive welding, which is the more established impact-welding process. At the moment, MPW is more applicable to tubular structures than to flat sheets. Mechanical joining of tubular cross sections (e.g., torque rods) is already in use for high-volume production. Magnetic pulse welding can also be used for joining structural parts for underwater applications and automotive space frames (Ref 11–13), joining of aluminum cans and cap wafers to avoid heat-generated problems encountered in tungsten inert gas arc welding (Ref 13), and welding of dissimilar-metal tubes (Ref 5). It is also applicable to create bimetallic driver shafts for lightweight applications. Magnetic pulse welding has been used in nuclear projects to join copper reactor tubes to ceramic plugs (Ref 43).

Magnetic pulse techniques have been extensively studied and are accepted for welding of axisymmetric parts; studies have been done to improve the weld quality, to develop modeling capabilities, and to determine suitable applications. Unfortunately, as of this writing, no similar studies have been performed for the

welding of flat sheets or nonaxisymmetric parts, processes for which research is still required to obtain commercially viable processes. Designing coils to generate the desired EM force distributions is a major challenge. The key to developing proper coils is an understanding of how EM-driven sheets interact at the time of impact and how this interaction affects the welds. Many researchers have now concentrated their research in the field of MPW, due to the potential application of MPW to join flat sheets of dissimilar or hard-to-weld metals in automobile and aerospace components. Analyzing the process analytically is difficult; the development of proper numerical models will be crucial for the future implementation of MPW. The need to weld dissimilar and difficult-to-weld metals has made it essential to study such new joining techniques as MPW.

Safety Guidelines While Handling the MPW Setup

Given the high currents, voltages, and material speeds involved in MPW, special care must be taken when implementing this technique. The MPW process has three types of potential hazards: sonic, electrical, and mechanical. These hazards can be avoided by following proper safety measures. Some safety measures are suggested as follows, but they do not form a comprehensive list; each individual application has its own unique set of circumstances and safety precautions. All of the safety and operation guidelines provided by the equipment manufacturer should be followed. The following are suggested measures to follow when working with MPW:

- No operator should work alone.
- It should be ensured that the floor is nonconductive.
- Ear protection should be used against such sonic hazards as spark gap triggering, impact of the sheets, and the very loud sparks that occasionally result from the process.
- No one should be in close proximity to the welding area when the machine is discharged. This precaution is necessary to avoid injury from accidental flying of stray objects and from exposure to magnetic fields.
- The capacitor banks should always be kept shorted to ground when not in use.
- Interlocking between system covers, doors, and operating switches on the control panel can prevent accidental operation of control panel switches while people are working with the machine.
- Manual grounding via a grounding rod to ensure complete discharge of the capacitors should be employed before the machine is touched by an operator.
- Extreme precaution should be used when handling high-voltage equipment.

Summary

It is possible to use MPW to weld various similar- and dissimilar-metal combinations that are difficult to weld by conventional welding methods. Magnetic pulse welding has been shown to produce good-quality welds that are stronger than the base metal. Defects in the welds are usually due to the entrapment of oxides. Impact velocity and angle play a vital role for complete removal of oxides from the weld interface. The impact velocity will depend on the energy imparted to the workpiece by the coil, which depends on the parameters of the system. The conductivity of the materials is a critical parameter for MPW because, all else being equal, the higher the conductivity, the higher the Lorentz forces induced.

Currently, EM welding is more suitable for axisymmetric components, such as tubes, because it is easier to produce the coils and design the process for such components. Magnetic pulse welding has potential as a means of joining sheet metal parts; however, designing coils for joining sheets by using MPW is a challenging task that requires a better understanding of the process and the availability of numerical predictive capabilities. Detailed research must be carried out on the design of flat coils in order for sheet metal joining to develop efficient coils with long working lives. The MPW technique should be further studied as part of the wider efforts to reduce vehicle weight and fuel consumption.

Cold Welding

Niels Bay, Technical University of Denmark

COLD WELDING (also known as cold pressure welding) is a solid-phase welding process normally carried out at ambient temperature. A large number of metals can be joined, as illustrated in Fig. 1 (Ref 1).

To obtain bonding in cold welding, plastic deformation of one or both metals is required, implying that a basic parameter is the degree of deformation. This is normally expressed as the surface expansion, X , or the degree of surface exposure, Y :

$$X = \frac{A_1 - A_0}{A_0} \quad Y = \frac{A_1 - A_0}{A_1} \quad (\text{Eq 1})$$

where A_0 is the initial and A_1 the final interface area. Figure 2 shows the shear bond strength obtained in roll bonding of sheets in various combinations (Ref 2, 3), plotted as a function of Y , which equals the thickness reduction in rolling:

$$Y = r = \frac{t_0 - t_1}{t_0} \quad (\text{Eq 2})$$

A threshold surface exposure must be reached before bonding occurs. Beyond this threshold, which depends on the metal combination, the bond strength increases rapidly, with Y reaching a level corresponding to the strength of the weaker metal. This relationship between

bond strength and surface exposure is fundamental to all cold welding processes, but the threshold surface expansion for a given metal combination is dependent on the type of forming process applied for cold welding. In the next section, a theoretical model explaining these phenomena is given based on metallographic studies and continuum mechanical analysis of the local plastic deformation in the weld interface.

Bonding Mechanisms and Theoretical Modeling of Bond Strength

Surface preparation before cold welding is of utmost importance. In most welding applications, surface preparation consists of degreasing followed by scratch brushing. Studies of the welded and subsequently fractured bonds in scanning electron microscopy (SEM) reveal the bonding mechanisms (Ref 4–6). The scratch brushing produces a hard, brittle surface layer that will crack when subjected to expansion (Fig. 3). At larger surface expansion (Fig. 4), virgin material is exposed, which extrudes through the cracks of the surface layer and meets similarly exposed surface area from the opposing metal. Figure 4(a and b) show the onset of extrusion at a surface exposure of $Y = 0.375$ but no visible bonds, whereas

Fig. 2 Bond shear strength versus surface exposure/reduction in cold roll bonding. Source: Ref 2, 3

Fig. 4(c and d), representing a slightly larger surface exposure, $Y = 0.383$, show ductile fracture of bonds on the top of the extrudate. At higher surface exposure, $Y = 0.72$, as shown in Fig. 5, extended areas of base metal have been bonded, and the unwelded regions of brittle surface layer are confined to small isolated islands. The ratio σ_B/σ_0 between weld strength and base-metal strength in the deformed state is indicated in Fig. 4 and 5.

Figure 6 shows a schematic outline of the bonding mechanism and how contact area between the two rough, virgin surfaces will build

Fig. 4 Bonding surfaces after fracture. (a) and (b) $Y = 0.375$, $p/\sigma_0 = 1.9$, $\sigma_B/\sigma_0 = 0.02$. (c) and (d) $Y = 0.383$, $p/\sigma_0 = 2.0$, $\sigma_B/\sigma_0 = 0.09$. Source: Ref 7

up with increasing surface expansion and contact pressure, forming a metallic bond (Ref 6).

Later investigations have revealed that scratch brushing creates a surface partly consisting of a relatively thick, hard, and brittle cover layer (approximately 20 μm , or 800 $\mu\text{in.}$) and a surface partly covered only by a contaminant film of oxides and water vapor. Bonding in these areas occurs when the contaminant film, which is of the order of 10 to 100 nm (0.4 to 4 $\mu\text{in.}$), is thinned to fracture (Fig. 7). Based on the metallographic studies, a continuum mechanic model for the bond strength for cold welding of two similar materials as a function of surface exposure and normal pressure has been established (Ref 7):

$$\frac{\sigma_B}{\sigma_0} = (1 - \beta) \frac{p - p_E}{\sigma_0} + \beta \frac{Y - Y'}{1 - Y'} \cdot \frac{p}{\sigma_0} \quad (\text{Eq 3})$$

where σ_B is the weld strength, σ_0 is the flow stress of the material after deformation, $\beta = \psi_f^2$, ψ_f is the fraction of film layer to the total area of the scratch-brushed surface, p is the normal pressure at base-metal surfaces, p_E is the pressure required for extrusion through cracks of the cover layer, and Y' is the threshold surface exposure for contaminant film.

The first term in Eq 3 represents the contribution to the weld strength from the area where fracture of the brittle cover layer appears. This applies to zones where one or both of the mating surfaces has a brittle cover layer, which appears in a fraction:

$$\beta = \psi_f^2 \quad (\text{Eq 4})$$

where ψ_f is the fraction of film layer on the scratch-brushed surface, which is determined by measurements on scanning electron micrographs of scratch-brushed surfaces. For Al 99.5, it has been determined that $\psi_f = 0.645$, implying $\beta = 0.4$. The pressure, p_E , required for extrusion through cracks of brittle cover layer is a function of the crack width, that is, the surface exposure. The relationship, which is shown in Fig. 8, is

Fig. 5 Bonding surfaces after fracture. $Y = 0.72$, $p/\sigma_0 = 1.8$, $\sigma_B/\sigma_0 = 0.71$. Source: Ref 7

determined by plane-strain slipline analysis. The threshold surface exposure for contaminant film breakdown of scratch-brushed Al 99.5 has been determined to be $0.30 \leq Y' \leq 0.35$ by studying a number of SEM micrographs with different surface exposure to see at what level welds first appear (Ref 7).

Figure 9 shows the bond strength normalized with the flow stress of the deformed material, σ_B/σ_0 , versus the surface exposure with the normalized normal pressure, p/σ_0 , as a parameter for cold welding of scratch-brushed Al 99.5 ($\beta = 0.4$, $Y' = 0.35$). At low normal pressure, $p/\sigma_0 < 2.0$, welding is initiated when $Y > Y'$ by fracture of the contaminant film. For $p/\sigma_0 = 1.5$, there is a bend on the curve at $Y = 0.49$, corresponding to the starting point of extrusion through the cracks and weld formation between the segments of brittle surface layer. For $p/\sigma_0 > 2.0$, welding is initiated by fracture of the brittle layer, extrusion through the cracks, and weld formation in between the segments of brittle surface layer. The film fracture mechanism comes into action later, namely at $Y = Y'$. This explains the bend at $Y = 0.35$ of the curves for $p/\sigma_0 > 2.0$ (Fig. 9). Figure 10 shows a comparison of the theoretically calculated weld strength as a function of surface exposure for two different normal pressures, $p/\sigma_0 = 1.85$ and $p/\sigma_0 = 5.1$, respectively.

The model was later expanded to include cold welding of dissimilar metals and to take ductility of the cover layer into account (Ref 9). Figure 11(a) shows the theoretical as well as the experimental bond strength for cold roll bonding of aluminum-aluminum with one-sided, electroless nickel plating, whereas Fig. 11(b) shows the bond strengths for aluminum-mild steel with one-sided, electroless nickel plating on steel.

The proposed model for the bond strength is of a generic nature, applicable to different types of cold welding by processes such as rolling, indentation, extrusion, and drawing. The different cold welding processes are presented in the section "Process Variants and Applications" in

this article. In addition to metal combination, the threshold surface expansion is dependent on the type of forming process applied for cold welding, because this controls the normalized normal pressure, p/σ_0 .

Alternative Methods of Surface Preparation

Although scratch brushing is normally applied as the method of surface preparation, it has certain disadvantages. The bond strength obtained is variable, with rather large scatter caused by the rough surface treatment. Cold welding must be carried out as soon as possible after scratch brushing and within 10 min.

Systematic investigations of cold roll bonding aluminum-aluminum, aluminum-copper, copper-copper, and aluminum-mild steel, applying different methods of dressing the workpiece surfaces before cold welding, show that electrochemical and chemical (also called electroless) plating are good alternatives to scratch brushing (Ref 10). As an example, Fig. 12 shows the weld interface surface after fracture of roll-bonded aluminum-aluminum prepared by electroless nickel plating

Fig. 6 Schematic outline of bonding mechanism. Source: Ref 6

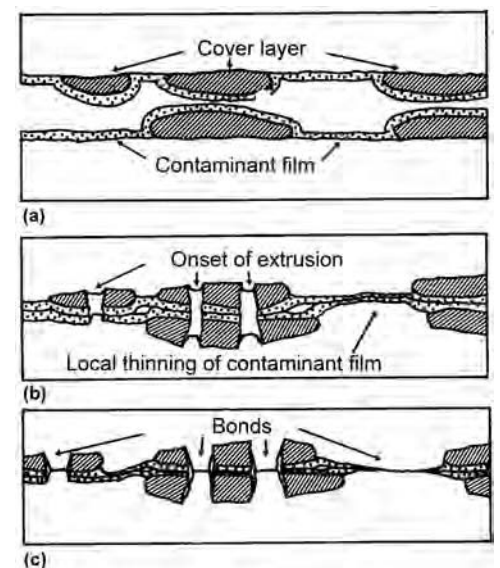

Fig. 7 Refined model for bonding mechanisms in cold welding. Source: Ref 8

of one of the two surfaces. Bonding is already obtained at a reduction $r = 0.35$, and at $r = 0.5$ extensive bonding is established in the cracks between the fragments of brittle cover layer.

Fig. 8 Required pressure, p_E . Source: Ref 7

Fig. 9 Normalized bond strength versus surface exposure with normalized normal pressure as a parameter for scratch-brushed aluminum-aluminum. Source: Ref 7

Fig. 10 Weld strength as a function of surface exposure for scratch-brushed aluminum-aluminum. (a) $p/\sigma_0 = 1.85$. (b) $p/\sigma_0 = 5.1$. Source: Ref 7

Figure 13 shows the weld strength in roll bonding aluminum-aluminum when adopting different methods of surface preparation. It is seen that electroless nickel plating leads to the earliest bond formation. Although anodizing of aluminum creates a very brittle cover layer, which is easily fractured by subsequent deformation, this surface-dressing method is not as efficient as nickel plating, electrochemically or electroless. This is due to the fragment size, which is substantially smaller than the one obtained by nickel plating. The optimum choice of surface preparation depends on the metal combination (Ref 9). Whereas electroless nickel plating is optimal for copper-copper and aluminum-aluminum, scratch brushing is the most efficient when cold roll bonding aluminum-copper and aluminum-mild steel.

Quality Control

The nature of the weld interface of a cold weld implies that nondestructive testing by, for example, ultrasonics is not applicable. The only way to test the quality is by destructive testing, implying that the surface preparation and subsequent cold welding should be handled with care to ensure good weld quality. Fingerprints on the scratch-brushed surfaces will have a detrimental effect on bond formation. This is due to the formation

of a thick contaminant film, which will impede bonding even in the areas uncovered after fracture of the cover layer.

Process Variants and Applications

A variety of metal-forming processes are suitable for production of cold welds. The following processes are most commonly applied in industry (Ref 8):

- Rolling
- Indentation
- Butt welding
- Extrusion
- Shear welding

Rolling

Roll bonding of two or more sheets is applied in a large variety of combinations. Evaporator plates for heat exchangers in aluminum and copper used in refrigerators (Fig. 14) and solar heat panels are made by roll bonding, applying stop-off ink prints to avoid bonding in the channels blown up after welding (Ref 12). Other roll bonding applications include compound plates of aluminum-copper and aluminum-stainless steel for cookware, aluminum-stainless steel

Fig. 11 Calculated and experimental weld shear strength as a function of reduction in roll bonding of (a) aluminum-aluminum with one-sided, electroless nickel plating and (b) aluminum-mild steel with electroless nickel plating on steel. Source: Ref 9

for vehicle bumpers, copper-stainless steel-copper for architectural purposes, cupronickel-copper-cupronickel for coins, and nickel-stainless steel-copper and nickel-iron-nickel for button cell batteries (Ref 13, 14).

After the sheets are cleaned, they are roll bonded together, reducing thickness to approximately 20%. The roll bonding may be carried out at elevated temperature to facilitate deformation in the case of harder metal combinations. Subsequent heat treatment may be applied to improve bond strength by diffusion.

The AlSn and AlZn alloys are roll bonded to mild steel for use in automotive slide bearings (Fig. 15). In this application, asymmetrical rolling is performed using a three-high mill, with a small work roll contacting the softer aluminum

Fig. 14 Evaporator plate made by roll bonding aluminum-aluminum

Fig. 15 Roll-bonded and subsequently machined and formed half of an automotive slide bearing

alloy and the larger work roll, of the same size as the supporting roll for the smaller work roll, contacting the harder steel strip. In this way, the aluminum alloy is smeared out on the steel surface in a kind of shear welding operation.

Precious-metal contacts for the electronics industry are also manufactured by roll bonding. Base metals such as alloys of copper, aluminum, nickel, iron, and stainless steel with inlays of gold, silver, palladium, and tin are roll bonded for connectors, lead frames, and industrial electronics (Ref 15).

Indentation

Lap joining by local indentation in the two plates or bars to be welded is a common cold welding operation, normally carried out by small tool indentation (Fig. 16). Indentation may be done from both sides with opposing indenters (Fig. 16a) or from one side only using an indenter tool and a flat anvil (Fig. 16b). The indenters may be of round or rectangular cross section with a diameter or minimum cross section typically being one to three times the thickness of the sheets. The required thickness reduction is 50 to 90%. As shown in Fig. 16, the indenters are usually provided with a shoulder that controls the amount of deformation, minimizes distortion, and promotes welding in the peripheral area surrounding the indenter. In welding dissimilar metals, it is often necessary to increase the size of the indenter or to employ a flat anvil on the softer metal side. Lap joining is typically applied to join aluminum-aluminum, aluminum-copper, and copper-copper, including alloys for electricity supply. Copper terminals are bonded to aluminum windings for transformers in automotive starter motors. Figure 17 shows some examples of lap joints.

Butt Welding

Cold butt welding of wires, bars, or plates end-to-end is performed by securing the two workpieces in special clamps in such a way that

Fig. 16 Lap joining by small tool indentation. (a) Double-sided indentation. (b) Single-sided indentation. Source: Ref 16

a free length of the workpieces protrudes from the clamps (Fig. 18). The free ends are pressed together, and the axial upset results in plastic deformation of the projecting ends that moves the original, contaminated end surfaces into the flash, thus forming a strong bond between virgin surfaces in the welding region. To obtain a good bond, upsetting is performed two to six times. When welding aluminum-aluminum, aluminum-copper, and copper-copper, the weld

Fig. 17 (a) Lap-joined aluminum outlets for a condenser. (b) Lap-joined copper sheet with a thickness of 0.14 mm (0.006 in.)

strength is greater than the base-metal strength, and there is no increase of electrical resistance in the welds.

Cold butt welding is applied for joining wire ends in wire-drawing production. It is furthermore applied for joining electrical busbars, for example, when providing aluminum busbars with copper terminals (Fig. 19). Automotive aluminum wheel rims have also been manufactured by cold butt welding flat aluminum band, which is subsequently roll formed to the required profile shape. Machines for cold butt welding include small, manually operated machine tools for thin wire combination (0.07 to 2.0 mm, or 0.003 to 0.08 in.) and hydraulic machines for larger butt welds (Ref 17, 18).

Fig. 18 (a) Schematic outline of cold butt welding with multiple upset. (b) Cold-butt-welded copper bar with a cross section of 3×5 mm (0.12×0.20 in.). Source: Ref 16

Extrusion

Tube transition joints of aluminum-stainless steel, aluminum-titanium, and zirconium-mild steel are manufactured for nuclear power and space technology by forward tube extrusion (Fig. 20a). The harder tube is placed nearest to the conical die opening. The punch is provided with a mandrel fitting the tube holes, thereby eliminating inward flow. Electronic devices and nuclear fuel elements are encapsulated by cold welding using an extrusion process, where the lid is joined to the can housing by an ironing operation (Fig. 20b).

Shear Welding

In several special cases, use of relative sliding between two surfaces in so-called shear welding has found application. Figure 21 (a-c) shows the principle of combining extruded aluminum profiles using a groove-and-tongue-like joint. The groove geometry ensures large local surface expansion, and the taper of the tongue ensures high normal-pressure in the interface, which, together with the shear deformation, establishes the conditions necessary for cold welding. This technique is applied for joining half-open aluminum extrusion profiles to closed sandwich constructions, as shown in Fig. 21(d). They are used for house construction as well as for stiffened panels for containers, trucks, vans, and ship sides. Figure 21(e) shows an air cooler assembled by the same technique (Ref 19, 20).

Fig. 19 Butt-welded and trimmed specimens. Aluminum-copper bars with cross sections of 5×15 mm (0.20×0.60 in.) and 10×100 mm (0.40×4.0 in.), respectively. Aluminum-aluminum sheet that is 0.3×35 mm (0.01×1.4 in.)

(a)

Cold weld riveting has been developed for welding aluminum sheet to aluminum frame profiles (Fig. 22). A hole is drilled through the sheet into the solid profile. An aluminum wire, oversized by 0.15 to 0.20 mm (0.006 to 0.008 in.), is forced into the hole, forming a cold shear weld along the hole side. The end of the wire is forged into a rivet head, using a pneumatic hammer. In this way, large roof and wall units have been mounted for industrial and public buildings.

Roll Welding and Laser Roll Welding*

Muneharu Kutsuna, Advanced Laser Technology Research Center Co., Ltd.

DISSIMILAR METALS in sheet or strip are joined for a variety of product applications. Domestic appliances such as electric frying pans and water boilers, for example, use combinations of dissimilar metals. Steel-aluminum sheet has structural application in automobiles and in antifriction parts such as cylinder liners and bushes. Dissimilar joining between steel and aluminum sheet also finds applications in liquefied natural gas storage tanks and steel supporting structure. Besides joining steel to aluminum to obtain higher strength than that of the base metals, other combinations of interest include:

- Steel to copper
- Steel to titanium
- Stainless steel to aluminum
- Galvanized steel to aluminum alloy
- Titanium to aluminum alloy

Joining for this purpose can be done in various ways, such as mechanical clinching, self-piercing riveting, adhesive bonding, diffusion bonding, explosion welding, friction welding, resistance spot welding, forge welding, and roll bonding.

This article describes two methods based on rolling of sheet. The first is roll welding, where two or more sheets or plates are stacked together and then passed through rolls until sufficient deformation has occurred to produce solid-state welds. The other process is laser roll welding, which is a hybrid process based on a thin-melting interface for a lap joint of dissimilar-metal sheets using a roller and one-sided laser heating.

Roll Welding

Two types of roll welding are common. In the first, the parts to be welded are merely stacked and passed through the rolls. The second method, usually termed pack rolling, involves sealing the parts to be rolled in a pack or sheath and then roll welding the pack assembly.

The first method is more generally employed in the cold welding of ductile metals and alloys.

Sometimes the stack to be welded is first tack welded at several locations to ensure alignment during rolling. Also, when using this method, the deformation during the first rolling pass must exceed the threshold for welding (typically greater than 60% for cold rolling) to keep the parts together. The required first pass reduction can be reduced by hot rolling, if the metals to be rolled can tolerate preheating without excessive oxidation. Once the first pass has been accomplished, the reduction per pass can be decreased, as is often desirable because roll-separating forces increase as the parts to be rolled become thinner. However, the nonuniform stress distribution that builds up during a sequence of very light passes can cause the weld to open up or "alligator." Therefore, the reduction for subsequent passes is generally a compromise between applying excessive separating forces and "alligatoring."

In pack roll welding, the parts to be welded are completely enclosed in a pack that is sealed (typically by fusion welding) and often evacuated to provide a vacuum atmosphere. This may be accomplished by a frame that surrounds the parts to be welded, which is sandwiched by two lids, or may simply consist of two covers formed to encapsulate the parts to be welded (Fig. 1). Semikilled or killed low-carbon steel is a common material for the pack but is not suitable for all alloy and temperature combinations. Although the preparation costs of pack roll welding are significant, the process has the following advantages:

- Provides atmospheric protection, which may be particularly important for reactive alloys such as those of titanium, zirconium, niobium, and tantalum
- Permits welding of complex assemblies involving several layers of parts.

A significant limitation of the process is that packs become difficult to process when their length exceeds several feet.

Titanium and titanium alloys are considerably more difficult to pack roll than are either steels or copper and aluminum alloys because most titanium alloys have very narrow working

temperature ranges. To overcome this problem, titanium alloys that are pack rolled are sometimes encased in a steel envelope, or can. The can is evacuated to minimize oxidation of the work metal, and it also serves to minimize heat loss to the relatively cold rolls upon deformation. The narrow working temperature range of titanium alloys makes the rolling of these materials labor-intensive. Rolling passes are done by hand on relatively small pieces, and many intermediate reheating steps are required. Some β -titanium alloys, however, are continuously rolled on hot and cold strip mills.

Nonpack rolling, of course, can employ continuous strip rolling. A seldom-used hybrid version of roll welding is to seal the edges of the parts to be welded by fusion welding prior to rolling. This method does not provide atmospheric protection to the outer surfaces, as in pack roll welding, but does occlude air from the more critical inner surfaces.

In roll welding, successful welding depends not only on the total amount of deformation but also on the pressure during rolling. A high isostatic pressure component during rolling is promoted by large reductions per pass, large roll diameters, and rough roll surfaces. A non-uniform distribution of normal stresses, referred

Fig. 1 Pack used for roll welding. The top cover, which would be welded in place before rolling, is not shown.

to as pressure hill effects, is caused by frictional and mechanical restraint and results in lower pressure near the outer edges of the parts being rolled. Therefore, rolling conditions must be such to ensure sufficient pressure near the edges to avoid weak welds in these regions.

Copper, aluminum, and their alloys are often cold roll welded. Hot rolling is applicable to a wide spectrum of alloys. Typically, hot rolling is performed above recrystallization temperatures. In practice, weldability is often improved by raising the temperature to the region where oxygen mobility becomes significant to promote oxide assimilation by diffusion. Also, welded assemblies are often postheat treated to cause recrystallization (in cold rolling), oxygen diffusion, and/or sintering. In welding dissimilar metals, selection of temperatures for rolling and postheating must take into consideration the possibility of intermetallic compound formation, eutectic melting, and/or porosity due to Kirkendall diffusion. The most common metals that are roll welded are low-carbon steels, aluminum and aluminum alloys, copper and copper alloys, and nickel. Low-alloy steels, high-alloy steels, nickel-base alloys, and titanium and titanium alloys have also been roll welded.

Roll-Welded Heat Exchangers

One of the more important applications of roll welding is the fabrication of heat exchangers. This process is used to fabricate flat solar collectors. In another method of heat-exchanger fabrication, three plates are stacked, with the middle plate containing the flow channels. The stacked plates are initially held together by tack fusion welds or resistance spot welds. This approach has been employed for both aluminum and steel heat exchangers. A second important application of this process is in the cladding of sheet metal products.

A principal application of roll welding is the production of heat-exchanger panels with flow tubes as an integral part of the composite. Millions of refrigerator evaporator plates have been formed by this process. A cross section of a similar application, solar collector panels, is illustrated in Fig. 2. Roll-welded heat-exchanger panels are most often made of aluminum, although copper and stainless steel panels have also been produced commercially.

The first major step in the production of roll-welded heat exchangers is to thoroughly clean the surfaces of the sheets to be joined by combinations of solvent cleaning, chemical cleaning, and wire brushing. Next, a stop-weld pattern is reproduced on one of the sheets that will later form the passageways in the heat exchanger. This is accomplished by transferring ink onto the surface by silkscreen processing. These stop-off inks contain materials such as graphite or titanium oxide.

The prepared plates are placed together and temporarily joined by spot welding to form a sandwich that is then roll welded, with at least

partial welding occurring during the first rolling pass. The sandwich sometimes is heated prior to this first rolling pass. Whether hot rolling or cold rolling is employed, the major reduction takes place in this first pass (50 to 80%). Subsequently, cold rolling may be employed to reduce the panel to final gage. Also, panels are generally given a postweld heat treatment. This heat treatment results in an annealed part and, particularly in the case of cold rolled panels, may improve the weld quality through recrystallization and diffusion. Finally, the passageways are formed by inflating them with air pressure while the sandwich is held between platens. The panel is then ready for trimming, additional forming, and painting, as required for the application.

The process has been used to produce heat exchangers for refrigerators, solar panels, poultry incubators, electronic equipment temperature controllers, industrial heat exchangers, and special applications such as thermal control of spacecraft. Modifications of the process permit as many as six sheets to be welded at one time and inclusion of passageways oriented along different principal directions at the different layers. Also, it is possible to produce panels where the passageways are expanded on one side only.

Cladding of Metals by Strip Roll Welding

The common early application of strip roll welding was the fabrication of bimetallic strips for thermostats. This remains an important application, with thermostats taking many complex forms and finding use in furnaces, color televisions, cars, and numerous industrial controls.

A key cladding application is the production of coins by the U.S. Mint. Silver shortages in the 1960s and 1970s resulted in the introduction of coins made from new materials. These coins required a unique set of properties for acceptance by the general public and use in automatic vending machines. Copper clad with cupro-nickel was found to meet these requirements (Fig. 3). The cladding process is relatively simple, although stringent in its requirement for surface preparation. Cladded strips are produced by continuous rolling, with the surfaces prepared just prior to rolling by processes such as wire brushing. Welding typically is accomplished in a single rolling pass. Subsequent heat treatments may be employed to improve the weld quality by processes such as sintering, diffusion, and recrystallization.

The starting material for the U.S. quarter is two outer layers of 75Cu-25Ni, each 1.2 mm (0.048 in.) thick, with an inner layer of pure copper that is 5.1 mm (0.20 in.) thick. To obtain good bond strength, the surfaces are chemically cleaned and wire brushed. The strips are then roll welded to a combined thickness of 2.29 mm (0.090 in.) (Fig. 4). A second rolling operation reduces the final thickness 1.36 mm (0.0535 in.). The strips thus undergo a total reduction of 82% (Ref 1).

Similar processing is applied to many new products, including electrical contacts, conductive springs, automotive windshield wiper sockets, automotive trim, clad cookware, wrap for underground cable, and electromagnetic shielding (Table 1).

Essentially all combinations of ductile metals and alloys can be clad by roll welding, although the oxides of some metals may make welding

Fig. 2 Cross section of an aluminum solar collector panel produced by the roll welding process

Fig. 3 Metallographic cross section of the edge of a cupronickel-clad copper coin

Fig. 4 Schematic showing 70% reduction in cross section of a U.S. Mint quarter coin (composed of an inside layer of pure copper sandwiched between two thin layers of cupronickel material) as it undergoes an initial roll welding operation. A second rolling operation further reduces the material to a final thickness of 1.36 mm (0.0535 in.) for a total reduction of 82%. Source: Ref 1

difficult and other combinations may suffer from intermetallic compound formation on heating. Most engineering metals and alloys can be processed into clad-laminate form, but some cannot (Table 2, Ref 2). One characteristic that makes some metals difficult or impossible to combine by deformation is low ductility. Such metals cannot be co-reduced to the extent necessary to achieve a metallurgical bond. Another characteristic that can cause problems is the tendency of some metals to form a tenacious oxide film that inhibits weld formation. Finally, some metals are thermally unstable; they form brittle intermetallic compounds when heated above a certain temperature. Those metals that are readily processed into clad laminates have opposite characteristics. They are ductile and easily cleaned of oxides, and they form no intermetallic

compounds. In most cases, when a metal is named, alloys of that metal also apply.

Laser Roll Welding

As noted, laser roll welding is a hybrid welding process—neither a fusion welding process nor completely a solid-state welding process. It is best described as a pressure welding process with a thin layer of melting from laser heating on one side of a lap joint. Using a roller and laser heating, it is typically used to join dissimilar-metal sheets. In the case of aluminum to steel with laser roll welding (Fig. 5), for example, the steel sheet is heated to 1300 °C (2370 °F) so that aluminum melts only near the interface with the steel.

The advantage of laser heating is the sharp focusing of energy for fast heating and cooling. Rapid heating and cooling minimizes the time for formation of brittle intermetallics by diffusion processes. The process of combining laser heating with roll bonding is intended to reach sufficient temperatures quickly, to form a bond while being pressed. Some basic process variables (Fig. 6) include laser power, travel speed, and roll pressure. By control of welding speed, laser power, and roll pressure, the interlayer thickness and formation of brittle intermetallic compounds can be minimized.

Different types of high-power lasers (on the order of 2 kW) can be used for laser roll welding of dissimilar-metal joints. A schematic of roll welding with a CO₂ laser is illustrated Fig. 5(a), and a setup with a fiber-optic laser

Table 1 Typical properties of common roll-welded clad laminates

Materials system	Composite ratio, %	Thickness		Width		Tensile strength		Yield strength		Elongation, %	Applications
		mm	in.	mm	in.	MPa	ksi	MPa	ksi		
Copper 10300/low-carbon steel	50:50	0.25–2.54	0.010–0.100	12.7–50	0.5–2	260(a)	38(a)	215(a)	31(a)	40(a)	Typically used for commutators in electric motors, replacing copper 10400. The lower conductivity of steel causes less heat loss during welding, resulting in faster, better-quality welds. The added strength of steel allows thickness reduction.
Deoxidized copper/carbon steel/deoxidized copper	5:90:5, 10:80:10, 15:70:15	0.25–2.54	0.010–0.100	≤610	≤24	420(b)	61(b)	250(b)	36(b)	35(b)	Used in heat exchangers, replacing brazing shim material. One-piece manufacturing eliminates separate shims and reduces assembly cost. Because no ferrous surfaces are exposed, no flux is needed.
Type 434 stainless/5052 aluminum	40:60	0.56–0.76	0.022–0.030	≤610	≤24	395	57	360	52	12	Widely used for automotive body moldings, drip rails, rocker panels, and other trim components, often replacing solid stainless steel or aluminum. Stainless steel provides bright appearance; the hidden aluminum base provides cathodic protection, corroding sacrificially to the body steel.
Copper 11000/1100 aluminum	50:50	0.51–2.54	0.020–0.100	50–510	2–20	180(c)	26(c)	12(c)	1.7	35(c)	Developed specifically for transition joints between copper and aluminum in refrigeration equipment. Usually used in the form of deep-drawn tubing.
C1008 steel/type 347 stainless steel/C1008 steel	43:10:45	0.36	0.014	305	12	393	57	195	28	35	Used in hydraulic tubing in vehicles, replacing terne-coated carbon steel tubing. The outer layer of carbon steel cathodically protects the stainless core of the tube, extending its life significantly.
Nickel 201/type 304 stainless steel/nickel 201	7.5:85:7.5	0.20–2.41	0.008–0.095	25–64	1–2.5	310	45	40	Used in formed cans for transistor and button cell batteries, replacing solid nickel at a lower cost.
Copper 10300/type 430 stainless steel/copper 10300	17:66:17, 20:60:20, 33:34:33	0.10–0.15	0.004–0.006	12.7–150	0.5–6	415(d)	60(d)	275	40	20(d)	Replaces heavier gages of copper and bronze in buried communications cable. The stainless steel provides resistance to gnawing by rodents, which is a serious problem in underground installations.
Phosphor bronze 51000/carbon steel/copper	10:85:5	0.38–1.52	0.015–0.060	≤610	≤24	455(e)	66(e)	435	63	16(e)	Used in automotive applications, such as windshield-wiper bearings. The bronze provides the bearing qualities, the steel provides strength, and the copper aids tooling life and provides corrosion resistance in service.

Fig. 5 Laser roll welding. (a) Schematic of laser roll welding process with aluminum and steel sheet. (b) Using a 2 kW fiber laser

is illustrated in Fig. 5(b). The diameter of the beam spot is approximately 3 by 5 mm (0.12 by 0.2 in.) on the metal sheet and 10 mm (0.4 in.) distance from the bottom of the roller. Incident angles of the laser beam were 45 μ m. CO₂ laser and 30 μ m. fiber laser, respectively.

Laser Roll Welding of Dissimilar Metals

Steel and Aluminum Sheet Joining

Fusion welding of aluminum to steel is impractical, because brittle intermetallic compounds such as FeAl₂, Fe₂Al₅, and FeAl₃ can

form during the melting and subsequent solidification. The reason for this is attributed to the great difference between their melting points (660 $^{\circ}$ C, or 1220 $^{\circ}$ F, for aluminum and 1538 $^{\circ}$ C, or 2800 $^{\circ}$ F, for iron), almost zero solid solubility in each other, and formation of brittle intermetallic compounds.

In the iron-aluminum system (Fig. 7), intermetallic compounds are grouped as iron-rich compounds (FeAl and Fe₃Al) and aluminum-rich compounds (FeAl₂, Fe₂Al₅, and FeAl₃). Mechanical properties of cast intermetallic compounds under compressive test are shown in Fig. 8. While the aluminum-rich intermetallic compounds are brittle, iron-rich intermetallic compounds show slight ductility and high

strength. The objective is to minimize formation of the brittle intermetallic compounds.

Although the complete elimination of brittle intermetallic compounds such as FeAl₃, FeAl₂, and Fe₂Al₅ is not possible due to their low free energy, their formation can be suppressed to some extent. Laser heating of the steel quickly reaches the temperature of the interface suitable to form ductile compounds such as FeAl and Fe₃Al (approximately 1250 $^{\circ}$ C, or 2280 $^{\circ}$ F). This results in melting of a very thin layer of aluminum—on the order of 10 μ m—at the interface. As this effect of laser heating is taking place, the heated zone is subjected to roll pressure to improve the contact area. This also helps in increasing the cooling rate, preventing

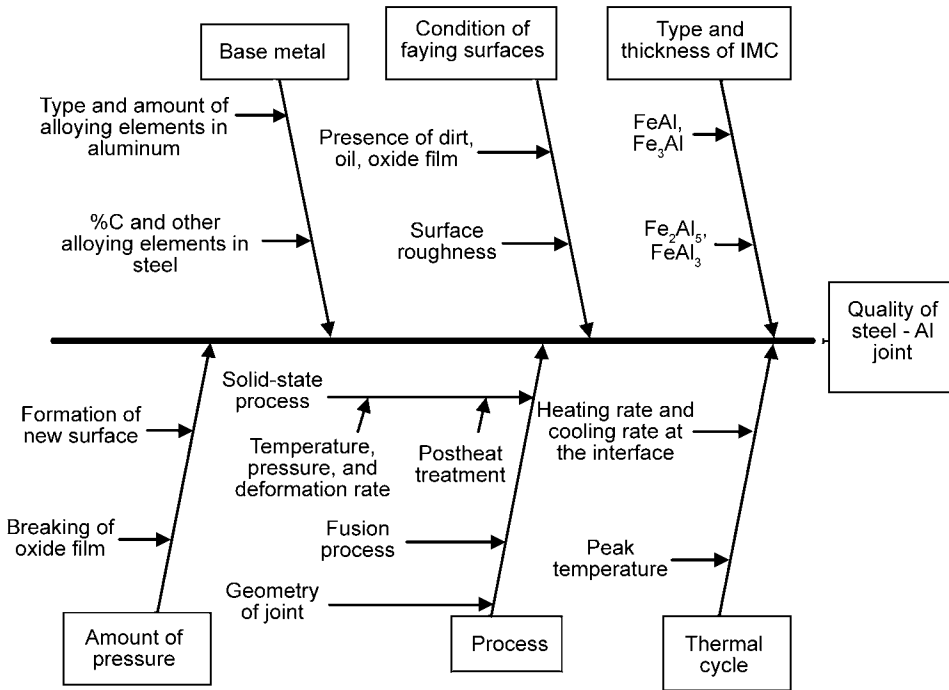

Fig. 6 Process parameter for laser roll welding. IMC, intermetallic compound

Fig. 8 Stress-strain curve in compressive test of iron-aluminum intermetallic compounds. Source: Ref 3

combined sections consisting of steel sheet with aluminum or aluminum alloy sheet. Attempts to use resistance spot welding with inserts for this purpose have already been made (Ref 3), with the major problem being the formation of brittle intermetallic compounds such as FeAl₃ and Fe₂Al₅ in the interface layer. It has also been reported that if the layer thickness of the intermetallic compound is limited to below 10 μm, the joint strength is improved (Ref 4).

In an example of laser roll welding, a low-carbon steel (JIS-SPCC, 0.12 C max, 0.5 Mn max, 0.04 P max, S 0.045 max) with a sheet thickness of 0.5 mm (0.02 in.) was joined with a 1 mm (0.04 in.) thick sheet of aluminum (A1050) and aluminum-magnesium alloy (A5052). A continuous-wave CO₂ laser was used to weld the steel sheet to the A5052 alloy, while a pulsed CO₂ laser was used to weld the steel sheet to the unalloyed aluminum sheet (A1050).

A lap joint was used, and the steel was placed on top of the aluminum to absorb the heat from the incident laser beam without melting and to conduct the heat to the interface. The overlap was 9 mm (0.36 in.), and the Gaussian beam was defocused to give an elliptical spot of 2.5 mm (0.10 in.) minor and 3.5 mm (0.14 in.) major diameter on the steel surface. A spring was used to press the joint against the table through the roll. Prior to joining, the faying surfaces of both sheets were cleaned ultrasonically to remove the hard aluminum oxide film, then treated with a brazing flux (KAIF₄: K₂AlF₅·H₂O) to prevent further oxidation.

Laser roll welding was conducted with varying travel speed, laser power, and roll pressure. The range of conditions was as follows:

- *Laser power:* 1.0 to ~2.0 kW
- *Travel speed:* 1.0 to 3.2 m/min (3.3 to 10.5 ft/min)
- *Beam spot diameter:* 3 to 5 mm (0.12 to 0.2 in.)
- *Roll pressure:* 100 to 200 MPa (14.5 to 29 ksi)
- *Shielding method:* Argon gas

Fig. 7 Aluminum-iron phase diagram

further diffusion at the interface. Such conditions restrict the intermetallic compound layer thickness to thin levels. The existence of a thin interface layer containing some ductile compounds is favorable for improved joint strength.

Welding Uncoated Steel Sheet with Aluminum Sheet. Low-carbon steel and aluminum alloy sheet products are common in the automobile industry for structural components. For weight reduction, one method is to use

In addition to these parameters, pulsed laser welding is used to weld the unalloyed aluminum A1050, which enables more control of the heating and cooling rates by changing the pulse.

The joints were cut transversely to observe the macrostructure and microstructure. Macrostructure examples are shown in Fig. 9. Specimens were used to identify and estimate the intermetallic compounds through the interface layer by electron probe microanalysis (EPMA) with wavelength-dispersion analysis. Based on the EPMA results, the thickness of the interface layer was divided into ductile compounds (FeAl and Fe₃Al) and brittle compounds (FeAl₃ and Fe₂Al₅). The EPMA analysis showed that the interface layer consisted of brittle intermetallic compounds (FeAl₃ and Fe₂Al₅) on the aluminum side and ductile ones (FeAl and Fe₃Al) on the steel side. As the travel speed increased, the total thickness of the interface layer decreased with increasing thickness of the ductile compounds.

Thickness of the interface layer could be controlled by changing pressure values and interface temperature (by varying the laser power or travel speed). Increasing the power has the same effect as decreasing the speed, but if the power reaches high values, it will

cause melting of the steel sheet, and if it reaches low values, the heat input may not be sufficient to produce a bond. As for the pressure, it is necessary to increase the contact area for a short time after heating to allow the diffusion process to take place and help to increase the cooling rate of the joint by heat conduction.

Figures 10 and 11 illustrate the effect of travel speed on interface layer thickness and shear strength. By increasing the travel speed, the interface layer thickness decreases at the same time shear strength increases up to 33 MPa (4.8 ksi) for A1050 and to 56 MPa (8.1 ksi) for A5052. With higher speeds, the percentage of ductile compounds is relatively high, but the shear strength drops for fast travel speed, owing to insufficient temperature due to the lack of heat energy at the interface layer. To evaluate the formability of the joints, the Erichsen test was carried out and evaluated with different speeds, as shown in Fig. 12. The cupping height increases with speed until it reaches a maximum value, then starts to decrease almost in the same manner as the shear strength analysis.

Welding Galvanized Steel Sheet with Aluminum Sheet. Laser roll welding of dissimilar-metal-joint zinc-coated steel with 6000-series aluminum alloy (A6000) has also been

evaluated. Like the uncoated steel sheet, the following conclusions were observed:

- Increase in the travel speed of the table led to decrease in the thickness of the intermetallic compound layer at the interface. Increase in travel speed led to lowering of the peak temperature and shortening of the holding time more than 500 °C (900 °F) at the interface.
- It is suggested that the intermetallic compound layer formed is mainly brittle FeAl₃. Because the travel speed is faster than 0.6 m/min (2.0 ft/min), zinc is confirmed in the aluminum alloy.
- When the intermetallic compound layer was less than 10 μm, failure of the specimen occurred at the base metal of the zinc-coated steel in tensile shear test.

Steel and Titanium Sheet Joining

Fusion welding of steel and titanium is difficult because of generating the brittle intermetallic compound, but laser roll welding allows some control over the formation of intermetallic compounds. In the case of laser roll welding of titanium to steel, the eutectic phase between titanium and TiFe intermetallic compound is formed from the liquid phase at the interface above 1180 °C (2155 °F). The melting interface and interlayer should be controlled to obtain a ductile phase at the interlayer.

Pure titanium sheet (JIS H4600-TP340C) and low-carbon steel (JIS SPCC) sheet were used for joining. The dimension of the titanium sheet and the steel sheet were 40 by 200 by 0.5 mm (1.6 by 8 by 0.02 in.).

Process parameters are shown in Table 3. Travel speed varied from 1.2 to 1.7 m/min (3.9 to 5.6 ft/min). The steel surface exposed to the laser beam was coated with graphite

Fig. 9 Macrostructure samples from joints after laser roll welding of low-carbon steel sheet (JIS-SPCC) with (a) A1050 aluminum and (b) aluminum-magnesium alloy A5052. Laser power, welding speed, and roll pressure were: (a) 1.5 kW, 1.5 m/min (4.9 ft/min), and 150 MPa (22 ksi) for A1050, and (b) 1.5 kW, 2.2 m/min (7.2 ft/min), and 200 MPa (29 ksi) for A5052

Table 3 Process parameters in laser roll welding of commercially pure titanium with steel sheet

Type of laser	Pulsed CO ₂ laser
Laser power	1.6–2.0 kW
Duty cycles	80%
Frequency	150 Hz
Travel speed	1.2–1.7 m/min (3.9–5.6 ft/min)
Overlap width	3 mm (0.12 in.)
Roll pressure	76–128 MPa (11–18.5 ksi)
Center shielding gas	Ar: 25 L/min
Side shielding gas	Ar: 25 L/min

to increase the absorption of the laser beam. The faying surface was polished and degreased. Argon gas at the flow rate of 25 L/min was used for shielding of joints.

The effect of laser power and travel speed on interlayer thickness is shown in Fig. 13. Interlayer thickness decreases significantly from 170 to 10 μm as the travel speed is increased from 1.3 to 1.5 m/min (4.3 to 4.9 ft/min) at a laser power of 1.8 kW.

A tensile shear test was done to investigate the performance of the welded joint. Tensile shear specimens after testing of laser roll-welded joints are shown in Fig. 14. Some

specimens were broken at the interface (Fig. 14a), and others were broken in the base metal of the steel sheet (Fig. 14b). When the interlayer thickness was less than 25 μm, failure of the specimen occurred in the base metal of the steel sheet.

Ultrasonic Welding

Janet Devine, Sonobond Ultrasonics Inc.

ULTRASONIC METAL WELDING is a solid-state welding process that produces coalescence through the simultaneous application of localized high-frequency vibratory energy and moderate clamping forces. Ultrasonic vibrations create frictional action between surfaces held together under pressure, dispersing oxides and contaminants to give metal-to-metal contact and bonding. Ultrasonic welding offers some advantages over other joining technologies in that it is a solid-state process with no melting; it can join dissimilar metals, weld thin sections to thicker sections, and weld through most oxides and surface oils; and it creates negligible odor and fumes. Ultrasonic welding requires no welding consumables, such as welding rods, fluxes, or solders; has modest space requirements; is environmentally friendly; has no arcs or sparks; and is cost-competitive.

Energy consumption is low when compared to resistance welding or self-piercing rivets. Weld times are short and equipment operation is similar to that needed for resistance welding, thus easing manufacturing acceptance.

The first ultrasonic welding patent for joining metals was awarded to AeroProjects in 1960, and the process has evolved to cover a wide range of applications. Most commercial applications involve nonferrous alloys. Although steel alloys can often be welded, there is a problem with the steel sticking to the welding tip after very few welds. Applications must be lap joints, not butt joints. The process has some welding thickness limitations, and generally the thinner sections are placed next to the welding tip, but the anvil tip side does not have the thickness limitation. The welding thickness limitation can be greatly extended by using a dual-head system in which the ultrasonic energy is introduced from both sides of the weldment.

Production applications include wire to wire and wire to terminals for wire harnesses for appliance, automotive, and the cable industry; buss bars; circuit breakers; contacts; ignition modules; motors; battery and capacitor foils; photovoltaic panels; passive solar heaters; heating, ventilation, and air conditioning (HVAC) tubing; and many others.

The advantages of ultrasonic welding include the ability to:

- Join metals without the heat of fusion, making it an efficient method, energy-wise
- Join dissimilar materials such as copper to aluminum
- Join thin materials to thick materials
- Join multiple layers of thin materials
- Provide strong joints with good thermal and electrical conductivity
- Require no filler materials or fluxes
- Require no special cleaning methods

Limitations include:

- Applications must be overlap joints, not butt welding.
- Materials are limited, for the most part, to nonferrous materials.
- Thickness of the top sheet is approximately 3 mm (0.12 in.) for aluminum and less for many other materials.
- Because the weld is generated by vibratory energy, there must be a gripping surface between the tooling and the parts that may deform the finished parts.

Equipment and Process Parameters

All ultrasonic systems include a power supply that converts line power to the high frequency and high voltage needed by a transducer or converter. The transducer transforms high-frequency electrical energy to vibratory energy because of its piezoelectric properties.

The transducer is incorporated in the welding head together with waveguides that transmit the energy to the welding tip or sonotrode. The tip is held against the desired weldment under pressure. The welding head may use pneumatic, hydraulic, or mechanical means to clamp the workpieces between the welding tip and an anvil or fixture that holds the parts to be welded in place in the desired configuration. Where large parts are to be joined with a series of spot welds, the anvil may be incorporated into a support frame or fixture, and the fixture can be moved by a robot in production use.

The most widely used frequency for operation is 20 kHz, which is a little beyond the range of human hearing, but there are also welders operating at 40 kHz and above. Because the waveguides are designed to be resonant at the operating frequency, the higher frequencies lead to smaller waveguides and limit the power capacity of the welder. For fine wire bonding, frequencies of 60 kHz and up are used because the parts are small and the power requirement is minimal.

Besides frequency, which is fixed for any particular machine, other parameters to be considered when selecting a suitable welder are power level and configuration. Larger sections require higher power levels and clamping force. For instance, spot welding of 1 mm (0.04 in.) thick aluminum alloy requires a minimum of 2500 W and approximately 150 N (34 lb) of clamping force. This power level would dictate a 20 kHz welder. Power and force can be controlled by the operator, so thinner weldments can be welded with the same machine, but the range of operation of a specific machine varies between manufacturers.

There are two basic designs: a wedge-reed system and a lateral-drive system (Fig. 1, 2). In the wedge-reed system, the transducer is attached to a reed that vibrates in flexure and is terminated by a heat treated steel tapered tip that fits into a cavity at the end of the reed. The lateral-drive system is an inline transducer, booster, and horn, where the welding tip may be integral with the horn or may be removable and held with a mechanical fastener.

In addition to the spot welders of Fig. 2, various welder configurations are available. These include a hand-guided weld gun used for spot welding or for closing and sealing copper tubes for HVAC assembly (Fig. 3) and a robot-controlled C-gun for welding automotive sheet metal assemblies, such as trunk lids or hoods (Fig. 4, 5). A continuous seam welder for foil welding is shown in Fig. 6.

Typically, welders use compressed air and a pneumatic cylinder with slide to bring the welder into location and apply the necessary clamping force. Machines are microprocessor controlled, and the operator can select and store job parameters from a control panel. Welds can

Wedge-reed system

Lateral-drive system

Fig. 1 Schematic depiction of wedge-reed and lateral-drive styles of ultrasonic welding heads

be controlled by time, by energy, or, if so equipped, by distance.

Wire welding requires that the wires to be bonded are gathered together in an anvil fixture with a slight pressure to prevent the wires from escaping from the intended weld area (Fig. 7). The most common application is the manufacture of wire harnesses for the transportation and appliance industries. Machines are available for welding wire bundles with cross-sectional area from 1 to 100 mm² (0.002 to

Fig. 3 Hand-guided portable ultrasonic welding gun with tooling to squeeze and seal copper tubing used in air conditioning systems and refrigerators

Fig. 6 A 50 kHz ultrasonic rotating disk welder used to join foil to foil or foil to metallized glass in photovoltaic systems

0.156 in.²). Ultrasonically welded wire bundles should meet or exceed the Wire Harness Manufacturing Association's IPC/WHMA-A-620 specification (Ref 1).

Spot welds can be circular, elliptical, or ringlike in geometry, as dictated by the size and shape of the tip and anvil. The tip vibrates in a plane parallel to the interface and perpendicular to the clamping force holding the parts together; tip geometry is selected based on the parts to be bonded. Multiple spots can be made with a single tip, although there are size restraints on the weld area that can be successfully bonded in a single weld cycle. Weld time is typically 0.5 to 3.0 s for spot welding.

Applications include wire to terminal; battery terminals; battery foils; buss bars; circuit breakers; ignition modules; small motors; capacitors; heating, ventilation, and vacuum tubing; and aluminum body panels.

A recent study (Ref 2) conducted on welding of aluminum body parts used heat treated tool steel tips with a gripping surface geometry that successfully reduced the tendency for sticking between the tip and surface of aluminum alloys (Fig. 8). The study included some thermocouple and infrared temperature measurements at the weld location. The temperature recorded did not exceed 420 °C (790 °F)—well below the melting temperature of aluminum.

The same joint venture program included micrographs of the bond produced at increasing levels of energy to make the joint. The micrographs show the growth and progression of the weld at increasing energy levels (Fig. 9–11). Tensile testing of the test coupons typically resulted in a button pullout, with the parent metal breaking before the weld failed (Fig. 12, 13). Failure loads are given in Fig. 14 and Table 1. A comparison of fatigue life attained by ultrasonic welding and other joining methods is shown in Fig. 15.

Nondestructive testing included determination of the welded area by ultrasound. As shown in Fig. 16 and 17, there was a good correlation between the indicated bond area size and weld failure load, as expected. The automotive alloys included in this study are listed in Table 2.

Continuous seam welds are produced when a disk-shaped ultrasonically activated roller is rotated and traversed relative to the materials to be bonded. Typical uses include joining foil ends at rolling mills and joining aluminum interconnects to metalized glass for photovoltaic panels. Foil in the range of 0.004 to 0.12 mm (0.0002 to 0.004 in.) thickness is weldable with the high-frequency (typically 50 kHz), low-power systems. There are 20 kHz systems available for welding heavier materials, including passive solar panels up to approximately 0.2 mm (0.008 in.) thick.

Microelectronic welding of fine wires was the earliest of the commercially successful ultrasonic metal-welding applications and still

accounts for a large volume of industrial activity. Wire diameters range from less than 0.025 to 0.5 mm (0.0010 to 0.20 in.). Vibratory action at 60 kHz and higher removes surface contaminants, induces material flow, and permits a solid-state weld between the wire and metalized bond pad or leads on semiconductor packages.

A combination of ultrasonic and thermocompression bonding, known as thermosonic bonding, is also a popular technique. The ultrasonic welding is achieved on heated substrates, typically with interface temperatures from 100 to 200 °C (212 to 392 °F).

Surface condition of the materials to be welded does not present much of a problem

Tip side of welded coupon

Fig. 8 Typical tip patterns for ultrasonic welding with good strength and minimum tip sticking when spot welding automotive aluminum

for most commonly welded materials, such as aluminum, copper, or brass alloys. These can usually be welded as-received from the mill or degreased with a common solvent or degreaser. Unless they are very thick, oxide coatings will

Fig. 9 Tensile shear strength of weld spots made at various energy levels showing weld strength increasing as the weld progresses, then leveling off at a strength level that gives a nugget when tensile tested to failure

Fig. 10 Micrograph of 0.9 mm (0.04 in.) 6xxx aluminum sheet metal. At 100 and 200 J, there is very little perturbation at the weld interface. The 400 and 600 J energy levels show increased perturbation at the weld interface.

disperse during the process. Some types of coatings, for example, chemically deposited tin and low-temperature magnet wire coating, can be penetrated during the weld cycle. Heavy coatings of tin and high-temperature magnet coating may need to be mechanically abraded before effective welding is achievable.

Adhesive Bonding. A layer of adhesive placed between the panels to be welded is a technique known as weld bonding. It can be used to provide a watertight joint and also to increase the weld strength beyond that achieved with ultrasonic spot welding or with adhesive bonding alone. A paste adhesive or a fabric-supported adhesive can be used.

Control of Resonance. Complex workpieces or large parts may be induced to vibrate

by the ultrasonic system. This can cause fractures in the workpiece or in previously made welds, resulting in inconsistent weld quality. This effect can be minimized or eliminated by applying pressure in strategic locations on the fixture or by applying pressure circling the weld spot to isolate the section being welded from the vibration produced at the weld spot. Such a device is called a product clamp. The part being welded can also be clamped to a rugged fixture or anvil to dampen the tendency to vibrate. It is best to avoid light materials such as aluminum for fixturing; steel is the preferred material.

Welding Tooling. Preferred material for welding tips is high-quality heat treated tool steel. A precise fit is needed between the tip and the waveguides to ensure efficient transmission of the vibratory energy. The wedge-reed-type system uses a locking (Morse) taper between the tip and the vibrating reed; this provides a long life and an easily replaced and oriented weld tip. The lateral-drive system typically has a one-piece horn and tip that may have several weld surfaces, with rotation of the horn exposing a new surface.

Certain alloys, when welded, tend to stick to the tips. This was an issue with the referenced program (Ref 2) to weld aluminum automobile panels but was largely overcome by selection of tip geometry and welding parameters. As many as 100,000 welds were made with a single tip. The testing was set up to weld multiple spots on multiple strips, using a robot that could work repetitively to give the large numbers of welds required for the test, as shown in Fig. 5.

Welding and anvil tips typically have a cross-hatched or serrated pattern (Fig. 8) to prevent sliding between the tips and the weldment. A typical cross-hatched pattern for welding aluminum is approximately 0.5 mm (0.02 in.) peak to peak and 0.2 mm (0.008 in.) deep.

Fig. 11 Micrograph of 0.9 mm (0.04 in.) 6xxx aluminum sheet metal ultrasonically welded at 800 J, showing perturbation and intermixing at the weld interface. Physical deformation at the weld interface and at the tip and anvil interfaces occurs concurrently. Mechanical mixing occurs at the interface. Some deformation of grains occurs at the interfaces of the tip and anvil with the weldments, and there is no evidence of melting.

Painted welded coupons

Fig. 12 Typical lap shear coupons before tensile shear testing in 6xxx aluminum alloy preprepared for automotive study

Personnel Requirements

Operators of the ultrasonic welding process do not need elaborate or extensive training. Once the process parameters have been determined by a process engineer, the operator is only required to load the parts into a nest of supporting/locating anvil assembly, press the palm buttons or other starting device, and then unload the finished part. In-process monitoring can be performed either electronically by using a microprocessor or visually by the operator, which usually requires the operator to look at a power indication gage. The process engineer must work closely with the equipment manufacturer for guidance regarding tooling design and the selection of process parameters.

No arc, spark, or molten filler material is associated with ultrasonic welding, and no electrical current passes through the weldment. Because the welder is usually configured in a press form with moderately high forces, the normal precautions must be observed to ensure

operator safety, that is, the use of anti-tie-down palm buttons or a similar provision to protect the hands of the operator. Another common consideration involves the high-frequency noise level produced by the ultrasonic vibration. In some instances, especially with the higher-power-level equipment, the noise exceeds the Occupational Safety and Health Administration (OSHA)-approved levels, and sound-deadening barriers or enclosures must be provided, or, at the least, operator hearing protection is required.

Applications

In addition to the spot welding of sheet metals, wire to wire and wire to terminals represent a large market for ultrasonic welders. The ultrasonic welds have good strength and electrical conductivity, there is no burning of the insulation, and no solder or other filler materials are required. Typical samples of stranded, braided, and solid wires, tinned and untinned, are shown in Fig. 18 to 20. A newly developing battery market requires the bonding of multiple layers of foil, and typical test samples are shown in Fig. 21.

Ultrasonic Additive Manufacturing

Karl Graff, Edison Welding Institute

THE ULTRASONIC ADDITIVE MANUFACTURING (UAM) PROCESS consists of building up solid metal objects by ultrasonically welding successive layers of metal tape into a three-dimensional shape, with periodic machining operations to create the detailed features of the resultant object. The process has applications that include prototype metal parts, injection molding dies, composite materials, armor, embedded sensors and actuators, thermal management, and cladding.

Ultrasonic additive manufacturing is part of the broad field of additive manufacturing (AM), which has been defined by ASTM International (Ref 1) as "... the process of joining materials to make objects from 3-D model data, usually layer upon layer." The field of AM originated in 1987 with invention of the polymer-based stereolithography process, followed by selective laser sintering introduced in 1992. In the ensuing years, numerous other processes have been introduced, including metal-based processes that involve laser sintering/melting of various metal powder alloys and electron beam melting of metal powders (Ref 2, 3). The UAM process was introduced by Solidica in 2001 under the identification ultrasonic consolidation, a term that is still in use (Ref 4).

Process Fundamentals

The key features of the UAM process are shown in Fig. 1. Thus, Fig. 1(a) shows a rolling ultrasonic welding system, consisting of an

ultrasonic transducer, a booster, the (welding) horn, and a second "dummy" booster. The vibrations of the transducer are transmitted to the disc-shaped welding horn (which is sometimes also referred to as the sonotrode, a term used in ultrasonic metal welding) rolling in the x -direction, and from there to the tape-metal base, which creates an ultrasonic solid-state weld between the thin metal tape (shown as aluminum in the figure) and a base plate. The continuous rolling of the horn over the tape welds the entire tape to the plate. This is the essential building block of UAM.

By welding a succession of tapes, first side by side and then one on top of the other (but staggered so that seams do not overlap), it becomes possible to build a solid metal part, as shown in Fig. 1(b). Through the course of the build, there will be periodic machining operations, using an integrated computer numerical control (CNC) system, to add features to the part, as suggested by the slot in Fig. 1(b), to remove excess tape material and to true-up the topmost surface of the part. Thus, the process also involves subtractive as well as additive steps. Each of these key features is described further.

Ultrasonic Welding System

The ultrasonic welding system is driven by an ultrasonic transducer, similar in form to those used for ultrasonic metal and plastic welding and of piezoelectric construction operating at 20 kHz. The ultrasonic power capability of the transducer can

vary, depending on design, and has ranged from 1.5 kW to several kilowatts (where, for the latter, special two-transducer systems capable of delivering up to 9 kW have been developed). The entire series of components, transducer-booster-horn-booster, is designed to be acoustically resonant at the transducer operating frequency (of 20 kHz). The acoustic design principles are generally similar to those employed in conventional ultrasonic metal and plastic welding systems, except that the rolling sonotrode requires more complex acoustic analysis.

Not shown in the simplified Fig. 1 is that the welding horn is pressed against the tape and base plate with a static force, necessary to couple the ultrasonic vibrations into the tape. This static force is applied through bearings that are mounted on the boosters and designed and located so as not to dampen the vibrations of the ultrasonic system.

The disc-shaped welding horn is a solid, acoustically tuned shape designed to create a transverse vibration, shown by the arrow at the base of the disc in Fig. 1(a), which produces the weld between the tape and base plate or between the tape and a preceding tape layer. The nature of the transverse vibration and welding action is the same as occurs in conventional ultrasonic metal spot or seam welding. The amplitude of vibration is low, ranging from 20 to 50 μm (790 to 1970 $\mu\text{in.}$), peak to peak. The actual shape details of the welding horn vary for different systems, so the shape shown in Fig. 1(a) should be simply considered as a representative concept.

Ultrasonic Welding during UAM

The core of the UAM process is the formation of a solid-state bond between successive layers of tape under the ultrasonic vibrations of the rolling welding horn. The mechanism of the process is that the welding horn, having a roughened surface (typically achieved by an electrical discharge machining, or EDM, process), grips the top surface of the tape, causing it to move with the vibrations of the horn. This in turn creates a frictionlike action at the interface between the top tape and the lower tape to which it is being joined. The asperities of the

Fig. 1 Ultrasonic additive manufacturing (UAM) process. (a) UAM welding system. (b) Machining operation

opposing interface surfaces are sheared and plastically deformed during this process, disrupting and dispersing oxides and contaminants and permitting pure metal-to-metal contact of the nascent surfaces. Numerous microbonds form between the surfaces, which grow in bond area until all or nearly all of the opposing surfaces are completely bonded by a solid-state weld. This continuous process of rolling and welding results in the bonding of one tape to another tape.

The process just described in terms of UAM is simply that which occurs in ultrasonic metal welding, in particular, the process of ultrasonic seam welding—a solid-state process well known since the 1950s (Ref 5). It is worth emphasizing the solid-state nature of the process, which means that bonding has occurred without melting of the materials being joined.

A final word is in order on the aforementioned frictionlike nature of the process. Ultrasonic additive manufacturing is not a friction process (nor, for that matter, is ultrasonic spot or seam welding). At its initial stages, there is a transverse rubbing motion between opposing surfaces which, although oscillatory in nature, is similar to a frictional motion and thus easily understood as frictionlike. However, as the shearing-deformation process progresses, continuous bonds form across the interface, which grow in extent, leading from a frictionlike early relative motion to ultimate full bonding and fixing of the opposing surfaces.

Materials

The illustration of UAM in Fig. 1 shows the joining of aluminum tape to an aluminum base plate, and aluminum tape-to-tape bonding to form the solid part. In fact, a number of materials have been, or should be capable of being, bonded by UAM. Much of the early work with UAM focused on softer alloys, such as Al 1100, Al 3003, and Cu 1100. These alloys were known to be easily bonded by ultrasonic metal welding and were first choices for UAM. The bonding of a number of more-advanced alloys has been reported, including 316L stainless steel, commercially pure titanium, Ti-6V-4Al, and Al 6061-H18 as examples. The full scope of UAM-bondable materials is not yet known but will be ultimately governed by the basic ultrasonic weldability of various materials and combinations and by the levels of ultrasonic power that can be applied to the process to affect the bond.

The dimensions of the tape being welded are important material parameters. Typical dimensions of Al 3003 tape are 25 mm wide by 0.15 mm thick (approximately 1.0 by 0.006 in.). The width of the tape is governed by the width of the weld face of the horn, which is typically 25 mm. Thicknesses of aluminum and other tapes have ranged from 0.1 to 0.2 mm (0.004 to 0.008 in.). It is not presently known what maximum tape thicknesses will

be possible, but because this will be governed by the amount of tape mass that must be vibrated, it is ultimately expected to be governed by the ultrasonic power of the transducer. In some cases, tape is replaced by a thin sheet of metal foil, and bonding of the sheet is achieved by repeated, side-by-side passes of the welding horn.

As shown in Fig. 1(a), the first tape is welded directly to a base plate that is attached to a heavy anvil plate. The base plate is typically of the same alloy as the tapes being applied, because a sound bond of the first tape is essential to the subsequent layers. In some cases, a variation of alloy between base plate and tape is possible. Thus, Ti-6V-4Al may be bonded onto a commercially pure titanium plate, Al 1100 may be bonded to Al 3003, or Cu 1100 may be bonded onto an Al 3003 plate. The thickness of the plate may range from 1.5 to 12 mm (0.06 to 0.5 in.).

Welding Parameters

The key ultrasonic welding parameters are vibration amplitude, static force, and travel speed; in this sense, they are the same as those for the ultrasonic seam welding process. The vibration amplitude refers to that at the outer diameter of the horn at the tape surface. The amplitude can be set at different levels (i.e., micrometers peak to peak), with the range depending on the system design. A well-designed ultrasonic control system will then maintain the set amplitude throughout the welding process. Likewise, the role of the downward static force in ensuring good coupling and vibration transmission into the tape and base plate has been noted. Force levels again will depend on the overall UAM system design and the particular materials being welded and can range from 300 to 400 N (67 to 90 lbf) in low-power systems up to 20 kN (5 kips) for high-power UAM systems. The travel speed refers to the linear speed of the welding horn across the part and can range from 75 to 1000 cm/min (30 to 390 in./min), depending on system power and materials being welded.

While amplitude, force, and travel speed would be the standard welding parameters, with settings easily changed from trial to trial, the texture and material of the welding horn should also be considered a variable of the process and hence a settable parameter. Thus, the aggressiveness of the EDM-produced texture may be varied, depending on the hardness and thickness of the tape material. In welding 0.15 mm (0.006 in.) Al 3003, it is found that a titanium horn having a texture of 7 μm R_a will be satisfactory. Welding thin tapes may require a texture of 2 μm R_a . In cases involving extremely hard materials, or where tape thicknesses exceed the commonly used 0.15 mm, more aggressive textures, such as 14 or 21 μm R_a , may be required.

The material of the horn may also vary, depending on tape material. While titanium may suffice for bonding a soft aluminum alloy, the use of tool steels, such as AISI grade 18Ni, is needed in bonding titanium and stainless steel tapes.

A final adjustable welding parameter is that of preheat of the anvil and base plate. Also not shown in the simplified drawing of Fig. 1 is a rigid, heated platen that underlies the steel anvil plate. The purpose of the platen is to preheat the base plate to a given temperature level, for the purpose of assisting the welding under the ultrasonic vibrations. As previously noted, ultrasonic welding depends on achieving shearing and plastic deformation of asperities at the tape-tape interface. Preheating can modify the yield strength of materials and hence their deformability under ultrasonic vibrations. This effect is especially noticeable in the softer aluminum alloys. Hence, UAM systems have provisions for applying preheats that range from 21 to 260 °C (70 to 500 °F).

Process Consumables

Based on the preceding description of the UAM process, it should be evident that there are four primary consumables associated with its application:

- **Metal tape:** This is the primary process consumable, with the amount of tape, in terms of weight, being roughly proportional to the volume of the part being constructed. Allowance must be made, in such calculations, for the excess tape at the start and end of a tape layer due to the mechanized tape feeding and cutting hardware. This tape is always trimmed away in the machining operations and is thus excess. For some UAM systems, this may be on the order of 7.5 cm (3 in.) at each end, while other system designs have reduced this excess to 5.0 cm (2 in.) at each end. For a small part, for example, 50 cm³ (3.2 in.³), excess could approximate the net part volume. Increasingly large parts naturally result in a decreased percentage of excess material.
- **Obtaining metal tapes in the desired materials at the desired thicknesses and widths should be allowed for in any design process.** In some cases, this requires diligence in locating suppliers able to deliver at reasonable prices and schedules.
- **Base plate:** The base plate, on which the UAM build is made, is typically of the same alloy as the metal tapes being welded to it (note has been made that similar, but not identical, alloys may be used). The plate is subsequently machined away from the build and thus becomes a process consumable. The surface and thickness dimensions of the base plate play an obvious role in the resulting plate costs. The former will be related to the lateral dimensions of the part

being built and thus will directly depend on part design.

Plate thickness may also be a variable, with the practice here varying among various users of the process. In the interest of cost, some users adopt base plate thickness on the order of 4.7 mm ($\frac{3}{16}$ in.) and use a vacuum system to clamp the base plate to the anvil plate. Others prefer a thick plate, typically 12 to 13 mm (0.5 in.), bolted to the anvil plate. The view on this latter approach is that an absolutely solid base is needed on which to weld the many successive layers of material.

- *Ultrasonic tooling*: The welding horn must be considered a consumable. The continued welding of tapes will wear the textured surface of the horn, requiring resurfacing and EDM retexturing, and is thus one of periodic maintenance. After several such retextures, the outer diameter will have been sufficiently reduced such that the horn and

overall UAM system resonance is taken out of the control range of the ultrasonic power supply system. At this point, a replacement of the horn is necessary.

- *Machine tools*: Integral to the additive steps of UAM are the material-removal steps, by way of conventional machining processes, necessary to arrive at final part features. This means there must be allowance for maintenance and replacement of the various end mills used in the removal steps, with considerations being no different than those associated with conventional machining of solid materials and shapes.

Applications

The ability of UAM to build solid metal parts is a key capability of the process. Applications of the process, ranging from demonstrated and tested, to proof of concept, to simply envisioned,

are extensive, cutting across many industrial sectors, and include rapid prototyping, molding and stamping dies, production of composite and smart materials and structures, lightweight armor, thermal management systems, and cladding, as examples. These fields of application can be broken down into the following broad functional areas:

- Solid metal parts and materials
- Embedded channels
- Embedded materials
- Dissimilar materials

Some examples of UAM-fabricated parts are shown in Fig. 2. Thus, Fig. 2(a) is the mold (or cavity) component of an injection molding die, made from Al 3003 and approximately 100 by 150 by 20 mm (4 by 6 by 1 in.); the associated plastic part is also shown. Figures 2(b) and (c) show another unique UAM capability, that of creating embedded channels. As a part build

Courtesy of Solidica Inc.

progresses, open channels can be machined at one stage and then covered by the next welding stage(s). Thus, the apparently solid aluminum block, 100 by 100 by 13 mm (4 by 4 by 0.5 in.), in Fig. 2(b) is shown by x-ray in Fig. 2(c) to consist of a complex, multilevel, interconnected network of channels. Channel sizes can range from 2 mm (0.08 in.) down to 10 to 20 μm (390 to 790 $\mu\text{in.}$).

Yet another UAM capability is that of embedding materials within a metal matrix. This can take the form of tapes, wires, meshes, or fibers, as shown by the two examples in Fig. 2(d) and (e). The approach is to build the part to a desired height, lay down individual or multiple wires or tapes, and then weld the next tape layer, which covers and embeds the underlying wires/tapes. The UAM welding vibrations essentially soften and plasticize the tape material, causing it to flow about and firmly embed any underlying wires or fibers. Thus, Fig. 2(d) shows an embedded NiTi wire, while Fig. 2(e) shows embedded nickel tapes.

The ability of ultrasonic metal welding to bond dissimilar materials is well known (Ref 6), so it is not surprising that various material combinations are possible with UAM, an example of which is shown in Fig. 2(f), where a titanium-aluminum laminate has been formed by successively bonding aluminum and titanium sheets with a subsequent hot pressing operation.

As noted, numerous applications of UAM have been put forth in addition to those mentioned. These include rapid prototypes (e.g., models), direct part manufacture, repair (e.g., helicopter blades), casting (positives), injection mold die cooling blocks, computer system and solar panel heat sinks, microchannel reactors, metal-matrix composites, sensors and actuators based on embedded smart materials, cladding, and transition joints. It is expected that many of these applications will move up the manufacturing-readiness-level chain as higher-power UAM systems come on line that are capable of dealing with an increasing range of materials.

Equipment and Procedures

Two types of UAM systems for fabrication of parts are shown in Fig. 3. The system in Fig. 3(a) features a moving UAM gantry with a stationary base plate and integrated tape laying, tape cutting, and CNC machining. Because of the fixed base plate, this type of system has been found to be very suitable for research and development operations due to its flexibility. The Formation system in Fig. 3(b) features a fixed UAM and tape-laying module integrated into a CNC machining center, with a moving base plate. This type of system has been found to be very suitable for high-precision fabrication.

Hybrid software, known as RPCam, is used to control both the ultrasonic additive manufacturing process as well as the

CNC material-removal stage. Thus, the software instructs the machine on both depositing and removing material.

The steps in producing a part by the UAM process are shown in Fig. 4 and consist of the following, numbered in accordance with the figure:

1. The UAM process begins by generating a computer-aided design (CAD) model of the desired part in its final design format.

2. An initial graphics exchange specification (IGES) translation of the finalized CAD model is imported into RPCam.
3. Through a series of user interface features, RPCam evaluates the model to determine the most effective tape layouts, making adjustments to account for the number of tape layers and tape joints relative to edges and features (e.g., cutouts).
4. Adjustments to individual tape placement are then made to account for voids or

Fig. 3 Ultrasonic additive manufacturing (UAM) systems. (a) Solidica UAM Beta system. (b) Solidica, Formation system. Courtesy of Solidica Inc.

- cavities that are designed into the part. The graphical interface allows the operator to shift the tape placement or weld position based on force.
5. Welding conditions, tape dimensions, and machining operations are imported into RPCam.
 6. RPCam and computer-aided manufacturing software (e.g., PowerMILL) interact to split the imported model into individual layers for creating the final welding and machining code.
 7. The finalized tool paths for welding and machining are then converted into G- and M-code commands that are imported into the main system controller for manufacturing of the part.
 8. Manufacturing of the part takes place.
 9. The final part is on the base plate, which is machined away, leaving the completed part.

In practice, the base plate of the material of the part to be fabricated is bolted to the anvil plate, and a “flat pass” milling operation serves to provide a true starting surface for tape layers. A single tape will then be fed under the weld horn and welded to the base plate, with some excess tape at either end of the weld necessary to allow for tape feed and cutting operations. The welding of the tape may comprise one to three steps, depending on the welding system and materials being used. Thus, a first “tack” pass may be used, under light welding parameters, to secure the tape in place. This will be followed by a welding pass, at full weld parameters, to completely weld the tape in place. In most cases, a tack pass incorporates a spot welding operation at the beginning and end to increase tape placement accuracy.

This process will be repeated as tapes are laid side by side across the base plate. Typically, the tapes are slightly overlapped (0.125 mm, or 0.005 in.) to ensure no gaps are present at the joints. The process is repeated for subsequent layers, making sure the joints between layers are staggered, in the manner of laying up bricks of a wall.

Every five to ten layers, a milling operation will be performed that trims off excess tape around the contour of the part, incorporates the desired features in the part, and again trues the top surface to flat for later tape welds.

This sequence of steps is repeated until the final part has been built on the base plate. The plate-part unit is then removed and the base plate machined away, leaving the desired fabricated part.

The sample part shown in CAD and final form in Fig. 4 also brings out the capability of UAM to achieve deep, narrow grooves and extremely sharp, deep corners—features that are challenging to conventional machining processes and often require recourse to supplemental EDM steps.

High-Power UAM Development. The UAM systems operating at 1.5 to 3.0 kW encounter some issues in seeking to bond

advanced materials, such as titanium alloys, stainless steels, some copper alloys, advanced aluminums, and nickel-base alloys. To a significant extent, these issues are related to the need for greater ultrasonic power in the bonding process. As noted in the description of UAM, making the ultrasonic bond depends on being able to shear and plastically deform opposing asperities. With increasing alloy strengths, greater interface shearing forces are required to bring about the necessary interface deformations, which directly require increased ultrasonic power. Likewise, the mass associated with increased tape thicknesses and/or widths requires increased ultrasonic power to be able to drive it in ultrasonic vibrations.

Developments are in progress for achieving greater ultrasonic power for UAM systems (Ref 7). These involve using two ultrasonic transducers, each of 4.5 kW or higher power, driving the ends of the welding horn in a push-pull arrangement that essentially adds the power of the individual units to the process. The ability of these power levels to bond stainless steel, titanium, and higher-strength aluminum alloys has been demonstrated.

Material Properties in UAM

The fundamental feature of UAM is the production of solid metal parts by way of ultrasonically welding together a succession of thin metal tapes or sheets. The metallurgical and mechanical properties of such parts must be determined to assess the range of materials and applications for which the process is suited. This is an active field of inquiry as new material systems are being investigated and modified and new UAM systems are being introduced.

Metallurgical Aspects of UAM Bonding

Metallurgical analysis of the interface between successive layers of tapes is critical to evaluating the nature and extent of UAM bonding, which, in turn, will relate to the mechanical properties of the parts.

By way of example, a metallurgical cross section of a build fabricated from 0.15 mm (0.006 in.) tape and taken from an interior cross section of a simple block build is shown in Fig. 5(b). The demarcation between the individual layers is evident, with some voids of unbonded regions along layer interfaces. To a significant extent, these voids are a result of the texturing on the surface of the weld horn. Thus, as the horn engages the top surface of a tape in making the ultrasonic weld, the horn texture is impressed on the tape surface. When the next layer of tape is laid down, the smooth bottom surface of the new tape is pressed against the textured top surface of the previous tape, resulting in voids at the interface (Ref 9). The welding action will smooth some of the

texture and plastically flow material into some of the void volume. Nevertheless, depending on the material being welded, the horn texture, and the power of the ultrasonic system, some voids may remain.

Metallurgical analysis of the underlying macro- and microstructures at the interface between successive layers of tapes is critical to evaluating the nature and extent of UAM bonding, which, in turn, will relate to the mechanical properties of the parts (Ref 10–16). Mechanical properties have also been related to the quality of bond at the interface between layers (Ref 8, 14). Optical microscopy is used to characterize the degree of bonding. Analysis of images taken with an optical microscope can provide a quantitative measure of the length of bonded regions. This measurement is often referred to as linear weld density (LWD) percentage (ratio of bonded region to length of interface). Certain literature quotes the same measurements in terms of linear void density (LVD), which is represented by $100\% - \text{LWD}$. An example LWD result (Ref 8) is shown in Fig. 5(a).

Thus, the LVD appears to vary across the height of the build (8.5 to 65.8 %). The corresponding optical microscopy image is shown in Fig. 5(b). By repeating this analysis over a large number of builds, it is possible to quantify the quality of the bonds made by the UAM process. Many authors have shown a direct correlation between peel strength of the bonds to the magnitude of LWD (Ref 10–16). In published literature, optimization of UAM process parameters has been driven by the desire to obtain higher LWD across the entire build volume. However, measures of LWD/LVD do not yield any of the critical microstructure information necessary to understand the fundamental bonding mechanisms.

Using a variety of characterization techniques, a number of researchers have accumulated extensive microstructure information at the bond interface (Ref 17–20). The work noted here covers the use of scanning electron microscopy and focused ion beam imaging, first reported by Johnson (Ref 17), and, more recently, the use of electron backscattered diffraction imaging and transmission electron microscopy to investigate the UAM bonding mechanism (Ref 18–20).

Some typical images from multiscale characterization of Al 3003 alloy UAM builds are now considered (Ref 19). The electron microscopy images from bottom, middle, and top of a typical build are shown in Fig. 6(a) to (c). The images from the bottom (Fig. 6a) and middle (Fig. 6b) regions did not show a sharp interface between adjoining tapes, which indicated that a metallurgical solid-state bond had been created. The grains at the interface zone were equiaxed in nature and quite different from that of elongated grains of the original Al 3003-H18 tapes. This indicates that the bond formation is associated with recrystallization. In addition to

Fig. 5 (a) Plot of linear void density (LVD) versus five interfaces and (b) the corresponding optical image of interface number 5. The LVD point for each interface was taken at the high point, as shown in (a). Note: Linear void density is the inverse of linear weld density. Source: Ref 8

the equiaxed grains, fine Al-Mn-Fe-base intermetallics were observed in the samples along the grain boundaries and within the matrix grains. However, these intermetallics were present in the original Al 3003-H18 tapes and were not a consequence of the UAM process.

The interface microstructure from the top region (Fig. 6c) had certain unique features. The original interface location is identified from the sudden change in the grain structure. The microstructure in the $(n + 1)^{\text{th}}$ tape shows the original pancake structure, which transitions sharply to a coarse, recrystallized grain structure close to the original interface location. The microstructure from the n^{th} layer does not show any pancake structure but rather a more recrystallized structure. A survey of many samples from different regions also showed that the interface regions contained fine recrystallized grains (500 nm, or 20 $\mu\text{in.}$) with relatively low dislocation density and coarse grains (500 nm to 2 μm , or 20 to 80 $\mu\text{in.}$) with relatively high dislocation density, as shown by dark-field microscopy. The original foil, before consolidation, showed pancakelike grains, as expected, from as-rolled material. Dislocations were present, although at a much lower concentration than in the grains along interfaces after UAM processing.

In addition to the bonded region, transmission electron microscopy has been performed at the void regions. Oxide layers are found along the surface of the voids. These layers transition from nearly linear and continuous to

discontinuous and disbursed toward the welded region. It would be expected that intimate contact between the two aluminum regions would yield a stronger bond and increased mechanical strength compared to the region with a continuous oxide scale present.

Based on the aforementioned observations, microstructure evolution at the interface is considered to be the product of recrystallization, which is similar to that of hot working. This hypothesis is in agreement with microstructural observations from copper builds made with very high-power UAM samples (Ref 21).

Mechanical Properties of UAM Builds

The mechanical properties of UAM-fabricated parts and materials govern the range of applications for which the process may be used. A number of mechanical tests have been used to evaluate UAM bonding, including tensile testing, peel tests (Ref 10, 11, 13, 15), lap shear tests (Ref 10), push-pin tests (Ref 22), bulge tests (Ref 23), bend tests (Ref 24, 25), and microhardness and nanohardness tests (Ref 11, 26, 27). In parts with embedded fibers, fiber push-out testing to characterize bonding between the fiber and the matrix has also been reported (Ref 12). Fatigue tests are being developed for small specimen sizes involved in some UAM builds. Given the anisotropic nature of UAM-fabricated materials, in some cases, separate tests may be required for the various axes.

Referring to Fig. 1, it can be seen that anisotropy can arise from the direction of tape lay and welding. The rolling welding horn and the tape are oriented in the x -direction (the y -direction is at right angles to the x -direction in the plane of the plate, while z is perpendicular to the plane), so that the mechanical properties of a plate-type build will vary between the x - y in-plane and z -direction out-of-plane (or transverse) relative to the build plate. By fashioning appropriately dimensioned ASTM-type dog-bone samples, the mechanical properties of a build can be determined.

Thus, using the dog-bone specimen shown in Fig. 7 (middle), testing the transverse tensile strength of Al 3003 UAM builds generally reveals a behavior similar to that of a brittle material, as shown in Fig. 8(a). The specimens exhibit a linear force-displacement relationship prior to a sudden rupture while still within the elastic region (Ref 8). The ultimate tensile strength of transverse tensile specimens has been found to be approximately 15% of the solid parent material (Ref 8). However, scanning electron microscopy revealed that the fracture surfaces show ductile failure with microvoid coalescence. The absence of an appreciable macrolevel ductility in the load-displacement curves is attributable to the voids (or unbonded regions). These observations suggest that UAM does not reduce the inherent ductility of the material (Ref 8).

A lap shear specimen (Fig. 7, left) was used in testing the shear strength of UAM builds. A linear force-displacement relationship was

Fig. 6 Transmission electron microscopy (TEM) images. (a) Bright-field TEM image taken from an interface location with apparent good bonding. The interface cannot be determined easily, indicating potential recrystallization across the interface. Small, white Al-Mn-Fe intermetallics can be seen. (b) Another interface location again showing the difficulty in discerning the bond line. (c) A third interface location where the bond line can be determined, as pointed out by two opposing arrows. A third arrow points to a small void that appears to have migrated from the interface into the bulk of the material. Source: Ref 19

observed before sudden failure of the build along a tape interface, as shown in Fig. 8(b), similar to the behavior of the transverse tensile specimens (Ref 8). Ultimate shear strength of UAM builds was found to be approximately 50% of that of the solid parent material (Ref 8). Here again, a ductile failure mode was observed under the scanning electron microscope (Ref 8).

Longitudinal builds (Fig. 7, right) were then tested. As shown in Fig. 8(c), longitudinal test specimens behave as ductile materials during tensile tests. First, an initially linear elastic

Fig. 7 Ultrasonic additive manufacturing (UAM) mechanical test specimens for shear (left), transverse tensile (middle), and longitudinal tensile (right) testing. Courtesy of The Ohio State University

region is observed, followed by a wide region of plastic deformation. Overall behavior of the longitudinal tensile specimens is similar to the solid parent material. However, the ultimate tensile strength is approximately 20% greater than the parent material, indicating that the foils are strengthened in the longitudinal direction during the UAM process.

It is noted that the aforementioned results were obtained from UAM builds fabricated using the same set of process parameters to bond Al 3003 tapes. By varying the process parameters, the strengths of the build could likely change. Further, the strengths could be different for other tape material.

Peel Testing. This is a method to evaluate how well a layer has bonded to another during UAM. The flap (or peel arm) of the tape extending outside of the weld is used to facilitate peeling of any given layer. A typical peel-testing apparatus (floating roller) (Ref 11, 28) is shown in Fig. 9(a), where the peel arm is loaded under tension to obtain a force-displacement curve, shown in Fig. 9(b). The maximum force encountered during peeling (highest resistance) provides a measure of the bond strength (Ref 11). Sometimes, the energy criterion (area under the force-displacement curve) is also used to characterize the degree of bonding (Ref 29). Depending on the strength of the bond, the force-displacement curves and fracture modes could be different (Ref 10, 13). The maximum peel force is then typically plotted as a function of vibration amplitude, normal force, and sonotrode travel speed to identify the effect of each of these parameters (Ref 10, 11).

In Al 3003 alloy UAM build, a 75% increase in amplitude, for instance, is reported to increase the peel force by approximately 25% (Ref 10). The peel test is also used in conjunction with LWD measurements to characterize bonding (Ref 9).

Peel tests provide a quick way of getting to the process window for UAM of a given material (Ref 9, 11, 13, 15). The test is fast, inexpensive, and requires very little sample preparation. Usually, a build consisting of two to three layers is adequate, compared to approximately 80 layers required for tensile testing. However, peel testing suffers from the disadvantage that it is primarily suited for determining the bonding strength of an adhesive (where peeling actually occurs) rather than the strength of welded joints. In the case of the latter, the tendency is more toward fracture (at the weakest region) than peeling, once good bonding has been achieved. Therefore, in well-bonded interfaces, failure can typically occur outside of the weld region, particularly at the transition between the weld and the peel arm, which is a region of stress concentration. Although such a fracture would signify a high degree of bonding, it may not be easy to quantify. Consequently, all well-bonded conditions may end up showing the same bond strength. Furthermore, the tests can only be comparative in nature, because correlating peel strength (peel force per unit width) to the more standard material strength parameters such as yield/tensile strength may also be difficult. The test can still serve as a rapid qualitative method to discriminate between poor and good bonding. Climbing drum peel test (Ref 30), T-peel test (Ref 31), and fixed-arm peel test (Ref 32) are other variants to the test.

Push-Pin Testing. This test, developed by Zhang, Deceuster, and Li (Ref 22), involves testing a UAM build under a compressive load applied normal to the layers (in the transverse direction). This is based on the premise that the overall strength of a laminated structure depends on the bond strength between individual layers (Ref 22). If the bonding between layers is poor, it can manifest as tensile loading between layers, pulling them apart and causing delamination (Ref 22). Alternatively, with good bonding, the layers may resist delamination and deform collectively until fracture. The test method is shown in Fig. 10(a) and can be performed on the Gleeble (Ref 22). The compressive force on the build layers is applied by means of a push rod that goes through the base plate and the build (Ref 22). The typical force-displacement curve obtained is shown in Fig. 10(b). As with peel testing, the maximum force or the deformation energy is considered to be a measure of the bond quality. Examination of fracture surfaces could also result in a correlation between the area of the bonded regions and LWD (Ref 22). However, unlike in peel or lap shear testing, a comparison of good versus better bonding could be very possible here. The force/energy values can be

Fig. 8 Ultrasonic additive manufacturing mechanical testing force versus displacement plots for (a) transverse tensile, (b) shear, and (c) longitudinal tensile tests. Courtesy of The Ohio State University

correlated with the process parameters to identify the best processing conditions for a given material. Vibration amplitude has been reported (Ref 22) to have the maximum influence on bond strength. In Al 3003 alloy UAM build, the deformation force was observed to be nearly doubled with a 20% increase in amplitude, indicating much better bonding at higher amplitudes (Ref 22). When similar testing of a solid block of the same material is done, it may be possible to estimate the strength of the part built by UAM relative to a solid block.

Push-pin testing could represent the bulk transverse tensile strength of the build, but with much fewer layers than a regular tensile test. Thus, it is simpler, faster, and cost-effective, allowing for a large number of tests to be performed over a wide processing range. However, the deformation and fracture behavior could

depend on the geometry of the sample. Consequently, for a thicker sample (with a greater number of layers being tested), delamination may occur even in well-bonded structures.

Microhardness/Nanohardness Testing. These tests are done on UAM builds to observe any strain hardening or softening of the original tape material, both at the interfacial region as well as away from it. Depending on the material condition and processing, there could be hardening or softening at the interface (Ref 8, 11, 21). While an increase in microhardness of up to 12% has been reported in aluminum alloys (Ref 8, 11), a 23% decrease in microhardness was observed in copper (Ref 21). A linear correlation between interfacial hardness and bond strength has also been reported (Ref 27). Nanohardness testing close to the SiC fiber embedded in an Al 3003 alloy UAM

build is reported (Ref 27) to show a 46% increase in hardness in comparison to the starting foil.

Impact of High Power on Properties

Preliminary studies in applying higher levels of ultrasonic power have shown excellent promise as the basis for increasing the range of materials and applications for the UAM process. Using a very high-power “test bed” system (the bed had full ultrasonic UAM welding capabilities but did not have CNC machining or automatic tape feed), welds were made in several advanced materials, with results as shown in Fig. 11.

At higher levels of ultrasonic power, which also involve higher tool vibration amplitudes and static forces, it is found that interface voids,

or any other readily apparent indications of lack of interface bond, are nearly absent, as seen in the examples in Fig. 11.

For example, bonding of Cu 1100 in Fig. 11 (a) shows 12 layers of 1.5 mm (0.06 in.) copper. Bond line interfaces are only faintly discernable at the given level of magnification; thus, the two parallel arrows locate one set of interfaces. (The lower-level shading discontinuity is an artifact of combining two photographic images.) Bonding in Al 6061 is shown in Fig. 11(b). The faint white horizontal lines locate the bond interfaces. While some voids can still be seen, there is a dramatic reduction in their number when compared to earlier results for Al 3003 (Fig. 5). Bonding of 1.0 mm (0.04 in.) thick titanium CP-4 tapes is shown in Fig. 11(c).

Quality Control

The objective, of course, is to produce a UAM-fabricated part or material having the desired level of quality as specified by the end-user service requirements. While these will obviously vary, the quality of the bond between tape layers would be expected to be common to most.

Assuming that a very high-power UAM set of RPCam-based weld process parameters have been developed for fabricating a given part or material, and that these have been validated by metallurgical and mechanical tests such as were described in the previous section, thus arriving at an acceptable quality level for the part/material, then considerations shift to maintaining quality levels while making large numbers of parts or carrying out continuous fabrication of materials.

The following are among those issues to be addressed in arriving at and maintaining UAM fabrication quality:

- *Design*: It is hardly unique to UAM to note that original design of the part will play a key role in its ultimate quality. Much of this will have to do with developing the RPCam program and assuring that the tape layouts are appropriate for the layout of edges, joints, and machined features.
- *System calibrations*: A variety of load cells, motion sensors, and ultrasonic units are integrated into a UAM system. Assuring that calibrations are kept current is critical. This likewise applies to the CNC machining equipment, for which there are several consensus American Society of Mechanical Engineers and International Organization for Standardization specifications.
- *Input materials*: For tapes, maintaining consistent chemistries, heat treat, dimensions, surface texture, and cleanliness specifications is a requirement. For the base plate, maintaining chemistries and heat treats is required. (Because the plate is typically machined to final size, incoming dimensions, texture, and cleanliness are less critical.)
- *Process monitoring*: Monitoring the running conditions of the system (forces, speeds, ultrasonic parameters, tape feeds) is recommended to maintain process consistency. In-process nondestructive evaluation (NDE) methods (e.g., infrared thermography) are not yet available on present UAM systems.
- *Postinspection*: In addition to visual inspections, NDE methods (e.g., ultrasonic inspection) may be used to verify bonding.
- *Tool texture*: In addition to simple visual inspection for evident wear, periodic surface roughness measurements should be made to determine if retexturing or replacement is required. The current practice for evaluating such textures is to conduct a three-dimensional surface microtexture measurement, a noncontact process based on white-light interferometry. Due to the graphical nature of this process, data recorded of the sonotrode in the as-cut condition can then be easily compared to that of a sonotrode having extended service.
- *Other maintenance*: Because it is basically a complex machine tool system, all maintenance procedures appropriate for such systems should be consistently followed.

Safety

The UAM system is basically a computer-controlled, robotic machine tool and must be treated with all of the cautions and safety considerations typically accorded such systems. This includes assuring that appropriate system safety interlocks are in place and fully operational. Allowance must also be made for the heated base plates present on some UAM systems.

Introduction to Integrated Weld Modeling*

Sudarsanam Suresh Babu, The Ohio State University

THE SCOPE of this article is to provide an overview of integrated weld modeling. It is not intended to provide a comprehensive review of integrated weld modeling activities in the literature but introduces methodology and relevant resources that can be accessed by the reader for further development, evaluation, and deployment.

Integrated weld modeling is an important activity that crosscuts many industries. In early 2000, the American Welding Society, Department of Energy, Edison Welding Institute, and industrial members from the heavy industry, aerospace, petroleum/energy, and automotive industries developed a research roadmap for the welding industry (Ref 1). The strategic goals for the welding industry by 2020 were identified to be the following:

- Increase the uses of welding by 25%, decrease the cost, and increase the productivity
- Enhance the process technology that allows for the use of welding across all manufacturing sectors
- Develop new welding technology along with new materials so that it can be used for all applications
- Assure that welding can be part of the six-sigma quality environment
- Increase the knowledge base of people employed at all levels of the welding industry
- Reduce energy use by 50% through productivity improvements

Although welding itself does not consume extensive energy, welding does play a critical role in the development and deployment of the materials for energy exploration, transfer, conversion, efficiency, and storage. The roadmap also identified that the engineering solutions for joining materials are not unique and do differ depending on the geometry, materials, and

applications. Due to this complexity of the problem, the development of joining technology for a given material is associated with extensive experimental trial-and-error optimization. To minimize this experimental approach, an integrated computational modeling was suggested as a solution (Fig. 1).

This leads to a fundamental question: Is it possible to develop physics-based computational models to describe the behavior of existing and

emerging materials subjected to joining processes? A review of the literature shows that the development of physics-based models is indeed challenging due to the complex interaction between physical processes during welding. Some of these physical processes include heat and mass transfer, phase transformations, electromagnetic phenomena, plastic strain, and reactions with the environment during welding/joining. Researchers, including Ashby (Ref 2),

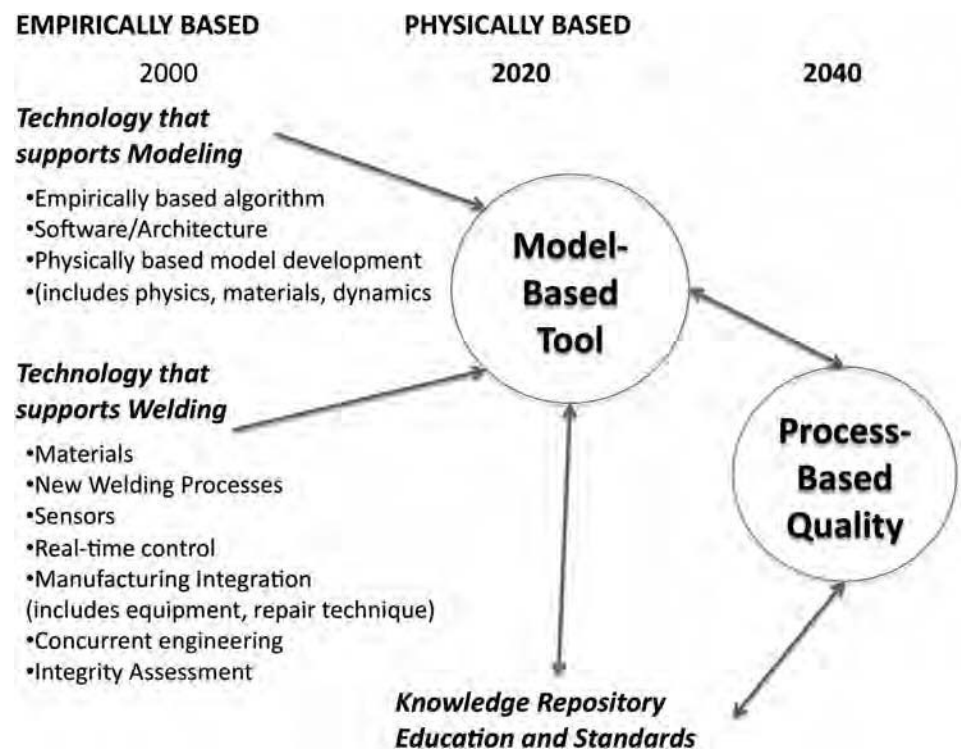

Fig. 1 Suggested roadmap for the development of a model-based tool in the year 2020 as a way of ensuring process-based quality by the year 2040

Bhadeshia (Ref 3), Cerjak (Ref 4), David (Ref 5), DebRoy (Ref 6), Eagar (Ref 7), Easterling (Ref 8), Goldak (Ref 9), Grong (Ref 10), Kirkaldy (Ref 11), Koseki (Ref 12), Kou (Ref 13), Leblond (Ref 14), Matsuda (Ref 15), Rappaz (Ref 16), Szekely (Ref 17), Vitek (Ref 18), Yurioka (Ref 19), and Zacharia (Ref 20), developed a framework for linking thermo-mechanical histories to microstructure development and mechanical heterogeneity in welds. These developments can be summarized in the form of a schematic diagram (Ref 11) published by Kirkaldy (Fig. 2). According to this diagram, by integrating individual sub-models for heat, mechanical, and material models, one can predict the overall performance

of welded structures. The approach starts with a heat-transfer model that will simulate temperature distributions in three dimensions [$T = f(x, y, z, \text{time})$] as a function of process parameters and time. Thermal cycle data will be used by material models to predict the microstructure evolution and its impact on transient mechanical (σ - ϵ relations) properties. The transient changes in temperature and mechanical properties will be fed into a finite-element structural model to predict plastic strain distribution. This information allows for the prediction of final properties, residual stress, and distortion in a complex welded geometry. This interdisciplinary approach may appear simple; however, it

requires collaboration between experts in metallurgy, finite-element analysis, welding process, and computer science (Ref 21, 22). To a limited extent, this vision has become a reality by pioneering work in many organizations and commercial software companies (Ref 23–27).

It is noteworthy that the scope of this article is not to provide a comprehensive review of integrated weld modeling activities in the literature. It is designed to provide an overview of the methodology and relevant resources that can be accessed by the reader for further development, evaluation, and deployment. The reader is also referred to other articles within this Volume that describe modeling of inertia welding, diffusion bonding, and the additive manufacturing process. The reader is also referred to some of the series of conference proceedings titled *Mathematical Modeling of Weld Phenomena* (Ref 4, 28–34) as well as *Trends in Welding Research* conference proceedings published periodically by ASM International (Ref 35, 36). These conference proceedings provide a detailed progression of integrated weld modeling and its capability for a wide range of joining processes. In addition, the reader is also referred to three classic text-books related to modeling of welding processes (Ref 37–39). This article discusses some of the salient features of each subprocess model that is indicated as part of the integrated weld modeling shown in Fig. 2. Most of the materials presented in this review have been adopted from Ref 40.

Fig. 2 Overview of integrated welding modeling methodology proposed by Kirkaldy (Ref 11) shows the importance of predicting transformation behavior and microstructural development as well as thermal and mechanical behavior

Process Modeling

The goal of process modeling is to predict weld pool shape, thermal cycles, and fluid flow conditions under transient (coordinate system fixed to the part) or steady-state (coordinate system moving with the welding heat source) conditions. This section discusses the fundamentals of the underlying physics and the methodologies to solve the same.

Underlying Physics and Methodologies

Modeling of Heat Transfer during Welding. Heat transfer in welding can be represented by equations of heat conduction in solids. For example, the spatial variation of the heating or cooling rate in a Cartesian coordinate can be related to the second derivative of the temperature gradients in x -, y -, and z -directions (Ref 39):

$$\frac{\partial T}{\partial t} = \frac{\lambda}{\rho c} \left[\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} \right] = a \left[\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} \right] \tag{Eq 1}$$

where T is temperature, t is time, λ is thermal conductivity, ρ is density, c is specific heat capacity, and a is the thermal diffusivity of the material being welded. With boundary

conditions imposed by the welding. Eq 1 can be solved for both transient and steady-state conditions of welding. A famous solution of the generic equation for steady-state distribution of temperature in a plate during arc welding was given by Rosenthal (Ref 41) as:

$$T\{x, R\} = T_0 + \frac{\eta VI}{2\pi\lambda} \left(\frac{1}{R}\right) \exp\left\{-\frac{v}{2a}(R+x)\right\}; R = \sqrt{x^2 + y^2 + z^2} \quad (\text{Eq 2})$$

where $T\{x, R\}$ is the temperature as a function of the radial distance (R) and distance (x) along the welding centerline, T_0 is the preheat or interpass temperature, V is the arc voltage, I is the welding current, v is the welding speed, a is the thermal diffusivity, and η is the arc efficiency. This solution is often referred as the Rosenthal equation and has been extensively used for obtaining approximate temperature isotherms during welding of plate as a function of process parameters. For example, Eq 2 was used to calculate the steady-state temperature distributions on a steel plate surface for two different welding speeds. The calculations (Fig. 3) show the formation of a teardrop-shaped weld pool with an increase in welding speed. The aforementioned distribution also can be used to calculate the heating and cooling rate. Equation 2 assumes a point heat source, which is not strictly applicable to arc welding heat sources. Modification of the previous equations for distributed heat sources has been attempted by many researchers. A review of the same can be seen in the book by Grong (Ref 39). In addition, this book also provides analytical solutions for other steady-state and transient welding cases.

Although analytical solutions provide a faster estimation, these solutions often ignore boundary conditions imposed by the geometries of a realistic welded structure. To address this limitation, finite-difference and finite-element formulations (Ref 42) have been developed. These formulations allow for both steady-state

and transient solutions (Ref 37). However, one of the biggest challenges in these formulations is to describe the heat flux into the weld pool. The extent and the distributions of heat flux determine the shape of the weld pool, peak temperature, and heating and cooling rates (Ref 43, 44). This challenge has been elegantly addressed by researchers from Goldak's group to distribute the power density within front and rear quadrants of the weld area. This methodology is schematically explained in Fig. 4. The power density distribution in the front quadrant is given by Eq 3:

$$q\{x, y, z, t\} = \frac{6\sqrt{3}f_f Q}{abc\pi\sqrt{\pi}} \exp\left\{\frac{-3x^2}{a^2}\right\} \exp\left\{\frac{-3y^2}{b^2}\right\} \exp\left\{\frac{-3[z + v(\tau - t)]^2}{c^2}\right\}; \text{front} \quad (\text{Eq 3})$$

$$q\{x, y, z, t\} = \frac{6\sqrt{3}f_r Q}{abc\pi\sqrt{\pi}} \exp\left\{\frac{-3x^2}{a^2}\right\} \exp\left\{\frac{-3y^2}{b^2}\right\} \exp\left\{\frac{-3[z + v(\tau - t)]^2}{c^2}\right\}; \text{rear} \quad (\text{Eq 4})$$

where Q is the energy input rate (in watts); the parameters a , b , and c are the dimensions that describe the ellipsoidal shape in x -, y -, and z -coordinates, respectively; τ is the lag factor; t is time, and f_f and f_r are the fractions of heat source deposited in the front and rear quadrant and are related to each other by Eq 5:

$$f_f + f_r = 1 \quad (\text{Eq 5})$$

By changing the dimensions of the a , b , c , f_f , and f_r values, it is possible to match most of the complex weld pool shapes that are observed in fusion welds. It is important to note that

these parameters must be obtained by the optimization procedure. For example, Kelly (Ref 45) must consider more than 2000 sets of such parameters to match the experimental weld pool size. In such calibration studies, it is often impossible to match all the experimental parameters, such as weld pool width, depth, curvature, and spatial variation of thermal cycles. Improvements to the aforementioned double ellipsoidal model are being pursued by many researchers (Ref 45). In this regard, it is important to understand fundamental reasons for such variations of the weld pool shape by using coupled heat- and mass-transfer models.

When the weld pool flux is calibrated using the double-ellipsoidal models, it is easier to describe steady and transient thermal cycles for complex welding conditions. An example of transient thermal simulation of laser cladding to build a nickel-base superalloy structure on a substrate is shown in Fig. 5 (Ref 46). The simulations were performed with

Fig. 4 Schematic of parameters used in describing the heat flux during welding. The reader is referred to Eq 3 and 4 in the text

Fig. 3 Calculated temperature isotherms during welding of low-alloy steels are shown in image and contour plots. The plots demonstrate the change of weld pool shape with an increase in welding speed from 1 to 5 mm/s

Fig. 5 Simulation of temperature transients while building a complex shape through the laser cladding process. (a) Thermal gradients are large at the early stage of cladding due to three-dimensional heat-transfer conditions. (b) With the buildup of sufficient layers, the heat-transfer condition changes to two dimensional. As a result, the thermal gradient is shallower. Such changes will affect the ensuing solidification and solid-state microstructure

commercial finite-element analysis software (ABAQUS) and user-defined subroutines. (Reference to any commercial software in this article does not imply endorsement of this software by the author or ASM International. Readers are requested to independently evaluate software for their own applications.) During the early stages of cladding, thermal simulations showed a small molten pool (Fig. 5a) due to the three-dimensional heat conduction mode. With the progress of the buildup, the heat conduction mode changes to two dimensional. As a result, the molten pool size increases, and there is remelting of the previous layers. The spatial and temporal variations of thermal cycles also change. These simulations demonstrated that for efficient laser cladding of the complex shapes shown in Fig. 5, the heat input must be changed based on local heat-transfer conditions. By coupling these thermal models with optimization software, it is possible to a priori design the path and heat input during laser cladding. The reader is referred to the article "Modeling of Laser-Additive Manufacturing Processes" in this Volume for more details.

Fluid Flow Modeling. As mentioned earlier, a complex weld pool shape develops due to heat transfer through conduction in the liquid and solid as well as convective transfer by way of electro-magnetic force, buoyancy forces, and shear stresses due to the spatial variation of surface tension with temperature. The effect of fluid flow on weld pool shape was initiated by the pioneering work of Kou (Ref 13), Zacharia (Ref 20), and DebRoy (Ref 6) and their collaborators. The underlying methodology relies on solving equations of energy and momentum conservation as well as continuity conditions. The first governing equation is the conservation of momentum:

$$\rho \nabla(V \cdot V) = -\nabla P + \mu \nabla(\nabla V) + (S_V - \rho \nabla \cdot (U_s V)) \quad (\text{Eq 6})$$

where ρ is density; V is the fluid flow velocity vector in the x -, y -, and z -directions, which is represented by u , v , and w ; respectively; U_s is the welding velocity; P is the effective pressure on the welding pool; and S_V is the source term that takes into account the buoyancy factor (S_b), Marangoni shear stress (τ_{mar}), and electro-magnetic force (Ref 13).

The buoyancy term (S_b) is described by $\rho g \beta (T - T_{\text{ref}})$, in which β is the thermal expansion coefficient at a temperature, T , with reference to a reference temperature (T_{ref}). The shear stress (τ) is given by $f_1 (d\gamma/dT) \nabla T$. In this relation, the parameter $d\gamma/dT$ is the variation of surface tension with temperature. This can take either positive or negative value and is shown to have large influence in the weld pool fluid flow conditions. The other parameter, f_1 , takes care of the reduction in shear stress near the mushy (mixture of liquid and solid) regions.

The second governing equation deals with the conservation of energy:

$$\rho \nabla(V \cdot h) = \nabla \cdot \left(\frac{k}{C_p} \nabla h \right) + S_1 + S_h - \rho \nabla \cdot (U_s h) \quad (\text{Eq 7})$$

where the total enthalpy of the material, h , is related to the sum of sensible heat and latent heat content, which takes into account the phase change (e.g., solid to liquid and liquid to solid); C_p is the specific heat; k is the thermal conductivity; S_h is a source term that takes into account the heat input from the welding source and convective and radiation heat loss; and S_1 is a source term that accounts for the latent heat of melting and the convective transport of latent heat. This term also takes care of the phase change during solidification. The aforementioned governing equations can be solved by numerical methods to calculate the spatial variation of fluid flow velocity (u , v , w) and temperature.

In the early 1990s, the previously mentioned methodologies were used on simple butt welds. In addition, the sensitivity of these calculations to the magnitudes of thermophysical properties was documented (Ref 47). Recently, the aforementioned methodology has been extended to fillet welds using coordinate transformation methods (Ref 48). The methodology to transform the fillet weld geometry in a real x , y , and z Cartesian coordinate system to a computational domain is shown in Fig. 6(a). After this coordinate transformation, the governing Eq 6 and 7 are solved in this domain. A typical result from such calculations is shown in Fig. 6(b). The plot shows the ability of fluid flow calculations to very effectively simulate the curvature of the welds as well as the penetration of the weld pool into the base materials. Comparisons of the calculated weld pool shapes to experimental weld shapes (Ref 49) are shown in Fig. 6(c). This example shows the predictive power of computational heat- and mass-transfer models. It is important to note that the change in weld pool shape shown in Fig. 6(c) also changes the spatial variation of cooling rates. As a result, the predictions of cooling rates are expected to be more accurate with the use of heat and fluid flow models. The fidelity of such calculations on the sensitivity of steel weld metal microstructure was demonstrated by Deb-Roy and his collaborators (Ref 50, 51).

Microstructure Modeling

The goal of microstructure modeling is to predict phase fractions as well as grain size in the heat-affected zone (HAZ) and weld metal region as a function of alloy composition and thermal cycles. Because thermal cycles are predicted by the process models described earlier, in this section, methods to predict the microstructures in the HAZ and weld metal are presented. The reader is also referred to a classic

textbook by Grong for in-depth treatment of this subject (Ref 10). In this section, the pioneering work done to predict the HAZ and weld metal microstructure in the early 1980s and 1990s is presented first. Later, the application of computational thermodynamic and kinetic models is also presented.

Prediction of HAZ Microstructure

Methods for predicting HAZ properties range from simple equations using the base material or weld metal chemistry to complex models that take many factors into account, including chemistry, initial grain size, heat input, and cooling rate. The overall goals and approaches are summarized schematically in Fig. 7. The approaches can be broadly classified into two main themes. In the first approach, the microstructure is not predicted explicitly; rather, the input parameters, such as base metal composition, microstructure, and welding process parameters, are related to one or more HAZ properties. In the second approach, the input parameters are used to calculate the HAZ microstructure and then are correlated with different properties. The historical development of these approaches is briefly discussed and is adopted from Ref 52.

First-generation approaches involve simple correlations between the steel composition and various properties, such as hardness, tensile strength, and cracking tendency. All of the formulas have a form of carbon equivalence that ignores the kinetics and does not consider the microstructure evolution explicitly (Ref 53). The second-generation methods (developed between the 1980s and the 1990s) build on the carbon equivalence formulas to consider the intricacies due to the peak temperature, initial precipitate type, cooling rates, and microstructure evolution. Yurioka et al. (Ref 54) have developed a carbon equivalent number (CEN):

$$\text{CEN} = C + A(C) \left(\frac{\text{Si}}{24} + \frac{\text{Mn}}{6} + \frac{\text{Cu}}{15} + \frac{\text{Ni}}{20} + \frac{\text{Cr} + \text{Mo} + \text{Nb} + \text{V}}{5} + 5B \right) \quad (\text{Eq 8})$$

where $A(C) = 0.75 + 0.25 \tan h \{20(C - 0.12)\}$.

The third-generation methods (developed between 1990 and 2000) started to focus on evaluating the HAZ microstructure with detailed thermodynamics and kinetics, because thermodynamic and kinetic models are generic and allowed for extrapolation to a wide range of steels. However, relating the microstructure to properties still relied on empirical correlations. Ion et al. (Ref 55) used a kinetic approach to predict the hardness and microstructure of weld HAZs. Their approach uses a modification of the Rosenthal equations (Ref 41) to provide a circular disc heat source rather than a point source. The hardness prediction is based on estimating the volume fractions of microstructural constituents (martensite, bainite,

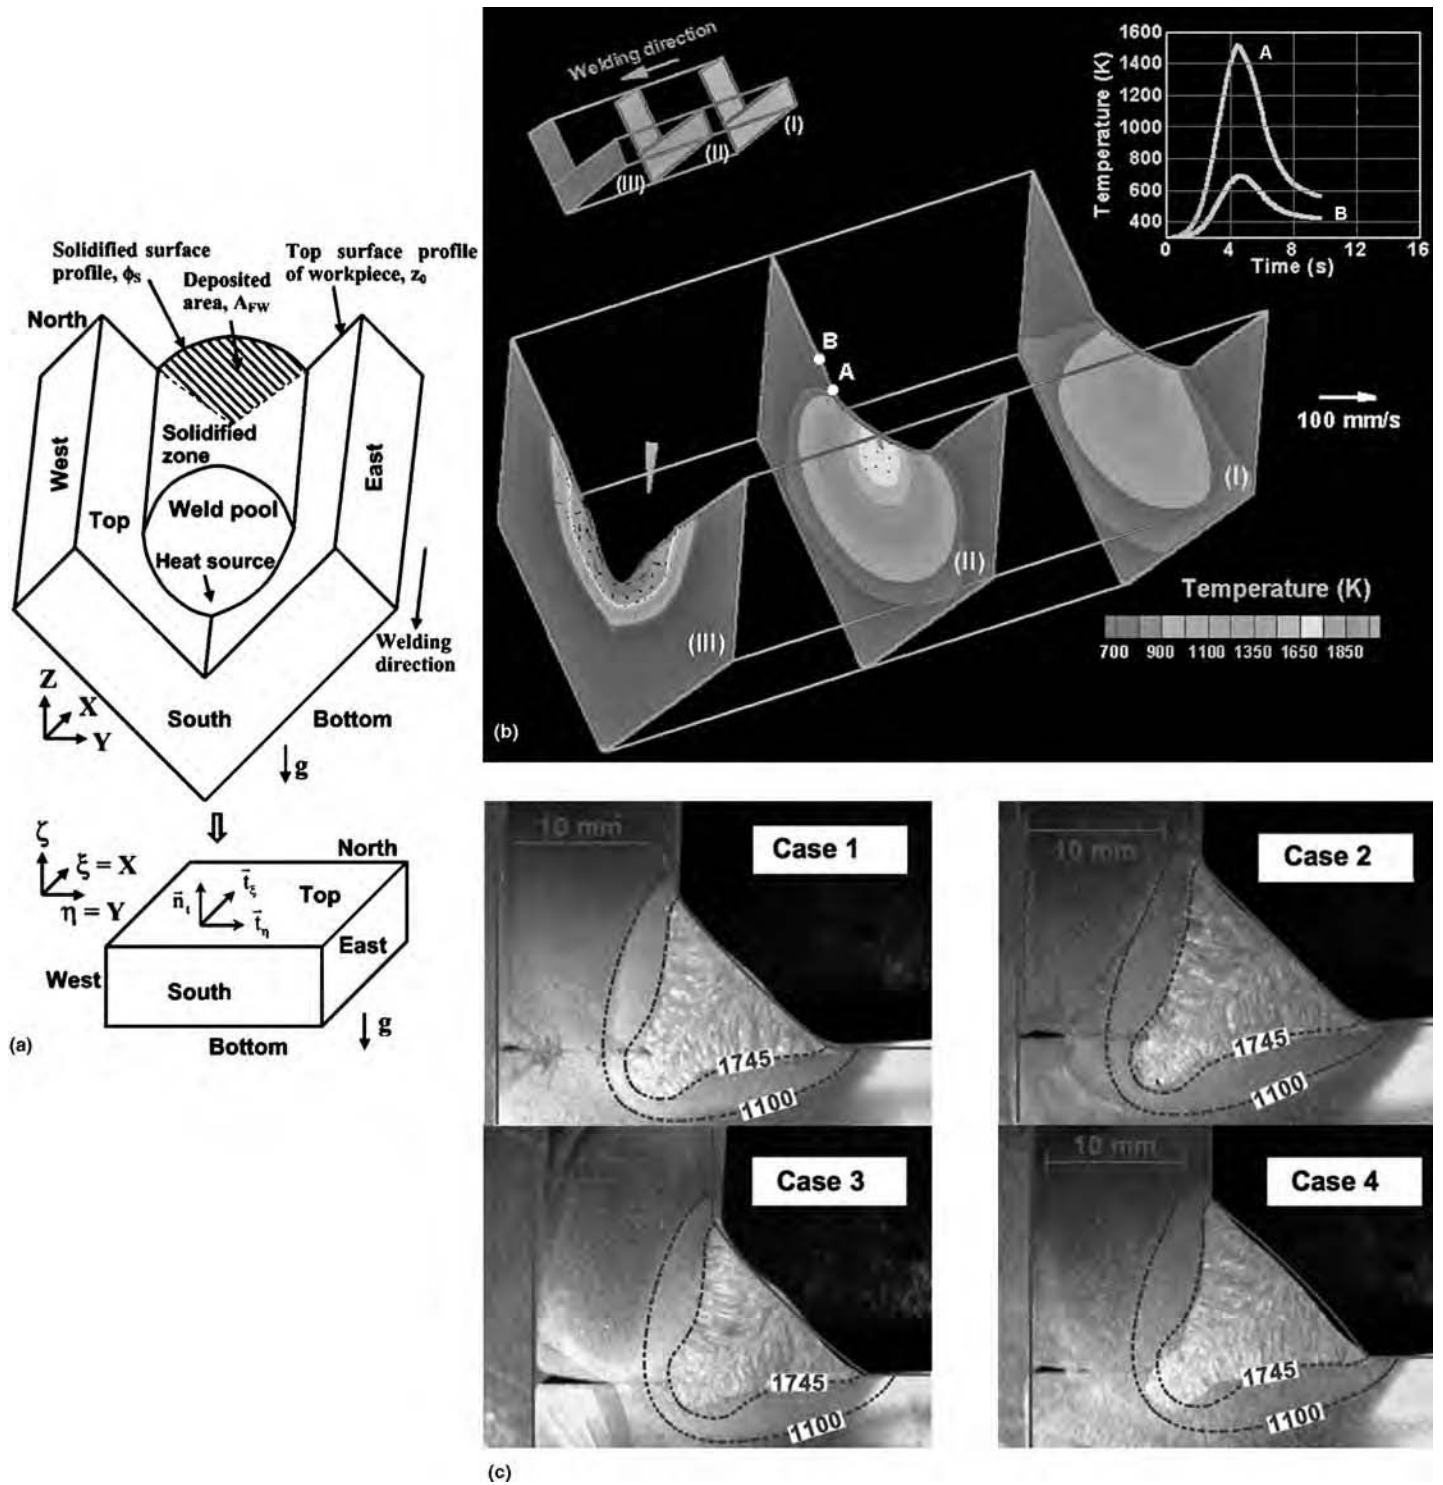

Fig. 6 (a) Technique to perform computational heat- and mass-transfer calculations for fillet welds using the coordinate transformation algorithm. (b) Typical result of such simulation shows the weld pool curvature as well as transients of temperature distributions. (c) Comparisons of predicted shape and size of the weld pool and the heat-affected zone for various welding process conditions show good agreement. Note the ability of these calculations to predict a change in curvature of the weld pool as one moves from top cap to the root of the weld. Such curvatures cannot be predicted without considering the fluid flow effects

ferrite, and pearlite) and using the rule of mixtures to approximate the hardness. The model takes into account many variables, including heat flow, austenite grain growth, precipitate dissolution and/or coarsening, and chemistry to predict the volume fraction of the

constituents. An example calculation is shown in Fig. 8. Using the model developed by Ion et al. (Ref 55), the microstructure and hardness of the HAZ for a given cooling rate (10 Ks^{-1}) and austenite grain size (50 m) for two different steels with 0.1 and 0.2 wt% C is shown. These

calculations show that a change in carbon content changes the HAZ microstructure from ferrite to a microstructure with predominantly martensite. In addition, the predictions also show an increase in hardness. Such calculations can be used to provide guidance for weld

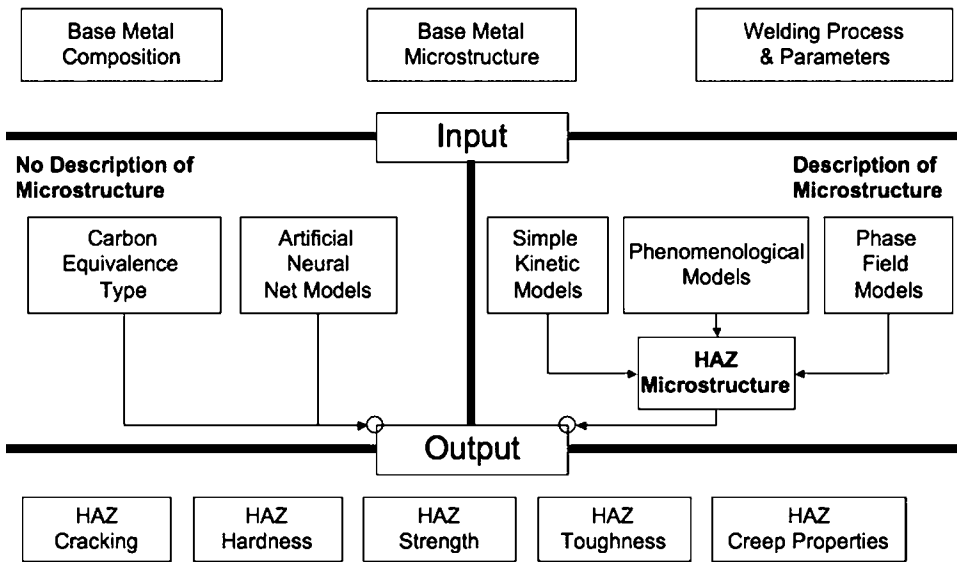

Fig. 7 Schematic illustration of various modeling methodologies to describe the heat-affected zone (HAZ) of steel welds

cooling rate control in the HAZ. An online version of these calculations is available (Ref 56).

Recently, prediction of HAZ microstructure and/or properties has relied on artificial neural networks (Ref 57) and detailed computational materials models coupled with either thermo-mechanical or fluid flow calculations. There has been much published literature that focuses on calculating the nucleation and growth of ferrite from austenite as a function of composition and cooling rate. These are essentially based on the calculation of time-temperature transformation diagrams and converting them to continuous cooling transformation diagrams (Ref 58). Advanced models that consider simultaneous formation of grain-boundary ferrite, Widmanstätten ferrite, pearlite, and bainite are also available (Ref 59). Some of these models are currently available in the form of public domain software (Ref 60). The models to predict microstructure evolution in the HAZ and weld metal region of age-hardening aluminum alloys can be found in the classic work of Myhr and Grong (Ref 61, 62). In this work, the dissolution of age-hardening precipitates and subsequent precipitation was described by isokinetic equations and assumed the additivity law.

In the previous treatments of microstructure evolution, in addition to phase transformation, an estimation of grain growth is important. For example, the steel microstructure predictions by equations given by Ion et al. (Ref 55) are sensitive to the prior austenite grain size. The austenite grain growth can be described by the following classic relationship:

$$\frac{dD}{dt} = nK \left[\frac{1}{D} - \frac{1}{\bar{D}_{\text{lim}}} \right]^{(1/n-1)} \quad (\text{Eq 9})$$

where D is the grain size (in micrometers); \bar{D}_{lim} is the limiting grain size (in micrometers), which is determined by the stability of the precipitates; and K and n are the rate constant and time exponent of grain growth, which depend on the materials and temperature, respectively. Therefore, if the composition and thermal cycle can be acquired from the steels and the welding parameters, the only thing needed for grain growth is the limiting grain size. In this article, the limiting grain size is determined by the pinning effect of precipitates (Ref 63):

$$\bar{D}_{\text{lim}} = k \frac{r}{f} \quad (\text{Eq 10})$$

where \bar{D}_{lim} is the limiting grain size; k is the Zener coefficient, which was first derived by Zener to be 0.75; r is the average radius of precipitates, with the unit of micrometers; and f is the volume fraction of precipitates. The limiting grain size is then related to stability (growth, coarsening, and dissolution) of grain-boundary pinning precipitates. Although, the aforementioned methodology has been extensively used, it does not provide morphological changes in grain shape and size. In this regard, pioneering work was done by Radhakrishnan et al. (Ref 64, 65) using Monte Carlo simulations. Using this methodology, thermal pinning of grain growth was also successfully simulated. This work has been pursued by other researchers to describe the HAZ grain growth in other alloy systems (Ref 66).

Prediction of Weld Metal Microstructure

The earliest models to calculate weld metal microstructure can be tracked to a classic paper

by Bhadeshia et al. (Ref 3) for steel welds. In this model, the sequential decomposition of the austenite phase into allotriomorphic ferrite (also known as grain-boundary ferrite), Widmanstätten ferrite, acicular ferrite, and martensite-austenite constituents is calculated. The basis of this model emanates from an ability to calculate the time-temperature transformation (TTT) diagram as a function of steel composition. The TTT diagrams are then converted into continuous cooling transformation (CCT) diagrams. Given an expression for the weld cooling curve and austenite grain size, the weld metal microstructure can be calculated using the flow chart shown in Fig. 9(a). Comparison of predicted microstructure and measured microstructure is shown in Fig. 9(b). The aforementioned model has been coupled with detailed heat- and mass-transfer models by DebRoy and his collaborators (Ref 50, 51). Microstructure development in the weld metal region of aluminum alloys (Ref 67) and nickel alloys (Ref 68) has been addressed through computational thermodynamics and kinetics, which are introduced in the next section (Ref 40).

Application of Computational Thermodynamics and Kinetics Tools

There are standard mathematical models to calculate multicomponent thermodynamics and diffusion-controlled growth of the product phase into a parent phase (Ref 69). A typical calculation of multicomponent equilibrium is demonstrated with the Fe-Cr-Ni system with liquid, δ -ferrite (body-centered cubic), and γ -austenite (face-centered cubic) phases at 1700 K (Fig. 10). Thin lines that go across the phase boundaries in this diagram correspond to tie lines. For further details on this subject, the readers are referred to other sections in this Handbook. In this section, application of these tools to weld metal microstructure prediction is described (Ref 40) for various reactions that happen as a function of high-to-low temperature during fusion welding.

Liquid-Gas Reactions. The prediction of weld metal composition in gas-shielded processes, including gas metal arc welding (GMAW) (Ref 70), gas tungsten arc welding (GTAW), laser beam welding, and low-pressure electron beam welding, has always remained a challenge due to competing phenomena with the arc, plasma, shielding gas, atmosphere, and consumables. For example, stainless steels with high nitrogen levels (Ref 71, 72) have been developed to reduce nickel concentration but still maintain an austenitic microstructure. However, predicting the amount of nitrogen that remains after GMAW or GTAW in these stainless steels as a function of welding parameters is indeed a challenge. Hertzman et al. (Ref 73, 74) concluded that the final nitrogen concentration is decided by the equilibrium

Fig. 8 Typical calculations of heat-affected zone microstructural constituent and hardness as a function of cooling rate. For a given low-carbon steel composition, (a) a slow cooling rate of 10 °C/s leads to a soft microstructure and (b) a faster cooling rate leads to a hard martensitic microstructure

between nitrogen activity and composition of the liquid metal after a critical time.

It is important to consider the effect of plasma environment, which may lead to enhanced nitrogen dissolution in steel welds. This phenomenon may play an important role at the early stages of nitrogen balance, as discussed by Hertzman et al. (Ref 73). Mundra and DebRoy (Ref 75), followed by Palmer and DebRoy (Ref 76), have developed models to

describe nitrogen dissolution (mono- and diatomic fashion) into liquid metal from the plasma environment. Enhanced nitrogen dissolution from laser plasma was leveraged by Babu et al. (Ref 77) to induce fine-scale carbonitrides during surface alloying of iron alloys. Similar to the kinetics of nitrogen dissolution (Ref 78–80), it is possible to describe the dissolution of oxygen (Ref 81) and hydrogen (Ref 82–84). Dissolved oxygen and sulfur (Ref 85)

have a major influence on the surface tension of liquid (γ_{surface}) and its variation with temperature ($d\gamma_{\text{surface}}/dT$). The sign and magnitude ($d\gamma_{\text{surface}}/dT$) has a large influence on the fluid flow characteristics in the weld pool (Ref 86, 87). In addition, evaporation from the weld pool has also been addressed by various researchers using thermodynamic and kinetic descriptions (Ref 88–90) and comprehensive heat- and mass-transfer models. Some preliminary efforts are also being made to predict the composition of the fume particles using the liquid-gas equilibrium (Ref 91).

Liquid-Slag Reactions. Most fusion welding processes encounter liquid and slag equilibrium, for example, shielded metal arc welding, submerged arc welding (SAW), and flux cored arc welding. There is a close similarity between these processes and steelmaking. As a result, ladle thermodynamics have been leveraged to describe liquid-slag equilibrium in welds. In the classic works of Mitra and Eager (Ref 92–94), thermodynamic theories were used to predict the final weld metal composition of SAW welds as a function of process, flux, and consumable characteristics. Many researchers considered interactions between flux/slag chemistry and consumables to evaluate final weld metal compositions (Ref 95–98) as well as the inclusion formation. As expected, these phenomenological theories were based on ladle thermodynamics (Ref 99).

Inclusion Formation. Inclusions that form in welds are either oxides, nitrides, carbides, sulfides, or a combination thereof. Certain oxide inclusions, with special characteristics, promote the formation of acicular ferrite (Ref 100, 101) during solid-state decomposition of austenite. Acicular ferrite is known to promote the toughness of welds. This beneficial effect of inclusion outweighs the deleterious effects on fracture initiation. Early work on predicting inclusion formation using ladle thermodynamics originated from many researchers, notably Olson, Liu, and Edwards (Ref 102), Thewlis (Ref 103), as well as Klukun and Grong (Ref 99). These researchers predicted that complex inclusions form due to sequential formation of oxides, including Al_2O_3 , SiO_2 , Ti_xO_y , MnO , and complex spinels. Even with the aforementioned classic work, the prediction of inclusion composition, size, number density, and type of surface oxide remained a challenge for some time. By coupling ladle thermodynamic theory, computational thermodynamics (Ref 104–106), and overall transformation kinetic theories (Ref 107–110), it is now possible to comprehensively predict inclusion characteristics. These models have also been extended to laser-surface alloying to predict dissolution of hard particles (Ref 111). These models have also been integrated with computational heat- and mass-transfer models (Ref 112–114). For example, Hong et al. evaluated the cyclic growth and dissolution of inclusions in a weld pool. The trajectory of the inclusion within a weld pool is shown in Fig. 11(a). This

Fig. 9 (a) Overview of methodology developed by Bhadeshia et al. (Ref 3) to predict the microstructure constituent in the as-welded region of low-alloy steels. In contrast to the carbon equivalence formula, this model is based on quasi-chemical thermodynamics and kinetic equations. TTT, time-temperature transformation; CCT, continuous cooling transformation. (b) Comparison of predicted and measured microstructure in the as-welded region shows good agreement

Fig. 10 Example of a calculated ternary phase diagram with tie lines and invariant triangles (three-phase equilibrium) in an Fe-Cr-Ni system at 1700 K. fcc, face-centered cubic; bcc, body-centered cubic

movement was calculated by using the fluid flow velocities (u , v , and w) calculated in x -, y -, and z -coordinates and by assuming no slip between the inclusion surface and liquid steel flow. The corresponding variation of temperature and the associated change in radius of the inclusion is shown in Fig. 11(b). Using such calculations and microstructure observations, the rapid rate of inclusion growth was rationalized based on a collision and coalescence mechanism (Ref 115).

Solidification. To comprehensively understand the weld metal microstructure, the following must be predicted:

- First phase to form from the liquid
- Solidification temperature range ($\Delta T_{\text{equilibrium}} = T_L - T_s$)
- Extent of alloying element segregation
- Morphology of the solidification grains
- Cracking tendency
- Nonequilibrium solidification as a function of composition and cooling rates

A multicomponent thermodynamic phase diagram can be calculated using computational thermodynamics tools, and this information can be used to predict the first phase to form from liquid during welding (Ref 116–118). Using Scheil-Gulliver calculations, the non-equilibrium solidification range as well as the maximum extent of segregation can be predicted (Ref 119). It is important to note that equilibrium and Scheil-Gulliver calculations provide two extreme conditions of weld solidification. In nominal weld cooling rates, some extent of diffusion is expected in the solid phase. This must be considered in the Scheil-Gulliver calculations. Classic papers from Dupont's group (Ref 120–122) focus on using a modified form of the computational thermodynamics tools to evaluate the solidification path and also the microsegregation effect in similar and dissimilar metal welding conditions for a wide range of nickel-base and stainless steel alloys.

To track the solid-liquid interface, diffusion in both liquid and solid phases as a function of cooling rate must be considered. Early work on modeling the weld solidification rate was done by Koseki et al. (Ref 123, 124). With the introduction of sidewise dendrite growth models in DictTra software (Ref 69), weld solidification for a wide range of alloy systems and cooling rates can be done easily. With an increase in cooling rate, an increase in the liquid-solid interface velocity is expected. This may affect solute partitioning between the liquid and solid and induce morphological changes in the solidification microstructure. Often, this increase in the liquid-solid interface may also trigger a nonequilibrium phase selection during solidification. For example, in steels, a transition from ferrite (body-centered cubic) solidification and austenite (face-centered cubic) solidification may occur (Ref 125, 126) with an increase in the liquid-solid interface velocity. Using levitation melting methods, Koseki and Flemings (Ref 127) developed phase stability and growth velocity criteria to describe these transformations. Fukumoto and Kurz (Ref 128) used growth velocity considerations for the phase selection of austenite instead of ferrite during rapid cooling conditions, using interface-response function models. This is illustrated in Fig. 12. The selection of the ferrite or austenite phase is governed by its dendrite tip temperature. This temperature can be calculated using the interface-response function theories. The calculations show that for slow interface

(b)

Fig. 11 Prediction of inclusion size distribution in low-alloy steel welds by tracking the growth and dissolution of thousands of inclusions as they gyrate through the weld pool. (a) Trace of an inclusion as it traverses through the weld pool with different temperature regions, before being trapped by the advancing liquid-solid boundary. (b) Corresponding variation of temperature and the associated growth and dissolution of an inclusion. The calculations show that the observed inclusion diameters could be interpreted without invoking Ostwald ripening, which is typical of a stagnant molten pool

Fig. 12 Transition from body-centered cubic (bcc) to face-centered cubic (fcc) mode of solidification with an increase in the liquid-solid interface velocity. The calculations show that in an Fe-Cr-Ni weld, the bcc mode of solidification is preferred below 2×10^{-3} m/s, and the fcc mode of solidification is preferred at higher velocities. These plots are used to rationalize the transition from δ -ferrite to the austenite mode of solidification in laser welds. Source: Ref 127

velocities, the dendrite tip temperature of ferrite is always higher than that of austenite. Under this condition, only ferrite solidification is expected. However, above a critical velocity, the dendrite tip temperature of austenite is higher than ferrite. This condition will lead to the austenite mode of solidification. Using these

theories, the transition from ferrite to austenite solidification modes during laser welding was rationalized.

Solid-State Transformation. The role of various microalloying elements (Ref 129) on the HAZ microstructure in thermomechanical-controlled processing in low-alloy steels has

been evaluated with computational thermodynamics (CT) and computational kinetics (CK) tools. The ferrite-to-austenite transformation in stainless steel welds (Ref 130) was simulated for a condition that is close to limited partitioning of the substitutional condition, which is in between the paraequilibrium and local equilibrium conditions. The effect of retained austenite in the steel microstructure on the re-austenitization kinetics during heating was rationalized using a thermodynamic criterion (Ref 131). To design new steels with improved properties and weldability, CT and CK tools are very effective. For example, a transformation-induced plasticity (TRIP) steel with good welding and galvanizing performance was designed with CT and CK tools. In this work, carbon, silicon, and phosphorous concentrations were optimized, and the microstructure evolution during steel processing was modified (Ref 132, 133). Kaputaska et al. used CT tools to describe the stabilization of δ -ferrite in the HAZ of aluminum-base TRIP steels (Ref 134). Using CT tools, blast-resistant steels with good weldability (Ref 135) have been developed. The HAZ microstructure evolution in duplex stainless steel weld metal was modeled using overall transformation kinetic models based on CT tools. This work stressed the importance of nitrogen concentration on the stabilization of austenite (Ref 136). Similar work on duplex steels has been performed by other researchers (Ref 137). In addition, the effect of minor variations in boron was rationalized based on the CCT diagrams predicted by CT and CK tools (Ref 138). Barabash et al. (Ref 139) showed the dissolution of gamma-prime precipitate and its effect on dislocation activity in HAZ

regions. These interactions were rationalized based on transmission electron microscopy, synchrotron radiation, and computational thermodynamic calculations.

Kelly (Ref 45) used CT and CK tools to obtain the parameters for the Johnson-Mehl-Avrami-Kolmogorov model, which is then coupled with a thermal model for laser near-net shaping of Ti-6Al-4V alloys. Using this thermal-microstructure model, Kelly described the microstructure evolution as a function of the heating and cooling cycle. This model was used to describe the formation of various morphologies of $\alpha+\beta$, including the grain-boundary, colony, basketweave, massive, and martensitic microstructures. Similar approaches to describe microstructure gradients in multipass welds in steels were performed by Reed and Bhadeshia (Ref 140). In these analyses, the austenite formation and its effect on increasing the fraction of the reheated region was described by coupling heat-transfer models with thermodynamic and kinetic calculations (Ref 141). Extensive work has been done by Keehan et al. (Ref 142–146) to develop high-strength and high-toughness weld metal compositions that are based on bainite microstructure. These developments relied on CT and CK tools (Ref 147). The reliability of weld microstructure models and their relation to properties have been reviewed by Bhadeshia (Ref 148).

To address the stability of weldment structures during postweld heat treatment and service, CT and CK tools have been used. In certain 9Cr steels, the addition of boron leads to a fine distribution of $M_{23}C_6$ and an increase in creep resistance. Thermodynamic calculations showed that boron will segregate to martensite lath boundaries and increase the driving force of boride precipitation. These precursor phases will act as heterogeneous nucleation sites for boron containing $M_{23}C_6$ (Ref 149). Simultaneous transformation kinetic theories of carbide precipitation (Ref 150) and neural network models (Ref 151) have been used to develop creep-resistant weld metals. The nucleation and kinetics of chi, sigma, and secondary gamma (face-centered cubic) phases during aging of a super duplex stainless steel weld metal were investigated with experimental characterization and thermodynamic driving force calculations (Ref 152). Similar work has been performed by Sieurin et al. (Ref 153, 154) to describe the sigma-phase precipitation and reforming of austenite during isothermal and continuous cooling. Ramirez et al. (Ref 155) used analytical electron microscopy and thermodynamic modeling to evaluate secondary austenite formation and its interaction with Cr_2N precipitation. Another form of degradation in high-chromium stainless steel welds is the tendency for low-temperature embrittlement. This occurs due to the phase separation of chromium-rich and chromium-lean regions through a spinodal decomposition (Ref 156) and the subsequent precipitation of gamma phase. Many researchers have characterized this

decomposition using the atom probe technique and compared it with CT and CK tools (Ref 157). The CT and CK models also have been used for evaluating the stability of dissimilar material welds. One successful example is the prediction of carbon migration in dissimilar material welds (Ref 158, 159).

Performance Modeling

The goal of performance modeling relates to the prediction of weldability, geometrical distortion, and/or locked-in residual stresses as a function of material, restraint, process, and process parameters as well as service temperature.

Weldability Prediction

One of the main uses of numerical modeling is to predict the cracking tendency in welds. Weld solidification cracking is governed by severe restraints (stress/strain state) and the composition of the base metal (affects epitaxial growth) and the filler metal (affects the solidification range). To predict the solidification-cracking tendency in welds, there is a need to couple the CT and CK calculations with finite-element analysis that predicts the spatial variation of stress, strain, and temperature (Ref 160–164). This is explained with an example from the published literature.

There is a growing need to develop joining processes and process parameters for single-crystal nickel-base superalloys (Ref 165). During such a development cycle, autogenous welding experiments showed cracking (Fig. 13a) on only one side of the weld. Orientation imaging microscopy showed that the cracking was associated with the formation of stray grains on only one side of the weld (Fig. 13b). The reason for such asymmetrical cracking and grain structure evolution was rationalized with integrated process-microstructure models. The first step was to rationalize the dendrite growth velocities on the left and right side of the weld. The weld pool shape was modeled with a simple analytical heat-transfer equation (Ref 166). Using a geometric model (Fig. 13c) developed by Rappaz et al. (Ref 16), the spatial variation of the temperature gradient and dendrite growth velocity was calculated as a function of weld pool shape and crystallographic orientation of the single crystal. Next, these spatial variations of gradients and velocities were plotted (shown as triangular markers) on a processing map (Fig. 13d) that predicts the probability of stray grain formation. This map is developed using the constitutional supercooling theory for nucleation of new grains ahead of the growing liquid-solid interface. The comparison of these values showed that the tendency for the formation of stray grains is more on the right side of the weld. The formation of high-angle grain boundaries has been attributed as the cause for weld metal cracking (Ref 167).

Solidification cracking also requires mechanical driving force. Park et al. (Ref 162) integrated these material models with thermomechanical models to develop processing maps for cracking tendency due to stray grain formation. The processing map developed by Park et al. focused only on weld cracking for single crystals; however, in other polycrystalline alloys, the weldability evaluations must consider weld penetration, porosity formation, HAZ liquation, centerline grain formation, and solidification cracking.

Dye et al. (Ref 163) developed such weldability maps (Fig. 14) for nickel alloys using a different functional relationship between power and velocity. This map shows microstructural evolutions that impact weld penetration, tendency for porosity formation, HAZ liquation, solidification cracking, and center grain formation as a function of welding power and welding speed. For a given welding power, an increase in welding speed will lead to a reduction in weld penetration. An increase in welding power, more than needed for weld penetration, will lead to the formation of porosity. Similarly, with a large increase in power at the same velocity, the thermal gradient in the middle of the weld will be reduced. Under these conditions, the formation of centerline grains will be promoted. The overlaying of all these vulnerabilities leads to a small processing window where the welds can be made without undesirable defects. It is important to note that this optimum process parameter region will shift depending on the materials and thermomechanical conditions.

Residual Stress and Distortion Modeling

The reader is referred to Ref 168 for a comprehensive review of various methodologies and applications for processes and mechanisms of welding residual stress and distortion. In this section, some examples are presented to show the capability of numerical models to predict residual stress and distortion during welding.

Residual-Stress Prediction. The origin of residual stresses during materials processing is discussed in depth in a review by Withers (Ref 169). For in-depth understanding of the mechanics, the reader is also referred to a classic textbook by Masubuchi (Ref 170). Macroscopic residual stresses develop in welding due to localized plastic strain induced by a severe temperature gradient brought about by localized heat sources. The predictions of residual stresses are usually done by finite-element analyses in either two- or three-dimensional conditions. Most of these computational simulations are also performed in a sequential fashion, as explained subsequently. First, for a given set of geometry and welding process parameters, the thermal distribution is predicted. In the next step, using thermal distribution and the associated variation of mechanical properties, the localized plastic strain

Fig. 13 (a) Optical micrograph of an autogenous gas tungsten arc weld made on a single-crystal nickel-base superalloy shows the transverse crack on only one side of the weld. (b) Orientation imaging microscopy showing the close correlation between the crack and the presence of high-angle stray grain boundaries. (c) Schematic illustration of a geometric model of the weld pool used for estimating the dendrite growth velocity as a function of welding speed. (d) Predicted tendency to form stray grains as a function of dendrite growth velocity and temperature gradients

distribution is predicted. Due to the mechanical equilibrium constraint, this localized plastic strain accumulation at high temperature leads to a distribution of locked-in elastic residual stresses. It is important to note that these predictions are sensitive to the boundary conditions used in the mechanical equilibrium calculations. For example, local constraints (clamps and fixtures) may affect the evolution of residual stress as well as postweld heat treatments such as temper-bead techniques (Ref 171, 172) and surface peening (Ref 173, 174). It has been demonstrated that the initial distribution of residual stress before the welding operation is important in the estimation of residual stress due to welding. For example, in automotive industries, the sheet metal forming process may induce a pattern of residual-stress distribution due to its inhomogeneous distribution of plastic strain (Ref 175). In addition, the postweld heat treatment affects the distribution of residual stress due to relaxation.

Residual stresses in welds can be measured by hole-drilling, x-ray diffraction, and neutron diffraction methods (Ref 169). The presence of residual stress has a large effect on fatigue life and stress-corrosion cracking. An example calculation of residual-stress prediction and experimental measurements using x-ray diffraction is shown in a steel weld (Fig. 15). The results (Ref 49) show that it is indeed possible to predict the distribution of residual stresses in welds with good accuracy. There has been a growing impetus to predict the effect of phase transformation on the magnitude of residual stresses in welds (Ref 176). This is partly driven by the need for the use of low-temperature-transformation wires to induce compressive residual stress near the toe of fillet welds to improve the fatigue life of welded components (Ref 49, 177).

Distortion Prediction. The distortion of the welded structure is essentially due to dimensional changes that occur during or after welding due to the imbalance of locked-in stresses.

Fig. 14 Calculated weldability map showing the tendency for various weld-defect formations as a function of welding power and speed. Many of these phenomena, including liquation, are predicted using computational thermodynamics and computational kinetics tools. Source: Ref 162

The distortion simulation can be performed by finite-element analysis in three dimensions (Ref 23, 168, 178), with consideration of elastic and plastic strain accumulation during welding. However, the application of finite-element simulation to large-scale structures (e.g., ship superstructure) with consideration of detailed local welding process effects and constraints may become computationally expensive and time-consuming. In this regard, a simplified procedure that is based on applied plastic strain has been developed (Ref 179 to 181). A comparison of three-dimensional elastic-plastic analysis and the simplified plasticity strain method is shown in Fig. 16. The predicted distortions are comparable and prove the applicability of this technique to large-scale structures. This technique is very useful for consideration of buckling distortion in long welds on thin sheet structures. The technique was used to derive the process parameters for the transient thermal tensioning technique to minimize buckling distortion in ship panel structures (Ref 182).

Property Predictions

After the microstructural gradients, residual stress, and distortion conditions in a weld have been described, the next step is to predict the low- and high-temperature properties of the weld. Some of the methodologies are presented as follows.

Low-Temperature Properties. Relevant low-temperature properties for welds are hardness distributions, tensile properties, toughness, and fatigue properties. Hardness distributions in welds are often predicted using empirical equations, which relate the composition of the alloys and the microstructure. For steel welds, this is discussed in detail by Ion et al. (Ref 8) and Bhadeshia (Ref 148). Using these hardness models, Santella et al. (Ref 183) and Yuping et al. (Ref 184) predicted the performance of

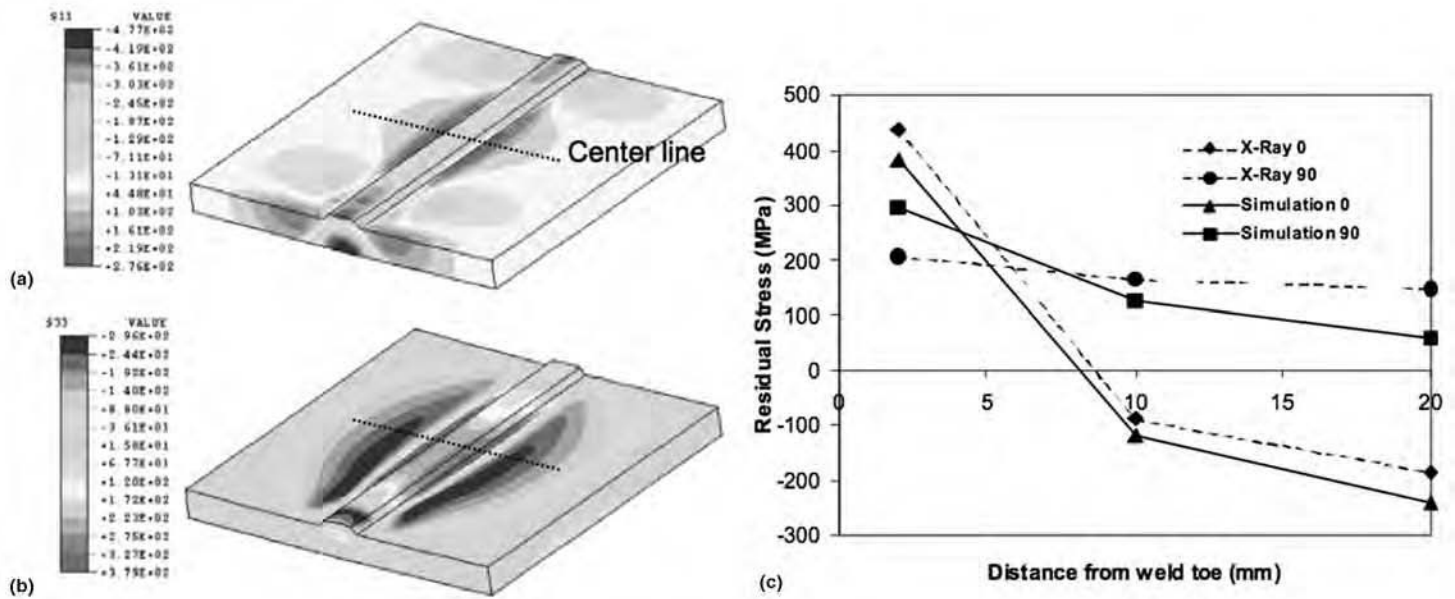

Fig. 15 Simulated residual stress in a butt weld in two directions: (a) perpendicular and (b) parallel to the welding direction. (c) The calculations are compared with the measurements by x-ray diffraction and show good agreement. Source: Ref 49

Fig. 16 Results from distortion modeling based on plasticity strain (Q-Weld) compared with fully three-dimensional coupled thermal elastic-plastic analysis (3D-EPA) model. The overall shape distortion (exaggerated) is comparable. In addition, the predicted displacement of the edges from the bottom plane is compared for both methods, demonstrating the applicability of the strain-based method for predicting the distortion of large-scale structures

steel spot welds. Similarly, the tensile properties of the welds are often predicted using additive law (Ref 185) and neural networks (Ref 151). An example of toughness prediction in steel weld metals, using artificial neural networks, is shown in Fig. 17. Using such maps, new filler metal compositions have been derived for low-temperature service (Ref 146). In welds, fatigue properties are often controlled by the crack propagation conditions. This is

partly because most of the welds often have submicroscopic features that provide an easy site for fatigue crack initiation. As a result, most of the research on prediction of fatigue-life estimation has relied on crack propagation conditions. Crack propagation is strongly affected by geometry (Ref 186) and the presence of compressive residual stresses (Ref 49, 171, 174, 175). An example calculation on the effect of tensile and residual stress is shown in

Fig. 18. The calculations indeed show an improvement of fatigue life near the toe of a fillet weld due to the presence of compressive residual stress. This has been experimentally evaluated by measurements (Ref 49).

High-Temperature Properties. The inherent creep properties of weld regions without the consideration of geometry can be predicted by using neural network models (Ref 148, 151, 187) or with hybrid models that consider the phase stability (Ref 188 to 190). It is also possible to develop detailed creep property calculations using detailed computational models, as described by To et al. (Ref 191). When the inherent properties are known, there is a need to map them to predict the creep life of structural components (Ref 192). Such calculations have become critical to evaluate the performance of welds made on new-generation high-chromium (P91) steels. These welds often show a soft zone in the HAZ. These regions will lead to localized reduction in creep strength. An example calculation of creep failure in the HAZ of a girth-welded pipe is shown in Fig. 19. In this model, different creep models (constitutive relations) were applied to the base metal and HAZ regions. In the next step, the damage accumulation in these regions was predicted for a given operating condition. These calculations have also been validated with experimental measurements.

Access and Delivery of Integrated Weld Process Models

The aforementioned examples clearly show that with an integrated weld-modeling framework,

it is possible to evaluate the welded structure, as envisioned by Kirkaldy (Ref 11). Some of the commercially available integrated weld-modeling software providers are listed in Table 1.

In addition, there are public domain software tools (Ref 193) that can be used for integrated modeling of welds. The listing of these resources is not an endorsement of the products, and readers are requested to make independent testing and evaluation for their own applications. It is important to note that this article did not include any reference to other forms of fusion welding (resistance, laser and electron beam) solid-state modeling techniques. There has been extensive work in this area, which is covered in other resources.

The discussions and references demonstrate that it is indeed possible to describe the weld properties in a wide range of alloy systems as a function of alloy composition and welding process parameters using integrated models. However, these models should be able to consider different processes (submerged, gas metal, gas tungsten, laser, etc.), process parameters, geometrical conditions (restraints, distortion), and mechanical integrity (residual stress, low- and high-temperature properties) in a simpler methodology. In addition, these integrated models should be seamlessly accessible to academic and industrial users. Although commercially available weld-modeling software exists (Table 1), it requires expertise in finite-element analysis as well as a computational and welding background. However, the presence of such expertise is often limited in small- and medium-scale industries. As a result, the use of computational weld mechanics has been widespread only in large-scale industries. To provide access to these models for small- and medium-scale industries, there is a need to develop methodologies for rapid deployment and easy-to-use applications.

To meet this crucial need, the E-WeldPredictor approach has been developed by researchers from the Edison Welding Institute (Ref 194). In this methodology, all of the expertise for developing and running a finite-element

analysis to calculate thermomechanical-metalurgical responses was ported into a supercomputing architecture. Simple, accessible, internet-based applications have been developed in collaboration with supercomputing expertise and have been deployed through a client-server computational architecture (Fig. 20). The steps are explained as follows.

First, the user provides the information for the welding processes. This allows the model to set the effective heat-transfer efficiency. In the next step, the user provides the overall geometry of the welding (pipe or plate) and the boundary conditions (thickness, diameter, and length). This information is used to set the overall simulation geometry within the finite-element software. In the next step, the user provides the detailed joint geometry (e.g., V- or J-groove). This information is used to calculate the extent of weld metal volume to be used for filling the void within the calculation framework. In the next step, the user provides the materials used for the base and filler metals. This information is used to calculate the microstructure and hardness. Currently, these material models do not consider the initial microstructure of the base metal, and a ferrite microstructure is assumed. In the next step, the user provides the information for heat input and geometry of the individual weld bead that will be used for filling up the joint. These parameters are then used to set the heat-flux conditions for simulating the weld pool (Ref 42). Finally, the model allows the user to check whether the intended weld geometry is indeed the one the user would like to consider. As soon as the user accepts and presses the submit button, the overall thermal-microstructure-mechanical model is evaluated in a sequential manner within a supercomputer architecture at the Ohio Supercomputing Center. The results of the calculations are formatted into a PDF and delivered to the user in an average time frame of 15 min. The

calculation time does increase with the number of beads. Currently, the E-WeldPredictor approach has been deployed for predicting microstructure, distortion, and residual stresses in pipe and plate welds for a wide range of steels. The reader is referred to the internet site listed in Ref 195 for more details and usage scenarios. In this section, a typical application of the tool for a case study to evaluate the use of X-65 steels instead of 2.25Cr-1Mo steels for a welded pipeline construction with the same filler and process parameters is discussed.

Case Study Evaluating Use of X-65 Steels

Case Study Involving Typical Use of the E-WeldPredictor Tool. While welding a 2.25Cr1Mo steel pipeline, a hard zone was observed in the HAZ. An ER70S6 filler wire was used in this situation. The focus of the case study was to substitute the 2.25Cr1Mo steels with traditional X-65 steels for the same process and filler wire conditions, without adverse effect in residual stress and distortion. The individual steps in running the simulations and input parameters are shown in Fig. 21. The results obtained based on these inputs are summarized in Fig. 22. The calculations indicated that there are no significant differences in the HAZ width, residual stress, or distortions by substitution of the 2.25Cr1Mo with the X-65 steel (Fig. 22). The most important difference was the formation of martensite in the HAZ of the 2.25Cr1Mo steels compared to a bainitic microstructure in the X-65 steels. This microstructural distribution is also reflected in the reduction of peak hardness in the HAZs of the X-65 steels. With this tool, the range of other process parameter and material combinations was evaluated, and some key conditions are

Fig. 17 Contour plot of Charpy toughness values, at a given temperature, as a function of manganese and nickel concentration constructed using an artificial neural network model. Such plots can be used to design welding consumables

Fig. 18 Calculated increase in fatigue life predicted by the modification of residual stresses (RS) in the weld. Note that an order of magnitude or more increase in fatigue life is predicted due to the presence of compressive stress near the root of the weld. Source: Ref 49

Use of Optimization Methodologies

With the development of these integrated models, it is now possible to use the models as a virtual process design tool. Similar to experimental trial-and-error optimization, these models can be run over a wide range of process and material parameters. However, there are two challenges in the implementation of this. These are the inability of the models to do an exhaustive search and the lack of robust material parameters that describe the physical processes. In this regard, optimization methodologies have proved to be useful. Muruganath et al. (Ref 196) have used commercial optimization software so that optimum weld metal composition can be designed for maximizing the weld metal toughness. In this work, the exhaustive search of an artificial neural network model for weld metal toughness was avoided by using generic and stochastic optimization algorithms. The optimization exercise led to a weld metal composition that was in agreement with experimental measurements (Fig. 23). Although, in this exercise, the time for one set of calculations is not more than 10 s, the previously mentioned methodology proved the utility of the optimization tools. Recently, the aforementioned methodology was used to arrive at weld metal compositions that will maximize acicular ferrite in pipeline steel welds (Ref 197).

The previous example is based on a condition that a model for Charpy toughness is verified and validated. However, in certain conditions, the uncertainties of the modeling results are related to the parameters and constants used in the models. For example, in fluid flow simulation of arc welding, there arc uncertainties in the arc efficiency (η), arc radius (r^*), arc energy distribution parameter (d), effective thermal conductivity (k^*), and effective viscosity (μ) of the liquid metal. To predict the weld pool shape with greater accuracy, it is necessary to obtain these parameters by calibration with a limited number of experimental data. Similar to the earlier example, an exhaustive search of parameter space for these variables (η , r^* , d , k^* , and μ) is computationally impractical. To address this challenge, De and DebRoy (Ref 198) developed an elegant optimization methodology to derive these parameters using optimization algorithms. The algorithm evaluates various combinations of parameter space and tries to minimize an objective function that is a function of difference between the experimentally observed weld pool size and the predicted weld pool size. The progress of the optimization is shown in Fig. 24. As soon as, η , r^* , d , k^* , and μ are calibrated using the aforementioned method, the heat-transfer and fluid flow model can be used for a wide range of process parameters. The previously mentioned methodology has become a standard technique among weld-modeling researchers.

being considered for detailed experimental evaluations. It is important to note that this tool now can be used for seamlessly evaluating the process-material effects and satisfies the need identified earlier.

Currently, this tool is not comprehensive for a wide range of geometries (fillet welds), boundary

conditions (restraints), processes (resistance, laser, friction stir welding, etc.), alloy systems (aluminum, titanium, etc.), and performances (toughness, creep, fatigue, etc.). However, the framework can be modified for these needs with the development of submodels for these processes, materials, and performances (Fig. 21).

Concluding Remarks

The integrated weld process modeling methodology presented in this article is in alignment with the needs identified by the National Materials Advisory Board. In a report, integrated computational materials engineering is considered as a transformational discipline for improved competitiveness and national security (Ref 199). The integrated weld-modeling activity will be crucial for developing and deploying advanced materials in practical applications. Moreover, these tools will also accelerate the critical development and deployment of hybrid materials (Ref 200), which rely on a wide range of materials joined in a specific geometric shape and are expected to fill the holes in the material property space (Ref 201).

ACKNOWLEDGMENTS

The author would like to thank the collaboration with world-class researchers in the area of integrated computational weld modeling from The Pennsylvania State University, Oak Ridge National Laboratory, Caterpillar, Edison Welding Institute, Lincoln Electric Company, Engineering Mechanics Corporation of Columbus, Lawrence Livermore National Laboratory, BAM (Germany), and The Ohio State University. Many of the plots and graphs used in the article are derived from these collaborative works.

The author also acknowledges the permission to use various figures derived from the published work of international researchers in this area.

Fig. 23 Methodology used to optimize welding consumable composition. The methodology integrates commercial optimization software with a neural net model for weld metal toughness. The model predicted the optimized weld metal composition for maximizing toughness as a function of temperature. The model predictions are also compared with experimental measurements. The agreement shows the feasibility of optimization methodologies.

Modeling of Heat and Mass Transfer in Fusion Welding

Wei Zhang, Oak Ridge National Laboratory

Rohit Rai, Pennsylvania State University

Amit Kumar, ExxonMobil Upstream Research Company

Igor V. Kivitsun, E.O. Paton Electric Welding Institute of the National Academy of Sciences of Ukraine

IN FUSION WELDING, parts are joined together by melting and subsequent solidification. Although this principle is simple, complex transport phenomena take place during fusion welding, and they determine the final weld quality and performance (Ref 1–3). The heat and mass transfer in the weld pool directly affect the size and shape of the pool, the solidification microstructure, the formation of weld defects such as porosity and humping, and the temperature distribution in the fusion zone and heat-affected zone (HAZ). Furthermore, the temperature evolution affects the kinetics and extent of various solid-state phase transformations, which in turn determine the final weld microstructure and mechanical properties. The formation of residual stresses and distortion originates from the thermal expansion and contraction during welding heating and cooling, respectively.

As discussed elsewhere in this Handbook, experimental observation of weld pool dynamics is challenging. Nevertheless, valuable insights have been gained into the mechanisms of heat and mass transfer in the weld pool. Such understanding is crucial to the development of sound and robust mathematical models. Unlike the experimental approach that directly measures the temperature or molten metal flow velocity, the mathematical models describe the heat and mass transfer using a set of partial differential equations (PDEs). The models solve those PDEs using numerical methods such as the finite-volume method to calculate the temperature and velocity fields. Over the past decades, the models of heat and mass transfer have evolved from simple two-dimensional (2-D) steady-state models to complex three-dimensional (3-D) transient models considering the free surface flow under metal droplet impact. These models have significantly improved the current understanding of welding transport phenomena (Ref 4), including various driving forces for molten metal flow in the weld

pool, effect of shielding gas composition, dendrite microstructure during solidification, vaporization and loss of alloying elements, and formation of weld bead humping, just to name a few.

The heat and mass transfer in fusion welding is truly a broad, multidisciplinary topic (Ref 1–3). In the published literature, there exist a large amount of models employing different approaches and simplifications. With ever-increasingly sophisticated experimental tools for probing and theoretical understanding of heat and mass transfer, models are constantly enhanced to tackle complex transport phenomena. The main objective of the present article is to provide a comprehensive review and critical assessment of the current state of the art in numerical modeling of heat and mass transfer in fusion welding. The article is focused on the fusion welding processes that have been modeled extensively in the published literature. They include gas tungsten arc welding (GTAW), gas metal arc welding (GMAW), laser welding, electron beam welding, and laser-arc hybrid welding. Furthermore, the models are based on the solution of governing conservation equations for mass, momentum, energy, and chemical species. The calculated results from the heat and mass transfer models, especially the temperature evolution in the weldment, are crucial for the understanding of other aspects of fusion welding, including microstructure evolution, residual stresses, and distortion.

The article is organized as follows. First, the mathematical equations of mass, momentum, energy, and species conservation are provided. The boundary conditions for heat flux and the various driving forces for fluid flow are also discussed. Second, applications of heat transfer and fluid flow models to different welding processes are reviewed. The modeling of mass transport such as gas absorption and vaporization of alloying elements is also presented.

Finally, approaches to improve reliability of and reduce uncertainty in numerical models are discussed.

Important Considerations

It is important to recognize that state-of-the-art models are only as good as the mathematical equations that they are solving and the materials properties that they are using. Even for some of the phenomena for which mathematical descriptions of the underlying mechanisms are well established, the difficulty in obtaining converged numerical solutions for highly nonlinear problems may render the simulation impractical. Furthermore, theories and detailed mathematical descriptions are still evolving for some of the important phenomena due to the multiphysics nature of the welding processes and their nonlinear interactions (Ref 5).

A prerequisite for developing sound models is the theoretical understanding of the problem that will be modeled numerically. Several excellent textbooks and review papers can be found in the reference section of this article. Other articles in the present Handbook are also good sources.

Because of the complexity of fusion welding, simplifications and assumptions are generally required to make the simulation tractable. Different approaches have been developed to model the heat and mass transfer in fusion welding, and each approach has its own strengths and weaknesses. Some consideration for choosing the modeling approach is discussed in the following.

For arc welding, an important option of modeling of heat and mass transfer in the weld pool is whether to directly simulate the arc plasma. For simplicity, the majority of the models published in the literature rely on prescribing heat flux distribution on the weld pool surface instead of direct arc plasma simulation.

A Gaussian profile is typically used for the heat flux distribution (Ref 6). Clearly, this approach will fall short when answering questions such as how the shielding gas composition affects the nugget penetration. There are several published efforts aimed at coupling the arc plasma with the weld pool. However, those models are currently limited to relatively simple gas tungsten arc or gas metal arc spot welding (Ref 7).

Unlike stress models where the transient formulation is typically used, the weld pool model often employs the quasi-steady-state formulation. In this formulation, a coordinate system that is attached to the welding heat source is used, and the material flows through the calculation domain (Ref 8). The temperature and flow velocities at a spatial location do not change with time when viewed in the moving coordinate system. This formulation fits well the Eulerian method used to discretize the mathematical equations of conservation where the material flows through the mesh. The main advantage of the quasi-steady-state formulation is that it is very efficient, because it requires 1 to 2 orders of magnitude less computational power than the transient formulation. On the other hand, the quasi-steady-state formulation is limited to linear welding and cannot capture transient behaviors such as those encountered in weld start and stop. Obviously, the transient formulation is needed for situations where the detailed dynamics are important, for example, the droplet transfer to weld pool.

In the autogenous GTAW and conduction-mode laser or electron beam welding, the weld pool surface is assumed to be flat and its position is known. However, the weld pool surface can be severely deformed by the arc pressure and droplet impingement in arc welding and the recoil force due to vaporization in laser and electron beam welding. In those situations, the position of the weld pool surface must be determined as part of the simulation, a requirement that adds significant complexity to the numerical model. The transport equation with additional variables (such as volume of fluid) is solved in order to track the evolution of the weld pool surface. More details on the free surface flow are provided in the section "Free Surface Flow" in this article.

A practical choice is the software platform (commercial, in-house, or open source) on which the weld model will be developed. Commercial programs typically offer a complete package of preprocessing (especially mesh generation), solving, and postprocessing (especially visualization of results). User-defined functions (or subroutines) can be used for implementation of specific functionalities relevant to the weld model. The specific functionalities needed for weld modeling can sometimes be difficult to realize due to the limitations in user-defined functions. In-house code gives full control over the implementation of the numerical solver. At the same time, development and quality-assurance efforts can be much more demanding

for in-house code than for commercial software. Open-source codes may offer flexibility in accessing and modifying the underlying numerical solver without the need to reimplement the basic numeric functions. However, to date (2011), there seems to be little work on the application of open-source code for weld modeling in the published literature.

Once a converged numerical solution is obtained, the validity of simulated results must be carefully examined. Experimental validation can include the comparison between the calculated and measured fusion zone size and shape and temperature profiles. It can also be beneficial to compare the simulated results with the published work for similar welding conditions. Finally, it is noted that there are always uncertainties in the input parameters (such as arc efficiency) of a model. Inverse modeling, discussed later in the section "Reliability of Models," can be a useful tool to reduce the uncertainties and improve model reliability.

Mathematical Description

Governing Transport Equations

The transport equations are available in many standard textbooks (Ref 9, 10). In this section, a concise summary of the governing transport equations for weld heat and mass transfer is provided. It is noted that these equations are applicable to both the weld pool and the arc plasma. For clarity, the following discussion is for the weld pool heat and mass transfer. The specifics relevant to the arc plasma are presented in a later section.

If an incompressible, laminar, and Newtonian liquid flow is assumed in the weld pool, the circulation of liquid metal can be represented by the following momentum equation:

$$\rho \frac{\partial u_j}{\partial t} + \rho \frac{\partial (u_i u_j)}{\partial x_i} = \frac{\partial}{\partial x_i} \left(\mu \frac{\partial u_j}{\partial x_i} \right) + S_j \quad (\text{Eq 1})$$

where ρ is the density, t is the time, x_i is the distance along the i^{th} ($i = 1, 2, \text{ and } 3$) direction, u_j is the velocity component along the j^{th} direction, μ is the viscosity, and S_j is the source term for the j^{th} momentum equation, which is as follows:

$$S_j = -\frac{\partial p}{\partial x_j} - C \left(\frac{(1 - f_L)^2}{f_L^3 + B} \right) u_j + S_{e_j} + S_{b_j} \quad (\text{Eq 2})$$

where p is the pressure. In Eq 2, the first term on the right side is the pressure gradient. The second term represents the frictional dissipation in the mushy zone according to the Carman-Kozeny equation for flow through a porous media (Ref 11), where f_L is the liquid fraction, B is a very small computational constant introduced to avoid division by zero, and C is a constant accounting for the mushy-zone morphology. The third and fourth terms, S_{e_j} and S_{b_j} , correspond to the electromagnetic and

buoyancy source terms, respectively. Their calculations are discussed in the section "Boundary Conditions" in this article.

The following continuity equation is solved in conjunction with the momentum equation to obtain the pressure field:

$$\frac{\partial u_i}{\partial x_i} = 0 \quad (\text{Eq 3})$$

To track the weld pool liquid-solid interface, that is, the phase change, the enthalpy-porosity method is commonly used (Ref 11). In this method, the total enthalpy, H , is represented by a sum of sensible heat, h , and latent heat content, ΔH , that is, $H = h + \Delta H$. The sensible heat, h , is expressed as:

$$h = \int C_p dT$$

where C_p is the specific heat, and T is the temperature. The latent heat content, ΔH , is given as $\Delta H = f_L L$, where L is the latent heat of fusion. The liquid fraction, f_L , can be assumed to vary linearly with temperature for simplicity:

$$f_L = \begin{cases} 1 & T > T_L \\ \frac{T - T_S}{T_L - T_S} & T_S \leq T \leq T_L \\ 0 & T < T_S \end{cases} \quad (\text{Eq 4})$$

where T_L and T_S are the liquidus and solidus temperatures, respectively. Thus, the thermal energy transportation in the weld workpiece can be expressed by the following modified energy equation:

$$\rho \frac{\partial h}{\partial t} + \rho \frac{\partial (u_i h)}{\partial x_i} = \frac{\partial}{\partial x_i} \left(\frac{k}{C_p} \frac{\partial h}{\partial x_i} \right) + S_h \quad (\text{Eq 5})$$

where k is the thermal conductivity. The source term S_h is due to the latent heat content and is as follows:

$$S_h = -\rho \frac{\partial (\Delta H)}{\partial t} - \rho \frac{\partial (u_i \Delta H)}{\partial x_i} \quad (\text{Eq 6})$$

If the transport of species in the weld pool is of interest, the governing equation is as follows:

$$\rho \frac{\partial C_A}{\partial t} + \rho \frac{\partial (u_i C_A)}{\partial x_i} = \frac{\partial}{\partial x_i} \left(D_A \frac{\partial C_A}{\partial x_i} \right) + S_{rxn} \quad (\text{Eq 7})$$

where C_A is the concentration of species A (such as sulfur), D_A is the diffusion coefficient of species A in the molten metal, and S_{rxn} is the volumetric reaction rate (equal to zero if there is no chemical reaction).

Equations 1 through 7 are based on the transient formulation. As discussed previously, the quasi-steady-state formulation is extensively used in modeling heat and mass transfer in the weld pool because of its high efficiency. In the coordinate system that moves along with the heat source, the energy conservation equation can be rewritten as follows:

$$\rho \frac{\partial (u_i h)}{\partial x_i} = \frac{\partial}{\partial x_i} \left(\frac{k}{C_p} \frac{\partial h}{\partial x_i} \right) - \rho \frac{\partial (u_i \Delta H)}{\partial x_i} - \rho U_w \frac{\partial h}{\partial x_1} - \rho U_w \frac{\partial \Delta H}{\partial x_1} \quad (\text{Eq 8})$$

where U_w is the welding speed in direction 1. The last two terms in Eq 8 represent the convective heat transfer due to the bulk material flow through the calculation domain at the welding speed. Similar equations can be formulated for the momentum and species conservation equations, and the details are available elsewhere in the literature (Ref 6, 8, 12).

Boundary Conditions

Heat Transfer into the Weld Pool. As discussed earlier, the prescribed heat flux distribution is typically used for the simulation of heat transfer and fluid flow in the weld pool, because the direct modeling of arc plasma and its interaction with the weld pool currently remains a challenging effort. For arc welding, the following Gaussian profile has been widely used to describe the heat flux distribution at the weld top surface:

$$q(r) = \frac{f_d \eta VI}{\pi r_b^2} \exp\left(-f_d \frac{r^2}{r_b^2}\right) \quad (\text{Eq 9})$$

where q is the heat flux at a given location at the weld top surface, r is the distance between the specific location and the heat source center, f_d is a distribution factor, V and I are the arc voltage and current, respectively, η is the arc efficiency, and r_b is the arc radius. The values of f_d , η , and r_b depend on the particular welding conditions, including electrode tip angle, arc length, shielding gas composition, and so on. Although arc plasma models (described in the section "Welding Arc Plasma" in this article) are increasingly used to determine these values, the current practice still relies largely on empirical data. Among the three parameters, the efficiency value has a significant effect on the resulting shape and size of the weld pool and the temperature distribution in the HAZ. Kou has summarized the efficiencies of the heat sources in various welding processes (Ref 2). An empirical formula for estimating arc efficiency is developed by Arenas et al. (Ref 13) based on the experimental data of Tsai and Eagar (Ref 14):

$$\eta = 7.48 \frac{r_b^{0.63} R_c^2}{L^{0.8} IV} \quad (\text{Eq 10})$$

where L is the arc length (mm), I is the arc current (A), V is the arc voltage (V), and R_c is the effective arc radius (mm), which is related to the arc radius r_b by the equation $R_c = 2.13 r_b$.

As shown in Eq 9, f_d and r_b together define the shape of the Gaussian profile. Higher f_d and smaller r_b indicate a more constrained and intense arc for the same arc efficiency, and vice versa. In the literature, two typical values of f_d have been reported. The f_d value of 3.0 seems to be favored for laser welding, whereas the value of 0.5 is favored for arc welding. When comparing r_b values, it is important to know the f_d value, because it is their combined form:

$$r_b / \sqrt{f_d}$$

that defines the shape of the Gaussian distribution.

In GMAW, the molten metal formed from the consumable electrode can carry a substantial amount of heat, mass, and momentum into the weld pool. Transient models based on the interface-capturing approach have been used to directly simulate the impingement of individual droplets into the weld pool. An alternative method for describing the heat transfer by droplets is the placement of an imaginary cylindrical volumetric heat source in the weld pool underneath the arc (Ref 6, 15, 16). This simplified method is found to be effective in capturing finger penetration in the fusion zone of GMAW.

The Gaussian heat flux distribution given in Eq 9 is also used for conduction-mode laser and electron beam welding. Heat transfer in keyhole-mode laser and electron beam welding is much more complex. Similar to the handling of heat transfer from metal droplets in GMAW, heat transfer from the keyhole can be either simulated directly or approximated using a volumetric heat source. More details are given in the section "Application to Fusion Welding Processes" in this article.

Driving Forces for Fluid Flow. Figure 1 is a schematic drawing of various driving forces for fluid flow in a gas tungsten arc weld pool (Ref 2, 17). The equations for calculating those forces are discussed in the following.

The electromagnetic force (\vec{F}_{emf}), shown in Fig. 1(a), can be calculated as:

$$\vec{F}_{\text{emf}} = \vec{J} \times \vec{B} \quad (\text{Eq 11})$$

where \vec{J} is the current density vector, and \vec{B} is the magnetic flux vector. The following analytical expressions developed by Kou and Sun (Ref 18) are widely used to calculate the \vec{J} and \vec{B} fields in the workpiece:

$$J_z = \frac{I}{2\pi} \int_0^\infty \lambda J_0(\lambda r) \exp(-\lambda^2 \sigma_j^2 / 12) \frac{\sin h[\lambda(c-z)]}{\sin h(\lambda c)} d\lambda \quad (\text{Eq 12a})$$

$$J_r = \frac{I}{2\pi} \int_0^\infty \lambda J_1(\lambda r) \exp(-\lambda^2 \sigma_j^2 / 12) \frac{\cos h[\lambda(c-z)]}{\sin h(\lambda c)} d\lambda \quad (\text{Eq 12b})$$

$$B_\theta = \frac{\mu_m I}{2\pi} \int_0^\infty J_1(\lambda r) \exp(-\lambda^2 \sigma_j^2 / 12) \frac{\sin h[\lambda(c-z)]}{\sin h(\lambda c)} d\lambda \quad (\text{Eq 12c})$$

where J_z is the vertical component of the current density, I is the current, J_0 is the Bessel

function of zero order and first kind, r is the radial distance from the arc center, σ_j is the current radius of the arc, c is the thickness of the workpiece, z is the vertical distance from the top surface, J_r is the radial component of current density, J_1 is the first kind of Bessel function of first order, B_θ is the angular component of the magnetic field, and μ_m is the magnetic permeability of the material. Because the electrical current distribution is assumed to be axisymmetric, J_θ , B_r , and B_z are equal to zero. Recently, Kumar et al. (Ref 19) used a numerical integration method to calculate the current density in the workpiece and then calculate the magnetic field using the Biot-Savart law. Zhang et al. (Ref 20) solved the electrical potential and the magnetic vector potential conservation equations using the finite-volume method for a moving arc in orbital GTAW of an aluminum alloy tube.

Marangoni shear stress (i.e., the spatial gradient of surface tension) arises as a result of spatial variation of temperature and composition, which can be expressed as:

$$\tau = \frac{\partial \gamma}{\partial T} \frac{\partial T}{\partial r} + \frac{\partial \gamma}{\partial C} \frac{\partial C}{\partial r} \quad (\text{Eq 13})$$

where τ is the shear stress due to surface tension (γ), T is the temperature, r is the distance along the surface, and C is the concentration of surface active element. In most cases, the $\partial \gamma / \partial C$ term is zero, and the shear stress depends only on $\partial \gamma / \partial T$ and the spatial temperature gradient $\partial T / \partial r$ at the pool surface. A widely used expression for calculating $\partial \gamma / \partial T$ as a function of both temperature and composition was developed by Sahoo et al. (Ref 21):

$$\frac{\partial \gamma}{\partial T} = A - R\Gamma_s \ln(1 + K a_i) - \frac{K a_i}{(1 + K a_i)} \frac{\Gamma_s (\Delta H^0 - \Delta \bar{H}_i^M)}{T} \quad (\text{Eq 14})$$

where A is the $\partial \gamma / \partial T$ value for pure metal, Γ_s is the surface excess at saturation, K is the adsorption coefficient, a_i is the activity of species i in the solution, ΔH^0 is the standard heat of adsorption, and $\Delta \bar{H}_i^M$ is the partial molar enthalpy of mixing of species i in the solution. Equation 14 shows that the value of $\partial \gamma / \partial T$ can be dramatically altered if a small yet significant amount of surface active elements such as sulfur and oxygen is present in the weld pool. The effect of $\partial \gamma / \partial T$ on the fluid flow pattern is illustrated in Fig. 1(b) and 1(c). Computed patterns of weld pool fluid flow driven by Marangoni shear stress are provided in the GTAW section.

The Boussinesq approximation is typically used in the calculation of buoyancy-force-driven flow, shown in Fig. 1(d). The buoyancy force can be expressed as:

$$F_b = \rho g \beta (T - T_{\text{ref}}) \quad (\text{Eq 15})$$

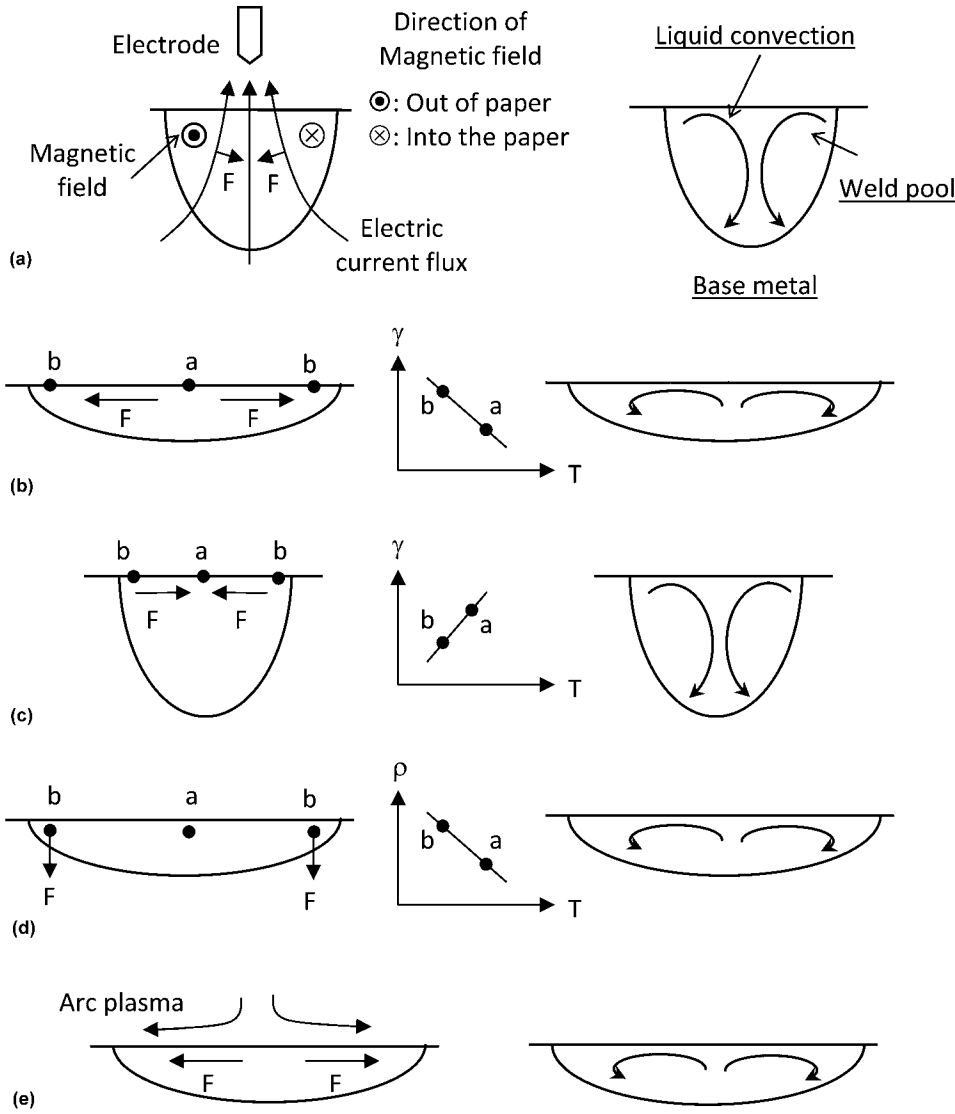

Fig. 1 Various driving forces and the resulting liquid convection in a gas tungsten arc weld pool. (a) Electromagnetic force. (b) Surface tension gradient force with negative $\partial\gamma/\partial T$. (c) Surface tension gradient force with positive $\partial\gamma/\partial T$. (d) Buoyancy force. (e) Plasma jet shear stress. The symbol γ is the surface tension, $\partial\gamma/\partial T$ is the temperature coefficient of surface tension, T is the temperature, ρ is the density, a and b are two locations in the weld pool, and F is the driving force. Adapted from Ref 17

where ρ is the density of liquid metal, g is the acceleration due to gravity, β is the thermal expansion coefficient, T is the temperature of the liquid metal, and T_{ref} is a reference temperature, often chosen to be the solidus temperature (T_S).

As shown in Fig. 1(e), the arc plasma moves outward at high speeds along the weld pool surface, which can exert an outward shear stress at the pool surface. It has been shown that the plasma shear stress may dominate both electromagnetic and surface tension gradient forces as the driving force for liquid convection when a long arc is used in GTAW (Ref 22). The arc plasma shear stress (τ_{ps}) is calculated based on Newton's law of viscosity:

$$\tau_{\text{ps}} = \mu_p \frac{\partial \vec{V}}{\partial \vec{n}} \quad (\text{Eq 16})$$

where μ_p is the viscosity of arc plasma, and the term $\partial \vec{V} / \partial \vec{n}$ represents the plasma flow velocity gradient in the direction normal to the weld pool surface. The calculation of the plasma shear stress using Eq 16 requires the direct simulation of arc plasma. As an alternative method, Cho (Ref 23) used an analytical solution of the wall shear stress produced by the normal impingement of a jet on a flat surface (Ref 24).

Turbulence

Due to the high energy density of the heat source in fusion welding, the top surface of

the weld pool experiences steep temperature gradients. The resulting strong surface tension gradients along with the other driving forces for fluid flow (electromagnetic, buoyancy, etc.) result in very high velocities in small weld pools (Ref 25–27). For example, surface velocities of the order of 1 m/s were measured by Ki et al. (Ref 27). Such high velocities in small confined spaces typically lead to turbulent weld pools. A criterion has been given by Atthey (Ref 28), based on weld pool width (w), maximum velocity (u_{max}), density (ρ), and viscosity (μ). The weld pool flow is turbulent if the following condition is met:

$$\text{Re} = \frac{\rho u_{\text{max}} w}{\mu} > 600 \quad (\text{Eq 17})$$

In a turbulent weld pool, the fluctuating velocity components increase the rates of heat and momentum transport in the weld pool. The enhanced rates of transport can be accounted for in the numerical model by taking “effective” values of viscosity and thermal conductivity (Ref 29). The turbulent thermal conductivity (k_t) is given as:

$$k_t = \frac{\mu_t C_p}{\text{Pr}_t} \quad (\text{Eq 18})$$

where μ_t is the turbulent viscosity, and Pr_t is the turbulent Prandtl number, which ranges between 0.7 and 0.9 (Ref 26, 30, 31). Various turbulence models are used to calculate the turbulent viscosity. Those models may be classified into categories depending on the number of equations that must be solved.

Zero-equation (or algebraic) turbulence models derive the turbulence characteristics from the average flow variables and do not require solution of additional equations. Although not as accurate as one-equation or two-equation models, they are simpler to use. According to mixing-length theory, the turbulent viscosity can be given as (Ref 26, 29):

$$\mu_t = \rho l_m u_m \quad (\text{Eq 19})$$

where μ_t is the density, l_m is the characteristic length scale for mixing, and u_m is the characteristic velocity. Several methods exist for the determination of l_m and u_m . One of the methods for calculating l_m is as follows (Ref 25, 29, 32):

$$l_m = \kappa y \left[1 - e^{-y^+ / A_0^+} \right] \quad (\text{Eq 20})$$

where $\kappa = 0.41$, and $A_0^+ = 26.0$:

$$y^+ = y \sqrt{\frac{\rho}{\mu} \left(\frac{\partial u}{\partial y} \right) \Big|_w}$$

where the term:

$$\left(\frac{\partial u}{\partial y} \right) \Big|_w$$

is the velocity gradient at the weld pool boundary.

One of the methods for determining u_m is given as:

$$u_m = l_m |\omega| = l_m \sqrt{\left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}\right)^2 + \left(\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z}\right)^2} + \sqrt{\left(\frac{\partial u}{\partial z} - \frac{\partial w}{\partial x}\right)^2} \quad (\text{Eq 21})$$

where ω is vorticity (Ref 25, 29, 32).

A one-equation model solves a single partial differential equation for a turbulence variable. Prandtl's one-equation model (Ref 29), for example, solves an equation for the turbulent kinetic energy (k_t):

$$\rho \frac{\partial k_t}{\partial t} + \rho \frac{\partial(u_i k_t)}{\partial x_i} = \frac{\partial}{\partial x_i} \left(\mu + \frac{\mu_t}{\sigma_k} \frac{\partial k_t}{\partial x_i} \right) + G - \frac{C_\mu \rho k_t^{3/2}}{l} \quad (\text{Eq 22})$$

where G is the rate of generation of turbulence energy, and σ_k and C_μ are two model constants. The turbulent viscosity can be determined from k_t by the equation $\mu_t = \rho k_t^{1/2} l$, where l is the Kolmogorov length scale (Ref 29).

The two-equation models solve two partial differential equations for turbulence. Generally, one of the equations is for the turbulent kinetic energy. The other equation solves for another characteristic of the turbulent flow, such as the turbulent dissipation rate, ε (k - ε model), or the specific dissipation rate, ω (k - ω model). The k - ε model is frequently used for welding processes (Ref 15, 31, 33) and involves the solution of the following equations for turbulent kinetic energy, k_t , and dissipation rate, ε :

$$\rho \frac{\partial k_t}{\partial t} + \rho \frac{\partial(u_i k_t)}{\partial x_i} = \frac{\partial}{\partial x_i} \left(\mu + \frac{\mu_t}{\sigma_k} \frac{\partial k_t}{\partial x_i} \right) + G - \rho \varepsilon \quad (\text{Eq 23})$$

$$\rho \frac{\partial \varepsilon}{\partial t} + \rho \frac{\partial(u_i \varepsilon)}{\partial x_i} = \frac{\partial}{\partial x_i} \left(\mu + \frac{\mu_t}{\sigma_\varepsilon} \frac{\partial \varepsilon}{\partial x_i} \right) + \frac{C_1 \varepsilon G}{k_t} - \frac{C_2 \rho \varepsilon^2}{k_t} \quad (\text{Eq 24})$$

where σ_ε , C_1 , and C_2 are model constants. μ_t can be calculated from k_t and ε because $\mu_t = C_\mu \rho k_t^2 / \varepsilon$, where C_μ is another model constant.

Boundary Conditions for Turbulent Flow. To apply the k - ε model to simulate weld pool turbulence, the zero flux boundary condition is typically used at the top surface:

$$\frac{\partial k_t}{\partial z} \Big|_{z=0} = 0, \text{ and } \frac{\partial \varepsilon}{\partial z} \Big|_{z=0} = 0 \quad (\text{Eq 25})$$

where $z = 0$ corresponds to the top surface. Near the solid-liquid boundaries, turbulence dies down, and the effective values of viscosity

and thermal conductivity reach their molecular values. A computationally efficient way to model the behavior near the wall is through the use of wall functions (Ref 34). However in the enthalpy-porosity method, there is no explicitly defined boundary between the weld pool and the surrounding solid; hence, no boundary condition or wall function is imposed at the weld pool boundary (Ref 15). An alternative method is used by Hong et al. (Ref 31), in which one block of elements is always kept in the liquid phase and the other block of elements is always in the solid phase. The interface between the two blocks of elements conforms to the weld pool boundary by way of dynamic mesh remapping. At this clearly defined solid-liquid interface, boundary conditions for turbulent kinetic energy and dissipation rate are:

$$k_t = \frac{u_\tau^2}{\sqrt{C_\mu}} \quad (\text{Eq 26a})$$

$$\varepsilon = \frac{C_\mu^{3/4} k_t^{3/2}}{\lambda d_n} \quad (\text{Eq 26b})$$

where u_τ is a function of local velocity, d_n is the shortest distance from the solid-liquid boundary to the mesh node where the wall function is applied, and λ is a constant.

Free Surface Flow

From the computational fluid dynamics point of view, weld pool fluid flow phenomena fall into the class of flows with moving boundaries, especially the surface-tension-dominated free-surface flow regime. There are two major numerical approaches for free-surface-flow modeling: interface tracking and interface capturing (Ref 35). In the interface-tracking approach, a boundary-fitted moving mesh is used and the free surface shape is exactly tracked. Boundary conditions such as the heat flux and surface tension can be precisely applied at the free surface. However, this approach is not suited for problems involving the breakup or coalescence of fluids (such as the impingement of metal droplets into the weld pool). Unlike the interface-tracking approach, the interface-capturing method uses stationary grids to resolve the location of the free surface. Additional variables, such as the volume fraction of each fluid, are solved in conjunction with the continuity and momentum conservation equations. The free-surface location is then extrapolated based on the gradient of the volume fraction. The volume-of-fluid (Ref 36) and level-set (Ref 37) methods are two representative methods in the interface-capturing approach. Very fine grids are required in order to obtain sufficiently accurate representation of the interface. As a result, the calculation can be computationally intensive.

The published literature on weld pool models can be divided into three groups according to the handling of the free surface. First, in the simplest situation of autogenous GTAW and conduction-mode laser and electron beam welding without filler-metal addition, the weld pool free surface is assumed to be rigid and does not deform. In other words, the position of the weld pool free surface is known and there is no need to solve for the surface position. Second, in the quasi-steady formulation, the weld pool free surface position is unknown, but it does not vary with time. The interface-tracking approach can be used where the surface position is determined by solving a total surface energy minimization equation. This method can be applied to GTAW with and without filler metal and GMAW. Third, transient models based on the interface-capturing approach are used to calculate the evolution of weld pool free surface with time. These transient models are suitable for describing the dynamic impingement of metal droplets into the weld pool and the liquid-vapor interface evolution in laser keyhole welding. Results from each group of models are presented in the section "Application to Fusion Welding Processes" in this article.

Welding Arc Plasma

There are many approaches and models for numerical investigation of transport phenomena in electric arc plasma, as well as of its interaction with electrodes, for various arc welding processes (Ref 38–44). In the majority of the published models (Ref 38–43), the arc plasma is considered to comprise a single component, that is, atoms and ions of shielding or plasma gas, which is usually inert. In reality, arc plasma is multicomponent, because it contains atoms and ions of the evaporated material of electrodes along with the gas particles. Therefore, an adequate mathematical model of the welding arc must allow for the multicomponent nature of the arc plasma (Ref 44, 45). Such a model must have another important characteristic: self-consistency, which makes it possible to account for the interrelation of physical processes occurring at electrodes and in the near-electrode regions with processes occurring in arc column plasma. A recent review on metal vapor in the welding arc is provided in Ref 45.

A self-consistent mathematical model of energy, mass, and charge-transfer processes taking place in the anode region and the arc column plasma in GTAW and GMAW can be developed using an approach in which the near-anode plasma bulk is conditionally subdivided into three zones (Fig. 2) (Ref 39, 46, 47). The first zone directly adjoining the anode surface is a space charge layer (sheath), wherein the condition of quasi-neutrality of plasma is violated and the main potential drop between the plasma and anode surface is

Fig. 2 Structure of near-anode plasma, scale lengths, flows of particles, and potential distribution in anode region of welding arc

formed. This layer can be considered as collisionless. The conditions for the sheath are:

- Pressure close to the atmospheric pressure
- Electron temperature (T_e) approximately 1 eV
- Thickness of this layer (\bar{x}), with a Debye radius (r_D) of approximately 10^{-8} m, which is much smaller than the characteristic lengths of free path (λ) (approximately 10^{-7} to 10^{-5} m) of the plasma particles (Ref 47)

The second zone is an ionization region of the nonisothermal quasi-neutral plasma (presheath), wherein the charged particles are generated by plasma electron ionization of the gas atoms desorbed from the metallic anode surface and of the evaporated metal atoms. The ions formed in this zone are accelerated toward the anode surface by the electric field, induced by more mobile electrons, and are recombined near the anode surface. Therefore, the condition of local ionization equilibrium is violated within this zone. Moreover, a marked change in the plasma potential takes place in the presheath, which can be comparable to its drop in the sheath. The third zone beginning outside the Knudsen layer, comprising the sheath and presheath, is a gas-dynamic region with a local thermodynamic equilibrium formed therein.

The self-consistent model of transport phenomena in welding arc includes two interrelated models: a model of the thermal, electromagnetic, gas-dynamic, and diffusion processes occurring in the multicomponent plasma of the arc column, and a model of the anode region. The thickness of Knudsen-layer boundary (L^0) is equal to several lengths of free path of the heavy particles (typically $L^0 < 10^{-4}$ m). Because L^0 is much smaller than the curvature radius of the anode surface (electrode metal droplet or weld pool), $R \sim 10^{-3}$ m, as well as characteristic scales in the arc column, the anode region can be assumed to be flat and infinitely thin. Therefore, the anode region is treated as a discontinuity surface in the self-consistent model, which makes it possible

to formulate boundary conditions at the anode surface required to solve the equations of the arc column model as well as to determine the characteristics of the thermal and dynamic effect of the welding arc on the droplet or weld pool surface.

Anode Region. To describe the processes occurring in the anode region of the arc with an evaporating anode, the plasma at the external boundary of this region is characterized by the following parameters: n_e^0 is the concentration of electrons; $n_{\alpha Z}^0$ is the concentration of atoms (charge number $Z = 0$) and ions ($Z = 1$) of the shielding gas (kind of particles $\alpha = g$), atoms ($Z = 0$), and ions ($Z = 1, 2$) of the metal vapor ($\alpha = m$); Ze is the ion charge; e is the elementary charge; T_e^0 is the electron temperature; T_h^0 is the temperature of the heavy particles, which is assumed to be identical for all kinds of atoms and ions but different from T_e^0 (i.e., this is a two-temperature plasma model); m_e is the electron mass; M_α is the masses of heavy particles (atoms and ions) of gas ($\alpha = g$) and metal ($\alpha = m$); and j_a is the electric current density at the anode surface. As noted previously, the anode region is considered as infinitely thin. Therefore, n_e^0 , $n_{\alpha Z}^0$, T_e^0 , T_h^0 , and j_a are specified at a given point on the anode surface, which is characterized by a local value of surface temperature (T_s).

It is assumed that all ions that go to the anode surface recombine there and return in the form of atoms, and that the current of electrons emitted by the anode is negligibly small, that is, that the electric current at the anode consists only of electrons and ions coming from the plasma. The current density at the anode surface is expressed as follows:

$$j_a = j_e - j_i (j_a > 0) \quad (\text{Eq 27})$$

where j_e is the electron current density and:

$$j_i = \sum_{\alpha=m,g;Z \geq 1} j_{\alpha Z}$$

is the total ion current density (for ions of all kinds and charge numbers).

Because the plasma potential is, as a rule, higher than that of the anode surface (Ref 39), electrons are decelerated by the electric field, and ions are accelerated toward the anode surface. In this case, the electron current density at the anode can be represented as (Ref 47):

$$j_e = \frac{1}{4} e n_e^0 v_{Te} \exp\left(-\frac{e\phi^0}{kT_e^0}\right) (\phi^0 > 0) \quad (\text{Eq 28})$$

where:

$$v_{Te} = \sqrt{\frac{8kT_e^0}{\pi m_e}}$$

is the thermal velocity of electrons at the external boundary of the anode region, k is the Boltzmann constant, and ϕ^0 is the plasma potential with respect to the anode surface (Fig. 2).

To determine the ion current, it is possible to use an approach based on the fact that the length of free path of ions relative to Coulomb collisions between them is much smaller than the length of their free path at collision with atoms and the ionization length (Fig. 2). This suggests that ions in the presheath are intensively maxwellized and acquire the common velocity. The value of the common velocity at the boundary between the presheath and the sheath is determined by the following equations (Ref 47):

$$\bar{V}_i \equiv V_i(\bar{x}) = \sqrt{\frac{\sum_{\alpha=m,g;Z \geq 1} k(ZT_e^0 + T_h^0)n_{\alpha Z}^0}{\sum_{\alpha=m,g;Z \geq 1} M_\alpha n_{\alpha Z}^0}} \quad (\text{Eq 29a})$$

$$\bar{V}_i = \frac{w^0}{2} \left[\sqrt{1 + \frac{4 \sum_{\alpha=m,g;Z \geq 1} k(ZT_e^0 + T_h^0)n_{\alpha Z}^0}{(w^0)^2 \sum_{\alpha=m,g;Z \geq 1} M_\alpha n_{\alpha Z}^0}} - 1 \right] \quad (\text{Eq 29b})$$

where w^0 is the vapor velocity at the Knudsen layer boundary. Equation 29(a) corresponds to the diffusion mode of evaporation (i.e., $w^0 \approx 0$), whereas Eq 29(b) corresponds to the convective mode of evaporation of the anode metal (i.e., $w^0 > 0$).

The concentration of charged particles at the sheath-presheath boundary can be determined from the following (Ref 46):

$$\begin{aligned} \bar{n}_e &\equiv n_e(\bar{x}) = n_e^0 \exp\left(-\frac{1}{2}\right); \bar{n}_{\alpha Z} \equiv n_{\alpha Z}(\bar{x}) \\ &= n_{\alpha Z}^0 \exp\left(-\frac{1}{2}\right), \alpha = m, g; Z \geq 1 \end{aligned} \quad (\text{Eq 30})$$

Then the ion currents to the anode surface for the diffusion mode of evaporation can be expressed as:

$$j_{\alpha Z} = Ze n_{\alpha Z}^0 \exp\left(-\frac{1}{2}\right) \bar{V}_i, \alpha = m, g; Z > 1 \quad (\text{Eq 31})$$

In the convective mode of evaporation of the anode, the $\exp(-1/2)$ term in Eq 30 and 31 is replaced by (Ref 47):

$$\exp\left[-\frac{(w^0)^2 \sum_{\alpha=m,g;Z \geq 1} M_\alpha n_{\alpha Z}^0}{8 \sum_{\alpha=m,g;Z \geq 1} k(ZT_e^0 + T_h^0)n_{\alpha Z}^0}\right] \left\{ 1 + \sqrt{1 + \frac{4 \sum_{\alpha=m,g;Z \geq 1} k(ZT_e^0 + T_h^0)n_{\alpha Z}^0}{(w^0)^2 \sum_{\alpha=m,g;Z \geq 1} M_\alpha n_{\alpha Z}^0}} \right\}^2$$

In Eq 28 through 31, the values of the electron and ion currents at the anode surface can be calculated. Then, the plasma potential (ϕ^0) relative to this surface or anode potential drop (U_a) can be calculated as follows:

$$U_a \equiv -\phi^0 = -\frac{kT_e^0}{e} \ln\left(\frac{e n_e^0 v_{Te}}{4[j_a + j_i]}\right) (U_a < 0) \quad (\text{Eq 32})$$

To calculate j_e , $j_{\alpha Z}$, and U_a , it is necessary to know temperatures T_e^0 and T_h^0 , as well as concentrations n_e^0 and $n_{\alpha Z}^0$ of the charged particles at the

external boundary of the anode region. Assuming that the multicomponent plasma in the arc column is in an ionization equilibrium state, the composition of the plasma can be determined by using the following system of equations (Ref 47).

The Saha equations allow for nonideality of plasma:

$$\frac{n_e^0 n_{\alpha Z+1}^0}{n_{\alpha Z}^0} = \left(\frac{2\pi m_e k T_e^0}{h^2} \right)^{3/2} \frac{2\theta_{\alpha Z+1}}{\theta_{\alpha Z}}$$

$$\exp \left[-\frac{e(U_{\alpha Z} - \Delta U_Z)}{k T_e^0} \right], \alpha = m, g; Z \geq 0 \quad (\text{Eq 33})$$

where h is the Planck's constant, $\theta_{\alpha Z}$ are the statistical sums for heavy particles of α -kind in charged state Z , $U_{\alpha Z}$ are the ionization potentials (for transfer of the α -kind particles from charged state Z to $Z + 1$), and:

$$\Delta U_Z = \frac{e(Z+1)}{r_D}$$

is the decrease of the ionization potential, where:

$$r_D = \left[k T_e^0 / 4\pi e^2 \left(n_e^0 + \frac{T_e^0}{T_h^0} \sum_{\alpha=m,g;Z \geq 1} (n_{\alpha Z}^0 Z^2) \right) \right]^{1/2}$$

The condition of plasma quasi-neutrality is given by:

$$n_e^0 = \sum_{\alpha=m,g;Z \geq 1} (n_{\alpha Z}^0 Z) \quad (\text{Eq 34})$$

The law of partial pressures is:

$$p = n_e^0 k T_e^0 + \sum_{Z \geq 0} n_{mZ}^0 k T_h^0 + \sum_{Z \geq 0} n_{gZ}^0 k T_h^0 - \Delta p \quad (\text{Eq 35})$$

where p is the plasma pressure near the anode and:

$$\Delta p = \frac{1}{6} \frac{e^2}{r_D} \left(n_e^0 + \sum_{\alpha=m,g;Z \geq 0} (n_{\alpha Z}^0 Z^2) \right)$$

is the decrease in pressure caused by plasma nonideality.

To close the system of Eq 33 through 35, the concentration of the metal vapor particles at the external boundary of the anode region is required. Detailed mathematical equations for determining the metal vapor concentration are provided elsewhere in the literature (Ref 46–48).

Consider now the energy-transfer processes occurring in the anode region of the electric arc. Heat flux, Q_a , from the near-anode plasma to the anode surface has the following form:

$$Q_a = Q_e + Q_i \quad (\text{Eq 36})$$

where Q_e and Q_i are the fluxes of potential and kinetic energy transferred with electrons and ions, respectively. For the convective mode of anode evaporation, the energy Q_v removed from the melt surface by the metal vapor flow

should be taken into account in the energy balance of the anode region:

$$Q_v = \sum_{Z \geq 0} n_{mZ}^0 v^0 \lambda_v \quad (\text{Eq 37})$$

Details for the calculation of Q_e and Q_i are available elsewhere in the literature (Ref 46–48). Figures 3(a) and (b) show the calculation results for a heat flux to the anode characteristic of tungsten inert gas welding of steel in

argon. As indicated by the calculation results, the values of Q_a grow with increase of the electron temperature in the near-anode plasma, the current density at the anode, and the temperature of its surface.

Arc Column. A total of five governing transport equations are solved in the gas-dynamic region of the arc plasma (i.e., the arc column). The first two equations express the conservation of mass and momentum (see the section ‘‘Governing Transport Equations’’

(a)

(b)

Fig. 3 Heat flux to iron anode in argon arc vs. (a) electron temperature in anode region at $T_s = 2472$ K and (b) anode surface temperature at $T_e^0 = 7 \times 10^3$ K. Curve 1: $j_a = 2 \times 10^6$ A/m²; curve 2: 5×10^6 A/m²; and curve 3: 10^7 A/m²

for the expressions). The third equation expresses the conservation of electrical charge (ϕ), which is defined by Poisson's equation, $\nabla(\sigma \nabla \phi) = 0$, where σ is the electrical conductivity of the plasma. The fourth equation expresses the conservation of energy. Two equations are solved to determine the temperatures of electrons (T_e) and heavy particles (T_h). In an axisymmetric coordinate system, these two equations are expressed as follows:

$$n_e C_{pe} \left(\frac{\partial T_e}{\partial t} + v \frac{\partial T_e}{\partial r} + u \frac{\partial T_e}{\partial z} \right) = \frac{1}{r} \frac{\partial}{\partial r} \left(r \chi_e \frac{\partial T_e}{\partial r} \right) + \frac{\partial}{\partial z} \left(\chi_e \frac{\partial T_e}{\partial z} \right) + \frac{k}{e} \left\{ j_r \frac{\partial [5/2 - \delta] T_e}{\partial r} + j_z \frac{\partial [5/2 - \delta] T_e}{\partial z} \right\} + \frac{j_r^2 + j_z^2}{\sigma} - \psi - \beta(T_e - T_h) \quad (\text{Eq 38})$$

$$\rho C_p \left(\frac{\partial T_h}{\partial t} + v \frac{\partial T_h}{\partial r} + u \frac{\partial T_h}{\partial z} \right) = \frac{1}{r} \frac{\partial}{\partial r} \left(r \chi \frac{\partial T_h}{\partial r} \right) + \frac{\partial}{\partial z} \left(\chi \frac{\partial T_h}{\partial z} \right) + \beta(T_e - T_h) \quad (\text{Eq 39})$$

where C_{pe} is the specific heat of the electron gas, χ_e is the electron thermal conductivity, δ is the constant of thermal diffusion of the electrons, ψ is the energy losses due to radiation (in the approximation of an optically thin plasma), β is the coefficient of heat exchange between electrons and heavy particles, C_p is the specific heat of heavy particles, and χ is the thermal conductivity of the heavy particles.

The fifth and final governing transport equation expresses the conservation of species in the multicomponent plasma as:

$$\rho \left(\frac{\partial C_m}{\partial t} + v \frac{\partial C_m}{\partial r} + u \frac{\partial C_m}{\partial z} \right) = \frac{1}{r} \frac{\partial}{\partial r} \left(r \rho D_{m0} \frac{\partial C_m}{\partial r} \right) + \frac{\partial}{\partial z} \left(\rho D_{m0} \frac{\partial C_m}{\partial z} \right) + \frac{1}{r} \frac{\partial}{\partial r} \left(r \rho \left[\bar{D}_{m1} \frac{\partial C_{m1}}{\partial r} + \bar{D}_{m2} \frac{\partial C_{m2}}{\partial r} \right] \right) + \frac{\partial}{\partial z} \left(\rho \left[\bar{D}_{m1} \frac{\partial C_{m1}}{\partial z} + \bar{D}_{m2} \frac{\partial C_{m2}}{\partial z} \right] \right) \quad (\text{Eq 40})$$

where C_m is the relative mass concentration of the metal vapor in the arc column plasma, C_{m1} and C_{m2} are the relative mass concentrations of metal ions, and D_{m0} , D_{m1} , and D_{m2} are the coefficients of diffusion of atoms, single- and double-charged metal ions. In addition, $\bar{D}_{m1} = D_{m1} - D_{m0}$ and $\bar{D}_{m2} = D_{m2} - D_{m0}$.

To solve these governing transport equations in the arc plasma, it is necessary to specify the physical properties as well as the boundary conditions determined from the anode region

model discussed in the section "Welding Arc Plasma" in this article. Details are available in Ref 46 and 47. The previous discussion completes the description of the self-consistent mathematical model of energy, mass, and charge transfer in the arc column plasma and anode region of the welding arc for GTAW and GMAW in inert gas.

Cathode Region. Similar to the anode region, there exists a cathode sheath region between the cathode and the plasma. Lowke et al. (Ref 49) considered the principal heating mechanism due to the ion current at the tungsten cathode surface in GTAW. The ion current is assumed to be equal to the difference between the theoretical thermionic emission current and the electron current. No consideration is made of the space charge sheath at the cathode. Ion current heating at the cathode surface is also considered in the GTAW arc model by Goodarzi et al. (Ref 50). In their model, the current density distribution on the cathode surface was adjusted so that the total current entering was equal to the applied current. The cathode fall voltage was determined based on the assumption that the electrons were in a free fall across the cathode sheath.

In GMAW, the workpiece is typically the cathode, whereas the consumable electrode is the anode. Murphy et al. (Ref 51) calculated the heat flux at the cathode (workpiece) surface by taking into account the influence of the measured cathode sheath voltage in accelerating electrons to excite atoms and the work function of the workpiece material. In the GMAW arc model by Hu and Tsai (Ref 52), the conduction heat exchange between plasma and workpiece at the cathode surface was taken into account, whereas the thermal effect due to the cathode sheath was not considered.

From the previous discussion, it is evident that a significant challenge in modeling welding arc plasma arises from the anode and cathode regions. Models employing closed-form expressions for describing the anode and cathode regions have demonstrated their usefulness in studying the effect of shield gases and active flux on the resulting weld pool geometry. Detailed numerical modeling of transport phenomena in the anode and cathode regions will help further improve the current understanding of heat and mass transfer in the complex welding arc.

Numerical Solution

Grid (or mesh) generation is an important consideration in computing numerical solutions to the partial differential equations governing the welding process. The generation of a mesh is an important numerical issue; the type and quality of mesh can determine the success or failure of the numerical model in attaining a

converged and accurate solution. Computational fluid dynamics (CFD) requires the subdivision of the computational domain into a number of smaller elements or grid cells, and the discretized domain needs to have adequate spatial resolution. During weld pool modeling, sufficiently fine mesh should be used to provide an adequate resolution of the important flow features in the weld pool. For turbulence models, it is recommended that recirculation vortices or steep flow gradients within the viscous boundary layers be properly resolved through local refining.

When the geometry is simple and regular, the most straightforward approach is to employ an orthogonal grid in a Cartesian coordinate framework. This type of grid is generally called a structured mesh. Structured mesh can also be applied for a more complicated geometry by creating a nonorthogonal mesh with deformed body-fitted grids. In this method, grid cells still retain a regular element shape in the form of either a skewed rectangle in two dimensions or a distorted hexahedron in three dimensions. The advantage of such a mesh is that the connectivity is straightforward because cells adjacent to a given elemental face are identified by the indices, and the cell edges form continuous mesh lines that begin and end on opposite elemental faces. The disadvantage, particularly for more complex geometry, is the increase in grid nonorthogonality or skewness, which can generate physically unrealistic solutions upon the transformation of the governing equations. The transformed equations, which accommodate the nonorthogonality, contain additional terms acting as the link between the structured coordinate system (such as the Cartesian coordinate) and the body-fitted (curvilinear) coordinate system, thereby augmenting the cost of numerical calculations and difficulties in programming. Consequently, such a mesh may also affect the accuracy and efficiency of the numerical algorithm that is being applied. Block-structured or multiblock mesh is another special case of a structured mesh.

Another meshing approach is based on what is called unstructured mesh, in which the cells are allowed to be assembled freely within the computational domain. The most typical shapes of unstructured elements in three dimensions are tetrahedral and hexahedral cells. Unstructured meshes are well suited for handling arbitrary shape geometries, especially for domains having high-curvature boundaries. However, there are several disadvantages to unstructured mesh. If triangular or tetrahedral cells with high aspect ratio (very long and thin shape) are placed adjacent to the wall boundaries, this configuration may create large inaccuracies in the approximation of the diffusive fluxes. Other disadvantages are the extra bookkeeping effort required to handle the connectivity of elemental cells, and the more complex solution algorithms needed to solve the flow-field variables, each of

which may result in increased computing times and erode the gains in computational efficiency. In recent years, many commercial CFD codes have made available the capabilities to mesh the interior domain using polyhedral cells. Polyhedral meshing has tremendous advantages over tetrahedral meshing with regard to computational accuracy and efficiency. An important aspect of the unstructured mesh is the mesh quality, which can be measured by such factors as aspect ratio, skewness, and warp angle. For instance, large aspect ratios should always be avoided in weld pool regions, because they can degrade the solution accuracy and may result in poor convergence.

Methods for discretizing and solving the governing transport equations are discussed in many textbooks. The majority of the published heat and mass transfer models are based on the control volume method (and its variations, including finite-volume and finite-difference methods). An excellent textbook on the control volume method is provided by Patankar (Ref 10). With the recent advance in computation, the numerical solution of transport equations has been implemented into fairly sophisticated solvers. The availability of such solvers allows one to focus on the specifics relevant to weld transport phenomena without expending much effort on basic code development. See the section "Important Considerations" for a discussion of the choice of solvers.

Dimensional Analysis

Although a detailed numerical solution is required to describe weld pool transport phenomena, some simple formulas have been established based on dimensional analysis to correlate welding parameters (such as current) to resulting weld characteristics (such as penetration).

Robert and DebRoy (Ref 53) studied the Peclet (Pe) and Marangoni (Ma) numbers in conduction-mode laser spot welding of materials with diverse properties, such as gallium, pure aluminum, aluminum alloy 5182, pure iron, steel, titanium, and sodium nitrate. It was found that for materials with high Prandtl number (Pr), such as sodium nitrate, Pe and Ma were high, and heat was transported primarily by convection within the weld pool. The resulting welds were shallow and wide. For low-Pr materials, such as aluminum, Pe and Ma were low in most cases, and low Pe made the weld pool deep and narrow. The cross-sectional areas of stationary and low-speed welds could be correlated with welding conditions and material properties using dimensionless numbers, as shown in Fig. 4.

Arora et al. (Ref 54) studied the formation of wavy weld pool boundary using dimensionless numbers derived from the Buckingham π -theorem. Their calculations show that in metallic systems the wavy fusion-zone boundary forms at a Marangoni number greater than

26,000 and a Prandtl number less than 0.06 for dimensionless heat input greater than 20. The wavy boundary originates from the interaction of counterrotating liquid metal loops at high Marangoni numbers.

Tello et al. (Ref 55) developed a scaling law for estimating the weld penetration in GTAW involving high current and travel speed. As shown in Fig. 5, the predicted penetration using the scaling expression is consistent with the

Fig. 4 Correlation between dimensionless cross-sectional area (DA) and dimensionless heat input (DH) for spot and low-speed laser welds. Adapted from Ref 53

experimental data for different materials and process parameters.

Application to Fusion Welding Processes

Heat and Mass Transfer in Arc Plasma

Figures 6(a) and (b) show the distributions of plasma temperature (within an isothermal plasma model) and plasma flow velocity in the arc plasma column calculated using the self-consistent modeling approach outlined previously. The GTAW is done in argon atmosphere with the following parameters: arc current (I) = 200 A, arc length (L_a) = 6.3 mm (0.25 in.), and temperature of the water-cooled anode surface (T_s) = 700 K.

Gas Tungsten Arc Welding

Among the various fusion welding processes, GTAW is perhaps the process most studied by numerical heat and mass transfer models. Some of the early models for GTAW include those developed by Oreper et al. (Ref 56), Kou and Sun (Ref 18), Zacharia et al. (Ref 57), Wu and Tsao (Ref 58), and Kanouff and Greif (Ref 59). Excellent review of those early models can be found in the papers by Matsunawa (Ref 22) and Jönsson et al. (Ref 60). This section summarizes some recent results on heat and mass transfer modeling for GTAW.

Mishra et al. (Ref 61) modeled gas tungsten arc butt welding of stainless steel plates containing different sulfur concentrations. The species conservation equation for sulfur is solved along with the governing equations of mass, momentum, and energy conservation. As shown in Fig. 7, both the simulated and experimental

results show significant shift of the fusion zone toward the low-sulfur steel. Flaring of the arc toward the low-sulfur side was found to be an important factor governing the shifting of the weld pool and the missed weld joint.

Lim et al. (Ref 62) calculated the fluid flow and heat transfer in a weld pool of nickel alloy Inconel 690 that is stirred by circular magnetic arc deflection. The arc stirring effect is modeled by considering an arc orbiting in a circle on the weld top surface. As a result, the heat flux, arc pressure, and electromagnetic force vary with time, depending on the center position of the arc. Numerical simulations predicted large changes in the temperature gradient accompanied by reversal of liquid/solid interface velocities (i.e., solidification and remelting) at a stirring frequency of 7 Hz.

Zhang et al. (Ref 63) modeled the transient heat transfer and fluid flow during gas tungsten arc spot welding of low-carbon steel. Figure 8 shows the evolution of calculated temperature and velocity fields in the workpiece, where the weld pool shape is defined by the solidus temperature isotherm. For clarity, only one-half of the weld is shown. Important solidification parameters, that is, the temperature gradient at the solidification front (G) and the solidification rate (R), are computed from the temperature data. The combination of solidification parameters G and R , that is, G/R and GR , were used to estimate the solidification morphology and substructure in a 1005 steel spot weld. A similar approach is used to study the solidification parameters in laser spot microjoining of 304 stainless steel by He et al. (Ref 64), linear GTAW of commercial pure aluminum (Ref 65), and conduction-mode laser and electron beam welding of single-crystal superalloy (Ref 66).

Hong et al. (Ref 31) showed that the weld geometry for 304 stainless steel, calculated

using a heat and fluid transport model along with the k - ϵ turbulence model, agreed with the experimental results (Fig. 9b). Assumption of laminar flow, on the other hand, resulted in overprediction of weld depth (Fig. 9a). Figure 9(c) shows the variation of the dimensionless viscosity, given as the ratio of turbulent and molecular viscosities, with location in the weld pool. Turbulence was stronger near the middle of the weld pool and decreased closer to the solid-liquid boundary. The enhancement of viscosity resulted in significant decrease in fluid velocities compared to calculations of the laminar flow model.

Gas Metal Arc Welding

Although the basic governing transport equations of heat and mass transfer are almost identical for GTAW and GMAW, the metal transfer in GMAW introduces additional complexities in the GMAW weld pool. Metal transfer in GMAW is a complex phenomenon of drop growth, neck formation, and detachment, and it can take place in three principal modes: globular, spray, and short-circuiting, depending on the welding conditions. The impingement of molten droplets onto the weld pool in GMAW greatly affects the shape of the free surface and the convective heat transfer in the weld pool. The deformed weld pool influences the current distribution in the arc and thus influences the heat and momentum fluxes transferred from the arc plasma to the weld pool. In addition, superheated metal droplets carry a significant amount of thermal and kinetic energy into the weld pool. The resulting weld pool is fairly deep at its root, and its geometry exhibits a characteristic “finger penetration” pattern (especially for the spray transfer mode). Due to complicated interactions among arc

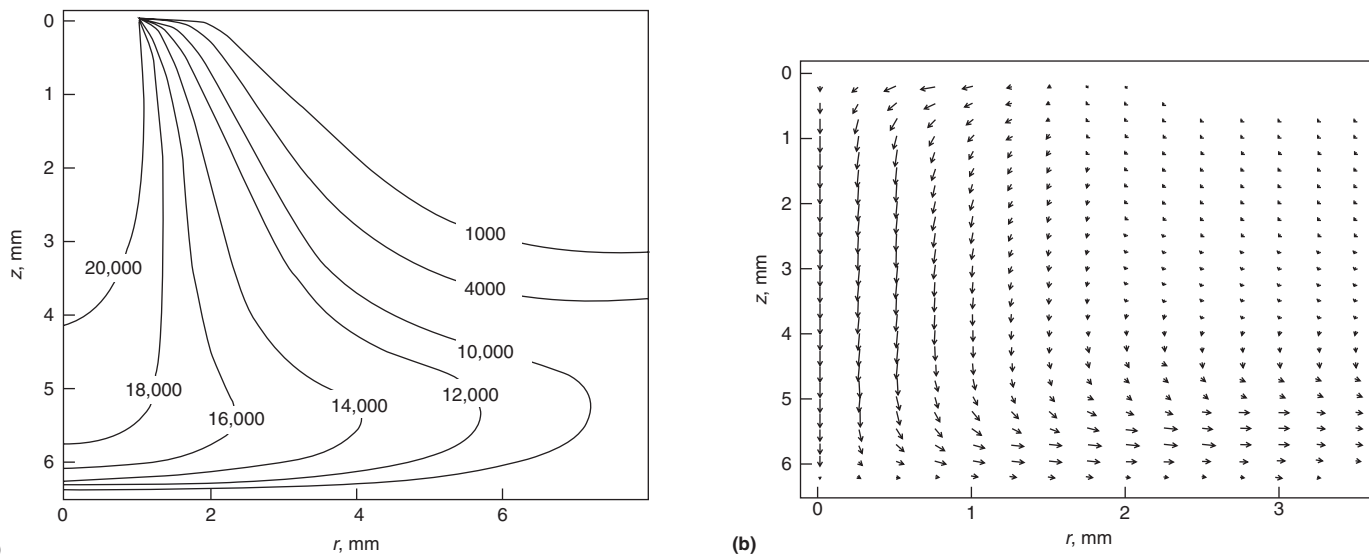

Fig. 6 (a) Plasma temperature distribution (in degrees K). (b) Plasma velocity distribution in argon arc. In (b), the maximum velocity magnitude is equal to 330 m/s (985 ft/s).

plasma, droplets, and weld pool, many existing numerical models only focus on one or two events of the GMAW process while simplifying the rest of the events. Depending on the physics incorporated in the models, the numerical models of GMAW can be classified into the following three groups.

The first group of numerical models focuses on understanding the mechanism of droplet formation. Among various models, the static force balance model (SFBM), dynamic force balance model (DFBM), and pinch instability theory (PIT) have been most widely used for metal transfer analysis (Ref 67–70). The SFBM predicts the detaching drop size by comparing the forces exerted on the drop in the globular mode (Ref 67–70). The forces affecting metal transfer are surface tension, electromagnetic, gravitational, and plasma drag forces. When the detaching force becomes greater than the attaching force, the drop detaches from the wire tip. Due to its static nature, the SFBM cannot take account of the effects of dynamic forces such as inertia. On the other hand, the DFBM includes the effect of inertial force. The PIT has been used for spray-mode analysis based on Rayleigh instability and provides the critical wavelength at which the current-conducting liquid cylinder breaks up (Ref 69, 70). All these

models provide useful closed-form equations to estimate the detaching drop size but fail to predict the drop size accurately in the high-current range. In the literature, other models have also been proposed to predict metal transfer more accurately. Nemchinsky (Ref 71) calculated the droplet shape affected by surface tension and electromagnetic force. Jones et al. (Ref 72) simulated the dynamic movement of a drop with a complex shape, including ellipsoids and tapered neck, calculating the spring and viscous damping forces and using correction factors; their calculations matched experimental results. Numerical techniques such as the volume-of-fluid (VOF) method have been employed to predict the drop profile and fluid flow within the drop (Ref 73–75). Choi et al. (Ref 74) showed that the pendant drop oscillates and the fluid flow within the drop affects drop detachment, which demonstrates that inertial force influences metal transfer. Haidar and Lowke (Ref 75) used an arc model to simulate the droplet formation in GMAW using VOF. The energy equation and the continuity, momentum, and current-conservation equations were solved for both the molten droplet and the surrounding plasma arc, and the shape of the droplet was predicted as a function of time. In their model, the fluid flow in the weld pool was not calculated, and only the heat conduction was considered.

The second group of models incorporates the effect of droplet and arc plasma by decoupling the physics and including the effect of these variables using boundary conditions. Yang and DeRoy (Ref 15) used the $k-\epsilon$ turbulence model to calculate the fluid flow inside a GMAW weld pool. They found that the dissipation of heat and momentum in the weld pool is significantly aided by turbulence. Figure 10 shows the distributions of turbulent viscosity, thermal conductivity, kinetic energy, and dissipation rate in the weld pool obtained by their model. Their modeling results show that the maximum values of these variables lie in the middle of the weld pool, and the values decrease progressively from the center to the periphery. This outcome is as expected, because the circulation of the molten metal is most intense near the surface, and the level of turbulence decreases progressively as the fluid approaches the solid surface. To model the heat carried by the droplets, they used the cylindrical volumetric heat source in the weld pool. In their model, the dimensions of the volumetric heat source were determined by such parameters as the drop size, shape, velocity, and frequency, using a model suggested by Kumar and Bhaduri (Ref 76). Although their model did not take into account the impinging force of the droplet on the free surface, the prediction of their model agreed well with the experimentally obtained fusion-zone geometry for several different welding conditions, as shown in Fig. 11. A similar cylindrical-heat-source approach was used later by Zhang et al. (Ref 25, 77). Kim and Na (Ref 78) presented a 3-D quasi-steady heat and fluid

flow analysis for the moving heat source of a GMAW process with a deformed free surface using boundary-fitted coordinates. Ushio and Wu (Ref 79) used a boundary-fitted nonorthogonal coordinate system to handle the largely deformed gas metal arc weld pool surface and predicted the weld pool dimensions. In those models, the heat delivered by the droplet was approximated by an internal heat-generation term, and the impact of droplets onto the weld pool was assumed to be a constant force acting on the surface. In other words, the actual droplet impinging process was not simulated. The dynamic change of the weld pool free surface was recently modeled by Wang and Tsai (Ref 80), Fan and Kovacevic (Ref 81), and Cao et al. (Ref 82) using the VOF method. All these models (Ref 80–82) assumed the droplets were already generated with a certain shape, volume, temperature, and initial velocity at a certain distance above the weld pool. The droplet was then accelerated to the weld pool by applying a drag force calculated from an empirical formula and an assumed plasma velocity. Recently, Hu et al. (Ref 83) developed a model to predict humping defects in GMAW. In their paper, they focused on weld pool dynamics and the formation of ripples, and they did not calculate the droplet generation. They found that during welding, a crater was opened as a result of droplet impingement, and its closeup was caused mainly by hydrostatic force. The crater open and closeup led to the “up-and-down” of the fluid level in the weld pool, as shown in Fig. 12. A ripple was formed as solidification proceeds in the welding direction. They concluded that the periodic impingement of droplets, weld pool dynamics, and solidification all contributed to the formation of ripples, and the “pitch” of the ripples depends on many welding parameters, including droplet size (electrode diameter), droplet momentum, drop frequency (wire-feed speed), welding speed, welding power (current and voltage), and others.

Models falling into the third group are more comprehensive in nature and incorporate the arc physics, droplet formation mechanism, and weld pool dynamics in an integrated manner. Very limited work is published in the open literature on this type of models. Hu and Tsai (Ref 43, 84) developed a model that simulates melting of the electrode, the droplet formation, detachment, transfer, and impingement onto the workpiece, and the transient flow in the weld pool. Their model predicted the crater and oscillations in the weld pool due to periodical droplet impingement. They calculated the current distribution in the droplet and workpiece through the coupling effect of the arc and the metal. In their model, the heat flux, arc pressure, and plasma shear stress are all obtained from the coupled arc domain. They found that the droplet transfer and the deformed weld pool surface have significant effects on the transient distributions of current density, arc temperature, and arc pressure, which are

Fig. 7 (a) Experimental weld pool geometry. The vertical line shows the joint of the two plates. (b) Calculated temperature and velocity fields in the weld pool. The contours represent the temperatures in degrees Kelvin, and the vectors represent the liquid velocity. (c) The contours represent calculated sulfur concentrations in wt%. The sulfur concentration on the top surface and the bulk of the weld pool was approximately 0.019 wt%. Welding conditions: 100 A, 10.2 V, and 3.4 mm s⁻¹ welding speed. Adapted from Ref 61

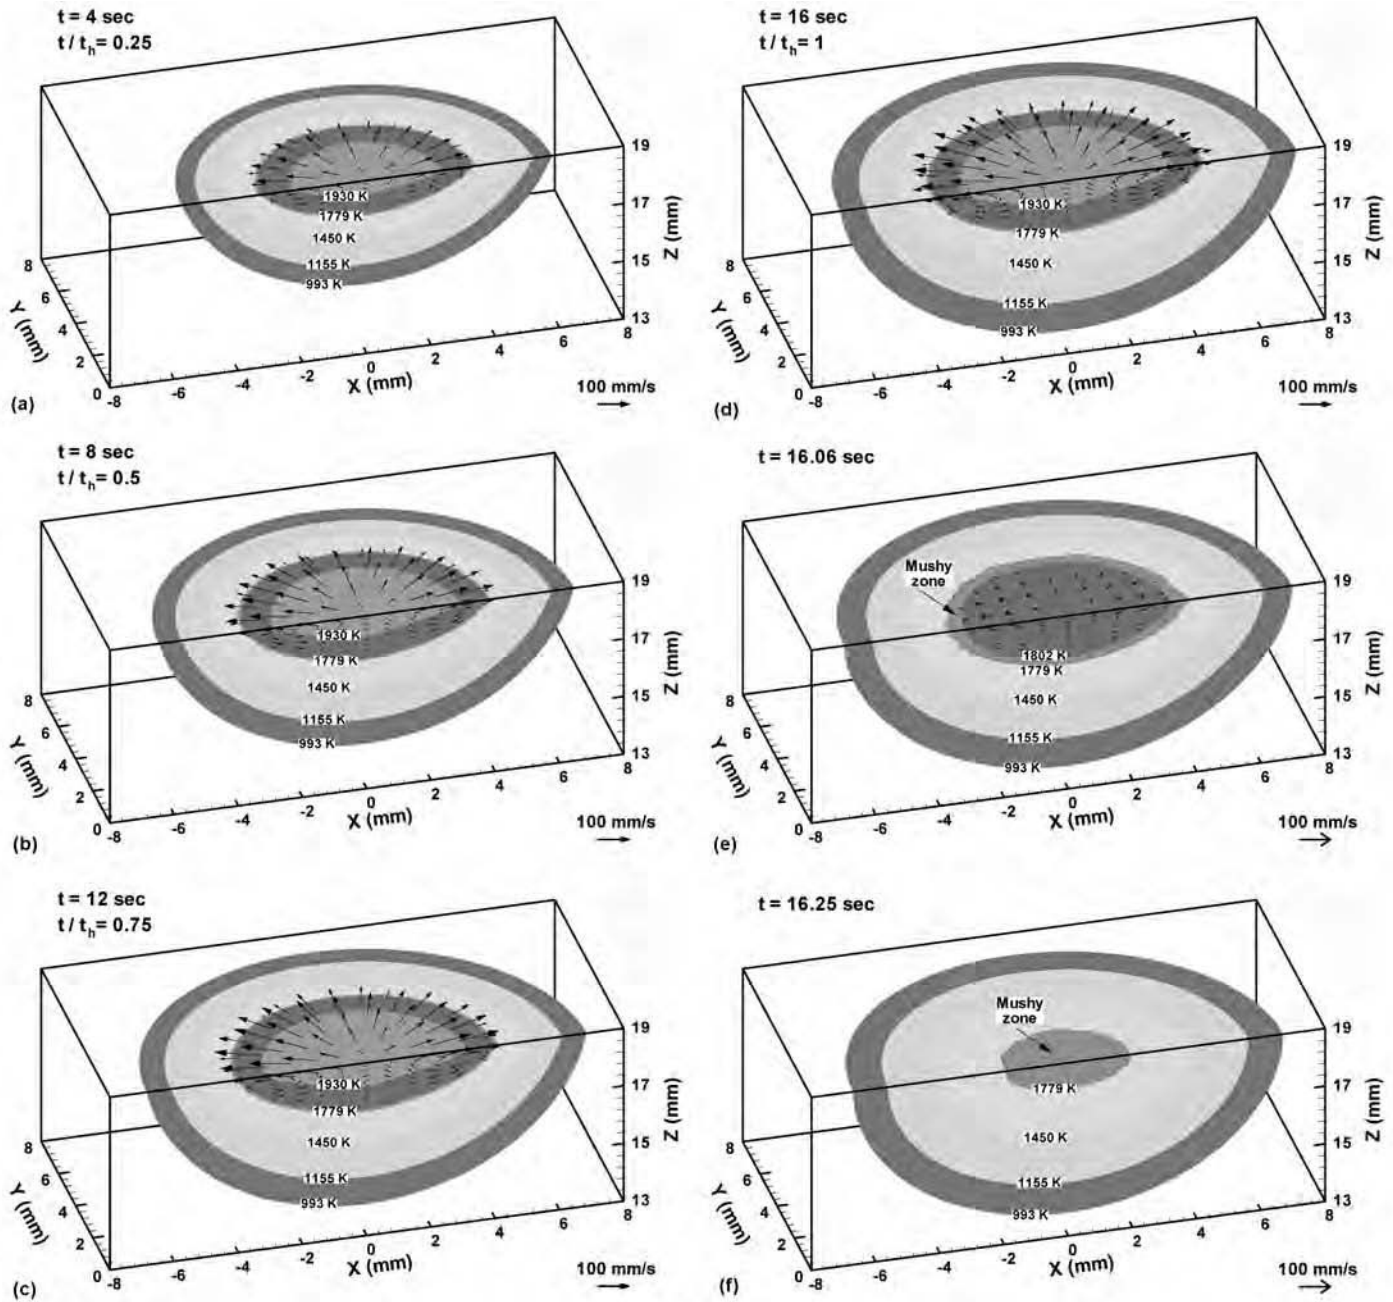

Fig. 8 Evolution of temperature and velocity fields at various times. Welding conditions: current = 120 A, voltage = 17.5 V, and arc on-time = 16 s. The velocities are represented by the arrows, while the temperatures are represented by the contours. Adapted from Ref 63

normally assumed to be constant Gaussian profiles. They also simulated the solidification processes of the electrode and weld pool after the arc is extinguished. Figure 13 shows the sequence of temperature distributions for droplet generation, detachment, transfer in the arc, impingement onto the weld pool, and weld pool dynamics (Ref 81). Modeling results show that a round droplet forms at the electrode tip and grows with time. Subjected to the arc pressure,

plasma shear stress, surface tension, and electromagnetic force, the detached droplet also changes its shape in the arc. The fluid flow in the detached droplet helps to mix the cold liquid in the droplet center with the hot liquid at the surface. Thus, a more uniform temperature distribution appears in the detached droplet than in the droplet hanging at the electrode tip. When the droplet hits the solid workpiece, it quickly spreads out on the workpiece, and

the droplet fluid is continually pushed downward and outward by arc pressure and arc shear stress, as shown in Fig. 13.

Laser Welding

When energy density of a laser or electron beam exceeds a threshold value, typically of the order of 10^5 W/cm², intense

It is noted that keyhole-mode welding is a highly dynamic process and the keyhole exhibits complex fluctuations. Keyhole instability is an important issue that often leads to defects such as spiking and porosity. Comprehensive, transient numerical models have been developed to study the dynamic behavior of keyhole and related instabilities in LBW. They have provided valuable insight into the mechanisms of keyhole collapse and defect formation. On the other hand, quasi-steady-state models, which are very computationally efficient, have shown their usefulness in understanding the weld pool shape and temperature evolution in LBW of different engineering materials.

The earliest studies identified surface tension, vapor pressure, and hydrostatic force as the key factors influencing keyhole shape and penetration depth (Ref 85–87). An early pressure-balance model, proposed by Klemens (Ref 85), defined the equilibrium between the forces that tend to keep the keyhole open and those that try to close it:

$$p_0(z) = \frac{\gamma}{r(z)} + \rho gz \quad (\text{Eq 41})$$

where $p_0(z)$ is the difference between the pressure in the keyhole and the ambient pressure, γ is the surface tension, $r(z)$ is the keyhole radius at a depth z from the top surface, ρ is the density, and g is the acceleration due to gravity. The first term on the right is the surface tension pressure, and the second term is the hydrostatic pressure. The pressure inside the keyhole near the top surface equals the sum of surface tension pressure and ambient pressure, because the hydrostatic pressure becomes negligible. Immediately outside the keyhole, pressure is equal to the ambient pressure. Continuity of vapor pressure near the top surface requires that the surface tension pressure should become small. A trumpetlike flare (Ref 87) or a constriction (Ref 85) of the keyhole near the surface would ensure a large radius of curvature (hence small surface tension pressure) and continuity of vapor pressure. Kaplan (Ref 88) argued that heat transport in the keyhole-mode LBW was planar due to the constant wall temperature (equal to the boiling point of the alloy) and nearly vertical keyhole walls. His model considered the multiple reflections of laser beam inside the keyhole as well as the inverse bremsstrahlung absorption of the laser beam by the plasma.

With improvements in computational power, more comprehensive models of heat and mass transport in keyhole-mode welding were developed. Zhou et al. (Ref 89, 90) used the VOF method to model the keyhole dynamics and suggested that porosity may be avoided by controlling the laser pulse shape. Ki et al. (Ref 27, 91, 92) studied the transient evolution of the liquid-vapor interface using the narrow-band level-set method to transform the problem to a partial differential equation and simplify

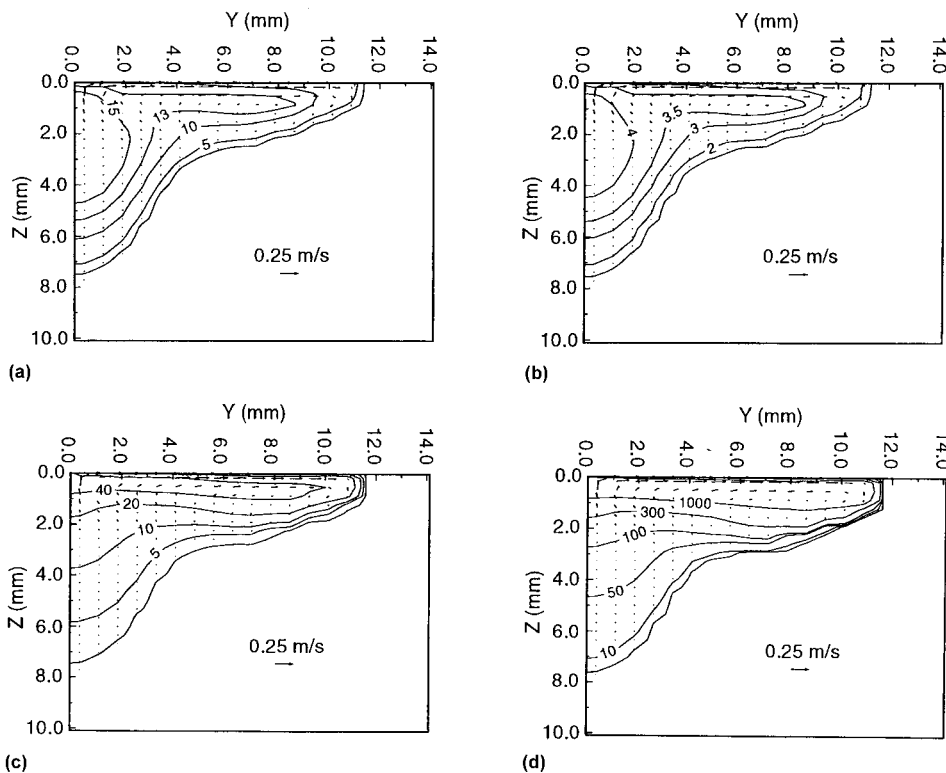

Fig. 10 Distribution of turbulent variables in the weld pool. (a) Dimensionless viscosity, μ/μ_0 . (b) Dimensionless thermal conductivity, k_e/k . (c) Turbulent kinetic energy, $\text{m}^2/\text{s}^2 \times 10^{-4}$. (d) Dissipation rate of turbulent kinetic energy, $\text{m}^2/\text{s}^3 \times 10^{-4}$. Adapted from Ref 15

vaporization of workpiece material results in formation of a deep and narrow vapor cavity (or keyhole) surrounded by liquid and solid metal. This section, and the next, focuses on this keyhole-mode welding. Modeling of laser

beam welding (LBW) done at relatively low energy densities is similar to the modeling of GTAW, which was previously discussed in the section “Gas Tungsten Arc Welding” in this article.

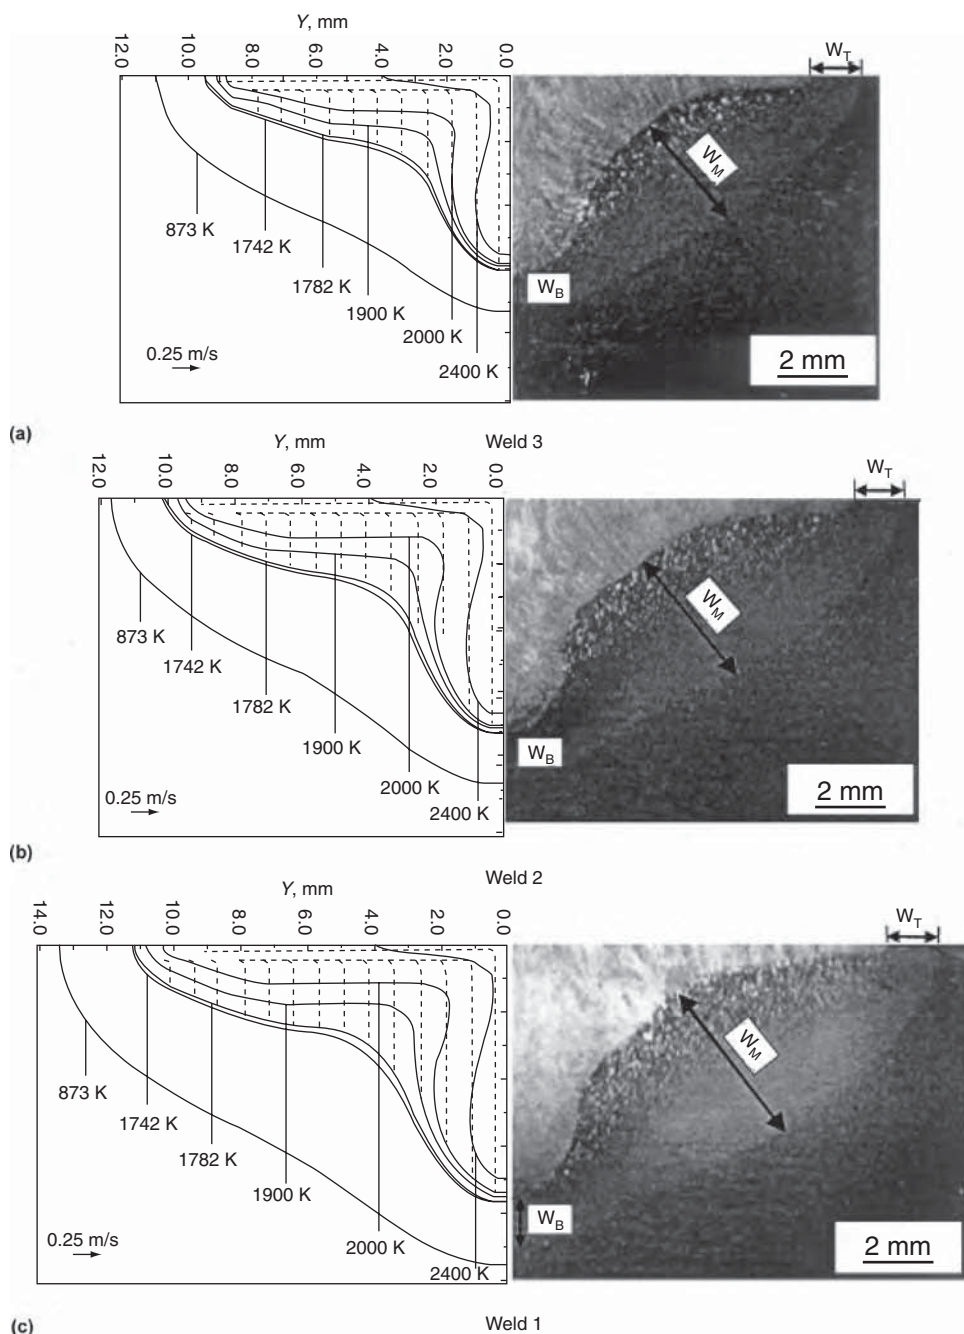

Fig. 11 Comparison of the calculated and experimental geometry of the fusion zone and the heat-affected zone (HAZ). The heat input per unit length for the three welds is (a) weld 3: 2.4 kJ/mm, (b) weld 2: 3.15 kJ/mm, and (c) weld 1: 3.94 kJ/mm. The symbols W_T , W_M , and W_B are the widths at the top, middle, and bottom of the HAZ, respectively. Adapted from Ref 15

the calculations of the surface curvature and the surface normal. A ray-tracing procedure was implemented to account for multiple reflections of the laser beam within the keyhole. The temporal evolution of the keyhole shape and temperature distribution for a steel weld made with a 4 kW laser beam of 0.5 mm (0.02 in.) beam diameter at 25 mm/s (1.0 in./s) welding speed is shown in Fig. 14. Due to the small time step required for convergence (10^{-6} s), the code

was optimized and parallelized to reduce the run time.

To reduce the computational requirements while preserving model accuracy, Rai et al. (Ref 25, 26) decoupled the keyhole calculation from the 3-D heat and fluid transport modeling. The keyhole profile was calculated using the energy balance at the liquid-vapor interface, which was assumed to be at a constant temperature. The calculations also considered multiple

reflections and plasma absorption in a manner similar to Kaplan's model (Ref 88). The 3-D temperature and velocity fields were subsequently calculated by solving the equations of conservation of mass, momentum, and energy coupled with a one-equation turbulence model based on Prandtl's mixing-length hypothesis. The model was validated for welding of several engineering materials, including aluminum alloys, steels, and titanium. Convection driven by surface tension gradients was found to significantly enhance the heat transport in the weld pool. A contrast in the weld pools of low-thermal-conductivity alloys such as steels and high-thermal-conductivity materials such as aluminum is apparent from Fig. 15. For low-thermal-conductivity materials, the greatly enhanced heat transport near the weld pool top surface results in a "nail-head" shaped weld. Such characteristic weld shape is usually absent in high-thermal-conductivity alloys because diffusive heat transport remains significant even in highly convective regions of the weld pool.

Electron Beam Welding

Although electron beam welding (EBW) is similar to LBW in many respects, there are some important differences in the two processes. The keyhole wall temperature at any depth in EBW or LBW can be estimated from the equilibrium temperature-pressure relation and the pressure-balance equation. In EBW, which is performed in a vacuum chamber, the increase of pressure with depth can result in significant corresponding increase in temperature (Ref 93, 94). However, in LBW, which is performed under atmospheric pressure, an increase in pressure results in a small temperature increase compared to that in EBW (Ref 25, 26, 85). Therefore, the assumption of constant keyhole wall temperatures commonly used in LBW models cannot be applied to EBW models.

Very few numerical heat and mass transfer models of keyhole-mode welding have focused on EBW. Elmer et al. (Ref 95) proposed heat conduction models based on distributed, point, and line heat sources. The choice of heat source depends on input power, power density, and depth-to-half-width ratio of welds. Wei and Chow (Ref 96) calculated keyhole wall temperatures based on a balance of surface tension and vapor pressure and found results comparable to the measurements of Schauer et al. (Ref 97). They also studied the effects of beam defocusing and alloying element vaporization on the keyhole shape on the assumption that the keyhole cross sections are circular. Their results (Fig. 16) showed that keyhole wall temperatures varied by approximately 600 K with depth and decreased with increasing concentration of alloying elements.

Fig. 12 Typical sequence showing the impinging of droplets, weld pool dynamics, and temperature distribution (side view). Adapted from Ref 83

A 3-D heat and mass transport model was developed by Rai et al. (Ref 93, 94) and tested for stainless steel and Ti-6Al-4V alloy welds by comparing the calculated weld geometries and thermal cycles with experimental results. The vapor pressure in the keyhole was calculated from the pressure balance at the keyhole walls, and the keyhole wall temperatures were calculated using the equilibrium pressure-temperature relationship. The 3-D model considered convection driven by surface tension gradients at the top surface and the keyhole walls, buoyancy, and turbulence. Figure 17 shows the variation of calculated keyhole pressure and wall temperatures with depth. Keyhole wall temperatures in EBW are lower than the normal boiling point of the alloy. As a result, lower wall temperatures are required in order to maintain the EBW keyhole, and penetration depth is greater compared to LBW (Fig. 18). However, due to the lower wall temperatures in EBW, less heat is transported in horizontal planes, and, as a result, welds are narrower than in LBW (Ref 93).

It is noted that compared to the work on keyhole dynamics in LBW, very little study has been done in EBW. Nevertheless, the keyhole

fluctuation and instability is an important issue in EBW. The results obtained using the quasi-steady-state model (Ref 93) provide a useful basis for developing future generations of comprehensive transient models to understand the keyhole dynamics in EBW.

Laser-Arc Hybrid Welding

The laser-arc hybrid welding process takes advantage of the benefits of both laser and arc welding, resulting in wide and deep welds in a single pass, with low distortion and residual stresses. As pointed out in an excellent review paper (Ref 98), the benefits of the laser-arc hybrid welding process mainly arise out of the physical interaction of the two heat sources. In situations where the laser and arc are separated by a distance at which no plasma interaction occurs, the process should be considered as tandem welding (Ref 99).

Laser-arc interactions are complex in hybrid welding. The synergistic interaction between the laser and the arc involve surface-heating interactions, stabilization of the arc cathode spot, and constriction of the arc plasma column (Ref 98). For simplicity, the majority of

published hybrid welding models to date do not consider the details of laser-arc interactions. Zhou and Tsai (Ref 100) developed a transient 2-D axisymmetric model to simulate the impingement of metal droplets into the weld pool containing a keyhole during laser-metal inert gas (MIG) hybrid welding. The laser-MIG hybrid weld pool was also simulated by Gao et al. (Ref 101). Unlike the model by Zhou and Tsai where the laser and arc are aligned coaxially, the laser and arc heat sources are separated at a horizontal distance of 4 mm (0.16 in.) in the model by Gao et al. Cho and Farson (Ref 102) developed a 3-D heat transfer and fluid flow model to evaluate the humping defect formation in CO₂ laser-GMAW hybrid welding. Cho et al. (Ref 103) developed 3-D transient simulations of CO₂ laser-GMAW hybrid welding for the laser trailing the arc. Their hybrid welding model is a combination of the arc welding model and the laser welding model, without any interactive effect between the two.

Ribic et al. (Ref 104, 105) assessed the arc-laser interactions in laser-GTAW hybrid welding. To match the predicted fusion-zone depth and width with the experimental data, the arc radius used in their 3-D heat transfer and fluid flow model was varied. The best-fit data show the arc radius must decrease to achieve the observed weld depth when the arc and laser are in close proximity.

In conclusion, laser-arc hybrid welding is one of the most challenging fusion welding processes to model numerically, because of the complexity of laser-arc interactions. Comprehensive mathematical description of such interactions is yet to be fully developed. The current generation of models has provided useful insights into the molten metal flow and heat transfer in hybrid welding. Those models will serve as a solid basis for the development of the next generation of models as understanding of laser-arc interactions improves.

Mass Transfer in Weld Pool

Nitrogen Absorption

Nitrogen is an important alloying element in modern steel chemistry, and its concentration can have significant effects on the mechanical and corrosion properties of weld metal. Many published data have shown that nitrogen absorption by the weld metal is enhanced above the equilibrium solubility of nitrogen predicted by Sievert's law. The existence of monatomic nitrogen dissociated from molecular nitrogen in the plasma is responsible for the enhancement of the nitrogen absorption in the low-nitrogen steel weld pool during arc welding (Ref 106).

Palmer and DebRoy (Ref 12) developed a comprehensive model for enhanced nitrogen dissolution in the weld metal during GTAW of iron. Their model works as follows. First,

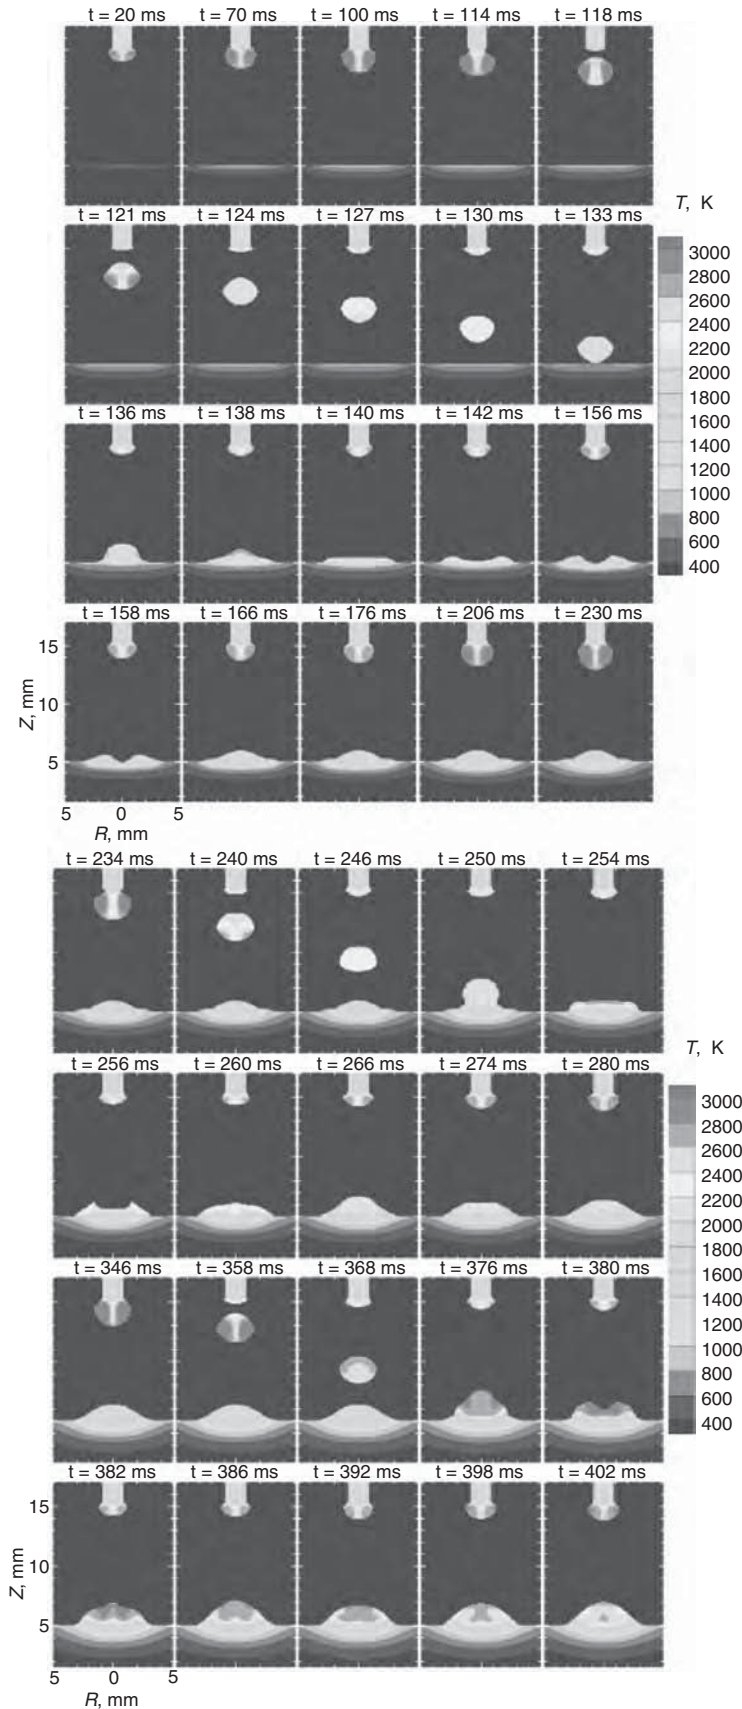

Fig. 13 Sequence of temperature distributions showing droplet generation, detachment, transfer in the arc, impingement onto the weld pool, and weld-pool dynamics. Adapted from Ref 84

monatomic nitrogen partial pressures are calculated as a function of the electron temperatures in the plasma phase. Second, nitrogen concentrations on the weld pool surface are calculated as a function of both the monatomic nitrogen partial pressure and the weld pool surface temperatures. Third, the model takes account of the fact that, once absorbed at the weld pool surface, nitrogen is transported predominantly by convection to the interior of the weld pool. The species conservation equation shown in Eq 7 is solved to obtain the distribution of nitrogen concentration in the weld pool, where the enhanced transport of nitrogen due to turbulence is modeled by increasing the nitrogen diffusion coefficient. Finally, nitrogen desorption is taken into account by placing a limit on nitrogen concentrations in the weld pool to define the concentration at which desorption occurs. As shown in Fig. 19, the modeling and experimental results are equivalent in magnitude for a given set of welding parameters and follow similar trends with changes in the nitrogen addition to the shielding gas.

Vaporization of Alloying Elements

During LBW of many important engineering alloys, an appreciable amount of alloying element vaporization takes place from the weld pool surface. As a consequence, the composition of the solidified weld pool is often significantly different from that of the alloy being welded. The composition change, in turn, can lead to significant changes in the microstructure and degradation of the mechanical and corrosion properties of the welds.

DebRoy et al. (Ref 107) combined the principles of gas dynamics and weld pool transport phenomena to calculate the rates of vaporization in CO₂ laser welding of pure iron and titanium. An extended method is used by He et al. (Ref 108) to study the composition change in 304 stainless steel weld metal during microjoining with short laser pulse. Two mechanisms for vaporization are considered. The first mechanism is the vaporization due to concentration gradient. For an element *i*, this diffusive vaporization flux (J_{ci}) can be calculated as:

$$J_{ci} = K_{gi} \left(M_i \frac{a_i P_i^0}{R T_i} - C_i^s \right) \quad (\text{Eq 42})$$

where K_{gi} is the mass transfer coefficient of element *i* between the weld pool surface and the shielding gas, M_i is the molecular weight of element *i*, a_i is the activity of element *i* in the liquid metal, P_i^0 is the equilibrium vapor pressure of element *i* over its pure liquid, R is the gas constant, T_i is the temperature on the weld pool surface, and C_i^s is the concentration of element *i* in the shielding gas.

The second mechanism is vaporization due to the pressure gradient. For element *i*, the vaporization rate due to this mechanism (J_{pi}) can be expressed as:

Fig. 14 Temporal evolution of keyhole shape and temperature distribution of a full-penetration keyhole weld. Laser power: 4 kW; welding speed: 25 mm/s (1.0 in./s); beam diameter: 0.5 mm (0.02 in.). Adapted from Ref 27

Fig. 15 Computed temperature and flow field for (a) SS 304L at 1000 W and 19 mm/s and (b) Al 5754 at 2600 W and 74.1 mm/s. For SS 304L, levels 1, 2, 3, and 4 correspond to 1697, 1900, 2100, and 3100 K, respectively. For Al 5754, levels 1, 2, 3, and 4 correspond to 880, 1100, 1400, and 2035 K, respectively. Adapted from Ref 25

Fig. 16 Measured and calculated variation of keyhole wall temperatures with depth for Al 1100 alloy. Welding parameters: 4.34 kW, 8 mm/s (0.32 in./s), 0.005 rad divergence, -4 mm (-0.16 in.) defocus, and 0.7 mm (0.03 in.) focal spot size. Adapted from Ref 96, 97

$$J_{pi} = a_i \frac{P_i^0 M_i}{P_i M_v} J_p \quad (\text{Eq 43})$$

where P_i is the vapor pressure on the liquid surface, and M_v is the average molecular weight of

Fig. 17 Variation of (a) vapor pressure in the keyhole and (b) keyhole wall temperature, with depth for electron beam welding of Ti-6Al-4V at 550 W and 16.9 mm/s (0.67 in./s). $z = 0$ at the surface of the workpiece. Adapted from Ref 93

the vapor. J_p is determined by using the following equation:

$$J_p = \rho_v M S \quad (\text{Eq 44})$$

where ρ_v is the vapor density, M is the Mach number, and S is the speed of sound in the vapor. Details on the procedure for the calculation of vaporization flux using Eq 42 through 44 are available elsewhere (Ref 107, 108).

He et al. (Ref 108) calculated the weld-metal composition change in 200 μm deep 304 stainless steel microjoints fabricated using millisecond-long neodymium: yttrium-aluminum-garnet (Nd-YAG) laser pulses. The temperature profile on the weld pool surface is obtained by solving the energy and momentum conservation equations. Figure 20 shows a fair agreement between the experimental and computed concentration changes of the various alloying elements in a 304 stainless steel microjoint.

In high-power LBW, the peak temperatures on the weld pool surface often exceed the material boiling point. In such situations, the escaping vapor exerts a large recoil force on the weld pool surface. As a consequence, the molten metal may be expelled from the weld pool. He et al. (Ref 109) studied the liquid metal expulsion during laser spot welding of 304 stainless steel. By comparing the vapor recoil force with the surface tension force at the periphery of the liquid pool, their model predicted whether liquid metal expulsion would take place under various welding conditions. It is found that a higher laser power density and longer pulse duration significantly increased liquid metal expulsion during spot welding.

For arc welding, Murphy (Ref 45) reviewed various methods for the calculation of the production rate of metal vapor. Among those methods, the Clausius-Clapeyron equation is worth noting, which is expressed as:

Fig. 18 Computed fusion-zone cross sections for Ti-6Al-4V welds at 1000 W and 17 mm/s (0.67 in./s). (a) Laser beam welding. (b) Electron beam welding. Adapted from Ref 93

$$P_{vap} = P_{atm} \exp \left[\frac{-H_{vap}}{R} \left(\frac{1}{T_1} - \frac{1}{T_b} \right) \right] \quad (\text{Eq 45})$$

where P_{vap} and P_{atm} are the vapor pressure and atmospheric pressure, respectively, H_{vap} is the molar heat of evaporation, T_1 is the temperature of the liquid metal, T_b is the boiling temperature of the metal at atmospheric pressure, and R is the ideal gas constant. In a unified numerical model taking into account the tungsten cathode, arc plasma, and weld pool, the Clausius-Clapeyron equation is used by Murphy et al. (Ref 51) to calculate the iron vapor concentration at the boundary between the arc and the weld pool. They found that the heat flux density and current density to the weld pool are reduced substantially by the presence of iron vapor in the helium arc. Tashiro et al. (Ref 110) simulated a series of processes from evaporation of metal vapor to fume formation from the metal vapor. They found that most of the fume was produced in the downstream region of the arc originating from the metal vapor evaporated mainly from the droplet in argon GMAW.

Dissimilar-Metal Welding

There are two approaches to modeling the mixing of dissimilar liquid metals in the weld pool, depending on the miscibility between the metals being joined. If the two metals are completely miscible, the species conservation equation (Eq 7) can be solved to obtain the concentration field. There is no interface between the two metals. This approach is used by Phani-kumar et al. (Ref 111) and Chakraborty (Ref 112) for a copper-nickel dissimilar couple and by Arghode et al. (Ref 16) for two aluminum alloys with different silicon contents. On the other hand, if the two metals are immiscible, the interface between them must be explicitly modeled. The models developed by Wei et al. (Ref 113) and Tomashchuk et al. (Ref 114)

Fig. 19 Comparison between experimental nitrogen concentrations and modeled results for several mass transport enhancement factors at electron temperatures between 3250 and 3000 K for a nitrogen supersaturation level of 75% at a travel speed of 8.5 mm/s (0.33 in./s). Adapted from Ref 12

Fig. 20 Comparison between calculated and experimentally determined composition change of 304 stainless steel. Laser power: 1067 W; pulse duration: 3 ms; and beam radius: 0.225 mm (0.009 in.). Adapted from Ref 108

are based on the second approach. Salient features of the aforementioned models are summarized as follows.

Wei and Chung (Ref 113) developed a transient 2-D model to simulate the Marangoni flow

in a weld pool during conduction-mode laser welding of two dissimilar metals. The equations for conservation of mass, momentum, and energy are solved for the dissimilar-metal mixture, with properties assigned weights based on

the volume fractions of each metal. The two metals are immiscible, and the interface between them is tracked using the VOF method. The predicted weld pool depth is found to be consistent with the experimental data for welding of copper to iron under different welding speeds. Figure 21 shows an agreement between the predicted and observed weld pool shapes in welding of copper to nickel.

Phanikumar et al. (Ref 111) developed a 3-D transient model to solve heat transfer and fluid flow conservation during conduction-mode laser welding of copper to nickel. Because they considered the copper-nickel system, which exhibits complete miscibility in both liquid and solid states, in their model the species conservation equation is solved to obtain the concentration field. They found that the weld pool shape becomes asymmetric even when the heat source is symmetrically applied on the two metals forming the couple. Using a similar approach, Chakraborty (Ref 112) studied the effects of turbulence on molten pool transport in a copper-nickel dissimilar couple. The turbulent transport model, based on a high-Reynolds-number k - ϵ model, shows that the turbulent mass diffusivity is approximately 10^7 to 10^8 times greater than molecular mass diffusivity, which results in better mixing between two dissimilar molten metals than the laminar transport model. The species distribution obtained from the turbulent transport model is shown to be in better agreement with the experimental data than that obtained from the laminar transport model.

Arghode et al. (Ref 16) developed a 3-D transient model for linear GMAW of two aluminum alloys with different silicon contents. In this model, the silicon concentration in the liquid metal is obtained by solving the species conservation equation. The effect of molten droplet addition to the weld pool is simulated using a cavity model, in which the droplet heat and species addition to the molten pool are considered as volumetric heat and species sources, respectively, and distributed in an imaginary cylindrical cavity within the molten pool. The Scheil equation is used to correlate the temperature to the liquid fraction, given the local silicon concentration in the binary aluminum-silicon system.

Tomashchuk et al. (Ref 114) developed a 2-D model for dissimilar copper-steel electron beam welds. The calculation domain corresponds to the horizontal plane of the weld, where a predefined circular keyhole is introduced as an interior boundary with constant wall temperatures set as the vaporization temperatures. The copper and steel are treated as immiscible, and their interface is captured using the level-set method.

Reliability of Models

Although numerical heat transfer and fluid flow models have provided significant insights

about fusion welding processes and welded materials, several model input parameters cannot be easily prescribed from fundamental principles (Ref 115–119). As a result, the calculated outputs of these models do not always agree with the experimental results. One valuable solution to this problem is the inverse modeling technique, a new research paradigm that is generally used to find the value of uncertain process variables using a limited volume of experimental data (Ref 115–131).

The purpose of inverse modeling is to quantitatively study the unknowns in the models. Figure 22 shows the difference between commonly used numerical models and the inverse models. In inverse modeling, both measured values and corresponding calculated quantities are required to estimate the values of uncertain input parameters. Because most inverse problems cannot be solved analytically, computational methods play a fundamental role (Ref 120–124). This is especially true for welding problems, which are invariably complex and nonlinear.

In the inverse modeling technique, the phenomenological models that govern the physics of the problem are generally called forward models, and the problem of solving them is called a direct problem. These models are then coupled with optimization algorithms to minimize an objective function representing the error between calculated outputs and the desired or experimentally obtained outputs. In the optimization problem, the uncertain model parameters are treated as control variables, and the objective function is related to a degree of fit (or misfit) between the model predictions and the experimentally observed data. Generally, a least-squares error function is used as an objective function, because it accounts for both positive and negative residuals without letting them cancel each other out, as would be the case if a simple summation form were used. Constraints enter the problem through physical restrictions on the values that can be considered for the fitted (i.e., optimal) parameters. Inverse modeling is an iterative process in which the optimization algorithm first starts the calculation by running the phenomenological model using the initial guessed values of uncertain input parameters. The optimization algorithms minimize the error between the predicted and the experimentally observed variable values by considering the sensitivity of these variables to each of the uncertain parameters. The calculation is repeated until the objective function reaches the prescribed tolerable value.

Several optimization techniques are available to estimate the values of uncertain input parameters. The most common methods include quasi-Newton methods, steepest ascent/descent methods such as Levenberg-Marquardt (LM) and conjugate gradient (CG), and global optimization algorithms such as genetic algorithms and simulated annealing (Ref 117, 123, 124, 131). Global optimization techniques are stochastic in nature and therefore typically have

slower rates of convergence. Furthermore, they require much higher numbers of runs of the forward model, if the initial starting values are not close to the optimal values. On the other hand, local optimization algorithms such as LM or CG methods may have difficulty in finding the global optimal values of uncertain parameters. Another disadvantage of using a local optimization technique is that the solution at which it arrives depends on the starting solution (Ref 116). Obviously, the combination of both local and global optimization approaches is promising in finding the robust optimal parameters.

One of the main issues in parameter estimation is that the models are overparameterized relative to the amount of information that is available to calibrate them (Ref 122–124). This problem arises when the model output being observed is not uniquely responsive to the parameter being estimated, for example, when errors in two different parameters cancel each other out in affecting the model response. However, measurements having systematic errors do not cancel each other with averaging. Therefore, the minimum value of the objective function is subject to systematic errors associated with experiments, measurement techniques, and the assumptions used in the heat transfer and fluid flow numerical model. During parameter estimation, it is generally assumed that the errors in the experimental data are independent and normally-distributed random variables with means of zero and constant variances. By performing a statistical analysis, it is possible to assess the accuracy of the calculated values of uncertain input parameters (Ref 121–124). If the errors are Gaussian in distribution, the minimization of the chi-square norm can be used for testing the accuracy of the parameters. Furthermore, confidence intervals for individual parameters and joint confidence region should be calculated to check the robustness of calculated values (Ref 123).

The inverse problem is much more difficult to solve than the direct problem because it is typically ill-posed in the sense that small perturbations in the observed parameters/functions may amplify into large changes in the

Fig. 21 Comparison between theoretical prediction and experimental observation of the fusion-zone shapes in welding copper to nickel with CO_2 laser. It is noted that the copper and nickel are treated as immiscible in the simulation. Adapted from Ref 113

corresponding solutions (Ref 126, 127) (i.e., the problem is ill-conditioned). This ill-conditioned problem requires special numerical techniques to stabilize the results of the calculations. In the LM method, the ill-conditioned nature of the inverse problem is alleviated by using an iterative procedure and adding a damping parameter to the coefficient of the diagonal sensitivity matrix. The damping parameter is made large in the beginning of the iterations, because the problem is generally ill-conditioned in the region around the initial guess used for the iterative procedure, which can be quite far from the exact parameters. A very small step is taken in the direction of the negative gradient. The damping parameter is then gradually reduced as the iteration procedure advances. The CG method differs from the LM method principally in the calculation of the search step size and the direction of descent. In the iterative procedure of the conjugate gradient method, at each iteration a suitable step size is taken along a direction of descent to minimize the objective function. The direction of the descent is obtained as a linear combination of the negative gradient direction in the current iteration and the direction of the descent in the previous iteration. This linear combination is such that the resulting angle between the direction of descent and the negative gradient direction is less than 90° and the minimization of the objective function is assured.

If the inverse problem involves the estimation of only a few unknown parameters, the use of an ordinary least-squares norm can be stable (Ref 121, 124). However, if the estimation of a large number of parameters is involved, excursion and oscillation of solutions may occur. One approach to reduce such instabilities is to use the procedure called Tikhonov's regularization, which modifies the least-square norm by the addition of a term having a regularization parameter and a whole-domain zeroth-order regularization term (Ref 128). Instabilities in the solution can be alleviated by proper selection of the regularization parameter (Ref 123).

The optimization schemes are computationally intensive because they require multiple runs of the forward model. The efficiency of these techniques is defined by the number of direct problem runs needed to find the values of uncertain input parameters. In the literature on the application of inverse modeling to welding processes, forward models have been simplified for the convenience of the computation. As a result, such applications to date have been largely based on rather simple heat conduction equations (Ref 132, 133), often using Rosenthal's analytical solution of heat conduction equation, which completely ignores convection in the weld pool. The primary focus of those works was to determine the distribution of heat flux at the workpiece surface exposed to an arc or a laser beam from measured temperatures at several monitoring locations in the solid region. Recently, researchers (Ref 116–

119,134–136) have developed inverse models to calculate such unknown input parameters as arc efficiency, effective thermal conductivity, and effective viscosity for transport-phenomena-based modeling of different fusion welding processes. Kumar and DebRoy (Ref 117) calculated the values of arc efficiency and enhancement factors for thermal conductivity and viscosity in a gas metal arc fillet welding process using a limited set of experimental data. Their results show that the arc efficiency increases slightly with increasing input power and decreasing wire-feeding rate (Fig. 23). This behavior is consistent with the fact that with a decrease in wire-feed rate, less power is consumed in melting the wire and more heat is available to the workpiece for the same heat input rate. Their results also show that the enhancement factor for thermal conductivity and viscosity increases with an increase in heat input per unit length. Using the values of

unknown parameters determined by an inverse modeling approach, good agreement was obtained between the model predictions and the experimental data of weld bead dimensions for various welding conditions. Their work shows that the reliability of the numerical heat transfer and fluid flow calculations in the weld pool can be significantly improved by including a suitable optimization model to determine the uncertain welding parameters from a limited volume of experimental data on weld dimensions.

Future Models

Over the past decades, significant progress has been made in the numerical modeling of heat and mass transfer in fusion welding. The numerical models have greatly expanded the quantitative understanding of weld transport

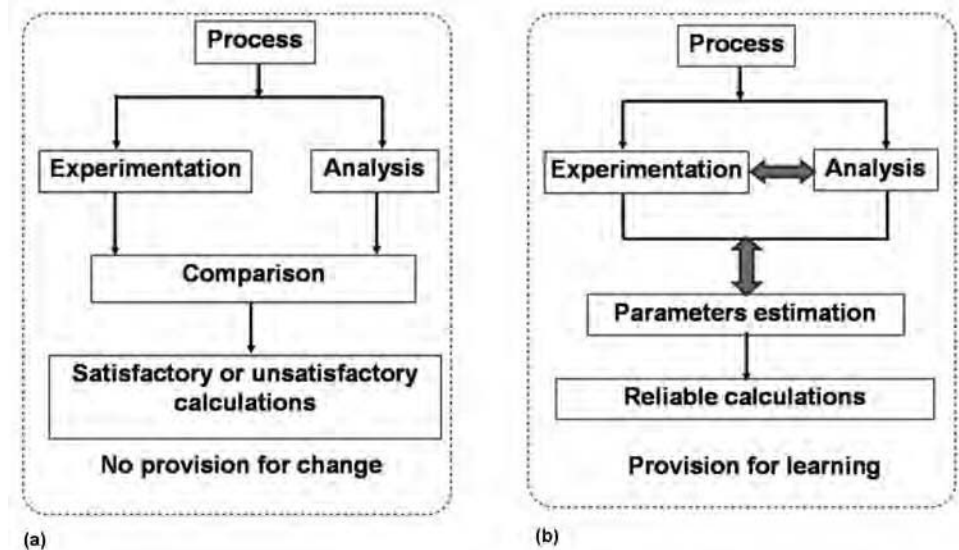

Fig. 22 (a) Common paradigm and (b) new paradigm of inverse modeling. Adapted from Ref 116

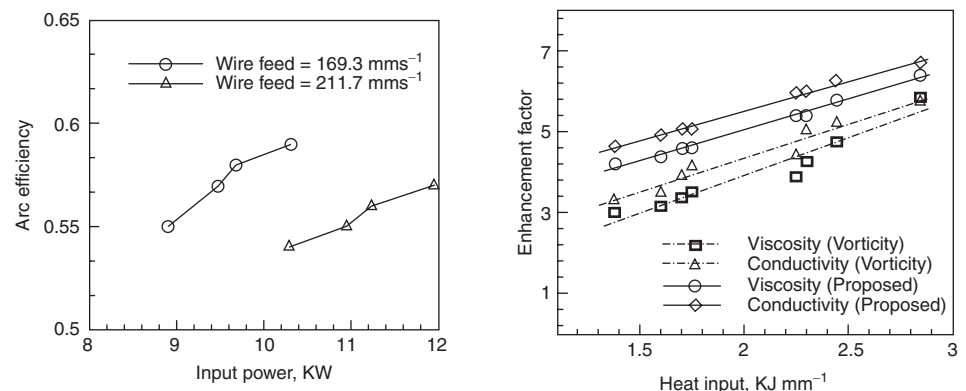

Fig. 23 (a) Computed values of arc efficiency. (b) Enhancement factor for thermal conductivity and viscosity using estimated values of unknown parameters for different welding conditions. Adapted from Ref 117

phenomena, including the formation of a wavy fusion-zone boundary, mixing in the weld pool of dissimilar metals, the effect of shield gas composition on heat transfer from arc plasma to weld pool, keyhole dynamics in laser welding, droplet impingement into the weld pool in GMAW and laser-GMAW hybrid welding, and much more. Such quantitative knowledge is essential for achieving the goal of science-based control of composition, structure, and properties for fusion welding.

Development of the next generation of heat and mass transfer models will benefit from progress in the following two areas. First, an improved fundamental understanding of weld transport phenomena is of importance. For instance, a more comprehensive and detailed mathematical description of heat and mass transfer in hybrid welding is achievable only with improved understanding of laser-arc interactions. To this end, experimental observations of welding transport phenomena are crucial. Furthermore, in view of the complexities of welding processes, numerical models must be tested by well-designed experiments. Second, advanced numerical algorithms (such as those for tracking free surface evolution) and parallel computing are needed.

A final emphasis is placed on the integration of models. A good example is the recent development of the unified model combining the arc plasma and the weld pool, which serves as an ever-increasingly sophisticated tool for improved understanding of the complex weld transport phenomena. Furthermore, the heat and mass transfer models enable the accurate prediction of temperature evolution in the workpiece. Such temperature history is a prerequisite for the calculation of the microstructural changes and the residual stresses and distortion during fusion welding. The integration of heat and mass transfer models with microstructure models and thermal-stress models is essential for intelligent process control and optimization to produce structurally sound and reliable welds (Ref 137).

Modeling of Thermal-Electrical-Mechanical Coupling in Fusion Welding

A. De, IIT Bombay

THE RESISTANCE SPOT WELDING PROCESS involves heating two or more metallic sheets under high-amperage current for a short duration through a pair of copper electrodes that hold the sheets under compressive force. The compressive force ensures adequate contact for the current to flow through the metallic sheets. Localized resistive heating at the contacting interface of the sheets results in melting, which, on solidification, provides a joint in the form of a spot. Throughout the welding process, the molten metal remains enclosed by the surrounding solid material supported by the electrode force. Thus, the process poses a heat-transfer-dominated problem that influences and is also affected by the electrical current flow and thermomechanical deformation along the contacting interfaces, which decide the overall current-carrying region. A coupled thermal-electrical-mechanical analysis is thus ideal for quantitative understanding of the process based on scientific principles.

A host of two-dimensional axisymmetric heat-transfer models using the finite-difference method were reported to compute the temperature field during spot welding of uncoated steels, considering uniform current density distribution (Ref 1–5). Coupled thermal-electrical simulation models were reported next, based on finite-difference (Ref 6, 7) and finite-element methods (Ref 6–17) that could also consider nonuniform current density distribution. Coupled electrical-thermal-mechanical models are also attempted to analyze resistance spot welding based on the finite-element method (Ref 18, 19). In short, numerical models are established as an effective route to carry out the coupled thermal-electrical and thermal-mechanical analyses in resistance spot welding. These numerical models have generally considered temperature-dependent material properties while the latent heat during melting and solidification is often neglected. Most of these models have considered the variation of contact resistance along the electrode-sheet and sheet-sheet interfaces based on experimentally measured data reported in independent literature (Ref 20–26). There are relatively fewer

attempts to model the spot welding process with spherical tip electrodes, considering the incremental change in electrode-sheet contact diameter during weld time (Ref 6, 18, 19). This article outlines a general approach to develop a coupled electrical-thermal-mechanical analysis to analyze the resistance spot welding process.

Thermal Analysis

The problem of heat flow in resistance spot welding is primarily a case of heat conduction associated with melting and subsequent solidification. Although the nature of heat flow is three-dimensional, a two-dimensional axisymmetric model is sufficient due to the circular cross section of the electrode that applies both electrical current and compressive force (Fig. 1). The merit of the axisymmetric formulation is that the symmetry with respect to θ , the azimuthal angle, considers the variation in heat transfer and current flow in radial (r) and vertical (z) directions only. The governing equation for transient state heat conduction in a cylindrical coordinate system, considering no variation of temperature with respect to the θ -axis, can be stated as (Ref 27–30):

$$\frac{1}{r} \frac{\partial}{\partial r} \left(rk \frac{\partial T}{\partial r} \right) + \frac{1}{r} \frac{\partial}{\partial z} \left(rk \frac{\partial T}{\partial z} \right) + \dot{Q} = sC \frac{\partial T}{\partial t} \quad (\text{Eq 1})$$

where \dot{Q} refers to the rate of resistive heat generation per unit volume, r and z are radial and axial coordinates, T and t refer to temperature and time variables, and s , C , and k refer to density, specific heat, and thermal conductivity of the material, respectively. The electrode internal surfaces in contact with cooling water (e.g., lines GH and HK in Fig. 2) can be considered to remain at ambient temperature. The external surfaces of the electrode can be considered as adiabatic because these are far away from the zone of resistive heating (Ref 27–30). Alternately, convective heat loss from the exterior electrode surfaces can be modeled by specifying a lumped surface heat-transfer coefficient, h_c , which is often estimated

as $h_c = 2.4 \cdot 10^{-3} \cdot \varepsilon \cdot T^{1.61}$, where ε is the emissivity of copper, and T is the temperature variable.

The term \dot{Q} in Eq 1 is evaluated using Ohm's law as (Ref 11, 28):

$$\mathbf{J} = \frac{1}{\rho} \mathbf{E} \quad (\text{Eq 2})$$

where \mathbf{J} is the current density vector, \mathbf{E} is the electric field intensity vector, and ρ is the electrical resistivity. Considering a small current-conducting cylinder of cross-sectional area ΔA and of length Δl (as shown in Fig. 3), the

Fig. 1 Schematic view of the sheet-electrode in a cylindrical coordinate system

Fig. 2 Cross-sectional view of one quadrant of the sheet-electrode system

current flow, ΔI , through the cylinder and the potential drop, ΔU , across the cylinder can be stated as (Ref 11):

$$\Delta I = J \cdot \Delta A \tag{Eq 3}$$

$$\Delta U = E \cdot \Delta l \tag{Eq 4}$$

So, the rate of heat generated per unit volume can be written as:

$$\dot{Q} = \frac{\Delta I \cdot \Delta U}{\Delta A \cdot \Delta l} = \rho(\mathbf{J} \cdot \mathbf{J}) \tag{Eq 5}$$

The dot product term, $(\mathbf{J} \cdot \mathbf{J})$, in Eq 5 can be simplified further by presuming the current paths to be predominantly axial ($J_z \approx J$, as indicated in Fig. 4) due to smaller sheet thickness in comparison to the electrode-sheet contact diameter. The term \dot{Q} can thus be evaluated as:

$$\dot{Q} = \rho \cdot J^2 \tag{Eq 6}$$

Electrical Analysis

Like heat-transfer analysis, the current conduction through the sheet-electrode can be analyzed in two-dimensional, axisymmetric form using cylindrical coordinates, assuming no variation of electric potential in the θ -direction. The governing equation for a steady-state current conduction can be expressed in terms of electrical potential, ϕ , as (Ref 11, 27–30):

$\Delta U =$ Voltage drop across the cylinder

Fig. 3 Schematic view of a circular current-conducting conduit

Fig. 4 Schematic view of current flow lines

$$\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{1}{\rho} \frac{\partial \phi}{\partial r} \right) + \frac{1}{r} \frac{\partial}{\partial z} \left(r \frac{1}{\rho} \frac{\partial \phi}{\partial z} \right) = 0 \tag{Eq 6}$$

where ρ is the electrical resistivity. Considering Fig. 2, the primary boundary condition for the current-conduction analysis can be considered as:

$$\frac{1}{\rho} \frac{\partial \phi}{\partial n} + J = 0 \text{ on surface } FG \tag{Eq 7}$$

where J denotes the applied current density on the top surface of the electrode, and n depicts normal to the surface. The other boundary condition is the assumption that no current loss occurs from the electrode surface to the atmosphere.

Discretization of Sheet-Electrode Geometry for Numerical Modeling

Figures 5(a) and (b) show the schematic views of typical sheet-electrode geometry with curved electrodes and the zone of analysis that can be considered for symmetric sheet thicknesses, respectively. The zone of analysis can be divided into a finite number of ring-shaped isoparametric rectangular elements (Fig. 6)

Fig. 5 (a) Sheet-electrode system with curved-face electrodes. (b) Zone of analysis

Fig. 6 Four-node isoparametric elements

with, whenever necessary, triangular cross sections to account for the curved boundary. Any variable, ϕ (e.g., temperature or potential), within a discrete element can be defined as:

$$\phi(r, z) = \sum_{i=1}^{\ell} N_i \phi_i \tag{Eq 8}$$

where ℓ is the number of nodes of an element, and N_i is the appropriately defined nodal shape function (often referred to as the interpolation function) (Ref 31).

In-Process Growth of Electrode-Sheet Contact

Figures 7(a) and (b) schematically present how the contact area along the electrode-sheet interface can grow, in particular for a curved-face electrode, during weld time because of thermo-elastic-plastic deformation. The coupled thermo-elastic-plastic behavior of the sheet and electrode materials in resistance welding can be described using the static equilibrium equation:

$$\frac{\partial \sigma_{ij}}{\partial x_j} + f_i = 0 \tag{Eq 9}$$

considering $\sigma_{ij} = \sigma_{ji}$ where σ_{ij} refers to the stress tensor, x_j refers to the Cartesian coordinate system, and f_i is the body force and can be neglected.

The constitutive equation in thermo-elastic-plastic deformation must be considered in an incremental manner as:

$$d\sigma_{ij} = 2Gd\epsilon_{ij} + \gamma\delta_{ij}d\epsilon_{ij} - (3\gamma + 2G)\alpha\delta_{ij}(T - T_r) - \left\{ \frac{9G^2 \sigma_{ij}^d \sigma_{kl}^d d\epsilon_{kl}}{\bar{\sigma}^2 (E_T + 3G)} \right\} \tag{Eq 10}$$

where the strain tensor, ϵ_{ij} , the deviatoric stress components, σ_{ij}^d , and the equivalent stress, $\bar{\sigma}$, are expressed as:

$$\epsilon_{ij} = \frac{1}{2} \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \tag{Eq 11}$$

Fig. 7 Schematic view of in-process growth of the electrode-sheet contact zone

$$\sigma_{ij}^d = \sigma_{ij} - \frac{1}{3}(\sigma_{ii} + \sigma_{jj} + \sigma_{kk}) \quad (\text{Eq 12})$$

$$\bar{\sigma} = \left(\frac{3}{2} \sigma_{ij}^d \sigma_{ij}^d \right)^{1/2} \quad (\text{Eq 13})$$

In Eq 10, E_T is the local slope of the stress versus plastic strain behavior of the material in the elastic-plastic regime, G and γ are expressed respectively as:

$$G = E/2(1 + \nu)$$

and

$$\gamma = \nu E / \{ (1 + \nu)(1 - 2\nu) \}$$

where E is the elastic modulus, ν is Poisson's ratio, and α is the linear coefficient of thermal expansion (or contraction). Lastly, $\delta_{ij} = 0$ for $i \neq j$ and $\delta_{ij} = 1$ for $i = j$. The incremental strain, $d\epsilon_{ij}$, is computed as:

$$d\epsilon_{ij} = d\epsilon_{ij}^{el} + \delta_{ij} (d\epsilon_{ij}^{pl} + d\epsilon_{ij}^{th})$$

where $d\epsilon_{ij}^{el}$, $d\epsilon_{ij}^{pl}$, and $d\epsilon_{ij}^{th}$ are the elastic, plastic, and thermal strain components, respectively. It is noteworthy that the plastic and the thermal strains are volumetric in nature. Moreover, cooling of the fusion zone or heat-affected zone can be associated with a phase transformation that will contribute to an additional volumetric strain in terms of dilation as:

$$\{d\epsilon_{ij}^d\} = C_1 (\Delta V / V) (\sigma_{ij} / \bar{\sigma})$$

where σ_{ij} is the applied stress, $\bar{\sigma}$ is the yield stress of the parent phase before transformation, ΔV is the volume change associated with phase change, and V is the volume of the parent phase.

The solution of Eq 9, neglecting body force (i.e., $f_i = 0$) and considering the constitutive equations in incremental form (Eq 10), further requires the application of boundary conditions and external loads. Considering a typical axisymmetric sheet-electrode geometry in resistance welding (Fig. 2), a zero axial displacement can be applied along AR and a symmetric displacement boundary condition should be applied along AO that will further eliminate the chance of rigid body movement when the electrode force will be applied along GF .

The solution of the final displacement and stress fields in the sheet-electrode system, considering the aforementioned phenomena, is, however, a real challenge primarily due to the uncertain nature of the mechanical behavior and properties of sheet materials at high temperature. An analytical approach is often followed to estimate the sheet-sheet and electrode-sheet contact area in a simple manner. At any particular time instant, the total electrode force, P , is considered to be supported by the sheet surface in contact to the electrode face as (Ref 27–30):

$$P = \int_0^{r_c} \sigma_y(T) 2\pi r dr \quad (\text{Eq 14})$$

where r_c is the radius of the projected area of the contact surface (Fig. 8) along the interface, and $\sigma_y(T)$ is the temperature-dependent flow stress. To incorporate this, a thin layer of elements (size 0.1 by 0.1 mm, or 0.004 by 0.004 in.) is considered along the electrode-sheet and sheet-sheet interfaces. At the beginning of each time step, r_c along an interface is estimated with $\sigma_y(T)$ evaluated at the average temperature, T_{av} , prevailing along the corresponding interface (Ref 27–30).

Incorporation of Latent Heat

The latent heat of melting and solidification can be included in the heat-transfer simulation through an increase or decrease in the specific heat of the material. The specific heat, C , is expressed as:

$$\begin{aligned} C &= C_1 \quad \text{for } T \leq T_S \\ C &= C_2 \quad \text{for } T \geq T_L \\ C &= C_m = [\lambda / (T_L - T)] + (C_1 + C_2) / 2 \quad \text{for } T_S \leq T \leq T_L \end{aligned} \quad (\text{Eq 15})$$

where λ is the latent heat, and T_S and T_L are the solidus and liquidus temperatures. For an element of volume undergoing phase change, the specific heat can be estimated as a weighted average of the associated specific heats, that is, C_1 and C_m (for solid to mushy state or the reverse), C_m and C_2 (for mushy to liquid state or the reverse), or C_1 , C_m , and C_2 (for a jump from solid to liquid state or the reverse) (Ref 27–30).

Estimation of Contact Resistivity

Greenwood proposed a generic relation to estimate electrical resistance between two contacting flat metallic surfaces (Ref 32, 33):

$$R = \frac{\rho}{nk} + \frac{\rho}{\pi n_a^2} \sum_{i \neq j} \frac{1}{S_{ij}} \quad (\text{Eq 16})$$

where nk is the number of spots formed by contacting surface asperities, $(r_a)_i$ is the radius of an i^{th} spot, ρ is the material electrical resistivity, and S_{ij} is the distance between i^{th} and j^{th} spots that were considered to be neighbors. The second term in Eq 16 accounts for the constriction resistance arising out of the tendency of the current flow lines to become crowded toward the conducting spots only. In actual practice, it is difficult to use Eq 16, and Holm proposed a more workable relation to estimate contact resistance (Ref 34):

$$R = \frac{\rho_1 + \rho_2}{2} \sqrt{\frac{H_m}{P_m}} \quad (\text{Eq 17})$$

where ρ_1 and ρ_2 are the bulk material electrical resistivities of two contacting materials, H_m is the Meyer's hardness number of the softer

material, and P_m is the applied pressure. Babu et al. proposed to calculate the unit area contact resistance, R_{CA} (in Ωm^2) as (Ref 13):

$$R_{CA} = (\rho_1 + \rho_2) \left[\frac{1}{4} \left(\frac{\pi \sigma_{YS}}{\eta F_P} \right)^{1/2} + \frac{3\pi}{16\eta^{1/2}} \right] \quad (\text{Eq 18})$$

where η is the contacting asperity density (m^{-2}), σ_{YS} is the yield strength of the softer material in contact, and F_P is the uniform contact pressure based on the apparent contact area. Babu et al. showed that the contacting asperity densities (η) can be determined experimentally as a function of the ratio of F_P and σ_{YS} . For typical aluminum alloys, an exponential decay of contact resistance as a function of temperature is also proposed (Ref 10):

$$R_k(T) = \frac{\alpha R_0}{\beta^{(T-T_0)/(T_L-T_0)}} \quad (\text{Eq 19})$$

where $R_k(T)$ is the temperature-dependent contact resistance, R_0 is the initial value of the contact resistance at room temperature, α and β are factors depending on the type of sheet metal and their surface coatings, T_L is the liquidus temperature of the sheet metal, T_0 is the ambient temperature, and T is the variable temperature. The distribution of contact resistivity along the sheet-sheet and electrode-sheet interfaces can further be estimated based on the discretized geometry used for the numerical modeling:

$$(\rho_k)_i = (R_k(T) \cdot A/h)(A/A_i) \quad (\text{Eq 20})$$

where $(\rho_k)_i$ is the contact resistivity of the i^{th} contact element, A is the cross-sectional area of the contact zone, and A_i and h are the cross-sectional area and height of the i^{th} contact element, respectively. The net resistivity of the i^{th} contact element $(\rho)_i$ is:

$$(\rho)_i = (\rho_k)_i + (\rho_b)_i \quad (\text{Eq 21})$$

Fig. 8 Anticipated sheet-electrode contact zone at any time instant

where $(\rho_b)_i$ is the temperature-dependent bulk resistivity of the i^{th} element.

Results and Discussions

Figures 9(a) and (b) show the discretized geometry of a typical sheet-electrode system and its zoomed view, showing primarily four-node quadrilateral and a few three-node triangular elements, especially along the curved electrode boundary. The sheet thickness confirms to 0.88 mm (0.03 in.). The discretized geometry is made finer along the interfaces and coarser away from the interfaces, because the temperature and current density gradients are expected to be negligible in the bulk electrode.

Figures 10(a) to (d) show the computed temperature fields at different time instants corresponding to a welding current of 7.0 kA and an electrode force of 2.2 kN. The temperature-dependent material properties of low-carbon steel, which are used in the model calculations, are reported elsewhere (Ref 29, 30). The red-colored zone ($>1500^\circ\text{C}$, or 2730°F) depicts the simulated weld nugget, and its extent along the axial and radial directions shows the penetration and radius of the weld nugget, respectively. The computed nugget diameter increases from 4.8 mm (0.2 in.) at 50 ms to 5.4, 6.0, and 6.3 mm (0.21, 0.24, and 0.25 in.) at 100, 150, and 200 ms, respectively. The computed nugget penetration increases from 0.4 mm (0.016 in.) at 50 ms to 0.45 mm (0.018 in.) at 100 ms and remains unchanged at higher weld time. The computed electrode-sheet contact diameter increases from 4.0 mm (0.16 in.) at 50 ms to 4.90, 5.7, and 6.0 mm (0.19, 0.22, and 0.24 in.) at 100, 150, and 200 ms, respectively. An initial contact resistance of $250\ \mu\Omega$ is considered along the sheet-sheet interface for all the calculations.

Figures 11(a) and (b) show the increase in computed weld nugget dimensions with the increase in welding current. For example, as the welding current increases from 6.5 to 7.5 kA, the computed values of nugget diameter, penetration, and electrode-sheet contact diameter increase from 4.8 to 6.4 mm (0.19 to 0.25 in.), 0.2 to 0.41 mm (0.01 to 0.02 in.), and 5.2 to 6.0 mm (0.2 to 0.24 in.), respectively.

Figures 12(a) and (b) show the influence of electrode force on the computed weld dimensions. As the electrode force increases from 2.2 to 3.0 kN, the computed values of nugget diameter, penetration, and electrode-sheet contact diameter decrease from 6.8 to 4.8 mm (0.27 to 0.19 in.), 0.6 to 0.2 mm (0.02 to 0.01 in.), and 6.4 to 5.2 mm (0.25 to 0.20 in.), respectively. The resistive heating in the sheet-electrode system is directly proportional to the weld time and to the square of welding current. Hence, the increase in weld nugget dimensions with increase in weld time and welding current is expected. With increasing electrode force, the effective contact area along

Fig. 10 Computed temperature isotherm of the sheet-electrode geometry (zoomed section) at (a) 50, (b) 100, (c) 150, and (d) 200 ms at current = 7.0 kA and force = 2.2 kN

Fig. 11 Computed temperature isotherm in sheet-electrode system at (a) 6.5 and (b) 7.5 kA. Other welding parameters: electrode force = 2.2 kN and weld time = 200 ms

Fig. 12 Computed temperature isotherm in sheet-electrode system at (a) 2.2 and (b) 3.0 kN. Other welding parameters: welding current = 7.0 kA and weld time = 200 ms

Fig. 13 Isocontours depicting computed current density distribution (A/mm^2) in the sheet-electrode geometry at (a) 5, (b) 20, (c) 40, and (d) 60 ms. Other welding parameters: welding current = 7.0 kA and electrode force = 2.2 kN

the electrode-to-sheet interface increases, thereby reducing the effective current density for a given value of welding current. Smaller current density reduces resistive heating, and thus, melting and subsequent weld nugget dimensions are reduced as the electrode force increases.

Figures 13(a) to (d) show the computed current density distribution in the sheet-electrode geometry at different time instants corresponding to a welding current of 7.0 kA and electrode force of 2.6 kN. The current density is at its highest at the edge of the electrode-sheet interface due to the change in cross section from the larger electrode diameter to the smaller electrode-sheet contact zone. Figures 13(a) to (d) also indicate the variation in the nature of the current density distribution in the sheet material at different weld times. An increase in temperature increases bulk material (for steel) resistivity while decreasing contact resistance. As a result, the current density distribution, which is inversely proportional to the net electrical resistivity, changes in a complex manner with increase in weld time.

The estimation of the electrode-to-sheet and the sheet-to-sheet contact diameters is essential for accurate calculation of current density distribution, subsequent resistive heating, and final temperature distribution in the sheet-electrode geometry. Figures 14(a) to (d) show the calculated variation of normal stress along the sheet-sheet and the electrode-sheet interfaces for various combinations of welding current and electrode force at a time instant of 5 ms. These calculations are done using a commercial finite-element software (ANSYS 10.0) following thermal-elastic-plastic analyses. The vertical dotted lines in each of these figures indicate the radius of the corresponding contact zone, that is, either electrode to sheet (referred to as E-S) or sheet to sheet (referred to as S-S). The negative values of stresses on the vertical axis refer to compressive stresses and vice versa. Figures 13(a) to (d) indicate that the magnitude of the compressive normal stresses is the maximum at the center of both the sheet-sheet and the electrode-sheet contact zones. The normal electrode-sheet contact stress is initially compressive and becomes tensile in nature at a certain distance away from the center. It is assumed that the perfect contact holds (both along the electrode-sheet and the sheet-sheet) up to this point, where the normal stress changes from compressive to tensile.

A comparison of Fig.14(a) and (b) shows that at a constant electrode force of 2.2 kN, as welding current increases from 7.0 to 8.0 kA, the S-S contact diameter increases from 6.5 to 6.8 mm (0.26 to 0.27 in.) while the E-S contact diameter remains nearly the same. A similar comparison of Fig.14(a) and (c) indicates that for a welding current of 7.0 kA, an increase in electrode force from 2.0 to 3.0 kN increases E-S and S-S contact diameters from 4.0 to 4.5 mm (0.16 to 0.18 in.) and 6.5 to 7.3 mm (0.26 to 0.29 in.), respectively. An overall

comparison of Fig.14(a) to (d) clearly indicates that the computed values of both E-S and S-S contact diameters are sensitive to both the electrode force and the welding current.

The numerically computed values of the E-S and S-S contact diameters are compared with

the corresponding analytically estimated values (Eq 14) in Fig.15(a) to (c). Although the nature of the computed values of the E-S and S-S contact diameters is nearly the same, the analytically estimated values are slightly underpredicted. This can possibly be attributed

to the simple one-dimensional nature of the analytical relation (Eq 14). In reality, a complex state of stress prevails along the interfaces that can certainly be captured more accurately through a full-fledged thermal-elastic-plastic analysis. Figures 15(a) to (c) also indicate that an analytical estimation of the E-S and S-S contact diameters as proposed through Eq 14 can be sufficiently reliable.

A comparison of the experimentally measured weld nugget dimension with the corresponding computed values is shown in Fig. 16(a) and (b) and in Fig. 16(c) and (d), respectively. The weld nugget boundary in the experimentally measured macrographs is indicated by a white line. The computed weld nugget is presumed to be the zone within the sheet material enclosed by the melting temperature isotherm (1500 °C, or 2730 °F). These figures clearly show that the weld dimensions can be estimated to a fair degree of accuracy using numerical models based on scientific principles.

Estimation of the peak temperature, weld thermal cycle, cooling rate, and the duration through which the weld fusion zone and heat-affected zone remain beyond some critical temperature are requisite to design weld schedules for optimum weld joint mechanical properties. From this point of view, the numerical models can serve as an efficient, off-line design tool. Figures 17(a) and (b) show the calculated weld thermal cycles during spot welding in steel sheets (0.88 mm, or 0.035 in., thickness) corresponding to two different welding currents. In these figures, the thermal cycles are drawn for four different positions along the weld nugget midplane: the center point (A), a point (B) residing approximately midway between the center and the periphery of the weld nugget, a point (C) that is almost at the edge of the weld nugget or fusion zone, and lastly, a point (D) that is within the heat-affected zone.

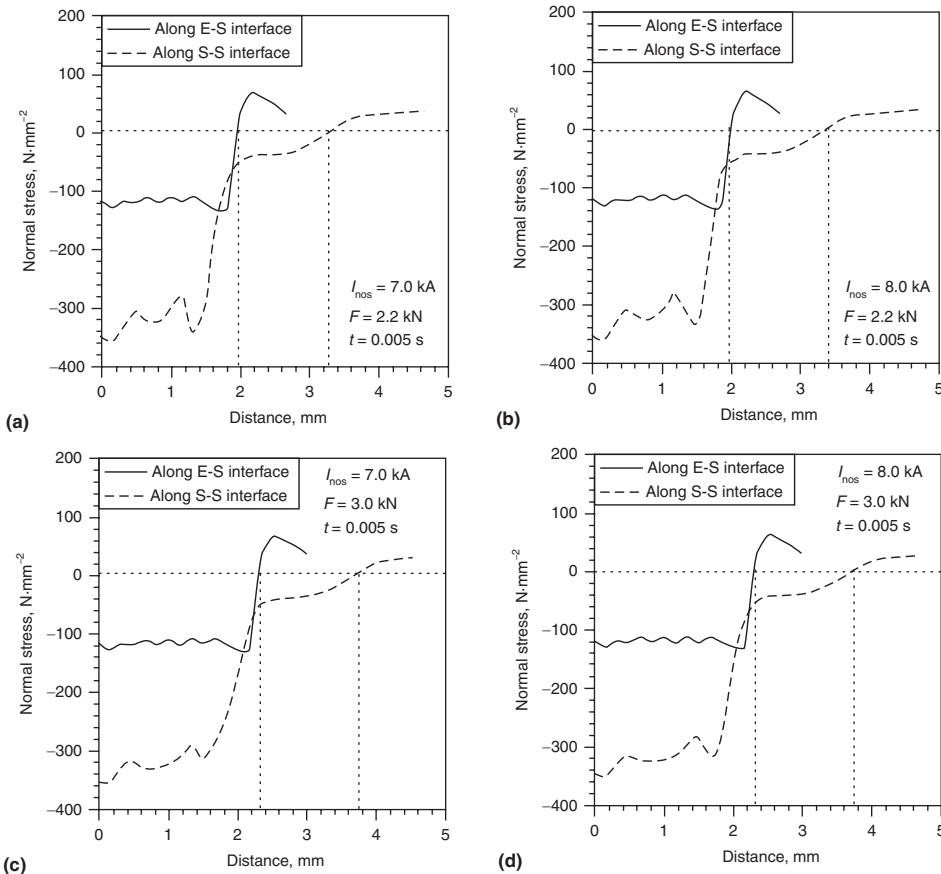

Fig. 14 Computed variations in electrode-to-sheet (E-S) and sheet-to-sheet (S-S) interface diameters at a specific time instant (0.005 s) for different combinations of welding current and electrode force. The thermal-elastic-plastic analyses are performed in ANSYS 10.0.

Fig. 15 Comparison of computed values of electrode-to-sheet (E-S) and sheet-to-sheet (S-S) contact diameters using ANSYS 10.0 with corresponding analytically estimated values for different combinations of welding current and electrode force

Figures 17(a) and (b) show that the rates of both heating and cooling increase toward the center of the weld nugget (fusion zone). The points within the fusion zone are observed to start cooling within the later part of the weld time, even if the welding current is on. The cooling rate is comparatively slower until the welding current is on (up to 0.2 s), and thereafter, a rapid cooling rate is observed. The point (D) within the heat-affected zone shows a smaller peak temperature and lower cooling rate. At a relatively higher welding current of 7.5 kA (Fig. 17b), the peak temperature at the center of the weld nugget (A) is slightly higher. The point (D) within the heat-affected zone exhibits a nearly constant temperature region at the later part of the weld time at higher welding current. This can possibly be attributed to a competitive effect between slow resistive heating and simultaneous conduction heat transfer to surrounding regions at point (D). The peak temperature of the point (D) within the heat-affected zone seems to remain unaltered for a change in welding current from 6.7 to 7.5 kA. It is also apparent from both Fig.17(a) and (b) that higher weld time at a constant current setting will simply delay the cooling with no appreciable increase

in the peak temperature. This can be attributed to the competitive effect between the slower resistive heating at the later part of weld time and simultaneous conduction heat transfer to the surrounding regions. The thermal cycles can be used further for more detailed and fundamental understanding of the metallurgical and mechanical properties of the weld and the surrounding heat-affected zone.

The organized efforts toward development of comprehensive numerical models have enriched the quantitative understanding of coupled thermal-electrical and thermal-electrical-mechanical phenomena involved in resistance welding processes. In particular, the increased availability of commercial software based on the finite-element method has enabled a greater number of welding researchers to develop such models. Although such commercial software generally facilitates coupled field analysis that is helpful to undertake coupled thermal-electrical and thermal-elastic-plastic phenomena, a linking of the two to provide a fully coupled electrical-thermal-elastic-plastic analysis has remained a challenge. At present, various user-defined schemes are followed to establish a link between the coupled thermal-electrical

and thermal-elastic-plastic analyses in a sequential manner such that the computed temperature field due to nonuniform current density from the former can be used to compute thermal-elastic-plastic displacement and stress fields from the latter. Provision of exclusive elements that can handle a fully coupled electrical-thermal-elastic-plastic analysis primarily for the resistance welding process in the commercial finite-element-method-based software is possibly a future solution.

Modeling of Metallurgical Microstructure Evolution in Fusion Welding

Ole Runar Myhr, Hydro Aluminium and Norwegian University of Science and Technology
Øystein Grong, Norwegian University of Science and Technology

MODELING OF THE MICROSTRUCTURE EVOLUTION is a rapidly expanding field of research. In particular, the integration of microstructure modeling with the detailed process histories available from modern finite-element analyses represents an increasingly important field of industrial applications. Even though microstructure models are readily available, they usually cannot be applied directly to welding problems because they tend to describe ideal conditions, such as isothermal heat treatment, often applied to ideal materials, such as pure metals or binary alloys (Ref 1). Before such ideal models can be used for welding processes, they must be recast mathematically so they can handle nonisothermal heat treatments. For this purpose, the internal state variable method is particularly well suited. The general method and its simplification for single-parameter models, in which the microstructure evolution may be treated as an “isokinetic” reaction, are outlined in the section “The Internal State Variable Approach” in this article.

In the section “Isokinetic Microstructure Models,” the general methods described in the previous section are applied to diffusional transformations in fusion welding, covering particle dissolution, growth, and coarsening of precipitates in the heat-affected zone (HAZ). Examples of applications of the methods include grain-boundary liquation in Al-Zn-Mg alloys and coarsening of TiN precipitates during steel welding. In this section, the evolution of the grain structure in the HAZ following recrystallization and grain growth is also dealt with, and isokinetic solutions are derived.

The internal state variable method is not restricted to single diffusion mechanisms but can even be used to capture transformations that occur sequentially (i.e., in succession) or in parallel during a weld thermal cycle, as described by an example from welding of duplex stainless steel in the section “Isokinetic Microstructure Models” in this article. However, this concept fails when attempting to

model welding as part of a multistage process chain, under which the transformation has a strong memory of the past process steps. This is typically the case for precipitation reactions occurring during heat treatment and welding of age-hardening aluminum alloys, where the detailed thermal history affects the evolution of the precipitate structure. In this case, nucleation, growth, and coarsening (and likewise dissolution) must be modeled as coupled processes within a single physical framework, as outlined in the section “Complex Microstructure Models Describing the Evolution of a Particle Size Distribution” in this article.

Finally, in the case studies presented in the section “Microstructure Modeling in the Context of Engineering Design,” the microstructure models are exploited in engineering design to optimize the load-bearing capacity of welded aluminum components.

The Internal State Variable Approach

There is a wide spectrum of modeling approaches available for predicting microstructure evolution in metals and alloys during welding, including empirical and statistical methods. Even though such methods can be useful for many problems, they usually require a considerable amount of experimental data to capture the behavior of the process, without offering substantial predictive power. This is particularly true if the chemical composition is varied (Ref 1).

Alternatively, the internal state variable method, as originally proposed by Richmond (Ref 2), can be applied to predict nonisothermal transformation behavior, as experienced in welding. This method offers a good compromise between the many conflicting requirements for broad application to industrial process modeling and offers useful predictive capability when calibrated to experimental data. Provided that the microstructure evolution is

captured mathematically in terms of the differential variation of the state variables with time, these may be integrated stepwise through any process history, using an appropriate numerical procedure. Usually, this computation can occur independently of the prediction of the thermal history itself, unless the microstructure evolution is strongly coupled to the macroscopic response.

General Methodology

A microstructure may be described by many different state variables; choosing the most relevant depends on the problem (Ref 1). Typical examples of state variables in the context of microstructure evolution are the mean grain size in single-phase alloys, the particle size and volume fraction in multiphase alloy systems, and the fraction of recrystallized grains in work-hardened and annealed materials. Collectively, the microstructural state variables are termed S_i .

State Variable Formulation. At the most general level for a thermally controlled process, the evolution of microstructure can be described by a simultaneous set of differential equations for each of the independent state variables, S_i (Ref 1):

$$\frac{dS_1}{dt} = h_1(S_1, S_2, \dots, T) \quad (\text{Eq 1a})$$

$$\frac{dS_2}{dt} = h_2(S_1, S_2, \dots, T) \quad (\text{Eq 1b})$$

where T is the instantaneous temperature. Given a process temperature history $T(t)$, these equations may be solved (usually numerically) to give the evolution of the state variables.

Most commonly, the instantaneous values are fed into a response equation for some dependent quantity, such as flow stress, σ (Ref 1):

$$\sigma = h_3(S_1, S_2, \dots) \quad (\text{Eq 2})$$

In some cases, it may be the final values of the state variables that are required, either when these are the output of interest or if they are to become the starting values for a subsequent processing step. For fully coupled problems, in which a significant quantity of heat is released by the microstructural change (as in solidification), $T(t)$ will itself depend on the material state. Then, the evolution laws must be solved simultaneously with the temperature history, including a further differential equation for temperature (Ref 1):

$$\frac{dT}{dt} = h_4(S_1, S_2, \dots, T) \quad (\text{Eq 3})$$

An important feature of a “true” state variable model of the form given by Eq 1 is that it does not depend on previous thermal history or microstructure; that is, given the instantaneous values of the state variables, their evolution in the next time increment is uniquely defined by these values and the current temperature alone.

Many important problems of microstructural evolution in thermal processing can be described by single-state variable models. In this case, it is sometimes possible to obtain closed-form solutions that include the temperature dependence of the reaction. Such a reaction is termed isokinetic, and the conditions under which it applies are examined subsequently. If a single-state parameter microstructure model is not isokinetic, or if there are two or more state variables besides temperature, then the solutions will be thermal path dependent.

Definition of an Isokinetic Reaction. The solution of a single internal state variable problem involving the evolution of a specific microstructural feature can be greatly simplified if the evolution law is isokinetic. Nonisothermal process histories can then readily be treated in a single computational step, by invoking the concept of the kinetic strength of the thermal cycle with respect to microstructure evolution. Broadly speaking, a reaction is said to be isokinetic if the increments of transformation in infinitesimal isothermal time steps are additive. Christian (Ref 3) defines this mathematically by stating that a reaction is isokinetic if the evolution equation for some state variable X may be written in the form:

$$\frac{dX}{dt} = \frac{G(X)}{H(T)} \quad (\text{Eq 4})$$

where $G(X)$ and $H(T)$ are arbitrary functions of X and T , respectively.

Equation 4 is a first-order (separable) differential equation that can be integrated as follows:

$$\int_0^X \frac{dX}{G(X)} = \int_0^t \frac{dt}{H(T)} \quad (\text{Eq 5})$$

The integral on the right side is termed the kinetic strength of the thermal cycle with

respect to the evolution of variable X . If the state variable X is a dimensionless parameter, the function $H(T)$ becomes a time constant that includes the temperature dependence of the reaction. In that case, the right side of Eq 5 reduces to the well-known Scheil integral (Ref 4):

$$I = \int_0^t \frac{dt}{t^*} \quad (\text{Eq 6})$$

where $t^* = t_r \exp(Q_d/RT)$ is the temperature-dependent time constant.

In the context of diffusional transformations, a direct consequence of Eq 5 is that the reaction is uniquely defined by a single C-curve, as shown schematically in Fig. 1. This C-curve represents the time taken to reach a given fraction $X = X_c$ under isothermal conditions. Under isokinetic conditions, the total time to reach $X = X_c$ during continuous cooling is simply obtained by adding the fractions of temperature-weighted time until the kinetic strength integral is equal to unity.

Isokinetic Microstructure Models

The majority of phase transformations that take place in alloys are diffusional and are preceded by thermally activated movements of atoms across a concentration gradient (Ref 5, 6). Of particular importance in relation to welding are precipitation reactions that are induced by a change in temperature of an alloy with a fixed bulk composition. If the precipitates form from a supersaturated solid solution, three major processes are involved (Ref 7–9): nucleation, growth, and coarsening. In the following, the additivity concept and the more general internal state variable formalism are applied to establish a basis for modeling nonisothermal diffusional transformations.

Particle Dissolution

Traditionally, the additivity concept has been associated with diffusion-controlled growth (Ref 3, 4, 10–13). Although growth and dissolution are not conjugate processes (Ref 14), the state variable formalism implies that the additivity concept is equally applicable to particle dissolution, because the phenomenon has its common origin in the form of the controlling differential evolution equation rather than the reaction mechanism itself.

The invariant size solutions of Whelan (Ref 15) provide a good starting point for a discussion of additivity and isokinetic behavior in relation to particle dissolution. These solutions are based on the assumption that the particle/matrix interface is stationary; that is, the diffusion field has no memory of the past position of the interface. It follows that the original rate laws describing dissolution of platelike and spherical precipitates are not strictly isokinetic, because time is also embedded in the

solutions. Still, they can be recast into isokinetic solutions according to the definition given previously by proper manipulation of the constitutive equations and subsequent substitution of variables.

Platelike Precipitates. In the case of platelike precipitates embedded in an infinite matrix, a flux balance at the particle/matrix interface leads to the following expression for the dissolution rate (Ref 15):

$$\frac{dB}{dt} = -\frac{k}{2} \sqrt{\frac{D}{\pi t}} \quad (\text{Eq 7})$$

where B is the half-thickness of the plate, and $k = 2(C_1 - C_0)/(C_p - C_1)$. This is not a strict state variable evolution equation, because time, t , enters on the right side, implying the time from the start of dissolution. Integrating Eq 7 gives:

$$B = B_0 - \frac{k}{\sqrt{\pi}} \sqrt{Dt} \quad (\text{Eq 8})$$

where B_0 is the initial half-thickness of the plate at time $t = 0$. Equation 8 can be rewritten in a dimensionless form by introducing the scaled particle volume fraction, $f/f_0 = B/B_0$, and a time constant, t_1^* , for complete dissolution:

$$\frac{f}{f_0} = 1 - \left(\frac{t}{t_1^*}\right)^{1/2} \quad (\text{Eq 9})$$

The next step is to introduce a chosen reference state to allow all unknown material constants to be replaced by a single time constant, t_{r1} , for the dissolution reaction. This time constant can be readily determined by calibration against experimental data. At the chosen reference temperature, T_r , the total time required for complete particle dissolution, t_{r1} , is given by:

$$t_{r1} = \frac{\pi}{D_r} \left(\frac{B_0^2}{k_r}\right)^2 \quad (\text{Eq 10})$$

Fig. 1 Schematic illustration of the principles of additivity, according to the theory advanced by Scheil. Source: Ref 1

where k_r and D_r refer to the values of k and D at the reference temperature, and B_0^* refers to a reference plate thickness. The time constant t_1^* at any other temperature may be found by appropriate scaling of k_r and D_r . Similarly, for any other plate thickness in the initial material, the time constant is scaled with respect to B_0 . Hence, in general, the time constant t_1^* is defined as:

$$t_1^* = t_{r1} \left(\frac{k_r}{k} \right)^2 \left(\frac{B_0}{B_0^*} \right)^2 \left(\frac{D_r}{D} \right) \quad (\text{Eq 11})$$

The time constant therefore contains all material- and temperature-dependent parameters.

By differentiating Eq 9 with respect to time, ff_0 can, after some manipulation, be expressed in terms of the Scheil integral, as follows (Ref 1):

$$\frac{f}{f_0} = 1 - \left(\int_0^t \frac{dt}{t_1^*} \right)^{1/2} \quad (\text{Eq 12})$$

Then, in the isothermal case, this clearly yields the original form of Eq 9. However, the appearance of the Scheil integral in Eq 12 shows that the reaction also is additive in the general sense defined by Christian (Ref 3), which makes it applicable to a wide range of thermal treatments under conditions where this solution is valid.

Spherical Precipitates. A similar flux balance for spherical precipitates leads to the following expression for the dissolution rate at a constant temperature (Ref 15):

$$\frac{dr}{dt} = -\frac{kD}{2r} - \frac{k}{2} \sqrt{\frac{D}{\pi t}} \quad (\text{Eq 13})$$

The $1/r$ term on the right side of Eq 13 stems from the steady-state part of the diffusion field, while the term $1/\sqrt{t}$ arises from the transient part. Because of the complex form of this equation, it is not possible to arrive at a closed analytical solution that can serve as a basis for establishing a valid nonisothermal rate law. However, if the transient part of the diffusion field is neglected, it is possible to proceed as before and to obtain a closed analytical solution for the variation of the particle radius, r , with time (Ref 14–16):

$$r^2 = r_0^2 - kD_r t \quad (\text{Eq 14})$$

This simplified solution is valid when $t > 100r_0^2/\pi D$.

Equation 14 can be manipulated and rewritten in a dimensionless form analogous to that done in the one-dimensional case. By introducing the scaled volume fraction $ff_0 = (r/r_0)^3$ and the corresponding time constant t_2^* for the reaction, the following is obtained (Ref 1):

$$\frac{f}{f_0} = \left(1 - \frac{t}{t_2^*} \right)^{3/2} \quad (\text{Eq 15})$$

where the time constant for complete dissolution is given by:

$$t_2^* = t_{r2} \left(\frac{k_r}{k} \right) \left(\frac{D_r}{D} \right) \left(\frac{r_0}{r_0^*} \right)^2 \quad (\text{Eq 16})$$

taking t_{r2} equal to:

$$t_{r2} = \frac{(r_0^*)^2}{k_r D_r} \quad (\text{Eq 17})$$

Similarly for platelike precipitates, Eq 15 can be expressed in terms of the Scheil integral (Ref 1):

$$\frac{f}{f_0} = \left(1 - \int_0^t \frac{dt}{t_2^*} \right)^{3/2} \quad (\text{Eq 18})$$

Although Eq 18 is derived on the basis of the steady-state part of the diffusion field around the particles, the preceding analysis shows that the additivity concept is readily applicable to particle dissolution. The salient point appears to be the form of the isothermal starting equation, which must be simple enough to allow substitution of time with the primary state variables f and T in the nonisothermal rate law. Again, a slight modification of the rigorous form of state variable evolution law is required, in that the evolution law also depends on the initial values of f and r .

Case Study: Grain-Boundary Liquefaction in Al-Zn-Mg Weldments. As a first example of applications of the principles outlined earlier, consider grain-boundary liquation, which may occur if the constituent phases situated at the boundaries do not dissolve before the eutectic temperature is reached (Ref 17).

This phenomenon can be modeled by assuming that dissolution occurs within a sphere surrounding each particle. This means that the dissolution can be predicted by combining Eq 18 with an appropriate heat flow model, as described in Ref 17. It is then possible to calculate the degree of particle dissolution occurring during single-pass butt welding of Al-Zn-Mg alloys for different starting conditions (Ref 17). The results are summarized in Fig. 2. Figure 2(a) shows a sketch of the temperature-time pattern within the subsolidus region of the HAZ during welding. It follows that points located close to the solidus isotherm are most liable to grain-boundary liquation because the heating rate increases with decreasing distance from the fusion boundary. The process diagram in Fig. 2(b) has axes of weld energy input, q_0/vd , and precipitate (plate) thickness, $2B_0$, and displays contours of $ff_0 = 0$ for various positions within the subsolidus region. Each of these contours defines the condition for achieving full particle dissolution at 475 °C (887 °F) during heating

to the indicated peak temperatures. Above the field boundaries, the risk of local melting is small, because the dissolution process is completed before the eutectic temperature is reached. Similarly, crossing these lines means that the melting reaction will be triggered, because remnants of the particles exist at the grain boundaries when the eutectic temperature of 475 °C (887 °F) is reached.

Particle Coarsening

When dispersed particles have some solubility in the matrix in which they are contained, there is a tendency for the smaller particles to dissolve and for the matter in them to precipitate on larger particles. The driving force for the reaction is provided by the consequent reduction in the total interfacial energy, and ultimately, only a single large particle would exist within the system (Ref 5).

Coarsening Kinetics. The classical theory for particle coarsening was developed independently by Lifshitz and Slyozov (Ref 18) and by Wagner (Ref 19). According to their analysis, the kinetics is controlled by volume diffusion through the matrix. Provided that no solute is lost to the surrounding matrix during the process (i.e., $df/dt = 0$), the time dependence of the mean particle radius, r , may be written as (Ref 18, 19):

$$r^3 - r_0^3 = \frac{c_1 t}{T} \exp\left(-\frac{Q_d}{RT}\right) \quad (\text{Eq 19})$$

where r_0 is the initial particle radius, Q_d is the activation energy for particle coarsening (here taken equal to the activation energy for diffusion of the less mobile constituent element), and c_1 is a kinetic constant.

Equation 19 can be written in a dimensionless form by introducing:

$$X = \frac{r^3 - r_0^3}{r_0^3} = \frac{c_1 t}{r_0^3 T} \exp\left(-\frac{Q_d}{RT}\right) \quad (\text{Eq 20})$$

Let t_{r3} denote the time taken to reach a certain value $X = X_c$ at a chosen reference temperature, $T = T_r$. Then:

$$X_c = \frac{c_1 t_{r3}}{r_0^3 T_r} \exp\left(-\frac{Q_d}{RT_r}\right) \quad (\text{Eq 21})$$

Dividing Eq 20 by Eq 21 gives:

$$\frac{X}{X_c} = \frac{t T_r}{t_{r3} T} \exp\left[\frac{Q_d}{R} \left(\frac{1}{T_r} - \frac{1}{T}\right)\right] \quad (\text{Eq 22})$$

Based on Eq 22, it is possible to define the time constant for the system:

$$t_3^* = t_{r3} \frac{T}{T_r} \exp\left[\frac{Q_d}{R} \left(\frac{1}{T_r} - \frac{1}{T}\right)\right] \quad (\text{Eq 23})$$

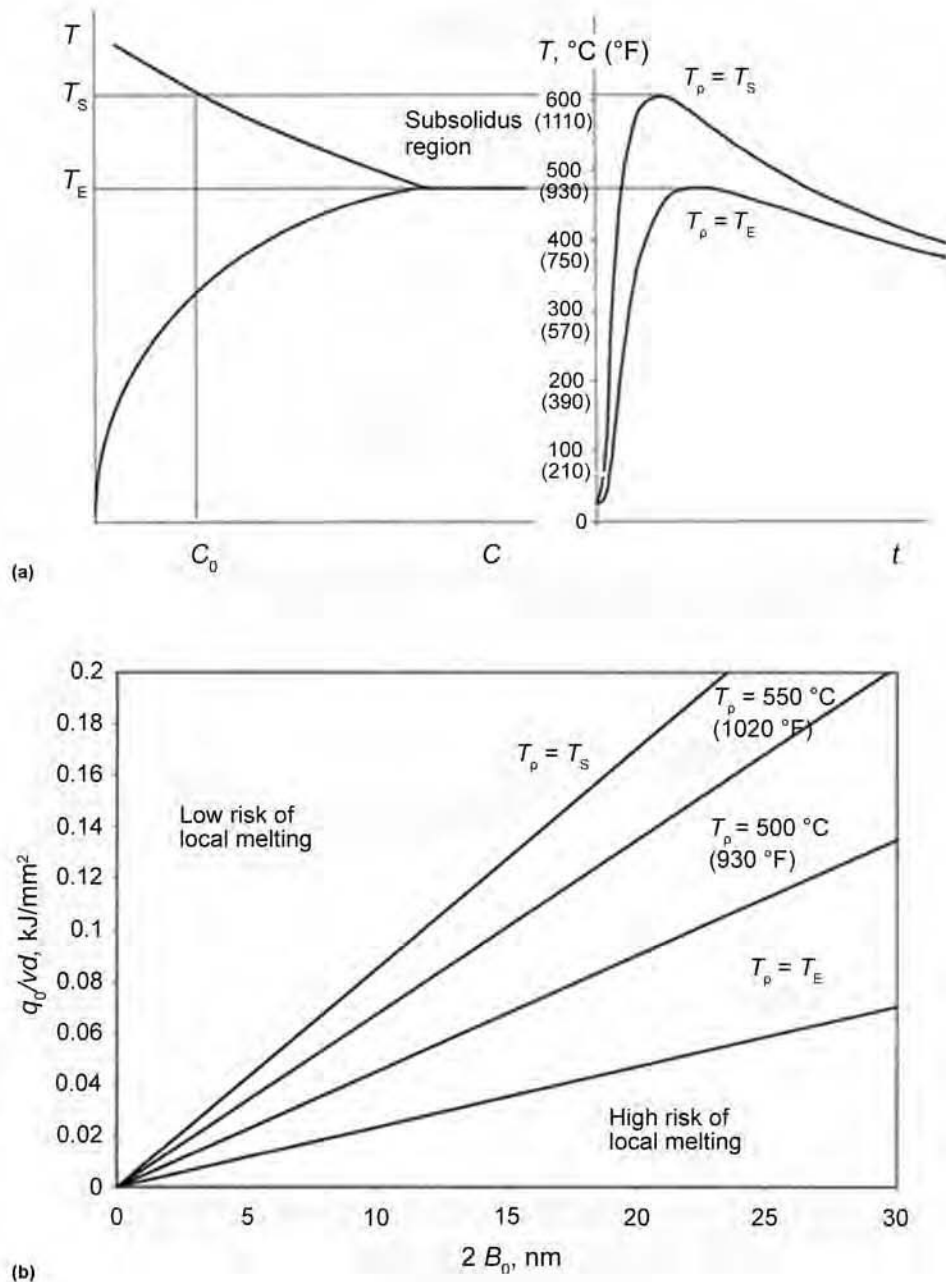

Fig. 2 Conditions for local melting during single-pass butt welding of Al-Zn-Mg extrusions. (a) Schematic representation of the temperature-time pattern within the subsolidus region of the weld heat-affected zone. (b) Process diagram showing contours of $f/f_0 = 0$ for various positions within the subsolidus region. Source: Ref 1, 17

which leads to the following expression for X :
$$\frac{dX}{dt} = \frac{X_c}{t_3^2} \tag{Eq 25}$$
 and
$$X = X_c \frac{t}{t_3^2} \tag{Eq 24}$$

Isokinetic Solution. Equation 24 provides a more general description of the original Lifshitz-Slyozov-Wagner (LSW) equation. To obtain the desired isokinetic solution, Eq 24 must first be rewritten in a differential form, followed by independent integration of the left and right sides:

$$X = X_c \int_0^t \frac{dt}{t_3^2} \tag{Eq 26}$$

From Eq 26, $X = X_c$ when the value of the Scheil integral is equal to unity. Thus, in the nonisothermal case, the total time to reach X_c

is obtained simply by adding the fractions of time to reach this stage isothermally until the sum is equal to unity.

Case Study: Coarsening of TiN during Steel Welding. The isokinetic coarsening law can be used to predict the extent of particle coarsening that occurs within the HAZ during welding of titanium-microalloyed steels. Details of the calculations can be found in Ref 20.

Problem Description. The situation is described in Fig. 3. The problem of interest here is to calculate the size of the TiN precipitates in different positions from the fusion boundary. This requires quantitative information about the weld thermal program (via a heat flow model) along with data for the coarsening kinetics of TiN in low-alloy steels (Ref 20). Coarsening of TiN may, in turn, lead to extensive austenite grain growth within the high-peak-temperature regions of the HAZ, with consequent formation of undesirable (low-toughness) microstructures such as upper bainite and Widmanstätten ferrite during the γ -to- α transformation.

Coarsening Behavior. By calculating the value of the Scheil integral at discrete points across the HAZ, the diagram in Fig. 4 can be constructed. In these calculations, it is assumed that coarsening occurs within small volume elements, where the length scale is considerably less than the actual HAZ thermal gradient. It is evident from this figure that significant coarsening of the precipitates occurs within the HAZ during welding, particularly in regions close to the fusion boundary where the peak temperature of the thermal cycle is high. Moreover, a comparison with relevant microstructure data shows that the predicted increase in the particle size is in fair agreement with experimental observations (Ref 20, 21). This suggests that the kinetics described by the classic LSW model is the dominant coarsening mechanism for TiN under the prevailing circumstances.

Recrystallization

Recrystallization of a cold-worked metal is a thermally activated transformation characterized by the nucleation and growth of new strain-free grains. The reaction is driven by the stored energy in the cold-worked matrix, and the reaction kinetics is a function of both the nucleation rate and the growth rate. Recrystallization leads to the formation of nearly defect-free crystallites and the subsequent growth of these into the surrounding structure (Ref 22, 23).

In welding, recrystallization may occur in the HAZ in positions where the peak temperature during the weld thermal cycle has been sufficiently high. The resulting recrystallized grain structure may impair the structural integrity of the weld, because of the associated reduction in strength and fracture toughness (Ref 24, 25).

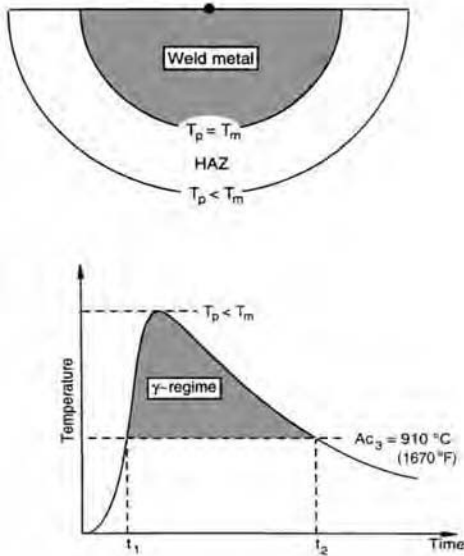

Fig. 3 Schematic diagrams showing some characteristic isothermal contours and the resulting time-temperature pattern within a weld heat-affected zone (HAZ). Source: Ref 1, 20

Recrystallization kinetics can be solved isothermally or isokinetically.

Isothermal Solution. By assuming a constant and isotropic growth rate and random spatial distribution of nucleation sites, the volume fraction of a transformed material, X_{rex} , can be described by an Avrami type of equation (Ref 26, 27):

$$X_{\text{rex}} = 1 - \exp(-t/\tau)^n \quad (\text{Eq 27})$$

where the temperature dependence of the time constant, τ , is given as (Ref 27, 28):

$$\tau = \tau_0 \exp(Q_{\text{app}}/RT) \quad (\text{Eq 28})$$

taking Q_{app} equal to the apparent activation energy for recrystallization.

Let t_{r4} denote the time taken to reach a certain value $X_{\text{rex}} = X_r$ at a chosen reference temperature, $T = T_r$. Then:

$$X_r = 1 - \exp(-t_{r4}/\tau)^n \quad (\text{Eq 29})$$

Combining Eq 27 to 29 gives:

$$X_{\text{rex}} = 1 - (1 - X_r)^{(t/t_{r4})^n} \quad (\text{Eq 30})$$

where t_4^* is given as:

$$t_4^* = t_{r4} \exp\left[\frac{Q_{\text{app}}}{R} \left(\frac{1}{T} - \frac{1}{T_r}\right)\right] \quad (\text{Eq 31})$$

Equation 30 provides a more general description of the original Avrami equation and is the basis for the isokinetic solution presented as follows.

Isokinetic Solution. To obtain the desired isokinetic solution, Eq 30 must first be rewritten in

Fig. 4 Predicted coarsening behavior of TiN during steel welding. HAZ, heat-affected zone. Adapted from Ref 1, 20

a differential form and then the left and the right sides independently integrated. This gives:

$$X_{\text{rex}} = 1 - (1 - X_r)^{I/n} \quad (\text{Eq 32})$$

where I is the Scheil integral, defined as:

$$I = \int_0^t \frac{dt}{t_4^*} \quad (\text{Eq 33})$$

Case Study: Recrystallization during Welding of Aluminum Alloys. The isokinetic recrystallization law can be used to predict the extent of recrystallization that occurs within the HAZ during welding of predeformed wrought aluminum-magnesium alloys.

Problem Description. The problem of interest here is to calculate the fraction recrystallized in different positions in the HAZ. This requires quantitative information about the weld thermal program (by means of an analytical heat flow model) along with data for the recrystallization kinetics for the actual aluminum alloy.

To illustrate the recrystallization behavior during welding of aluminum-magnesium alloys, a set of mutually consistent kinetic data have been obtained by reexamining the experimental data reported by Sarrazin (Ref 28). In this case, $T_r = 673$ K (400 °C, or 750 °F), $t_{r4} = 4.7$ s, $X_r = 0.63$, $Q_{\text{app}} = 183$ kJ/mol, and $n = 1.23$ are deemed to be representative of work-hardened AA5086 in the H24 condition.

Recrystallization Behavior. By calculating the value of the Scheil integral at discrete points across the HAZ, the fraction recrystallized can be obtained as a function of the distance from the weld centerline, as illustrated in Fig. 5(a). These plots show a comparison between calculated and measured fractions of recrystallized grains following welding. Figure 5(b) shows similar plots for hardness, where the predicted fractions recrystallized from Fig. 5(a) are converted to hardness by means of a simple regression formula. It follows that significant softening takes place within the HAZ during welding of this specific aluminum alloy. The inclination to recrystallization during welding is even more clearly revealed in Fig. 6, which displays contours of constant fraction recrystallized X_{rex} in q_0/vd (alternatively $\Delta t_{3/2}$) and T_p space. Based on this diagram, it can be concluded that recrystallization of the high-peak-temperature regions of the HAZ cannot readily be avoided but will occur even at very low values of q_0/vd representative of laser and electron beam welding.

Grain Growth

A general problem associated with welding of metals and alloys is the instability of the matrix grain structure following coarsening or dissolution of the pinning grain-boundary precipitates (Ref 1). Depending on the circumstances, this may lead to either normal or

Fig. 5 Comparison between measured and predicted recrystallization behavior following welding of preformed AA5086-H24. (a) Fraction of recrystallized grains vs. distance from fusion line. (b) Hardness vs. distance from fusion line. Adapted from experimental data from Ref 28

abnormal grain growth. Normal grain growth is a thermally activated process driven by the reduction in the grain-boundary surface energy. Physically, it occurs by growth of the larger grains at the expense of the smaller ones, which tend to shrink.

Grain Growth Kinetics. A common observation in metals and alloys is that the size distributions of grain aggregates during normal growth become equivalent when the measured grain size parameter, g , is normalized (scaled)

by the time-dependent average of this metric, \bar{g} . This means that grain structures are completely characterized, in a statistical sense, by simple probability functions of the standard deviation of the distribution together with the time dependence of the average-sized scale, \bar{g} .

In its simplest form, the fundamental rate law describing the change in \bar{g} with time and temperature under various grain-boundary pinning conditions can be written as (Ref 29):

$$\frac{d\bar{g}}{dt} = M_0^* \exp\left(-\frac{Q_{app}}{RT}\right) \left[\frac{1}{\bar{g}} - \frac{1}{\bar{g}_{lim}}\right]^{(1/n)-1} \quad (\text{Eq 34})$$

where n is the time exponent for grain growth (≤ 0.5), M_0^* is a mobility term (with the dimension $m^{1/n}/s$), Q_{app} is the apparent activation energy for grain growth, and \bar{g}_{lim} is the limiting grain size, which, according to Hellman and Hillert (Ref 30), is given as:

$$\bar{g}_{lim} = \frac{8r}{9f} \quad (\text{Eq 35})$$

The form of Eq 34 shows that the rate of grain growth depends on the current value of the three primary state variables, \bar{g} , T , and \bar{g}_{lim} , where the latter is a group parameter that incorporates two other variables (i.e., the particle radius, r , and the volume fraction, f).

Dimensionless Evolution Equation. Equation 34 can be written in a dimensionless form by introducing the scaled state variables $X = \bar{g}/\bar{g}_0$ and $Y = \bar{g}_{lim}/\bar{g}_0$, where \bar{g}_0 is equal to the initial grain size of the material at time $t = 0$. After substitution and some manipulation, the following equation is obtained (Ref 1):

$$\frac{dX}{dt} = \frac{1}{t_5^*} \left[\frac{1}{X} - \frac{1}{Y}\right]^{(1/n)-1} \quad (\text{Eq 36})$$

where t_5^* is the time constant for the reaction, defined as:

$$t_5^* = t_{r5} \exp\left(\frac{Q_{app}}{RT}\right) \quad (\text{Eq 37})$$

taking $t_5^* = \bar{g}_0^{1/n}/M_0^*$.

Based on Eq 36, a number of special solutions can be derived that apply to normal grain growth under various grain-boundary pinning conditions. Some of these are presented as follows.

Grain Growth in the Absence of Pinning Precipitates. In the absence of grain-boundary pinning precipitates, $f = 0$, $\bar{g}_{lim} \rightarrow \infty$, and $1/Y = 0$. Under such conditions, Eq 36 becomes a first-order separable differential equation, which can be integrated as follows (Ref 1):

$$X = \left[1 + \frac{1}{n} \int_0^t \frac{dt}{t_5^*}\right]^n \quad (\text{Eq 38})$$

This solution again contains the Scheil integral, which shows that the governing evolution equation is isokinetic in the general sense defined by Christian (Ref 3).

Grain Growth in the Presence of Stable Precipitates. If grain growth occurs in the presence of stable precipitates (e.g., oxide inclusions in steel weld metals) (Ref 20), the state variable representing the limiting grain size becomes constant and independent of temperature (i.e., $Y = Y^*$). In the limiting case where $n = 0.5$, Eq 36 yields the following closed isokinetic solution:

$$-XY^* - (Y^*)^2 \ln\left(1 - \frac{X}{Y^*}\right) + Y^* + (Y^*)^2 \ln\left(1 - \frac{1}{Y^*}\right) = \int_0^t \frac{dt}{t_5^*} \quad (\text{Eq 39})$$

from which the mean grain size can readily be obtained. In other cases ($n < 0.5$), numerical integration methods must be employed to evaluate X .

It follows from Eq 39 that the grain-growth inhibiting effect of the precipitates is very small during the initial stage of the growth process in situations where $\bar{g}_0 \ll \bar{g}_{lim}$, corresponding to $X \ll Y^*$. Under such conditions, the grains will coarsen at a rate comparable with that observed for free grain growth, as described by Eq 38. The grain-coarsening process gradually retards as the matrix grain size increases, until it comes to a complete stop when X approaches Y^* .

Grain Growth in the Presence of Growing Precipitates. If grain growth occurs in the presence of growing precipitates, \bar{g}_{lim} will no longer be constant but will evolve with time. In the limiting case of pure particle coarsening, an approximate isokinetic solution for Y can be found by substituting Eq 19 into Eq 35. Taking Y^0 equal to the value of Y at time $t = 0$:

$$Y = \left[(Y^0)^3 + \int_0^t \frac{dt}{t_6^*} \right]^{1/3} \quad (\text{Eq 40})$$

where

$$t_6^* = t_{r6} \frac{T}{T_r} \exp\left(\frac{Q_d}{RT}\right) \quad (\text{Eq 41})$$

and

$$t_{r6} = \frac{9^3 f^3 (\bar{g}_0)^3 T_r}{8^3 c_2} \quad (\text{Eq 42})$$

Under nonisothermal conditions, Eq 36 and 40 must be solved in a fully coupled manner to obtain the actual grain size, using inputs from a separate heat flow model. However, the situation becomes much simpler if heat treatment is instead carried out isothermally, due to the fact that the time constants t_5^* and t_6^* then only differ from each other by a constant factor, $m = t_5^*/t_6^*$ (Ref 20, 31). It follows that the extent of grain growth depends on the initial value of m . If m is large, the grain-boundary precipitates will completely outgrow the matrix grains, leading to a grain-coarsening behavior quite similar to the one observed during free grain growth. Conversely, at small m values, the drag exerted by the particles becomes appreciably larger, which ultimately brings about a complete stop in the grain-growth process when X approaches Y . This type of response is characteristic of a system containing stable precipitates, as defined by Eq 39.

Grain Growth in the Presence of Dissolving Precipitates. An analogous situation exists if

the grain-boundary precipitates dissolve during heat treatment. Under such conditions, the scaled limiting grain size increases from its initial value $Y = Y^0$ at $t = 0$ toward infinity, as shown in Ref 20 and 31:

$$Y = \frac{(Y^0)^3}{(Y^0)^2 - \int_0^t \frac{dt}{t_7^*}} \quad (\text{Eq 43})$$

where t_7^* is the time constant for the reaction, which, according to Eq 17, may be written as:

$$t_7^* = \left(\frac{9\bar{g}_0}{8f}\right)^2 \frac{1}{kD} \quad (\text{Eq 44})$$

In the isothermal case, the ratio between the time constants t_5^* and t_7^* becomes constant and equal to m^* . From this it can be seen that the stability of the second-phase particles is sensitive to variations in the proportionality constant, m^* . Normally, the precipitates will exert a drag on the grain boundaries as long as they are present in the metal matrix. However, when the dissolution process is completed, the matrix grains are free to grow without any interference from precipitates. This means that the grains, after prolonged heat treatment, will coarsen at a rate that is comparable with free grain growth. Conversely, if the dissolution process is more sluggish (conforming to small m^* values), the grain-growth behavior becomes similar to that predicted from Eq 39, which applies to a system containing stable precipitates.

Grain Growth in Welding of Structural Steels. Welding diagrams similar to the one

shown in Fig. 6 for recrystallization are also very useful for grain growth, because they summarize the effect of the important process variables on the austenite grain evolution in a quantitative manner. At the same time, they provide a good overall indication of the grain-growth behavior of various grades of steel during welding. The welding diagrams presented in the following sections are constructed on the basis of the nonisothermal grain-growth models described previously in combination with analytical heat flow models (Ref 20).

Titanium-microalloyed steels are widely used in welded structures. From a thermodynamic standpoint, additions of small amounts of titanium to steel would be expected to impede austenite grain coarsening during welding by virtue of its ability to form stable nitrides even at high temperatures.

The response of titanium-microalloyed steels to the temperature history in the limiting case of thick-plate welding is shown in Fig. 7. This diagram reveals that the presence of finely dispersed TiN particles in the base material will retard austenite grain growth within certain regions of the HAZ during welding. However, because particle coarsening is a physical phenomenon occurring at temperatures well below the equilibrium solvus of the precipitates, the problem cannot be eliminated. This means that a coarse-grained region will always form adjacent to the fusion boundary, even at very low heat inputs, as indicated by the nomograms in Fig. 7.

Niobium-Microalloyed Steels. This class of steel is used for a variety of applications,

Fig. 6 Computed heat-affected zone recrystallization diagram for thin-plate welding of predeformed AA5086-H24 showing contours of X_{rex} for various combinations of q_d/v_d and T_p

Fig. 7 Computed heat-affected zone grain-growth diagram for thick-plate welding of a titanium-microalloyed steel. Source: Ref 1, 20

including shipbuilding, pressure vessels, oil platforms, and bridges. The steels contain small amounts of microalloying elements, such as niobium, vanadium, and aluminum, which, during thermomechanical processing, combine with carbon and nitrogen to form fine dispersions of grain-boundary pinning precipitates. They are readily weldable but suffer from severe HAZ grain coarsening due to dissolution of the carbonitrides at elevated temperatures (Ref 20, 21, 32).

It is evident from the nomograms in Fig. 8 that considerable austenite grain coarsening occurs during welding of niobium-microalloyed steels because of dissolution of the grain-boundary pinning precipitates. On average, the HAZ austenite grain size adjacent to the fusion boundary is four to six times larger than that observed for titanium-microalloyed steels, as shown previously in Fig. 7. This gives rise to a high HAZ hardenability, which facilitates formation of low-temperature transformation products such as martensite and bainite during cooling (Ref 20).

Coupled Reactions in Duplex Stainless Steel Weldments

In duplex stainless steel weldments, the microstructure evolution occurs in a coupled manner. In the model by Hemmer and Grong (Ref 33), this is handled mathematically by assuming that the reactions occur in series

(i.e., succession) rather than in parallel, which allows a one-way exchange of inputs and outputs between the various submodels.

Problem Description. Referring to Fig. 9, the important reactions that must be modeled are the dissolution of austenite during heating, subsequent grain growth in the delta-ferrite regime, and finally, the decomposition of delta ferrite to austenite during cooling.

Due to the complexity of the rate phenomena involved, a differential formulation of the underlying diffusion problems is required, based on the internal state variable approach. However, a significant reduction in the programming and computational effort can be achieved if the solutions are rewritten in a closed (isokinetic) form, as described previously in the section “Definition of an Isokinetic Reaction” in this article. In the present treatment, the temperature dependence of the reactions is captured mathematically in terms of the Scheil integral (i.e., Eq 6), which represents the kinetic strength of a given thermal cycle with respect to microstructure evolution. In a calibrated form, these solutions yield results that are within 10% of the values calculated from the corresponding differential evolution equations. Further details are given in Ref 33.

Dissolution of Austenite. As shown in Fig. 9, dissolution of austenite occurs during the initial heating leg of the thermal cycle and is well described by the following equation (Ref 33):

$$\frac{f}{f_0} = 1 - \left[\int_{t=0}^{t_1} \frac{dt}{t_{8d}^*} \right]^{1/2} \tag{Eq 45}$$

where f and f_0 are the current and the initial volume fraction of austenite in the material, respectively, while t_{8d}^* is the time constant for the reaction, defined as:

$$t_{8d}^* = t_{r8d} \left(\frac{C_{\delta,i}^r - C_{\delta}^r}{C_{\delta,i}^r - C_{\delta}^r} \right)^2 \frac{(C_{\gamma} - C_{\delta,i})(C_{\gamma} - C_{\delta,i})}{(C_{\gamma}^r - C_{\delta,i}^r)(C_{\gamma}^r - C_{\delta,i}^r)} \left(\frac{x_{\gamma}}{x_{\gamma}^r} \right)^2 \exp \left[\frac{Q_d}{R} \left(\frac{1}{T} - \frac{1}{T_{r1d}} \right) \right] \tag{Eq 46}$$

In a real welding situation, full dissolution of the austenite phase will occur within the high-peak-temperature region of the HAZ. This requires a separate treatment of the austenite formation on subsequent cooling. Conversely, within the partly reverted region, back diffusion of nitrogen leads to renewed growth of the parent austenite phase during cooling, which tends to reverse the previous dissolution process and restore the original phase balance. Still, this is a very delicate problem to handle mathematically, because a differential formulation of the nitrogen flux balance is required. However, as shown in Ref 33, a simple isokinetic solution can be found if the phase transformation is split into two different subreactions:

$$\frac{f}{f_0} = 1 - \left[\int_{t=0}^{t_1} \frac{dt}{t_{8d}^*} \right]^{1/2} + \left[\int_{t_1}^{t_2} \frac{dt}{t_{8g}^*} \right]^{1/2} \tag{Eq 47}$$

taking

$$t_{8g}^* = t_{r8g} \left(\frac{C_m^r - C_{\delta,i}^r}{C_m^r - C_{\delta,i}^r} \right)^2 \frac{(C_{\gamma} - C_m)(C_{\gamma,i} - C_{\delta,i})}{(C_{\gamma}^r - C_m^r)(C_{\gamma,i}^r - C_{\delta,i}^r)} \left(\frac{x_{\gamma}}{x_{\gamma}^r} \right)^2 \exp \left[\frac{Q_d}{R} \left(\frac{1}{T} - \frac{1}{T_{r1g}} \right) \right] \tag{Eq 48}$$

The first term on the right side of Eq 47 represents the contribution from the initial dissolution that occurs during heating, while the latter term includes the subsequent growth of the parent austenite phase on cooling. Note that the integration limit, t_1 , refers to the time at which the interface concentration, $C_{\delta,i}$, drops below the matrix concentration, C_m , during cooling. This defines the onset of the transient growth period.

Delta-Ferrite Grain Growth. In general, growth of the delta-ferrite grains will occur both during and after the decomposition of the austenite phase. In the former case, the extent of grain growth is determined by the rate of austenite dissolution and is well described by the following equation (Ref 33):

$$\bar{g}_{\delta} = 2 \left[\frac{x_{\gamma}}{f_0} - x_i \right] \tag{Eq 49}$$

Fig. 8 Computed heat-affected zone grain-growth diagram for thick-plate welding of a niobium-microalloyed steel. Source: Ref 1, 20

Fig. 9 Schematic representation of the heat-affected zone microstructure evolution during welding of duplex stainless steels. Source: Ref 1, 33

where x_i and x_γ are the current and initial half-thickness of the austenite plates, respectively, while \bar{g}_δ is the mean delta-ferrite grain size.

Normal grain growth takes place within the fully reverted region of the weld HAZ and is conveniently described by an isokinetic solution of the form (Ref 33):

$$Z = \frac{(\bar{g}_\delta)^{1/n} - (\bar{g}_{\delta,0})^{1/n}}{(\bar{g}_{\delta,0})^{1/n}} = Z_r \int_{t_1}^{t_2} \frac{dt}{t_0^*} \quad (\text{Eq 50})$$

where n is the time exponent for grain growth, Z_r is the value of Z at the chosen reference time $t = t_{r9}$ and temperature $T = T_{r2}$, and t_0^* is the time constant for the reaction defined as:

$$t_0^* = t_{r9} \exp \left[\frac{Q_{app}}{R} \left(\frac{1}{T} - \frac{1}{T_{r2}} \right) \right] \quad (\text{Eq 51})$$

The resulting delta-ferrite grain size can then be found by solving Eq 50 with respect to \bar{g}_δ :

$$\bar{g}_\delta = \left[\bar{g}_{\delta,0}^{1/n} (1 + Z) \right]^n \quad (\text{Eq 52})$$

where $\bar{g}_{\delta,0}$ is the initial delta-ferrite grain size following complete dissolution of the austenite phase (equal to $2x_\gamma/f_0$).

Delta-Ferrite Decomposition. During the cooling leg of the thermal cycle, delta ferrite starts to decompose to austenite below the A_4 temperature, as shown in Fig. 9. As a starting point, the delta-ferrite grains are assumed to be spherical (with a radius $r = r_\delta$). Under such conditions, the austenite phase will start to grow from the outside of the sphere and toward the center. If the cooling rate is sufficiently high that soft impingement due to nitrogen depletion can be neglected (as in electron beam welding), the thickness $r_\delta - r_i$ of the austenite layer is given by the following three-dimensional isokinetic solution (Ref 33):

$$s_i = \sqrt{\frac{1}{3} r_i^2 + \frac{2}{3} r_\delta^2} - r_\delta = s_i^r \left(\int_{t_1}^{t_2} \frac{dt}{t_0^*} \right)^{1/2} \quad (\text{Eq 53})$$

where s_i^r is the value of s_i at the chosen reference time $t = t_{r10}$ and temperature $T = T_{r3}$, and t_0^* is the time constant for the reaction defined as:

$$t_0^* = t_{r10} \left(\frac{C_0^r - C_{\delta,i}^r}{C_0 - C_{\delta,i}} \right)^2 \frac{(C_{\gamma,i} - C_{\delta,i}) (\bar{C}_\gamma - C_0)}{(C_{\gamma,i}^r - C_{\delta,i}^r) (\bar{C}_\gamma^r - C_0^r)} \exp \left[\frac{Q_d}{R} \left(\frac{1}{T} - \frac{1}{T_{r3}} \right) \right] \quad (\text{Eq 54})$$

To quantify the extent of delta-ferrite decomposition occurring during welding, it is necessary to convert the current value of r_i into an equivalent volume fraction of austenite. For the spherical grain morphology assumed in the model, the volume fraction of austenite is simply given by Ref 33:

$$f = \frac{\frac{4}{3} \pi r_\delta^3 - \frac{4}{3} \pi r_i^3}{\frac{4}{3} \pi r_\delta^3} = \frac{r_\delta^3 - r_i^3}{r_\delta^3} \quad (\text{Eq 55})$$

Case Study: Application to Electron Beam Welding. The direct coupling between the various microstructure models is illustrated in Fig. 10, which shows the calculated microstructure evolution in two different positions within the HAZ. Considering the fully reverted region (Fig. 10a), the austenite dissolves completely during the heating leg of the thermal cycle. This process is succeeded by free delta-ferrite grain growth and partial decomposition of the delta ferrite to austenite during cooling below the A_4 temperature. In the partly reverted region of the HAZ (Fig. 10b), the austenite dissolution

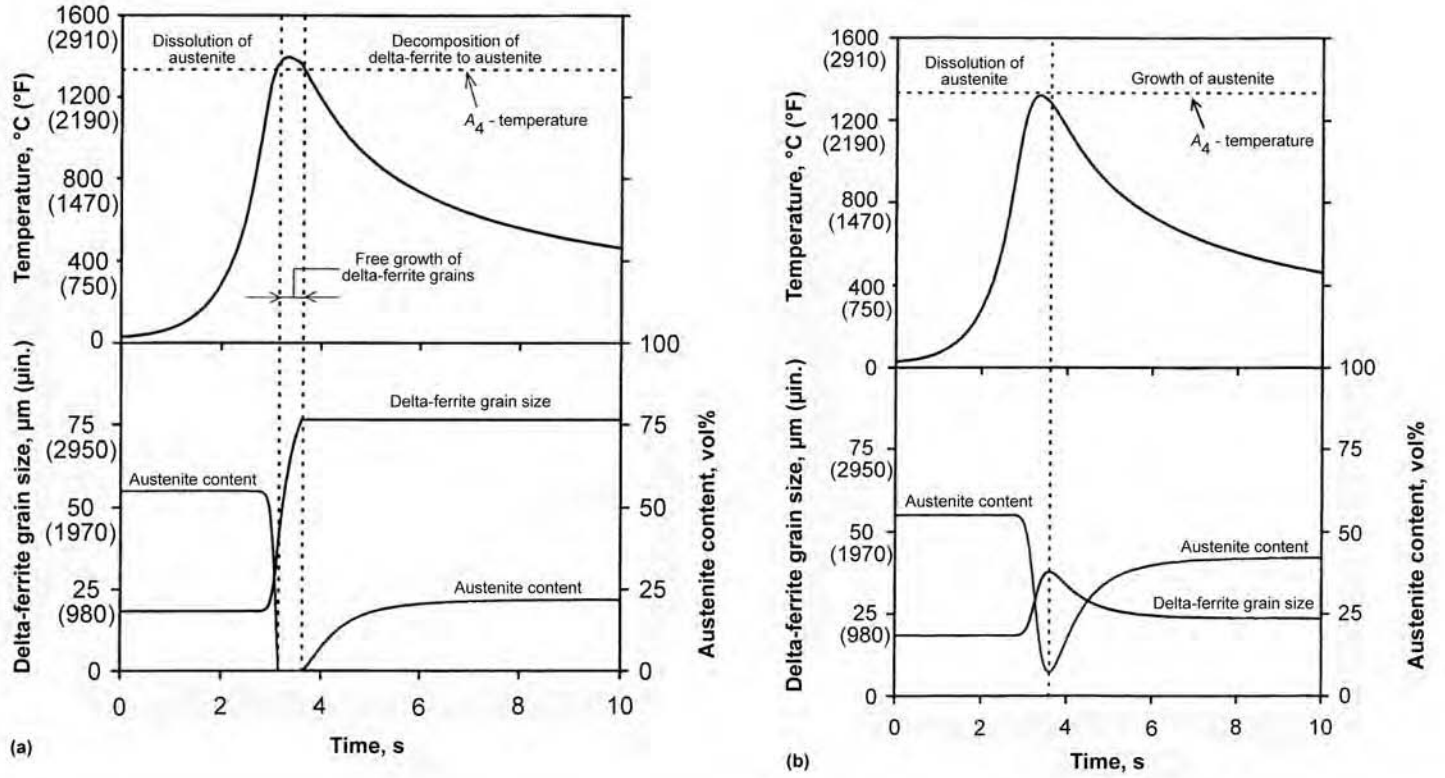

Fig. 10 Examples of outputs from the process model for duplex stainless steels showing details of the microstructure evolution at various locations within the weld heat-affected zone (HAZ). (a) Fully reverted region. (b) Partly reverted region. (c) Optical micrograph showing the sharp boundary between the fully and partly reverted regions of the weld HAZ. Source: Ref 1, 33

is incomplete, and hence, extensive growth of the austenite occurs on cooling due to back diffusion. This retransformation explains why the boundary between the two regions during electron beam welding is quite sharp with no indication of the previous austenite dissolution, as illustrated by the optical micrograph in Fig. 10(c).

Summary of Isokinetic Solutions

In the previous sections, the versatility of the internal state variable approach in modeling of nonisothermal transformations for various materials and processes has been demonstrated. In cases where the reaction is isokinetic and the temperature dependency can be captured mathematically in terms of the Scheil integral (i.e., Eq 6), simple analytical solutions exist that are quick and easy to implement and are accessible to most users. Table 1 summarizes the various analytical solutions presented in the previous sections, showing that a wide range of processes can be described by the same type of equation based on the Scheil integral formulation.

Complex Microstructure Models Describing the Evolution of a Particle Size Distribution

So far, only reactions that involve a single diffusion mechanism (e.g., dissolution or coarsening of precipitates) have been considered. Although these represent idealized cases, the isokinetic models can be applied to a wide range of problems that are relevant to thermal processing of metals and alloys. However, they fail when the diffusion problem is more complicated and requires a full description of the particle size distribution as well. For example, this is the case during industrial heat treatment and welding of age-hardening aluminum alloys, because the transformation has a strong memory of the past process steps due to interactions between different groups or classes of particles that form at various temperatures (Ref 34). In the following, a numerical solution is presented, capable of handling nucleation, growth, and coarsening, and likewise dissolution, of hardening precipitates in Al-Mg-Si alloys during aging, welding, and postweld heat treatment (PWHT). By coupling this to a separate strength model for shearing and bypassing of particles by dislocations, the evolution of the macroscopic yield stress at room temperature can be calculated at each time step.

Microstructural Changes during Heat Treatment and Welding of Al-Mg-Si Alloys

During artificial aging, a high density of fine, needle-shaped β'' particles form uniformly in

the matrix, as shown in Fig. 11(a), which is the dominating hardening phase in T6 heat treated Al-Mg-Si alloys (Ref 35). However, because these precipitates are thermodynamically unstable in a welding situation, the smallest ones will start to dissolve in parts of the HAZ where the peak temperature has been above, say 250 °C (480 °F), while the larger ones will continue to grow (Ref 36). Close to the weld fusion line, full reversion of the β'' particles is achieved (Ref 20, 35, 37). At the same time, coarse, rod-shaped β' precipitates may form in the intermediate-peak-temperature range between 250 and 480 °C (480 and 900 °F), as indicated in Fig. 11(b). In the model, these refer to the largest particles in the distribution, which will grow rapidly in the presence of the abundant solute being supplied from the small, dissolving β'' precipitates.

If welding is succeeded by a PWHT reprecipitation of hardening, β'' particles will take place within the high-peak-temperature regions of the weld HAZ, as shown in Fig. 11(c). The extent to which this occurs depends on both the matrix vacancy concentration and the level of magnesium and silicon in solid solution, according to classic nucleation theory (Ref 20). Accordingly, the reprecipitation would be expected to be most extensive in the fully reverted region close to the weld fusion line, owing to the combined effect of a high solute content and a high concentration of quenched-in vacancies. Conversely, the renewed β'' formation will be suppressed in parts of the HAZ where the peak temperature is lower, because the aluminum matrix in these regions will be depleted with respect to vacancies and solute. This eventually leads to the development of a permanent soft region within the weld HAZ after PWHT, in agreement with experimental observations (Ref 38, 39).

If this simplified description of the microstructure evolution is accepted, it is possible to simulate the sequence of precipitation and reversion reactions occurring during artificial aging, welding, and PWHT of age-hardening Al-Mg-Si alloys, along the lines indicated by Myhr and Grong (Ref 34). A brief description of the basic features of the model is given as follows.

Precipitation Model

The precipitation model consists of the following three components:

- A nucleation model, which predicts the number of stable nuclei that form at each time step
- A rate law, which calculates either the dissolution or growth rate of each discrete particle size class
- A continuity equation, which keeps record of the amount of solute being tied up in the precipitates

A brief summary of the main constitutive equations is given subsequently. Further details are given in Ref 34, 38, and 39.

Nucleation Law. Following classic nucleation theory, the nuclei form as a result of localized compositional fluctuations that occur statistically within the supersaturated matrix. The nucleation rate, j , during artificial aging and welding is conveniently expressed as follows when the effect of quenched-in vacancies on the nucleation rate is included in the expression (Ref 39):

$$j = j_0 \exp \left[\frac{-\Delta H_v}{R} \left(\frac{1}{T_p} - \frac{1}{T_{ss}} \right) \right] \exp \left[- \left(\frac{A_0}{RT} \right)^3 \left(\frac{1}{\ln(\bar{C}/C_e)} \right)^2 \right] \exp \left(- \frac{Q_d}{RT} \right) \quad (\text{Eq 56})$$

where j_0 is a pre-exponential term, A_0 is a parameter related to the potency of the heterogeneous nucleation sites in the parent material (with the units J/mol), Q_d is the activation energy for diffusion, \bar{C} is the mean solute content in the matrix, C_e is the equilibrium solute content in the matrix (given by the phase diagram), ΔH_v is the enthalpy of vacancy formation in aluminum, and T_{ss} is the solutionizing temperature, which corresponds to the chosen input value of j_0 (i.e., 530 °C, or 985 °F). In practice, j_0 and A_0 must be determined experimentally for a specific family of alloys within the Al-Mg-Si system (Ref 35, 36), while Q_d and ΔH_v can be obtained from literature data (Ref 35).

The simple form of Eq 56 makes it easy to implement in a numerical code. At the same time, the nucleation law is sufficiently relevant and comprehensive to facilitate modeling of coupled welding and PWHT operations, as described previously, because the vacancy concentration established in the former operation is embedded in the expression via the T_p term, representing the peak temperature of a specific HAZ position. Although this analytical formulation of the nucleation problem means that a consideration of diffusion and annihilation of vacancies at grain boundaries and incoherent particle/matrix interfaces during subsequent cooling/reheating is neglected, it is thought to be a reasonable approximation in the context of the model being developed.

Rate Law. The next step is to invoke the growth model. When a particle with radius r and solute concentration C_p is introduced into the system, it will either dissolve or grow, depending on whether the solute concentration in the matrix at the particle/matrix interface, C_i , exceeds \bar{C} or not. The rate at which this occurs can be expressed as (Ref 40):

$$v = \frac{dr}{dt} = \frac{\bar{C} - C_i}{C_p - C_i} \frac{D}{r} \quad (\text{Eq 57})$$

Precipitates: -small β^{II} -larger β^{II} -coarse β^I

is divided into a series of small “radius” elements, each with a size Δr . Analogous to the diffusion problem, the growth or dissolution of particles that occurs during a small time increment, Δt , can be regarded as a flux of matter in or out of the elements. Let J denote the particle flux, while N is the number density of particles within Δr . A mass balance then gives (Ref 34, 38):

$$\frac{\partial N}{\partial t} = -\frac{\partial J}{\partial r} + S \tag{Eq 59}$$

where the source term, S , describes the formation of new particles at each time step Δt . In the context of diffusional transformations, S is equal to the nucleation rate, j .

The particle flux, J , through the volume element is, in turn, given by the following equation (Ref 34, 38):

$$J = N v \tag{Eq 60}$$

where v is the growth or dissolution rate of a particle defined by Eq 57.

Hence, the governing evolution equation may be written as (Ref 34, 38):

$$\frac{\partial N}{\partial t} = -\frac{\partial(Nv)}{\partial r} + S \tag{Eq 61}$$

Moreover, if the particle size distribution is continuous, the mean solute concentration in the matrix can be expressed as (Ref 34, 38):

$$\bar{C} = C_0 - (C_p - \bar{C}) \int_0^\infty \frac{4}{3}\pi r^3 \phi dr \tag{Eq 62}$$

where ϕ is the size distribution function.

Note that Eq 62 is simply a mass balance relating the amount of solute tied up in particles to the amount of the solute drained from the matrix.

Numerical Solution. To calculate the values of N at discrete grid points, the particle size

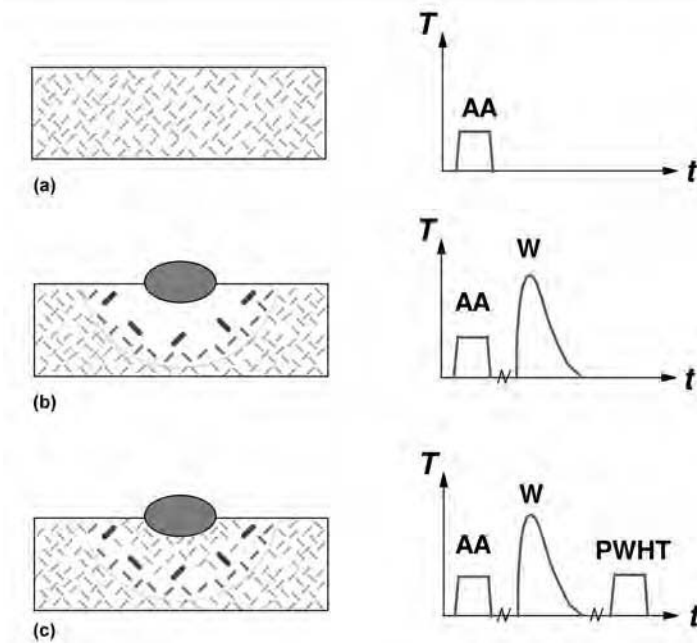

Fig. 11 Schematic diagrams showing the microstructure evolution during multistage thermal processing of Al-Mg-Si alloys involving heat treatment and welding. AA, artificial aging; W, welding; PWHT, postweld heat treatment. The outer boundary of the heat-affected zone is indicated by the semicircles in the diagrams. Adapted from Ref 36, 38

Based on the Gibbs-Thomson equation, it is then possible to obtain an explicit expression for the critical radius, r^* , of a particle that will neither grow nor dissolve (Ref 34, 38):

$$r^* = \frac{2\gamma_i V_m}{RT} \left(\ln \left(\frac{\bar{C}}{C_c} \right) \right)^{-1} \tag{Eq 58}$$

where γ_i is the particle/matrix interfacial energy, and V_m is the molar volume of the precipitates.

Because r^* depends on the current value of C_c , the thermal stability of the precipitates is sensitive to changes in the temperature during heat treatment. It follows that reheating promotes particle dissolution, whereas cooling or isothermal annealing favors nucleation, growth, and coarsening in a successive manner.

Inclusion of the Particle Size Distribution. The control volume approach is used to capture the flux balance for a distribution of particles. As a starting point, the particle distribution

distribution is divided into small intervals $[r_i, r_{i+1}]$. The continuity equation (Eq 62) may then be written as (Ref 34, 38):

$$\bar{C} = C_0 - (C_p - \bar{C}) \sum_i \frac{4}{3} \pi r_i^3 N_i \quad (\text{Eq 63})$$

where $N_i = \phi_i \Delta r_i$. From Eq 63, the particle volume fraction, f , can be calculated, taking $f = (C_0 - \bar{C}) / (C_p - \bar{C})$ as a first approximation.

Consider now a small grid-point configuration that is isolated from the particle size distribution, as shown in Fig. 12. This is delimited by dashed lines at "w" and "e," which represent the west and east boundaries, respectively. To obtain equations for N at discrete grid points, one starts by integrating the governing evolution equation over the control volume. By ignoring the source term S , Eq 61 gives (Ref 34, 38):

$$\int_w^{e} \int_t^{t+\Delta t} \frac{\partial N}{\partial t} dt dr = - \int_w^{e} \int_t^{t+\Delta t} \frac{\partial(Nv)}{\partial r} dr dt \quad (\text{Eq 64})$$

The integral on the left side of Eq 64 is equal to (Ref 34, 38):

$$\int_w^{e} \int_t^{t+\Delta t} \frac{\partial N}{\partial t} dt dr = (N_p - N_p^0) \Delta r \quad (\text{Eq 65})$$

while the right-side integral is given by (Ref 34, 38):

$$\int_w^{e} \int_t^{t+\Delta t} \frac{\partial(Nv)}{\partial r} dr dt = ((Nv)_e - (Nv)_w) \Delta t \quad (\text{Eq 66})$$

The velocities v_e and v_w at each control volume interface can be calculated from Eq 57. By combining Eq 64 to 66, the equations for discrete grid points can be cast into the following standard form (Ref 34, 38):

$$a_p N_p = a_E N_E + a_W N_W + a_p^0 N_p^0 \quad (\text{Eq 67})$$

The values of the coefficients a_p , a_E , a_W , and a_p^0 depend on the directions of the interface

Fig. 12 Grid-point configuration used in the finite-difference model showing particle fluxes entering and leaving a control volume. Adapted from Ref 34, 38

velocities, as described in Ref 34. Finally, the desired number densities are obtained by solving the set of mutually dependent equations of the form defined by Eq 67, using a standard Gaussian elimination method (Ref 34, 41).

Microstructure Evolution during Multistage Thermal Processing

In the following, the process model described in the previous section is applied to predict the microstructure evolution in Al-Mg-Si alloys during multistage thermal processing involving heat treatment and welding.

Evolution of Precipitate Structure during Artificial Aging. Referring to Fig. 11(a), the first process stage to model is artificial aging. Figure 13 shows examples of outputs from the model following prolonged artificial aging at 180 °C (355 °F) for an Al-Mg-Si alloy with a nominal composition close to AA6082 (i.e., approximately 0.9 wt% Si and 0.6 wt% Mg). Because the incubation period during nucleation is disregarded, the nucleation rate is seen to be fairly constant over an appreciable period of time, as illustrated in Fig. 13(a). The nucleation rate then drops quickly due to solute depletion, as \bar{C} approaches C_e . This coincides, in time, with the observed peak in the particle number density. Moreover, a comparison with Fig. 13(b) shows that the nucleation period is accompanied by rapid growth of the particles during the early stages of the aging process, which gradually shifts to pure coarsening when r^* approaches \bar{r} . At the entry of the coarsening period, the characteristic Lifshitz-Slyozov-Wagner (LSW) distribution is obtained (Ref 18, 19), as shown by the plots in Fig. 13(c).

Precipitate Structure in the HAZ Following Artificial Aging, Welding, and PWHT. As schematically illustrated in Fig. 11(b) and (c), the precipitate structure formed during artificial aging changes significantly during the subsequent welding and PWHT operations. These changes are readily captured by the model, as shown in Fig. 14, where predicted microstructure quantities are compared with corresponding quantities obtained from measurements carried out on Gleeble simulated weld HAZs of AA6005. Figures 14(a) and (b) show how the particle number density and mean particle size, respectively, vary with distance from the centerline. Because the distance from the centerline is directly related to the peak temperature, the corresponding T_p values are indicated by the upper abscissae in the graphs for comparison. During reheating of the peak-aged material, the smallest particles will be unstable and dissolve, while the largest ones will grow. As seen from the curves presented, the microstructure model adequately captures this behavior. If weld simulation is accompanied by a subsequent PWHT, full reprecipitation of the hardening particles takes place within the high-peak-temperature region

of the specimen, where both the vacancy concentration and the solute level are inherently high.

Figure 15 shows the predicted sequence of reactions occurring during artificial aging, welding, and PWHT for a fixed position in the HAZ where the peak temperature has been 350 °C (660 °F), conforming to the partially reverted region. Figure 15(a) summarizes the thermal history, where the peak temperature within the weld HAZ is seen to reach 350 °C during welding. Figure 15(b) shows the nucleation rate, j , and the corresponding change in the particle number density, N_v , as a function of time. During artificial aging, N_v reaches the peak value after approximately 1.25 h before it starts to level off as the nucleation rate, j , drops and the combined growth and coarsening regime is entered. It follows from Fig. 15(c) that this regime is characterized by a steady increase in the mean particle radius, \bar{r} , with time. At the same time, the particle volume fraction, f , increases, leading to a gradual decrease in the matrix solute content until the equilibrium concentrations of magnesium and silicon are reached after long times at the actual aging temperature.

During subsequent welding, the microstructure within the partly reverted HAZ changes dramatically over a very short period of time. Although the nucleation rate, j , again increases, reheating to $T_p = 350$ °C (660 °F) implies that both N_v and f drop initially as a result of particle dissolution. This change is accompanied by rapid growth of some of the largest particles within the distribution, taking advantage of the abundant solute being supplied from the dissolving precipitates. Thus, when the final PWHT stage is entered, neither the solute content nor the vacancy concentration within the partly reverted HAZ is high enough to promote extensive precipitation of new hardening β'' particles. Instead, the remaining particles will continue to grow, mainly by consumption of excess solute. This is observed by the almost constant value for N_v in Fig. 15(b) along with the monotonic increase in \bar{r} and f in Fig. 15(c), both during welding and subsequent PWHT.

Yield Strength Model

For predictions of the structural integrity of weldments, it is not the precipitate structure, as such, but rather the macroscopic room-temperature yield stress that is of main concern. However, due to the intimate connection between the precipitate structure and the yield stress of age-hardening aluminum alloys, the yield stress can be estimated when the particle size distribution is known (Ref 35). This is done by coupling some key precipitate parameters extracted from the particle size distribution to a separate strength model for shearing and bypassing of particles by dislocations, as shown subsequently. This, in turn, allows the evolution of the macroscopic yield stress at room

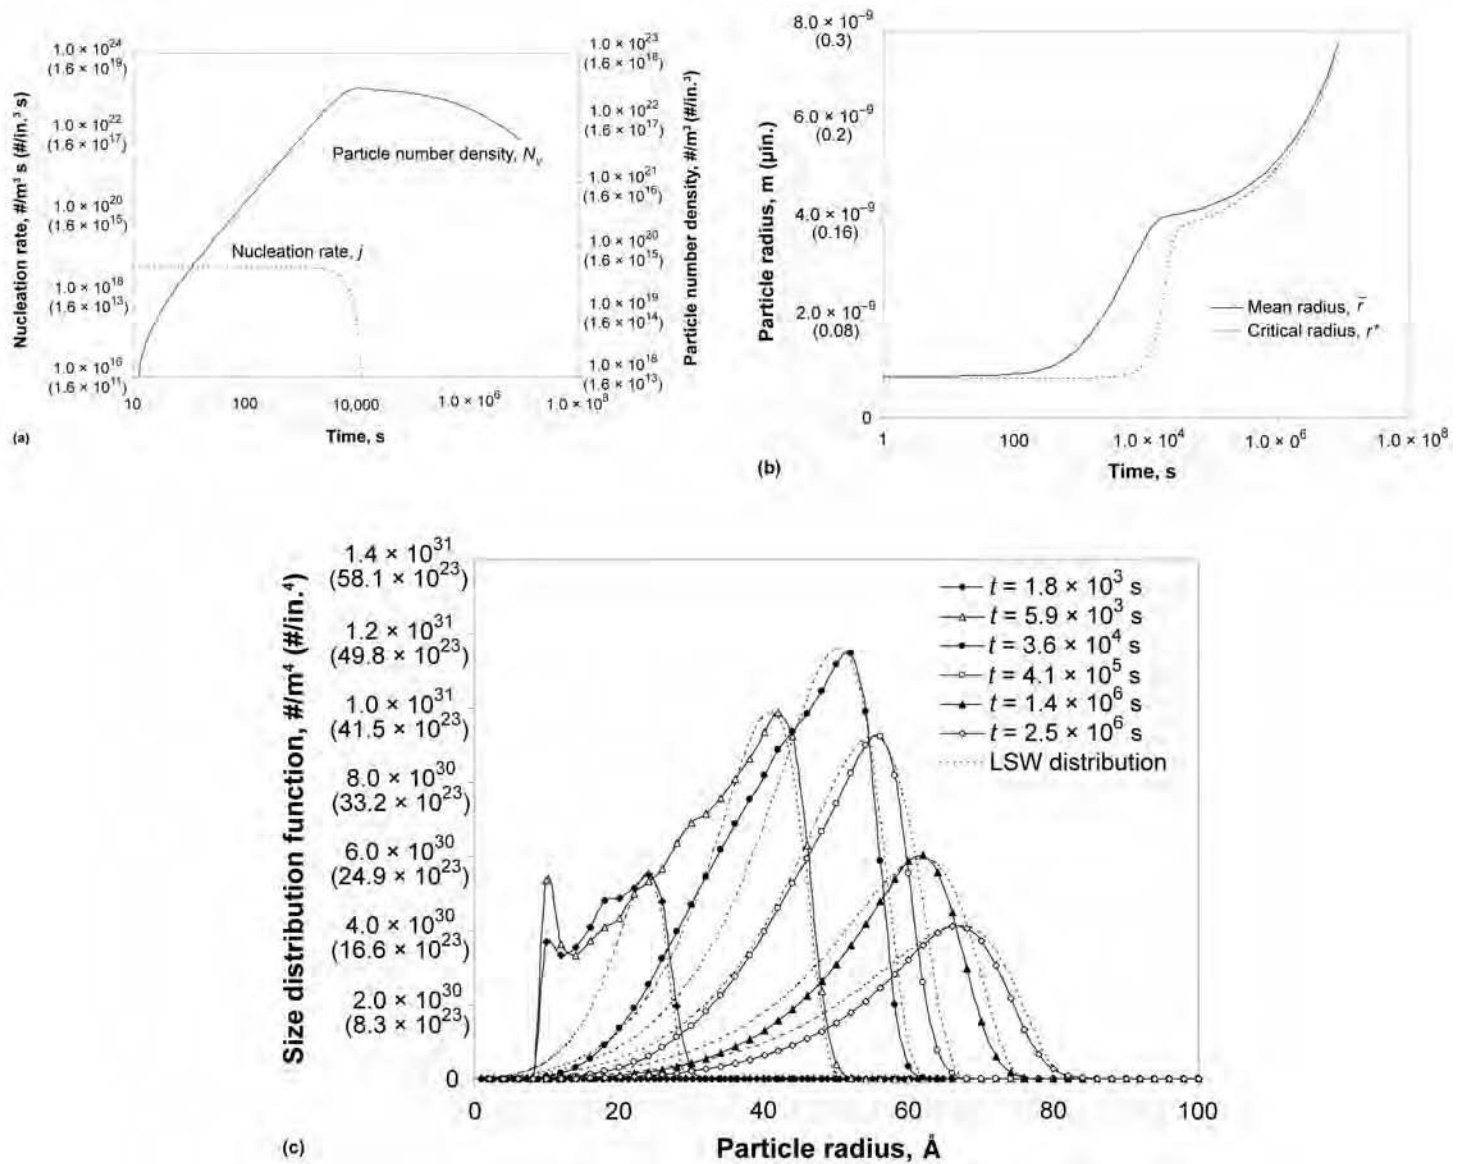

Fig. 13 Examples of outputs from the precipitation model following prolonged artificial aging at 180 °C (355 °F). (a) Change in nucleation rate, j , and particle number density, N_v , with time. (b) Increase in the mean particle radius, \bar{r} , and the critical radius, r^* , with time. (c) Snapshots of the particle size distribution at different aging times. The corresponding Lifshitz-Slyozov-Wagner (LSW) distributions are indicated by the broken curves in the graph for comparison. Source: Ref 34

temperature to be calculated at each time step during heat treatment and welding.

For age-hardening aluminum alloys, the following contributions are of importance: precipitation hardening due to shearing and bypassing of particles by dislocations, σ_p , and solid-solution hardening effects, σ_{ss} (Ref 42–45).

Precipitation Hardening. The relationship between the macroscopic yield strength, σ_p , and the mean obstacle strength, \bar{F} , can be written as (Ref 45):

$$\sigma_p = \frac{M\bar{F}}{bl} \quad (\text{Eq 68})$$

where M is the Taylor factor, b is the magnitude of the Burgers vector, and l is the mean

effective particle spacing in the slip plane along the bending dislocation.

Assuming a monodisperse system of spheres, the effective particle spacing, l , in the slip plane can be expressed in terms of the mean particle size, \bar{r} , the particle volume fraction, f_v , and the mean obstacle strength, \bar{F} , using the Friedel formalism (Ref 46), as done in Ref 45. Substituting this expression for l into Eq 68 gives (Ref 36):

$$\sigma_p = \frac{M}{b^2\sqrt{G}} \sqrt{\frac{N_v\bar{r}}{\beta}} \bar{F}^{3/2} \quad (\text{Eq 69})$$

where G is the shear modulus of the aluminum matrix, and β is a constant close to 0.5.

In the general case, where the alloy contains a mixture of weak (shearable) and strong (non-shearable) particles, the mean obstacle strength is conveniently defined as:

$$\bar{F} = \frac{\sum_i N_i F_i}{\sum_i N_i} \quad (\text{Eq 70})$$

where N_i is the number density of particles that belongs to a given-size class r_i , and F_i is the corresponding obstacle strength.

In practice, the parameter F_i will be a function of the particle radius, r_i . For weak particles, it is a fair approximation to assume that F_i is proportional to the particle radius as long

as r_i is smaller than the critical radius for shearing, r_c (Ref 35, 45, 47):

$$\bar{F}_i = 2\beta G b^2 \left(\frac{r_i}{r_c} \right) \quad (\text{Eq 71})$$

Conversely, for strong (nonshearable) particles, characterized by $r_i > r_c$, the obstacle strength, F_i , will be constant and independent of r_i (Ref 35, 45, 47):

$$\bar{F}_i = 2\beta G b^2 \quad (\text{Eq 72})$$

Solid-Solution Hardening. In age-hardening aluminum alloys, elements such as magnesium, silicon, and copper give rise to considerable solid-solution strengthening. Provided that the contribution from each element is additive, the solid-solution hardening potential of the alloy, σ_{ss} , can be expressed as (Ref 46, 48):

$$\sigma_{ss} = \sum_j k_j C_j^{2/3} \quad (\text{Eq 73})$$

where C_j is the concentration of a specific alloying element in solid solution, and k_j is the corresponding scaling factor.

Overall Yield Strength. In alloys where several strengthening mechanisms are operative at room temperature, it is reasonable to assume that the individual strength contributions can be added linearly. Thus, taking σ_i equal to the intrinsic yield strength of pure aluminum, the resulting expression for the overall macroscopic yield strength, σ_y , becomes:

$$\sigma_y = \sigma_i + \sigma_{ss} + \sigma_p \quad (\text{Eq 74})$$

Equations 69 to 74 represent the important link between precipitation structure and strength, because they convert the relevant output parameters from the precipitation model into an equivalent room-temperature yield stress. An example application is presented in Fig. 16, which shows the evolution of the resulting room-temperature yield stress, σ_y , as well as the individual contributions from solid-solution hardening, σ_{ss} , and precipitation hardening, σ_p , respectively, to the total strength level for the case study previously presented in Fig. 15. During artificial aging, σ_p increases at the expense of σ_{ss} , because nucleation and growth of the β'' particles give rise to substantial precipitation hardening. This, in turn, leads to a corresponding increase in σ_y , although the aluminum matrix becomes drained with respect to solute, thereby reducing σ_{ss} .

Moreover, a comparison between Fig. 15(b) and 16 reveals that the observed drop in σ_p and σ_y during welding arises from the corresponding drop in the particle number density, N_v , because of particle dissolution. It follows that the small increase in σ_{ss} is not sufficient to compensate the softening that occurs due to particle reversion, resulting in a local room-temperature yield strength of approximately 155 MPa (23 ksi) after

Fig. 16 Predicted change in overall room-temperature yield stress, σ_y , and individual strength components solid-solution hardening, σ_{ss} , and precipitation hardening, σ_p , with time for the industrial case study presented in Fig. 15. The ordinate to the right in the diagram indicates the corresponding hardness level. AA, artificial aging; W, welding; PWHT, postweld heat treatment. Source: Ref 36

completion of the welding operation. Finally, because the combination of a low solute content and a reduced vacancy concentration implies that the resulting aging response of the partly reverted region is weak, this leads to a permanent strength loss in the HAZ after PWHT.

Microstructure Modeling in the Context of Engineering Design

In the following, the microstructure model for age-hardening Al-Mg-Si alloys, presented in the previous section, is exploited in engineering design to optimize the load-bearing capacity of welded aluminum components.

In welding of age-hardening aluminum alloys and particularly artificially aged Al-Mg-Si alloys such as AA6082-T6, HAZ softening is of particular concern. In engineering design, this strength loss must be taken into consideration, both the total width of the reduced strength zone and the corresponding minimum strength level.

Calculation of the Design Stress

To illustrate how the design stress depends on the minimum strength level and reduced strength zone width, the two idealized loading conditions are considered more in detail. If the loading is perpendicular to the weld, the nominal stress, σ_{\perp} , is given as (Ref 49):

$$\sigma_{\perp} = \frac{P}{A} = \frac{P}{d w} \quad (\text{Eq 75})$$

where P is the tensile or compressive force being applied perpendicular to the axis of the weld, and A is the cross section of the joint (equal to the plate thickness, d , times the width, w , of the component).

Provided that the HAZ is also the softest part of the weld, and yielding is not permitted during service, the design stress, σ_{\perp} , cannot exceed the minimum HAZ yield stress, σ_{\min} . This, in turn, imposes a restriction on the design stress, $\sigma_{\perp} \leq \sigma_{\min}$. Hence, the metallurgical parameter, σ_{\min} , has a direct physical meaning in engineering design and is the key parameter determining the joint strength when the loading is perpendicular to the weld.

Similarly, if the loading is parallel to the weld, Mazzolini (Ref 49) introduces the so-called reduced cross-sectional area, A_{red} , as a basis for calculating the design stress, σ_{\parallel} , which, according to the definitions in Fig. 17, can be written as:

$$A_{\text{red}} = A - 2y_{\text{red}}^{\text{eq}} d(1 - \beta) \quad (\text{Eq 76})$$

where A is the total cross-sectional area of the joint (including the weld reinforcement), $y_{\text{red}}^{\text{eq}}$ is the equivalent half-width of the reduced strength zone (including the weld metal) of strength σ_{\min} , while β is a metallurgical efficiency factor that takes into account the degree of softening occurring due to welding ($\beta \leq 1$).

Thus, provided that yielding is not permitted during service, β is equal to the ratio between the minimum HAZ yield stress, σ_{\min} , and the base-metal yield stress, σ_b :

$$\beta = \frac{\sigma_{\min}}{\sigma_b} \tag{Eq 77}$$

Similarly, the equivalent half-width of the reduced strength zone, $\Delta y_{\text{red}}^{\text{eq}}$, of strength σ_{\min} can be calculated by considering the idealized yield strength profile shown in Fig. 17 and solving the integral (Ref 39):

$$\Delta y_{\text{red}}^{\text{eq}} = \frac{\int_{y_m}^{\infty} (\sigma_b - \sigma(y)) dy}{(\sigma_b - \sigma_{\min})} \tag{Eq 78}$$

where the lower integration limit, y_m , refers to the fusion boundary of the weld, and the upper integration limit, y_{tot} , refers to the total half-width of the reduced strength zone as defined in Fig. 17.

Note that Eq 78 is conservative in the sense that it just considers the HAZ yield strength profile and ignores the strength contribution from the weld metal.

In the following, the previously described precipitation and yield strength models for Al-Mg-Si alloys are combined with thermal field calculations obtained from WELDSIM, which is a general-purpose finite-element code for welding (Ref 37, 38, 50). By this means, the complete HAZ yield stress distributions can be calculated, from which the desired design parameters σ_{\min} and $\Delta y_{\text{red}}^{\text{eq}}$ may be extracted.

Process Diagrams for Al-Mg-Si Butt Welds

Figure 18 shows the predicted local yield stress distribution across the HAZ following welding and subsequent natural aging of butt welds of AA6082-T6 for various combinations of q_0/vd , h , and d . Note that if steel backing is used, the plate thickness, d , must also be specified to uniquely define the HAZ thermal program. It is evident from these plots that the critical parameters controlling the joint strength depend on complex interactions between

several process variables that are not accounted for in the current design codes for aluminum weldments (Ref 51, 52). The most important variables, in addition to the alloy composition and initial temper condition, are the applied heat input during welding, the heat-transfer coefficient between the aluminum plate and the steel backing, as well as the extent of natural aging occurring after welding.

Figure 19, which applies to butt welding of AA6060-T6, AA6005-T6, and AA6082-T6, respectively, shows predicted design parameters σ_{\min} and $\Delta y_{\text{red}}^{\text{eq}}$ being defined previously in Fig. 17 for different combinations of q_0/vd , h , and d . Note that the curves for $h = 0$ are not limited to a specific plate thickness, as opposed to those in Fig. 19(b), which hold for 2 mm (0.08 in.) sheet material only. As expected, the design parameters are seen to depend both on the applied heat input during welding as well as on the actual value of the heat-transfer coefficient between the aluminum plate and the steel backing. The absolute value of σ_{\min} is, in turn, determined by the alloy composition, which represents a third option that can be exploited in engineering design. However, for a given alloy composition, minimization of the HAZ strength loss will require that the q_0/vd ratio is kept as low as possible during welding. At the same time, the aluminum plate should be properly clamped to the steel backing (if this is practically feasible) to make sure that the excess heat from the fusion zone is effectively transferred to the steel plate and not allowed to diffuse into the HAZ.

Optimization of the Load-Bearing Capacity of Welded Aluminum Structures

Until now, only predictions involving the yield stress were considered because this property is usually the most critical in engineering design. However, for complex nonlinear finite-element simulations of the load-bearing capacity of welded structural members, complete

stress-strain curves are required in all positions of the solution domain. As illustrated in Fig. 20, such curves can be obtained by using output from the precipitation model to calculate the yield stress, as described in the section ‘‘Yield Strength Model’’ in this article, and the rate of work hardening during plastic deformation by invoking an appropriate work-hardening model.

In age-hardening aluminum alloys, the work-hardening behavior is controlled by the so-called geometric slip distance and the corresponding volume fraction of nonshearable Orowan particles in addition to the solute content, which determines the rate of dynamic recovery (Ref 53). In practice, all of these parameters can be extracted from the predicted particle size distribution.

A brief outline of the work-hardening model developed for Al-Mg-Si alloys is given subsequently. Further details are given in Ref 53.

Work-Hardening Model. In the work-hardening model presented subsequently, the total dislocation density, ρ_t , is taken equal to the sum of the geometrically necessary dislocations, ρ_g , and the statistically stored dislocations, ρ_s . The geometric slip distance, λ_g , is a measure of how far the dislocations move before they are stored around particles that are dispersed within the matrix material. This storage of dislocations is necessary to obtain compatibility between the two phases during deformation. The parameter λ_g is therefore a characteristic of the microstructure and is related to the type and distribution of the hardening precipitates in the material. According to Ashby (Ref 54), the geometrically necessary dislocations will dominate if the geometric slip distance, λ_g , is smaller than the corresponding slip distance for statistical storage of dislocations, λ_s , as measured from the length of the slip lines in the work-hardened material. In the other extreme, when $\lambda_g > \lambda_s$, their contribution to the total dislocation density becomes negligible and can be ignored.

To establish a useful work-hardening model for commercial Al-Mg-Si alloys, it is necessary to convert the current values of the dislocation densities into an equivalent room-temperature flow stress, σ . Because the Ashby approach (Ref 54) is based on the assumption that the two dislocation densities can be added linearly in stress-strain space, their total contribution to the net flow stress, $\Delta\sigma_d = \sigma - \sigma_y$, is given by the following equation:

$$\Delta\sigma_d = \sigma - \sigma_y = \alpha M G \mathbf{b} \sqrt{\rho_t} = \alpha M G \mathbf{b} \sqrt{\rho_s + \rho_g} \tag{Eq 79}$$

where α is a constant with a numerical value close to 0.3, M is the Taylor factor, G is the shear modulus, and \mathbf{b} is the magnitude of the Burgers vector.

The form of Eq 79 suggests that the work-hardening behavior of Al-Mg-Si alloys can be captured mathematically by considering the

Fig. 17 Schematic diagram showing the yield strength profile across an AA6082-T6 butt weld following complete natural aging. The equivalent half-widths of the reduced strength zones, $y_{\text{red}}^{\text{eq}}$ and $\Delta y_{\text{red}}^{\text{eq}}$, of minimum strength, σ_{\min} , are defined to the right and left in the diagram, respectively. HAZ, heat-affected zone. Adapted from Ref 39

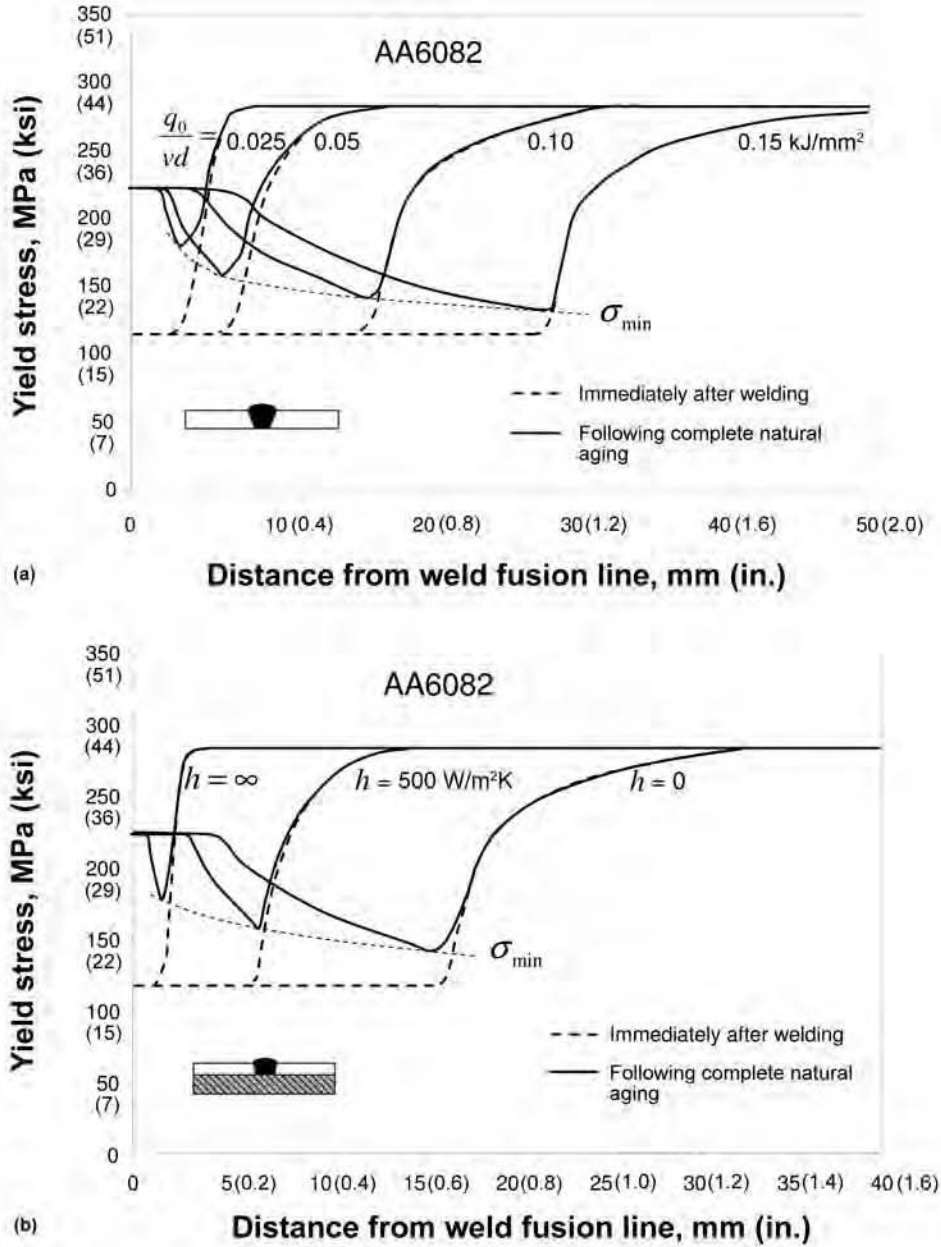

Fig. 18 Predicted heat-affected zone (HAZ) yield strength profiles for single-pass butt welds of AA6082-T6 immediately after welding and following complete natural aging. (a) Effect of the applied heat input, q_0/vd , on the HAZ yield strength distribution for $h = 0$ (adiabatic surfaces, no heat loss to the surroundings). (b) Effect of the heat-transfer coefficient, h , on the HAZ yield strength distribution for $q_0/vd = 0.1$ kJ/mm². net contribution from dislocation hardening, $\Delta\sigma_d$, using ρ_s and ρ_g as the independent internal variables of the system.

Contribution from Shearable Particles and Alloying Elements in Solid Solution. Experiments have shown that the work-hardening behavior of Al-Mg-Si alloys in the naturally aged (T4) condition is essentially similar to that in the as-quenched (W10) condition (Ref 53). Hence, in the context of the model developed, no distinction is made between small shearable particles in the form of Guinier-Preston zones

(or clusters) and atoms in solid solution. This means that the balance between statistical storage and dynamic recovery of dislocations in both types of matrix materials is conveniently described by the evolution equation proposed by Kocks (Ref 55, 56):

$$d\rho_s = (k_1 \rho_s^{1/2} - k_2 \rho_s) d\varepsilon_p \quad (\text{Eq 80})$$

where k_1 is a constant being characteristic of the material under consideration, whereas the

k_2 parameter, which determines the rate of the dynamic recovery during plastic deformation, depends on the solute content of the alloy.

For Al-Mg-Si alloys, k_2 is well described by the following analytical expression (Ref 53):

$$k_2 = k_1 \frac{\alpha M G \mathbf{b}}{k_3 (\hat{C}_{\text{Mg}})^{3/4}} \quad (\text{Eq 81})$$

where k_3 is a characteristic material constant, while \hat{C}_{Mg} is a weight parameter that takes into account the combined effect of magnesium and silicon on the resulting rate of dynamic recovery. The expression for \hat{C}_{Mg} is (Ref 53):

$$\hat{C}_{\text{Mg}} = \bar{C} + 0.5C_{\text{Si}}^{\text{eff}} \quad (\text{Eq 82})$$

where \bar{C} is the mean concentration of magnesium in the aluminium matrix (given by Eq 63 in the precipitation model), and $C_{\text{Si}}^{\text{eff}}$ is the corresponding silicon concentration following a correction for the amount of silicon being tied up as coarse $\alpha\text{-Al}_{15}(\text{FeMn})_3\text{Si}_2$ particles in the alloy (Ref 35).

Contribution from Nonshearable Orowan Particles. The density of geometrically necessary dislocations, ρ_g , in a dispersion-strengthened material is interrelated to the geometric slip distance, λ_g , and the imposed shear strain, γ , through the following relationship (Ref 53):

$$\rho_g = \rho_g^{\text{ref}} \frac{\lambda_{g,o}^{\text{ref}} \gamma}{\lambda_{g,o} \gamma^{\text{ref}}} \quad (\text{Eq 83})$$

where $\lambda_{g,o}$ specifically refers to the geometric slip distance of hardening precipitates in Al-Mg-Si alloys that fulfill the Orowan criterion.

Because the accumulation of dislocation loops around the precipitates (and thus ρ_g) cannot increase without limit, as predicted by Eq 83, ρ_g will, in practice, saturate at some given (critical) plastic strain, $\varepsilon_p = \varepsilon_c$. This threshold strain depends, in turn, on the volume fraction, f_o , of the dispersed Orowan particles (Ref 54). Taking $\varepsilon_c = \varepsilon_c^{\text{ref}}$ when $f_o = f_o^{\text{ref}}$ for the chosen reference alloy, a rational expression for ε_c is (Ref 53):

$$\varepsilon_c = \left(\frac{f_o^{\text{ref}}}{f_o} \right) \varepsilon_c^{\text{ref}} \quad (\text{Eq 84})$$

Overall Stress-Strain Response. Eventually, after integration and some manipulation of the resulting analytical solutions, the following analytical expressions for the relationship between $\Delta\sigma_d$, ρ_s , ρ_g , and $\rho_{g,s}$ are derived (Ref 53):

$$\Delta\sigma_d = \alpha M G \mathbf{b} \sqrt{\left(\frac{k_1}{k_2} \right)^2 \left(1 - \exp\left(-\frac{k_2 \varepsilon_p}{2} \right) \right)^2 + \rho_{g,s}^{\text{ref}} \frac{\lambda_{g,o}^{\text{ref}} \varepsilon_p}{\lambda_{g,o} \varepsilon_c^{\text{ref}}}} \quad (\text{Eq 85})$$

when $\varepsilon_p < \varepsilon_c$

and

$$\Delta\sigma_d = \alpha M G b \sqrt{\left(\frac{k_1}{k_2}\right)^2 \left(1 - \exp\left(-\frac{k_2 \varepsilon_p}{2}\right)\right)^2 + \rho_{f,s}^{\text{ref}} \frac{\lambda_{g,o}^{\text{ref}} \varepsilon_c}{\lambda_{g,o} \varepsilon_c^{\text{ref}}}}$$

when $\varepsilon_p \geq \varepsilon_c$ (Eq 86)

where the actual value of ε_c is given by Eq 84.

Expressions for $\lambda_{g,o}$ and f_o . Following calibration, the present work-hardening model relies solely on outputs from the precipitation model. In addition to the mean matrix solute content, \bar{C} , the two other microstructure

parameters that control the work-hardening behavior of Al-Mg-Si alloys are the geometric slip distance, $\lambda_{g,o}$, and the corresponding volume fraction, f_o , of nonshearable Orowan particles in the matrix material. Both parameters can be extracted from the predicted particle size distribution. Let the Orowan particles be characterized by their radius $r_o > r_c$, where r_c is the critical particle radius for dislocation bypassing, analogous to that done in the yield strength model (Ref 35, 36). Then $\lambda_{g,o}$ and f_o are readily calculated from the following expressions (Ref 53):

$$\lambda_{g,o} = \left(8 \sum_{r=r_o}^{r=\infty} r_i^2 N_i\right)^{-1} \quad (\text{Eq 87})$$

$$f_o = \frac{4\pi}{3} \sum_{r=r_o}^{r=\infty} r_i^3 N_i \quad (\text{Eq 88})$$

where N_i is the number of particles per unit volume within the size class r_i .

Application of the Combined Precipitation, Yield Stress, and Work-Hardening Model.

As an example, the combined precipitation, yield stress, and work-hardening model outlined in Fig. 20 is used to optimize the load-bearing capacity of a welded aluminum component that has been subjected to a series of thermal and mechanical operations during fabrication. As a starting point, the thermal module in WELDSIM (Ref 37, 38, 50) is used to predict the temperature field resulting from the welding, including the peak-temperature distribution in the HAZ shown in Fig. 21(a). The calculated thermal history is input to the combined precipitation, yield stress, and work-hardening model, which calculates the full stress-strain curves for all positions within the solution domain, including the three positions labeled "A," "B," and "C" in Fig. 21(a). These curves are shown in Fig. 21(b). It follows that each region yields a unique stress-strain response, where position "B" corresponds to the softest part of the HAZ.

Finally, a commercial finite-element code (Ref 58) is used to simulate the load-bearing capacity of the welded component, subjected to the loading situation shown in Fig. 22(a). These simulations are carried out using a shell-based modeling approach in which the predicted stress-strain curves for each position of the solution domain correspond to the mechanical model (Ref 57). The resulting predicted load-displacement curves are shown in Fig. 22(b). It follows that a change in the alloy

Fig. 19 Predicted process diagrams for Al-Mg-Si butt welds showing the variation in the design parameters σ_{min} and Δy_{red}^{eq} with q_0/vd and h for the alloys AA6060-T6, AA6005-T6, and AA6082-T6 following complete natural aging. composition from a soft AA6060 to a medium-strength AA6082 alloy results in a significant increase in the predicted ultimate load.

These simulation results are interesting, both from an academic and practical point of view, because they illustrate in a quantitative manner how the present modeling approach can be used

to optimize the load-bearing capacity of welded aluminum structural components simply by manipulating the alloy composition and the applied heat treatment schedules.

Numerical Aspects of Modeling Welds*

John Goldak and Mahyar Asadi, Carleton University
Lennart Karlsson, Luleå University of Technology

THE DESIGN OF A STRUCTURE that achieves its highest performance levels with the least chance of failure can be facilitated by the mathematically based prediction modeling of weld behavior in a variety of circumstances. One aspect of a weldment that can be predicted with remarkable accuracy, given certain data, is the transient temperature field. Distortion also can be predicted with considerable accuracy. Although residual stresses and microstructure predictions are less accurate, they are still useful.

At the present time, some aspects of the arc and the weld pool are difficult to predict. Although the prediction of specific defects can be difficult, the conditions that make it likely for specific kinds of defects to form can be predicted. This situation is similar to that of predicting weather conditions that suggest a high risk of tornadoes, but not being able to predict individual tornadoes.

Reality, Models, and Mathematics. Like cartoons, mathematics is not real. Yet, even in cartoons, some relationship to reality is nearly always intended. To understand either cartoons or mathematics, every individual must define his own relationship to reality.

Unlike cartoons, mathematics has two fundamental pillars. A set of axioms, which are sometimes called assumptions, laws, primitives, or other terms, is assumed to be given and to be true. When these assumptions or axioms are combined in ways that obey a strict logic, results remain true, that is, for the purposes of mathematics, rather than for the real world. The meaning of the axioms, as interpreted in the real world, is irrelevant to mathematics. For example, given a sphere of radius r , mathematicians can prove that volume equals $(4\pi r^3)/3$. Whether any particular ball can actually be described or approximated as a sphere of radius r is not a question that mathematics considers. In fact, one cannot prove that the formula for the volume of a sphere is correct by measuring the volume of balls. Rather, the exercise is a matter of judgment and

interpretation for those who are interested in the volume of a real ball.

This example is presented in order to show that the confusion and controversy that occur in the modeling of welds and other areas arises from a failure to separate mathematics that are correct from mathematics that represent a useful model for a particular weld. Although this point is often not understood, those who can appreciate it are able to use models more effectively.

Modeling of Welds

The first assumption should be that the weld has been specified, and therefore, all information needed to produce the real weld has been given. This includes the geometry of the welded structure and the weld joint, the composition of the base and weld metal, the distribution of input energy, the preheat temperature, the welding path and speed, the hydrogen content in the arc, the start time and start position of each weld pass, the fixtures, and other factors. It is usually assumed that the transient temperature field is the most critical field, in the sense that if this temperature field is wrong, then the predictions of the model are likely to be wrong. It is also most critical in the sense that different welds usually have different temperature fields. After computing the transient temperature field, the evolution of microstructure in the heat-affected zone and the fusion zone is computed. Then the thermal stress, strain, distortion, and residual stress are computed. The next objective, which is a current research issue, is to predict the mechanical properties of the weldment, including fracture toughness, ductile-brittle transition temperature, and the probability that defects will occur. The ultimate objective is to predict the manufacturing cost and the reliability of both the weld and the welded structure.

Computational weld mechanics described in algorithmic notation comprises the following steps:

- Define the geometry, material properties, heat inputs, boundary conditions such as thermal convection, and mechanical support
- Compute the transient temperature field
- Compute the evolution of microstructure. If latent heats of transformation are to be included, then the transient temperature and evolution of microstructure become an iterative problem.
- Compute the displacement; strain and stress fields, including the effects of temperature and microstructure on material properties; thermal expansion; and phase transformations. Usually, a thermoelastoplastic stress-strain relationship is used. The displacement or distortion can significantly impact the cost of welding.
- Estimate material properties of the weldment, the probability of defects, and the risk of failure due to fatigue, ductile or brittle failure, and corrosion. Although very little research has been published on this step, it is clearly an important objective of computational weld mechanics.

The results of such an analysis are shown in Fig. 1 to 5. It has been assumed that the weld

Fig. 1 Finite-element mesh for a weld described in a Eulerian reference frame. Note that filler metal is added. The weld pool, which is not shown, is not needed in this analysis because the temperature is prescribed at the weld-pool boundary. The mesh is finest just in front of the weld pool.

Energy Equation and Heat Transfer

The conservation of energy is the fundamental principle that underlies all thermal analysis, including that of welds. In the simplest terms, it states that while energy can be added or extracted, no energy can be created or destroyed in the domain being analyzed. The essential material behavior for heat conduction is that a flux of energy, q ($J/m^2 \cdot s$), flows from hot regions to cold regions under the influence of a temperature gradient, ∇T , and the thermal conductivity of the material, κ :

$$q = -\kappa \nabla T \quad (\text{Eq 1})$$

The energy required to change the temperature of a material is defined by another material property, the specific heat, C_p , or enthalpy, H , of a material. The enthalpy is defined with respect to a reference temperature, T_{ref} , as:

$$H(T) = \int_{T_{\text{ref}}}^T C_p dT \quad (\text{Eq 2})$$

In terms of the enthalpy, thermal flux, and a distributed heat-source term, S ($J/m^3 \cdot s$), the energy equation in differential form is:

$$H - \nabla \cdot q - S = 0 \quad (\text{Eq 3})$$

or, in terms of temperature, it is:

$$\rho C_p T - \nabla \cdot (-\kappa \nabla T) - S = 0 \quad (\text{Eq 4})$$

This is a parabolic partial differential equation. The essential parts of any such equation are the boundary conditions, the initial conditions, and the parameters such as specific heat, C_p , thermal conductivity, κ , and heat source per unit volume, S . The boundary conditions can be either essential (prescribed temperature) or natural (prescribed thermal fluxes) for all time. The part of the boundary on which essential boundary conditions are prescribed is called $\partial\Omega_D$, whereas the part of the boundary on which natural boundary conditions are prescribed is called $\partial\Omega_N$. These two parts must make up the entire boundary, and they must not overlap at any point, that is, at no point can both be essential and natural. In mathematical terms, this is expressed as $\partial\Omega = \partial\Omega_D \cup \partial\Omega_N$ and $\partial\Omega_D \cap \partial\Omega_N = \emptyset$. The essential boundary condition is:

$$T(x, t) = F_D(x, t), \quad x \in \partial\Omega_D, t > 0 \quad (\text{Eq 5})$$

and the natural boundary condition is:

$$q(x, t) = F_N(x, t), \quad x \in \partial\Omega_N, t > 0 \quad (\text{Eq 6})$$

The initial conditions describe the distribution of temperature or enthalpy at all points in the interior of the domain, Ω , at time zero:

$$T(x, t) = F_{\text{init}}(x), \quad x \in \Omega, t = 0 \quad (\text{Eq 7})$$

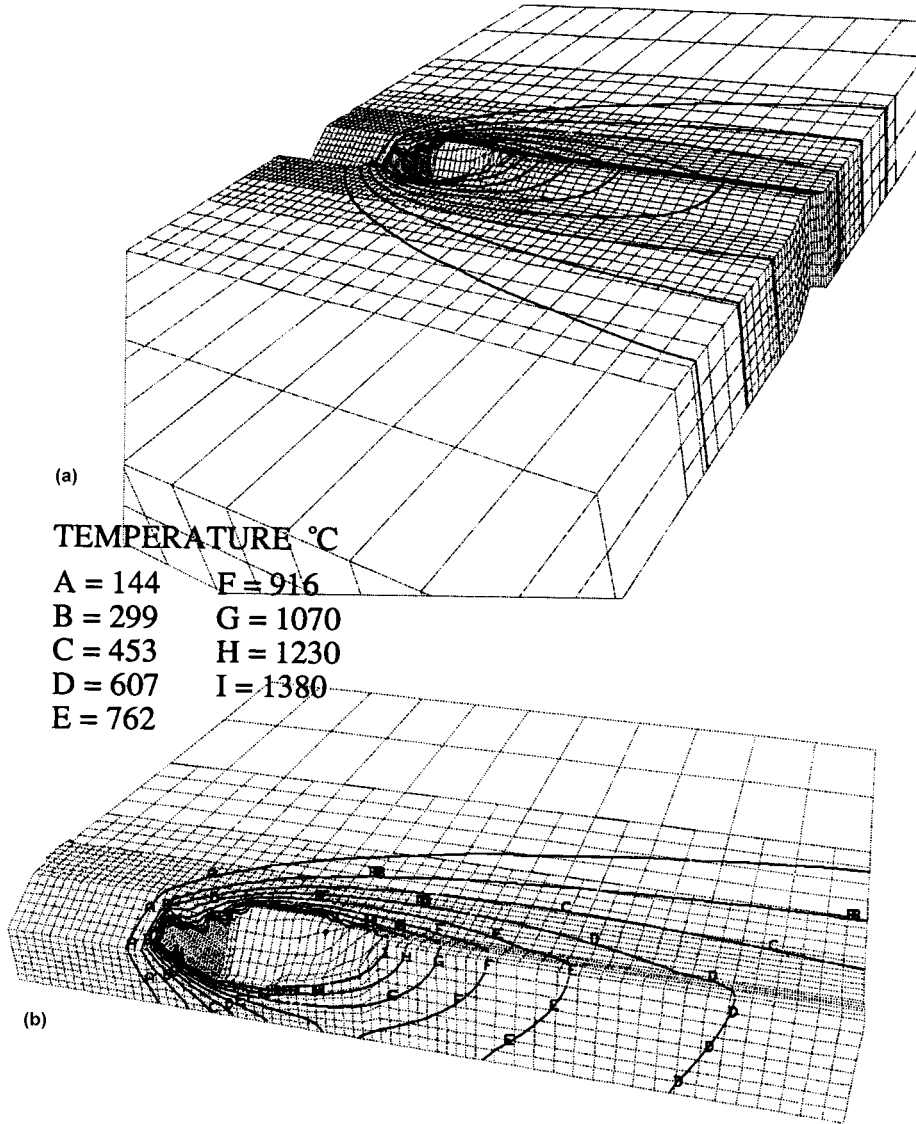

Fig. 2 Temperature contours of a weld in low-carbon steel. (a) For whole mesh. (b) For the region around the weld pool

pool is characterized by known data. The weld pool behavior has not been predicted. In order to predict weld pool behavior, most researchers would assume that the distribution of thermal flux, the current density, and the velocity and pressure in the arc are known data. With these data, they would solve the conservation of mass, momentum, and energy to compute the temperature, velocity, and pressure fields in the weld pool and the position of the weld-pool liquid-solid and liquid-plasma interfaces.

The proceedings of recent conferences in computational weld mechanics are now embodied in the literature (Ref 1–4).

Geometry of Weld Models

Most computational models have analyzed bead-on-plate welds, because of their

simple geometry. In addition to bead-on-plate welds, this discussion considers V-groove welds, girth welds, and branch welds on pipes (Fig. 1–9). The geometry specifies the region of space that is to be analyzed. This region is called the domain, Ω , and its boundary is denoted $\partial\Omega$. To analyze the weld, the geometry will usually be represented by a finite-element mesh. Because temperature, stress, and strain change rapidly near the weld, it is useful to use a fine mesh near the weld for resolution and accuracy. However, a coarse mesh is preferred at a site far from the weld, in order to reduce computational costs without unduly sacrificing accuracy or resolution. For this reason, it is desirable to have the ability to grade the mesh or to adaptively refine and coarsen a finite-element mesh for analyzing welds (Ref 5).

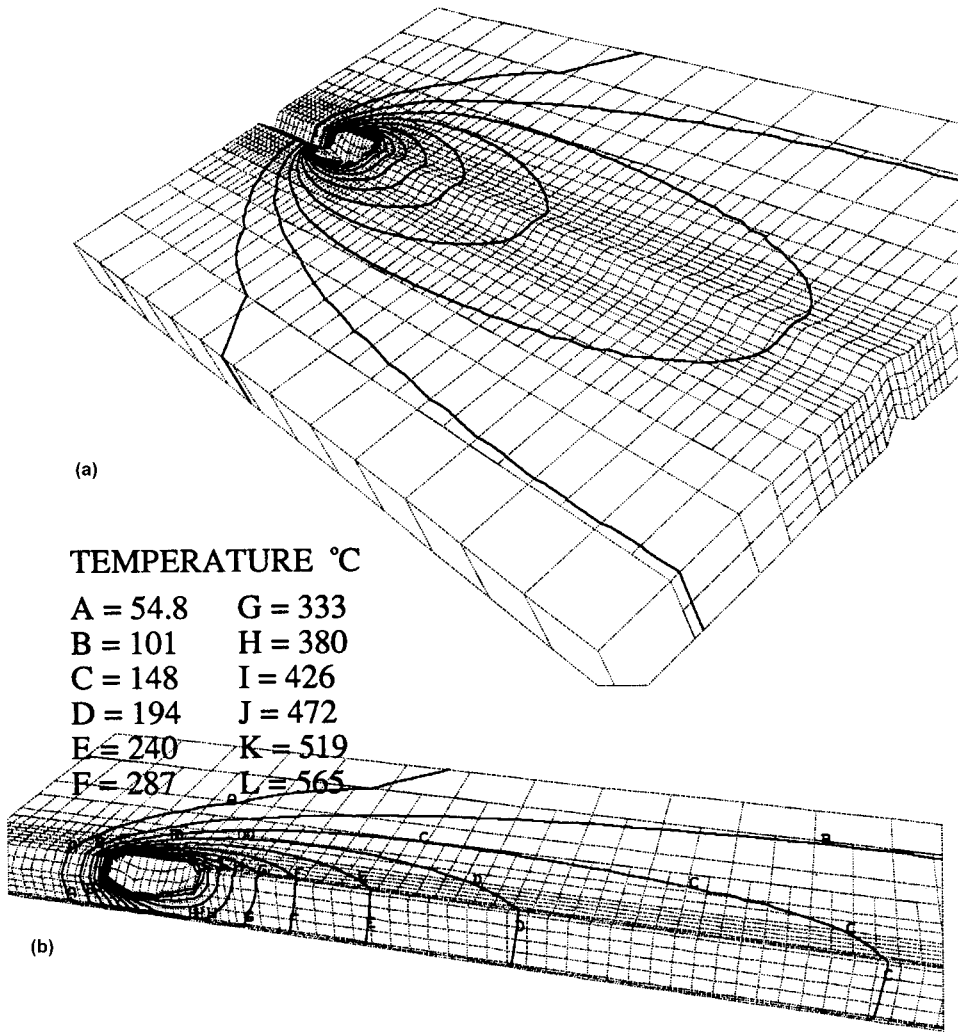

Fig. 3 Temperature contours of a weld in aluminum alloy. (a) For whole mesh. (b) For the region around the weld pool. Because the thermal diffusivity of aluminum is higher than steel, the mesh can be coarser, particularly in front of the weld pool.

Fig. 4 Distortion (magnified by a factor of 2) of a steel plate

If the latent heat of phase transformations is to be considered, then the initial distribution of the density of each phase, ρ_i , is also needed:

$$\rho_i(x, 0) = \rho_{init}(x), \quad x \in \Omega, t = 0 \quad (\text{Eq 8})$$

The known functions, that is, data, are F_D , F_N , F_{init} , and ρ_{init} .

To include the effect of phase transformations, such as liquid to solid and the decomposition of austenite in low-alloy steels, it would be necessary to have equations describing the evolution of each phase. However, this has not been included in this energy equation. The latent heat of solid-state transformations, such as austenite to ferrite in steel, has a detectable effect on the temperature field, but it is not large. To date, this effect has not played an important role in the thermal analysis of welds.

Solving the Energy Equation. The energy equation defined previously can now be solved for a specific welding situation. Finite-element methods (FEMs) have been the method of choice for stress analysis. Finite-difference methods (FDMs) have been the method of choice for fluid flow. Whether the FDM or FEM method is best is an old argument. In rough terms, FEM has been used more frequently for complex geometries and for stress analysis, whereas FDM has been used

more frequently for fluid-flow analysis. However, FDM can be used for complex geometries that use body-fitted coordinates. Some have argued that FDMs are computationally more efficient than FEMs. The computational efficiency depends on the implementation. There is no fundamental reason why one method should have a computational advantage. The FEM is used here because of its familiarity and because it is better established for stress analysis.

The FDM directly discretizes the partial differential equation by approximating derivatives with finite-difference expressions. The FEM transforms the partial differential equation to an integral form and then approximates the integrals. A Green's identity is usually used to reduce the degree of the highest derivative from order two to order one. In addition, it introduces the natural boundary conditions in a natural and elegant manner. The resulting integrals are approximated by a finite set of basis functions, usually piecewise polynomials. The piecewise polynomials can be interpreted as being defined by choosing a mesh of elements and nodes. Within each element, a polynomial is chosen for each node. Usually, it has a value of 1 for its node and a value of 0 at all other nodes in the element.

These basis functions can be used to interpolate the temperature field by using the value of the temperature at each node. For example, if the (x,y) nodal coordinates of a triangle are $(1,0)$, $(0,1)$, $(0,0)$, and the basis functions for a triangle are chosen to be $\phi_1(x,y) = x$; $\phi_2(x,y) = y$; and $\phi_3(x,y) = 1 - x - y$, then the temperature at any point (x,y) in the element can be expressed as:

$$T(x, y) = \phi_1(x, y)T_1 + \phi_2(x, y)T_2 + \phi_3(x, y)T_3 \\ = \sum_{i=1}^3 \phi_i(x, y)T_i \quad (\text{Eq 9})$$

where T_i is the temperature at node i . Note that if distorted triangles are used, then understanding the mathematics becomes more complex, because the polynomial basis functions are distorted into rational functions. If the distortion is excessive, then the basis functions can become singular. However, distorted elements do not make FEM programs more difficult to use, as long as the distortion is not excessive.

To solve the energy equation defined previously, FEM can be interpreted as minimizing a potential, solving a variational problem, projecting an exact solution from an infinite dimensional space onto a finite dimensional space, or finding the best approximation to the exact solution in the finite dimensional space in some least-squares sense. All of these interpretations lead to the same set of ordinary differential equations, which can then be converted to the same set of algebraic equations in order to solve:

Fig. 5 (a) Distortion of weld shown in a cross section. Note the rigid body motion of the region far away from the weld nugget. (b) Contours of the longitudinal residual-stress component, σ_{xx} . Note that the maximum stress is not located at the surface. (c) Contours of fraction of bainite at end of weld; maximum fraction of bainite is just under 0.3. (d) Contours of prior-austenite grain size at the end of weld

$$\left(\bar{C}_p \frac{G}{\delta} + \theta K\right) \Delta T = S^1 - K T^1$$

$$-\bar{N}(U) H^1 \rightarrow K_{\text{eff}} \Delta T = b_{\text{eff}} \quad (\text{Eq 10})$$

where \bar{C}_p is the specific heat per unit volume, G is the gram matrix, δ is the length of the time step, θ is a parameter that determines the time-integration method, $\Delta T = T^3 - T^1$ is the increment in the temperature in this time step, S^1 is the nodal load vector that is due to external thermal loads, $\bar{N}(U) H^1$ is the nodal load vector that is due to advection evaluated at the beginning of the time step, K_{eff} is the effective stiffness matrix, and b_{eff} is the effective load vector.

For a detailed presentation of FEM theory, refer to any textbook on the subject, such as Ref 6 to 8. Space constraints here do not allow a more detailed explanation.

Because commercially competitive FEM programs typically require hundreds of man-years to write, as well as special expertise, it is assumed that most readers will choose not to write an FEM program, but will use an FEM program written by others. When choosing an FEM program, four main issues should be considered: functionality, computational efficiency, ease of use, and ease of learning. Because most of the costs of analysis are in preparing data and training, the latter two issues are nearly as important as functionality.

Convection, Radiation Boundary Conditions, and Contact Conductance. Given a body at temperature T immersed in a fluid at temperature T_{amb} , convection assumes that a thermal boundary layer exists with conductance, h ($\text{J}/\text{m}^2 \cdot \text{s} \cdot ^\circ\text{C}$), such that the

temperature difference across the boundary layer causes a flux, q ($\text{J}/\text{m}^2 \cdot \text{s}$), given by:

$$q_{\text{con}} = h(T - T_{\text{amb}}) \quad (\text{Eq 11})$$

If the fluid is flowing with velocity, v , and pressure, p , over a plate with a Prandtl number, Pr , and a Reynolds number, Re , then the convection coefficient can be estimated to be:

$$h = 0.332 \frac{k}{\lambda} \text{Re}^{1/3} \text{Pr}^{1/3} \quad (\text{Eq 12})$$

Given a body at temperature T radiating to a body at temperature T_{amb} , radiation assumes an emissivity and Stefan-Boltzmann constant, σ ($\text{J}/\text{m}^2 \cdot \text{s} \cdot \text{K}^4$), such that the temperature difference causes a flux, q ($\text{J}/\text{m}^2 \cdot \text{s}$), given by:

$$q_{\text{rad}} = \epsilon \sigma (T^4 - T_{\text{amb}}^4) \quad (\text{Eq 13})$$

Fig. 6 Temperature isotherms near the weld pool in Barlow's weld. Note that contour "I" has two pools: one under the arc and one in the region behind the arc. This heat source was modeled as a prescribed-temperature region.

Fig. 7 Distortion of a bar being welded. Note the change of curvature. Near the weld pool, the center of curvature is below the bar. Far behind the weld pool, the center of curvature is above the bar.

This is usually linearized as:

$$q_{rad} = \epsilon \sigma (T^2 + T_{amb}^2)(T + T_{amb})(T - T_{amb}) \equiv h_{rad}(T - T_{amb}) \quad (\text{Eq 14})$$

Then, the effects of radiation and convection can be combined into a single effect if the

ambient temperatures are equal. Of course, the ambient temperature for convection and radiation need not be equal.

In an FEM program, this boundary condition is applied by specifying the values of the convection coefficient and the ambient temperature at the nodes on this part of the boundary.

The program computes a contribution to the nodal thermal load and the stiffness matrix.

Modeling the Heat Source in a Weld. Rosenthal (Ref 9) and Rykalin (Ref 10) modeled the heating effect of the arc traveling on a thick plate as a point source; that is, they assumed that all the energy is input into a point. In an FEM model, this could be approximated by specifying a thermal load at a node shared by very small elements.

It is worth exploring the difference between the FEM approximation and the Rosenthal solution for the point source. The most notable difference is that the temperature at the point source is infinite in the Rosenthal solution, whereas it is finite in the FEM approximation. The explanation is that in the Rosenthal solution, a finite amount of energy is being put into zero volume at the point. This causes an infinite temperature. In the FEM approximation, a finite amount of energy is being put into the elements containing the node, which is the point source. Because these elements have a finite volume, the temperature is finite.

If the temperature is plotted near the point source, the Rosenthal solution varies exponentially with position. The FEM solution has a polynomial dependence on position that comes from the polynomial basis functions. If the finite-element mesh size goes to zero, then the FEM approximation to the Rosenthal solution becomes more accurate.

Rosenthal and Rykalin chose a point source, not because they believed the arc was of zero size, but because it enabled them to solve the energy equation. Their solution was a useful approximation at points that were sufficiently accurate far from the arc. With the FEM, there is no advantage in choosing a point source. It is preferable to use a more-accurate approximation to the energy distribution in the arc.

Pavelic et al. (Ref 11) used a truncated Gaussian distribution of a prescribed flux in a circular disk moving with the arc over the weld joint. This can be accurate as long as the arc does not suppress the weld-pool surface too much and convection effects in the weld pool are not too large. If the arc-pool surface depression is large and/or if the velocity in the weld pool is large, then it can be more accurate to model the heat input, not as a distributed flux but as a distributed power density heat source that defines the heat input per unit volume per unit time at each point in the weld-pool region.

Goldak et al. (Ref 12) proposed a truncated Gaussian distributed heat source in a double-ellipsoid region. More-complex weld-pool shapes can be approximated by superimposing distributed heat sources.

Various phenomena can be introduced into these heat-source models, such as radiation, evaporation, and latent heat of fusion. However, it is useful to perform the following thought experiment to clarify their role. Assume that the exact temperature field is known as a function of time. Now, prescribe

Fig. 8 Contours of the longitudinal stress for the weld shown in Fig. 7

G = 1290; H = 1470; I = 1650

Fig. 9 Cutaway views of a branch pipe or T-joint weld. Top figure uses only eight node bricks. Note that the temperature gradient through the thickness of the pipe is negligible, except near the weld pool. The mesh in the bottom figure uses thermal shell elements and is both more accurate and more efficient.

that temperature field in the FEM equation. The reaction at each node is the nodal thermal load, which includes the net effect of all such phenomena. This can be for any shape of weld pool. Therefore, these phenomena can be included implicitly in the distributed heat source model, if desired, or they can be treated separately. If they are treated separately, then the definition and value of the distributed heat source should be changed accordingly.

Prescribed-Temperature Heat Source. If an estimate of the temperature in the weld pool is available, then it is often more convenient to model the heat source by prescribing the temperature in the weld-pool region (Ref 13). For example, the temperature on the surface of the weld pool and a cross section of the weld nugget could be measured. The liquid-solid interface could be assumed to be at or slightly below the solidus temperature. Then, nodes in the weld-pool region could have their temperatures prescribed. The reactions at these nodes would be the prescribed nodal thermal load that produces the same temperature distribution. Thus, the prescribed-temperature heat-source model and the prescribed distributed thermal load heat source are equivalent in the sense that either can be used to produce the same temperature solution. The experience of the authors has shown that estimating the prescribed-temperature distribution is much easier than estimating the distributed heat source, particularly for complex weld-pool shapes. For example, the authors were not able to estimate a distributed power density source that could model the weld shown in Fig. 6, whereas modeling this weld with a prescribed-temperature source was not difficult.

Material versus Spatial Reference Frames. Although Rosenthal used a spatial reference frame, most FEM analyses of welds have used a material reference frame. A spatial frame is fixed in space, and any space can be chosen. Rosenthal chose a space that was tied to the arc. It may be easiest to visualize this as an arc that is fixed in space, where the plate being welded moves under the arc through the spatial mesh. It is equally valid to imagine the plate fixed in one space and the arc fixed in a second space. In this case, Rosenthal used the second space.

A material reference frame defines the configuration of the body either at some point in time (usually, time zero) or at the beginning of each time step. The displacement field defines the mapping from the reference configuration to the configuration of the body at any other time. Imagine that each node in a finite-element mesh is associated with a material point. The node and its associated material point move through space as a function of time. This defines a material reference frame.

Most FEM analyses of welds have used a material reference frame, also called a Lagrangian reference frame, in which the heat source moves as a function of time. However, because the FEM is discretized in time, the usual FEM analysis is equivalent to a series of spot welds. If the time steps are sufficiently small so that

the distance the heat source moves in one time step is sufficiently small, such as half its diameter, then the effect of this discretization need not be excessive. If the time step is so large that the heat source moves more than, say, three times its diameter, for example, then the difference between the computed and measured temperature field will be large.

The use of a spatial frame, which is often called a Eulerian frame, avoids this problem. However, it introduces an advective term into the FEM equation. This term is nonlinear, and the usual formulation leads to an asymmetric set of equations to solve. Recently, Gu (Ref 14) implemented the Eulerian formulation and demonstrated its advantages (Fig. 1–5). The spatial frame enables longer time steps to be taken as the weld approaches steady state.

Transient versus Steady State. In a spatial frame that is tied to the heat source, the temperature near the arc of a long weld parallel to the prismatic axis of a prismatic body soon reaches a steady state. Indeed, the Rosenthal solution is an example of such a steady state. The weld pool typically reaches steady state in one to three weld-pool lengths. A rough guide is that any isotherm will approach the steady state in one to three isotherm lengths. Thus, lower temperatures require longer times and longer lengths to reach steady state. In analyzing long prismatic welds, computational efficiency can be gained by analyzing the steady state. Leblond et al. (Ref 15) and Gu (Ref 14) provide details, and the results of a steady-state analysis are shown in Fig. 1 to 5.

Modeling the Addition of Filler Metal. Bead-on-plate welds can have the simplest geometry and meshes, and they can exploit symmetry to reduce computing costs. When joint details are included, the mesh is somewhat more difficult to create. If welds are not on the symmetry plane, then symmetry cannot be exploited and the computational cost increases. These difficulties are minor, when compared with the difficulties of modeling the addition of filler metal. The first models used a material reference frame, created a mesh, and then turned on or activated those elements to which filler metal was added as they filled (Ref 14, 16). When it is applicable, a spatial frame offers a more-elegant approach, because the weld pool can be fixed or varied slowly, as desired (Ref 14) (Fig. 6). Figures 2 and 3 show the transient temperature field in a groove weld with added filler metal.

Microstructure Evolution

Microstructure strongly affects the material behavior and hence constitutive parameters, such as thermal conductivity, specific heat, and Young’s modulus. Volume changes associated with phase changes, such as austenite to ferrite, can cause large strains. For these

reasons, microstructure can have a dominant effect in the stress analysis of a weld.

This discussion is limited to welds in low-alloy steels. The phase, or equilibrium, diagram identifies the phases that are present, their composition, and the fraction of each phase present in a steel as a function of alloy composition, temperature, and pressure. Because as many as 10 alloying elements can be significant in low-alloy steel, the phase diagram could be in a space of 11 dimensions. To make this more tractable, this discussion uses pseudobinary iron-carbon diagrams. As functions of composition, the Ae_3 (austenite to austenite-ferrite line) and Ae_1 (eutectoid) temperatures are of particular interest when analyzing the decomposition of austenite.

At each temperature, the system tends to equilibrium. Phases that are unstable tend to transform to stable phases. Although the direction is largely controlled by thermodynamics, the rate is largely governed by kinetics. Following Kirkaldy (Ref 17), it is assumed that the decomposition of austenite into ferrite, pearlite, and bainite can be described by ordinary differential equations of the form:

$$\frac{df}{dt} = B(G, T)f^m(1 - f)^p \tag{Eq 15}$$

where $(1 - f)$ is the fraction of austenite; f is the fraction of the transformation product, for example, ferrite; the function $B(G, T)$ reflects the influence of grain size, undercooling, the alloy and temperature dependence of the solute diffusivity, and the phase fractions that are present; and m and p are parameters of the alloy system. This is essentially the model that was developed by Henwood et al. (Fig. 10). It was used to compute the microstructures in the heat-affected zone (HAZ) of the problems analyzed in Ref 19. Vandermeer (Ref 20) has proposed a modification to include the effect of carbon accumulation in the austenite during the transformation.

Austenite grain growth in the HAZ is computed from the ordinary differential equation:

$$\frac{dG}{dt} = \frac{1}{2G}ke^{-Q/RT} \tag{Eq 16}$$

where G is the austenite grain size, k is a parameter, Q is the activation energy, R is the

universal gas constant, and T is the absolute temperature. The grain size of austenite has a dominant effect on the hardenability of steel and hence the decomposition of austenite. The authors suspect that errors in the predicted austenite grain size are a significant cause of errors in the evolution of microstructure in the HAZ. In particular, this grain size is the average grain size. The equation was developed for grain growth in annealing essentially homogeneous regions. In a heterogeneous HAZ with steep temperature gradients across single grains, it is not clear that this equation is appropriate (Ref 21).

The aforementioned microstructure models, with the exception of that proposed by Vandermeer, do not consider the composition of each phase or the composition changes that are due to solute diffusion between phases. They only consider the composition of the system. Phase fractions are density functions that specify the mass fraction of a phase per unit volume. Grain size is also a density function. Thus, there is no representation of the microstructure and no capability to draw the microstructure being analyzed.

Thermal Stress Analysis of Welds

Stress analysis deals with the equilibrium of forces, the kinematics of deformation, and the relationship between deformation and force. The existence of a stress tensor field, a strain tensor field, a displacement vector field, and a constitutive relationship between stress and strain are assumed. The conservation of momentum is the fundamental conservation law.

From another viewpoint, the equilibrium of forces is expressed by the conservation of momentum and the definition of the stress tensor, σ , the traction vector, τ , and the body force, b , in the differential equation:

$$\nabla \cdot \sigma + b = m\ddot{x} \quad (\text{Eq 17})$$

In welding, it is typical to assume that the inertial forces are negligible, that is, $m\ddot{x} \approx 0$. This implies that the rate of change of loads is small, relative to the time required for a stress wave to propagate across the domain and for a stress wave to decay.

The solvability equations require the integrals of the external forces, that is, the traction vector, τ , and the body force, b , to be in equilibrium with themselves:

$$\int_{\Omega} b \, d\Omega + \int_{\partial\Omega} \tau \, d\Omega = 0 \quad (\text{Eq 18})$$

Whether or not the deformed body is rigid, the external forces must be in equilibrium.

The kinematics or deformation is described by the displacement and strain fields. For a total displacement field, $[u, v, w]^T = [u(x, y, z, t), v(x, y, z, t), w(x, y, z, t)]^T$, at the point (x, y, z, t) , the Green's strain is defined as:

$$\epsilon = \frac{\nabla u + \nabla u^T + \nabla u^T \nabla u}{2} \quad (\text{Eq 19})$$

where ∇u is the deformation gradient:

$$\nabla u = \begin{bmatrix} \frac{\partial u}{\partial x} & \frac{\partial v}{\partial x} & \frac{\partial w}{\partial x} \\ \frac{\partial u}{\partial y} & \frac{\partial v}{\partial y} & \frac{\partial w}{\partial y} \\ \frac{\partial u}{\partial z} & \frac{\partial v}{\partial z} & \frac{\partial w}{\partial z} \end{bmatrix} \quad (\text{Eq 20})$$

The Green's strain is a symmetric tensor. It measures the change in distance between points in the neighborhood of a point caused by the deformation.

The material properties are described by the constitutive, or stress-strain, relationship, $\sigma = D\epsilon$, where D is the fourth-order tensor that maps the elastic strain tensor to the stress tensor. Thermodynamic arguments require D to be symmetric positive definite. For isotropic elastic materials, D is defined by two constants, such as Young's modulus and Poisson's ratio.

Most FEM analyses of welds have used an additive decomposition of the total strain rate into elastic, thermal, plastic, and transformation plasticity strain rates:

$$\dot{\epsilon}^{\text{Tot}} = \dot{\epsilon}^{\text{Elas}} + \dot{\epsilon}^{\text{Therm}} + \dot{\epsilon}^{\text{Plas}} + \dot{\epsilon}^{\text{TransPlas}} \quad (\text{Eq 21})$$

Plasticity theory and numerical algorithms based on the multiplicative decomposition of the deformation gradient $\mathbf{F} = \mathbf{F}^e \mathbf{F}^p$ were developed in the period 1985 to 1994 (Ref 22). This theory is better suited to finite strain analyses. Although the creep strain rate could be included, the authors are not aware of published studies of creep in the modeling of welds, to date.

Equation 18 is an elliptic partial differential equation. Boundary conditions are an essential part of any such equation, and they can be either essential (prescribed displacement) or natural (prescribed traction). They must be prescribed for all time. The part of the boundary on which essential boundary conditions are prescribed is called $\partial\Omega_D$, whereas the part of the boundary on which natural boundary conditions are prescribed is called $\partial\Omega_N$. These two parts must make up the entire boundary, and they must not overlap at any point. In mathematical terms, this is expressed as $\partial\Omega = \partial\Omega_D \cup \partial\Omega_N$ and $\partial\Omega_D \cap \partial\Omega_N = 0$. The essential boundary condition is:

$$u(x, t) = F_D(x, t), \quad x \in \partial\Omega_D, t > 0 \quad (\text{Eq 22})$$

The natural boundary condition is:

$$\tau(x, t) = F_N(x, t), \quad x \in \partial\Omega_N, t > 0 \quad (\text{Eq 23})$$

Although an elliptic boundary value problem does not have initial conditions, initial data describing the distribution of the displacement, strain, or stress can be specified at all points in the interior of the domain, Ω , at time zero:

$$\begin{aligned} \sigma(x, t) &= F_{\text{init}}(x), \quad x \in \Omega, t = 0 \\ \epsilon(x, t) &= F_{\text{init}}(x), \quad x \in \Omega, t = 0 \\ u(x, t) &= F_{\text{init}}(x), \quad x \in \Omega, t = 0 \end{aligned} \quad (\text{Eq 24})$$

If microstructure evolution is considered, then only the macroscopic (average) stress, strain, and displacement fields will be considered. In other words, the variations in the fields, below some length scale, are averaged or ignored. This is inherent in a finite-element mesh, because an FEM analysis cannot detect spatial frequencies higher than those captured by the polynomials in the mesh.

Given the transient temperature-rate field in a weld, the thermal volumetric strain rate is:

$$\begin{aligned} \dot{\epsilon}^{\text{Therm}} &= \bar{\alpha} T \\ \delta t \dot{\epsilon}^{\text{Therm}} &\approx \Delta \epsilon^{\text{Therm}} = \alpha \Delta T \\ \bar{\alpha} &= \alpha + \frac{d\alpha}{dT} (T - T_{\text{ref}}) \end{aligned} \quad (\text{Eq 25})$$

The coefficient of thermal expansion, α , is a property of the material.

If the stress, body force, traction, strain, and displacement fields are sufficiently smooth, then this is a well-posed problem and the mathematics is well understood. The aforementioned continuum mechanics problem can be solved by an FEM approximation. In particular, the total strain rate is approximated by:

$$\dot{\epsilon}^{\text{Tot}} = B\dot{u} \quad (\text{Eq 26})$$

where \dot{u} is the nodal displacement rate or velocity, and B is the discrete symmetric gradient operator.

Examples of stress analysis of welds are shown in Fig. 7 and 8. For a general reference on continuum mechanics and stress analysis, refer to Ref 23 and 24.

Transformation Plasticity. Although the transformation of austenite to ferrite, pearlite, bainite, and martensite causes only a small effect on the temperature field, it can have a major effect on the stress field. This arises through the phenomenon of transformation plasticity (Ref 25, 26). The rate of transformation of austenite, \dot{Z} ; the deviatoric stress, τ_{ij} , and constant, K , that includes the volume change associated with the phase change; and the yield strength all determine a contribution to the strain rate and strain increment, given by:

$$\dot{\epsilon}_{ij}^{\text{TransPlas}} = K \tau_{ij} \dot{Z} \quad \Delta \epsilon_{ij}^{\text{TransPlas}} = \int_{t_1}^{t_2} K \tau_{ij} \dot{Z} d\xi \quad (\text{Eq 27})$$

This effect is greatest in high-strength steels such as HY-80 because the decomposition of austenite occurs at lower temperatures, where the volume change associated with the phase change is largest (Fig. 11). In addition, plastic deformation that occurs after the phase transformation is complete tends to hide or blur the effects of transformation plasticity. When the transformation occurs closer to room temperature, the effects of transformation are blurred

Fig. 11 (a) Experimental data published by Corrigan (Ref 27) for the residual stress in an HY-130/150 weld. (b) Predicted values of residual stress, published by Hibbitt and Marcal (Ref 28), who ignored the austenite-to-martensite transformation in their finite-element method (FEM) analysis of the residual stress. (c) Predicted values of longitudinal residual stress, as predicted by FEM analysis of Oddy (Ref 26), who has taken into account the effects of the phase transformation and transformation plasticity. Clearly, the effects of the phase transformation dominate the stress analysis in this case.

the least. In lower-strength steels and higher weld heat inputs, the transformation of austenite tends to occur nearer the eutectoid temperature, and the effect on the final residual-stress state is less pronounced.

Because the transformation plastic strain rate strongly affects the deviatoric stress, and because the deviatoric stress strongly affects the transformation plastic strain rate, the integration of Eq 27 requires some care in order to avoid instability. Details are provided in (Ref 26).

Stress Analysis near the Weld Pool. At temperatures below 800 to 1200 °C (1470 to 2190 °F) in steel welds, it has often been assumed that the viscous strain, or creep, rate can be neglected in welds, because the time at high temperatures is relatively short. If this assumption is accepted, then the material can be modeled as a thermoelastoplastic material. The theory for this is rather well accepted. Above some temperature, it is expected that the viscous strain, or creep, rate will become important, possibly becoming the dominant

deformation mechanism, in which case the material would behave as a viscoelastoplastic material. The theory for this behavior is not well established.

When a solid melts, the material changes from elastic behavior to a viscous fluid. This change is reflected in the Deborah number. It has been argued that even at the melting point, the crystal maintains a yield strength of the order of 5 MPa (0.7 ksi). When it melts, the yield stress drops to zero. Matsunawa (Ref 29) estimated that the viscosity of a liquid increases by a factor of 2×10^{13} upon solidification. The essence of elastic behavior is the existence of a reference state with zero stress. In a crystal, this reference state is crystal lattice. A liquid has no such reference state. Thus, there is a profound change in the physical behavior and the relevant mathematics upon melting. To deal with the change, the liquid and solid regions are typically considered as separate problems. On the interface, the temperature and the traction are continuous.

Because the authors do not know of any careful stress analysis in this temperature range for welds, this problem is left open.

Stress Analysis of Welds in Thin-Walled Structures. The use of plate and shell FEM elements can reduce cost and improve numerical accuracy significantly (Ref 30, 31). These elements usually assume that those stress components that project onto the normal-to-the-midsurface plane are zero, that is, s_{zz} , s_{xz} , and s_{yz} are 0 if the z -axis is normal to the midsurface. In heat-transfer analysis, the projection of the temperature gradient onto the midsurface normal plane is assumed to be 0, that is, $\partial T/\partial z = 0$. This is usually an excellent approximation, except near the intersection of surfaces, such as a pipe T-joint. It can be a good approximation of near-deep-penetration electron-beam and laser-beam welds but is usually not accurate near arc weld pools. Figure 9 shows an example of a weld that would not be accurately approximated by shell elements near the weld pool. Except in such regions, shell and plate elements can be effective. Combining shell and brick elements often provides the best approximation.

Fluid Flow in the Weld Pool

Thus far, weld pool data, that is, an adequate approximation of size, shape, and position, have been known as functions of time. Either the weld pool temperature or the power density and thermal flux distribution also have been known as functions of time. To predict weld penetration, solidification mode and microstructure, and other phenomena that are sensitive to the weld-pool physics, such as hot cracking and the stress and strain near the weld pool, it is necessary to model the weld pool. The model should predict the temperature, pressure, and velocity distribution in the weld pool, as well as the position of the liquid-solid and

liquid-plasma boundaries. It is also desirable to predict the current density, velocity, and pressure fields in the arc. Matsunawa (Ref 29) presents an excellent review of weld-pool analyses.

The major forces that drive convection in the weld pool are electromagnetic, gravitational or buoyancy, surface tension, and aerodynamic drag. The electromagnetic and gravitational forces act on the interior of the weld pool, whereas the surface tension and aerodynamic drag forces act on the surface, producing a traction force.

The conservation of mass, or continuity, equation for an incompressible liquid in the weld pool is:

$$\nabla \cdot \mathbf{v} = 0 \quad (\text{Eq 28})$$

The conservation of momentum in the interior of the weld pool in spatial coordinates is:

$$\rho \dot{\mathbf{v}} + \rho \mathbf{v} \cdot \nabla \mathbf{v} + \nabla p + \nabla \cdot \boldsymbol{\mu} \nabla \mathbf{v} + \mathbf{J} \times \mathbf{B} + \mathbf{f} \quad (\text{Eq 29})$$

where ρ is the density, and p is the pressure. The boundary conditions on the weld pool and arc interface are the traction that is due to the gradient in the surface tension, $-(\partial\gamma)/(\partial T)\nabla_s T$, and the traction, τ_D , that is due to drag from the velocity of the plasma:

$$\boldsymbol{\sigma} \cdot \mathbf{n} = -\mu \dot{\mathbf{e}} \cdot \mathbf{n} = -\frac{\partial\gamma}{\partial T} \nabla_s T + \tau_D \quad (\text{Eq 30})$$

where \mathbf{n} is the direction normal to the weld pool and arc interface, and the gradients are gradients in the surface. On the interface between the weld pool and solid, the velocity is zero, and the traction vector is continuous. The pressure must be specified at one point in the weld pool. When dealing with an incompressible fluid, it is important to remember that the pressure is not a thermodynamic variable but a constraint to enforce incompressibility.

The conservation of energy in the interior of the weld pool in spatial coordinates is:

$$\rho \frac{\partial H}{\partial t} + \rho \mathbf{v} \cdot \nabla H = \nabla \cdot \boldsymbol{\kappa} \nabla \mathbf{v} + \mathbf{f} \quad (\text{Eq 31})$$

The velocity in the energy equation is determined from the momentum and continuity equation. The thermal flux from the arc is prescribed on the weld pool and arc interface. With these data, the energy equation determines the position of the liquid-solid interface. With a new temperature distribution, the momentum equation is solved. If this iteration procedure converges, then the result is said to be a solution.

The mathematical nature of the aforementioned equations that model the weld pool and their numerical solution is significantly more difficult than those needed to model the behavior of welds below, say, 0.7 of the melting temperature. The physics is also more difficult. Most analyses of the weld pool have used either finite-difference or finite-volume methods.

They have achieved interesting results and have done much to clarify the physics of the weld pool. However, in Matsunawa's view (Ref 29), the capability to accurately predict weld-pool shape and size is still limited. See Ref 30 and the references therein for more recent research on weld-pool modeling. Continued progress in weld-pool modeling is needed and can be expected.

Modeling of Thermomechanical Phenomena in Fusion Welding

C. Schwenk, BAM—Federal Institute for Materials Research and Testing, Berlin, Germany

THE LONG-TERM TARGET in the processing industry is to fully cover the production process—from the raw material, through the individual fabrication steps, to the end product—in the form of a so-called virtual process chain. A continuous simulation of all relevant fabrication segments is necessary to achieve a reduction of development and fabrication costs but more importantly, an optimization of the products and all fabrication procedures. An essential link in this virtual process chain is welding simulation, because of the central position of welding in the process chain.

Welding simulation enables early statements to be made regarding the thermomechanical phenomena in fusion welding, that is, mainly the welding-specific temperature fields, distortions, and residual stresses in components. Therefore, simulation helps to minimize the number of iteration loops currently required in the development process by adopting the simultaneous engineering concept. In addition, it provides information that can only be gained experimentally with disproportionately high expenditure or sometimes not at all, for example, transient evolution of thermal strains in the overall component during the ongoing process. Hence, simulation provides a basis for specific identification of the causes of welding-induced distortion and residual-stress conditions, thereby permitting a structured approach to component and process optimization.

Basic Principles and Heat Effects of Welding

A particularly significant potential application of welding simulation is seen in the engineering services market. Increasingly, large corporate groups (original equipment manufacturers) delegate the development of individual components to industry suppliers (in most cases, small- and medium-sized enterprises), to whom a time-saving and cost-efficient development process is of vital interest because of sharply increasing requirements and

international competition. Welding simulation can make valuable contributions to assist them; some industrial application examples are given in Ref 1. For trouble-free communication with the customers, a defined and generally applicable guideline for execution, analysis, and postprocessing is imperative to assure reliability and relevance of the calculation results. Furthermore, a defined mode for displaying results will provide a basis for effective comparison of various computation projects. Such certainty is essential to both the potential customers and the respective contractors. It helps to encourage a wide application of welding simulation and hence to fully exploit the potential of this powerful computational method. While being covered by various welding simulation tools that are designed for fast and easy prediction of the heat effects of welding via special modeling approaches, these aspects are not generally covered for transient three-dimensional (3-D) numerical welding simulation because of the complexity of the application and the necessary user experience. For differentiating the applicability of various welding simulation methods as well as unifying the prerequisites and steps to be taken in simulation, normative codes are required as a reference for the user. Standardized documents do not yet exist in this field; to address this topic, some work has recently been done to create a standardized guideline for verification and validation (Ref 1) as well as for a common workflow for welding simulation (Ref 2, 3).

The procedure explained in the following sections is valid for a specific aspect of welding simulation—the 3-D transient approach—in order to obtain high-quality results. It relates to the simulation of line welds produced by fusion welding processes such as arc or beam welding as well as by respective process combinations. It presupposes the occurrence of a quasi-stationary process regime that is reached during welding. A further prerequisite is that the nonstationary regimes at the weld start and end must be reproducible and fit for the simulation. Such simulations deal with the subdomain

of structure simulation (Fig. 1), which serves to calculate the thermomechanical phenomena in fusion welding, namely the structural temperature field and the ensuing distortions and stresses, also referred to as computational weld mechanics (Ref 4). It additionally concerns individual aspects of materials simulation if phase transformation of the material is taken into account, which implies that couplings between structure and material simulation are well within the scope of the procedure.

The following sections refer to 3-D transient (time-dependent) numerical welding simulations. Furthermore, the recommendations given for deviations and limits are true for possible high-quality results. Depending on the application case and the intended conclusions of a simulation task, a lower accuracy may sometimes be sufficient to obtain the simulation statements required, so that it is possible to deviate from the prespecified details in order to save time and effort, which must be decided by the user. For special calculation tasks, an even higher accuracy may be needed, for example, for calculation of phenomena in the direct vicinity of the weld pool, such as cracking behavior. With the current state-of-the-art in commercially available welding simulation software, various tasks can already be modeled not only in a research environment but also with industry-related applications (Ref 1, 6).

This article concentrates on the necessary basics for such simulations and gives an overview of the specific aspects to be considered for such a simulation project. These include the required material properties, the experimental data needed for validation of the simulation results, the simplifications and assumptions as a prerequisite for modeling, and finally the thermomechanical simulation itself. The article concludes with some information about the sensitivity of the material properties data with respect to the simulation results, providing hints about the central challenge of having the right material properties at hand for a specific simulation task.

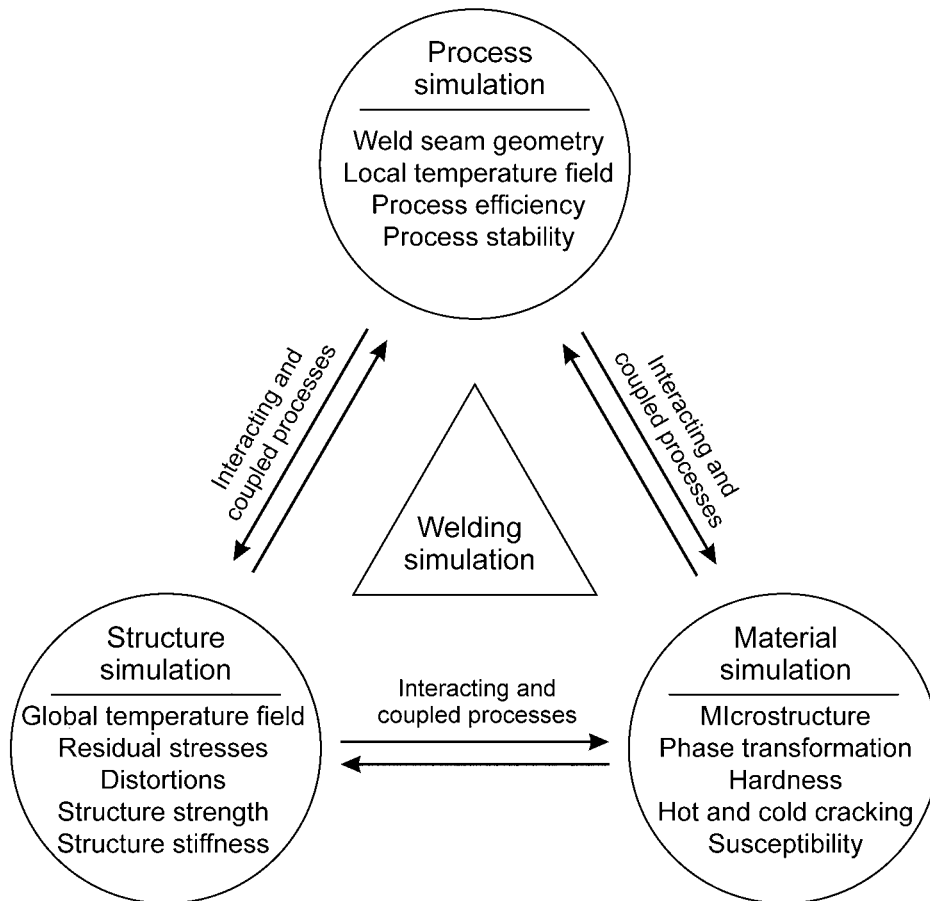

Fig. 1 Subdomains of welding simulation showing the main target and coupling factors. Adapted from Ref 5

Required Material Properties and Measurement Techniques

One of the most important challenges of a high-quality simulation of the thermomechanical phenomena in fusion welding is the lack of temperature- and phase-dependent material properties that are needed as input data. For most modern alloys, these data are not yet available from the supplier or in the literature. Consequently, an experimental determination of the values is often required in order to obtain high-quality simulation results. One remaining aspect is the inevitable scatter of the experimental data, especially at relatively high temperatures. These uncertainties can have major effects on the subsequently calculated temperatures and distortions (Ref 7–9). Furthermore, the correct measurement of the necessary properties is a demanding task with respect to time, costs, and accuracy, especially at elevated temperatures and for alloys with phase transformation. Some measurement techniques that are suitable for this task, as well as the corresponding equipment, are described in this section.

As previously stated, the numerical welding simulation requires a wide range of material

properties as input data. Considering the temperature field calculation, the required thermophysical properties are:

- Density, ρ
- Specific heat capacity, C_p
- Thermal conductivity, λ

Instead of the specific heat capacity and density, the enthalpy of the alloy can also be used, because of the mathematical relationship of these properties, which is described in detail in Ref 10. Information about the application of enthalpy in welding simulation can also be found in Ref 11. For calculation of distortions and stresses, the required thermomechanical properties are:

- Yield strength, $R_{p0.2}$
- Hardening behavior
- Young's modulus, E
- Thermal expansion, α
- Poisson's ratio, ν

All of these properties must be expressed with temperature dependencies from room temperature to the solidus temperature and above. The calculated temperatures can easily reach

values of 2500 °C (4530 °F) and more, and the numerical approach presupposes available data for all the temperatures that occur. From an experimental point of view, measurement at these temperatures is usually extremely difficult or even impossible, especially for the thermomechanical properties. A common practical compromise is to measure properties from room temperature to approximately 0.8 T_{Solidus} of the alloy. In addition to this wide temperature range, alloys with phase transformation must identify phase dependencies (e.g., ferrite, austenite, bainite, martensite), including the continuous cooling transformation (CCT) diagram.

The measurement of the required material properties involves a thermophysical and a thermomechanical part. During all experiments, one must take care that the rising temperatures do not affect the surface of the material. To prevent scaling that can influence the accuracy of optical detection methods, all measurements should be done under an inert atmosphere. For the thermophysical data, one special aspect must be taken into account. The material used in the automotive industry, as well as in other industries, is often coated (galvanized) with zinc to prevent corrosion. These coatings must be removed prior to measurement, because a clean and matte surface is necessary for correct measurement of the thermal diffusivity, $k(T)$, using a laser flash method. The density and specific heat capacity can be determined using commercially available equipment and standard specimen preparation. After the experiments, a calculation of the thermal conductivity as input for the simulation is done using the gathered data in combination with Eq 1:

$$\lambda(T) = k(T) \cdot \rho(T) \cdot C_p(T) \quad (\text{Eq 1})$$

Measurement of thermomechanical material properties must be done with consideration of two important aspects that are characteristic for welding. Depending on the welding technique and the specimen thickness, the heating and cooling rates can be very high. While the heating rate has a direct influence on the strain rates and therefore the yield strength and hardening behavior of the material, the cooling rate is an important factor for the phase-transformation effects of an alloy and the corresponding thermal expansion.

Tensile tests for the determination of the yield strength and hardening behavior must be executed with both a quasi-static and at least one higher strain rate. This is necessary in order to reflect the influence on the mechanical properties caused by the higher strain rates, as mentioned previously. The value for the expected higher strain rate can be approximated by using Eq 2:

$$\dot{\epsilon} = \alpha(T) \cdot \dot{T} = \alpha(T) \cdot \frac{\Delta T}{\Delta t} \quad (\text{Eq 2})$$

For example, the temperature rate for laser beam welding with high power and velocity

can easily reach $\dot{T} = 4000\text{K/s}$ ($7200\text{ }^\circ\text{F/s}$). With an assumed averaged thermal expansion coefficient of $\alpha_{st} = 1.3 \times 10^{-5}/\text{K}$ ($7.2 \times 10^{-6}/^\circ\text{F}$) for steel and $\alpha_{al} = 2.5 \times 10^{-5}/\text{K}$ ($1.4 \times 10^{-5}/^\circ\text{F}$) for aluminum alloys, the strain rates during laser beam welding can be estimated to values of $\dot{\epsilon}_{st} = 0.05/\text{s}$ and $\dot{\epsilon}_{al} = 0.1/\text{s}$ in correspondence with literature values (Ref 12). These values must be adapted to the welding technique that is to be simulated and are also the values that should be considered for tensile tests with higher strain rates. For other processes, such as gas metal arc welding (GMAW) or tungsten inert gas (TIG) welding, different heating rates are typical.

In the measurement setup of a tensile test at elevated temperatures, some special characteristics must be known that are based on specific thermomechanical effects which only occur under special conditions. Here, in particular, the Portevin-LeChatelier effect is of interest because it can cause a stress-strain behavior that is somewhat different than the overall behavior of the alloy.

At certain alloy-dependent conditions with a special combination of specimen temperature and given strain rate, metallurgical effects can cause problems with machine usage while running in force-control mode. In such cases, the measured curves can show a steplike behavior because of the Portevin-LeChatelier effect, where the atomic diffusion in the material has the same velocity as the movement of the dislocations. The movement of the dislocations is locked, resulting in fluctuation of the material flow and stiffness of the specimen. This leads to difficulties in the force control of the testing machine, observable in the tensile test plots as a high scatter in the recorded curves, as shown in Ref 13, and can be overcome using the distance-control mode. Consequently, the testing machine should be run in distance-control rather than force-control mode for all tensile tests at elevated temperatures.

The Young's modulus of the alloys should not be derived from tensile test results. Especially with rising temperatures and higher strain rates, the gradient at the beginning of the data curves normally shows very high scatter. Instead of using tensile test results (which are the basis of the original definition of Young's modulus), this value can be measured much more accurately with an ultrasonic device based on monitoring the signal after an ultrasonic excitation of the material. This approach yields good results even for high temperatures. Nevertheless, the extracted values should be cross-checked later with available tensile test results up to approximately $0.5 T_{\text{Solidus}}$ of the considered alloy. The temperature-dependent measurement of Poisson's ratio is not necessary when doing a distortion calculation because the influence on the results is negligible, and a room-temperature value is sufficient for a welding simulation (Ref 7, 13).

As stated, the cooling rates have a direct influence on the phase-transformation behavior

and the corresponding thermal expansion. This fact must be accounted for in the measurement of the thermal expansions, that is, the dilatometric curves of the alloys. One typical parameter for the weldability of alloys is the cooling time between temperatures of 800 and $500\text{ }^\circ\text{C}$ (1470 and $930\text{ }^\circ\text{F}$), the so-called $t_{8/5}$ time. During high-power welding processes with a concentrated heat input, such as laser beam welding, extremely low $t_{8/5}$ times of less than a second are possible and must also be reached in the experiments. As for the tensile tests, the welding technique has a significant influence on the cooling rates, too, and leads to different $t_{8/5}$ times, for example, for GMAW or TIG processes. More information about the measurement of dilatometric curves and the analysis of the generated data can be found in the next section.

While the correct measurement of the material properties data is one very important task for a welding simulation project, it is nevertheless only the first part of generating a dataset suitable for simulation of the thermomechanical phenomena in fusion welding. The second part consists of the plausibility check of the monitored raw data as well as comparison with scatter bands of comparable alloys from published literature or previously executed experiments. This second part is explained in the following section.

Analysis of Material Properties Input Data

One necessary step after the experimental determination of the material properties

necessary for the simulation task is the analysis of these data to ensure the correctness of the measurements and to check their appropriateness for a numerical welding simulation. This is important because the material property data have a strong and direct influence not only on the result quality but also on the convergence behavior of the numerical calculation and, as a result, on the overall computation time (Ref 14).

The cross check of the measurement data with scatter bands from literature values is shown exemplarily in Fig. 2 for the specific heat capacity of three alloys; further information about the alloy contents and the material characteristics can be found in Ref 14. Both the austenitic steel H400 (EN 1.4376) and the dual-phase steel DP-W 600 (EN 1.0936) are well within the scatter bands for high-alloy steel and mild steel, respectively. The data show only minor scatter; the progression of the graphs is smooth. The curve for Ecodal 608 (EN-AW 6181, AlMgSi alloy group with precipitation hardening) shows some characteristics that must be investigated. The general behavior is consistent with the data for pure aluminum and AlMgSiCu taken from Ref 15 and 16. Nevertheless, the deviations in certain temperature intervals are significant.

The local minimum in the temperature range between 200 and $300\text{ }^\circ\text{C}$ (390 and $570\text{ }^\circ\text{F}$) is caused by an extensive precipitation of Mg_2Si particles and the subsequent dissolution. Analyses show that this local minimum of the specific heat capacity has only small effects on the calculated temperature field and the following macroscopic mechanical behavior and can be neglected (Ref 13). As stated previously, such local effects in the material data curves

Fig. 2 Comparison of experimentally determined specific heat capacity, C_p , and literature values. Adapted from Ref 5, 15, 16

can have a major effect on the convergence and computation time. Other examples for a similar nonlinear behavior are the specific heat capacity peak of the phase transformation or the latent heat of fusion. If the peaks must be considered in the material dataset because their influence cannot be neglected, one possible solution is to stretch extremely steep or step-wise peaks over a slightly larger temperature interval. The effects on the result quality are negligible, but the convergence behavior is much improved in most cases; that is, depending on the steepness of the gradient, a factor of up to 2 to 3 (typical values of approximately factor 1.5) in the calculation time can be observed.

As stated in the description of the measurement techniques, the strain-rate effect during tensile tests can be significant due to the high strain rates during welding. The combined effect of the temperature and the strain rate on the yield strength can be checked in accordance with Eq 3, proposed by Makhnenko (Ref 17):

$$\frac{\sigma_y(T)}{\sigma_{y,0}(T)} = \left(\frac{\dot{\epsilon}}{\dot{\epsilon}_0}\right)^{m(T)} \quad (\text{Eq 3})$$

Here, the parameters are the yield strength $\sigma_y(T)$ at temperature T and strain rate $\dot{\epsilon}$, as well as the yield strength $\sigma_{y,0}(T)$ at the quasi-static strain rate $\dot{\epsilon}_0$. The temperature- and alloy-dependent exponent, $m(T)$, is a measure for the dependence of the yield strength $\sigma_y(T)$ during a variation of the strain rates. A high value of the exponent $m(T)$ stands for a high dependency of the yield strength from the strain rate.

Figure 3 shows the extracted measurement data in comparison with literature values from

Makhnenko (Ref 17). In Fig. 3(a), the strain-rate influence for the dual-phase steel DP-W 600 becomes significant for temperatures above 500 °C (930 °F), while the yield strength of the austenitic steel H400 is independent of the strain rate up to 700 °C (1290 °F). The values for Ecodal 608 (Fig. 3b) show that the strain-rate effect becomes visible for temperatures above 300 °C (570 °F). The information gathered using Eq 3 indicates that the tensile tests at elevated temperatures must be executed with different strain rates for temperatures above 500 °C (930 °F) for DP-W 600, 700 °C (1290 °F) for H400, and 300 °C (570 °F) for Ecodal 608.

The thermal expansion of a specimen undergoing high heating and cooling rates is normally measured with a special dilatometric device, for example, a Gleeble machine. Here, $t_{8/5}$ times of approximately 3 s for a thin-sheet metal specimen can be reached with passive cooling via the clamping devices. In contrast, the extremely low $t_{8/5}$ times of less than a second during laser beam welding necessitate an active cooling that can be done using a direct inert gas spray on the specimen. As shown in the following paragraphs, this behavior results in challenges for optical measurement of the lateral contraction of the specimen and leads to deviations in the monitored dilatometric curves. The thermal expansion experiments must be conducted with a variation of the $t_{8/5}$ time in order to monitor the phase transformation correctly and to obtain the correct temperature intervals of the transformation. The appearance of a small hysteresis between both cycles, caused by the very short heating and cooling of the specimen, is normal and, in most cases, inevitable.

The experimental raw data for thermal expansion are shown exemplarily for DP-W 600 in Fig. 4(a). Monitoring of the thermal expansion was done with a laser-based optical device to record both the expansion in the longitudinal direction of the specimen and the perpendicular longitudinal axis. The heating branch of the curves shows no noteworthy deviations for all four measurements. In contrast, in the cooling branch between 900 and 400 °C (1650 and 750 °F), the curves for all cooling times except $t_{8/5} = 3.1$ s are deviated. The reason is that active cooling of the specimen with inert gas causes flickering effects, that is, an optical deviation of the gas flow due to steep changes in the temperature of the gases, resulting in a different refraction index. While necessary to reach the high cooling rates, here the cooling gas interferes with the optical measurement of the specimen.

Therefore, for use in numerical simulation, the cooling branches of the curves achieved with active cooling must be corrected using the general characteristic of the $t_{8/5} = 3.1$ s curve with passive cooling. Coming from the high-temperature region of the curve, the gradient of the austenite expansion coefficient can be elongated until transformation takes place at approximately 400 °C (750 °F) (Fig. 4b). These corrected curves can now also be used to evaluate the required transformation temperatures A_{r1} and A_{r3} for the correct description of the CCT behavior. Using the standardized method in Ref 18 leads to the derived values given in Fig. 4(b).

The exemplary analysis of the measurement data gives an overview of the possible scatter of the material properties. A detailed

Fig. 3 Comparison of exponent m for measured data and literature values in (a) steels and (b) aluminum alloys. Adapted from Ref 17

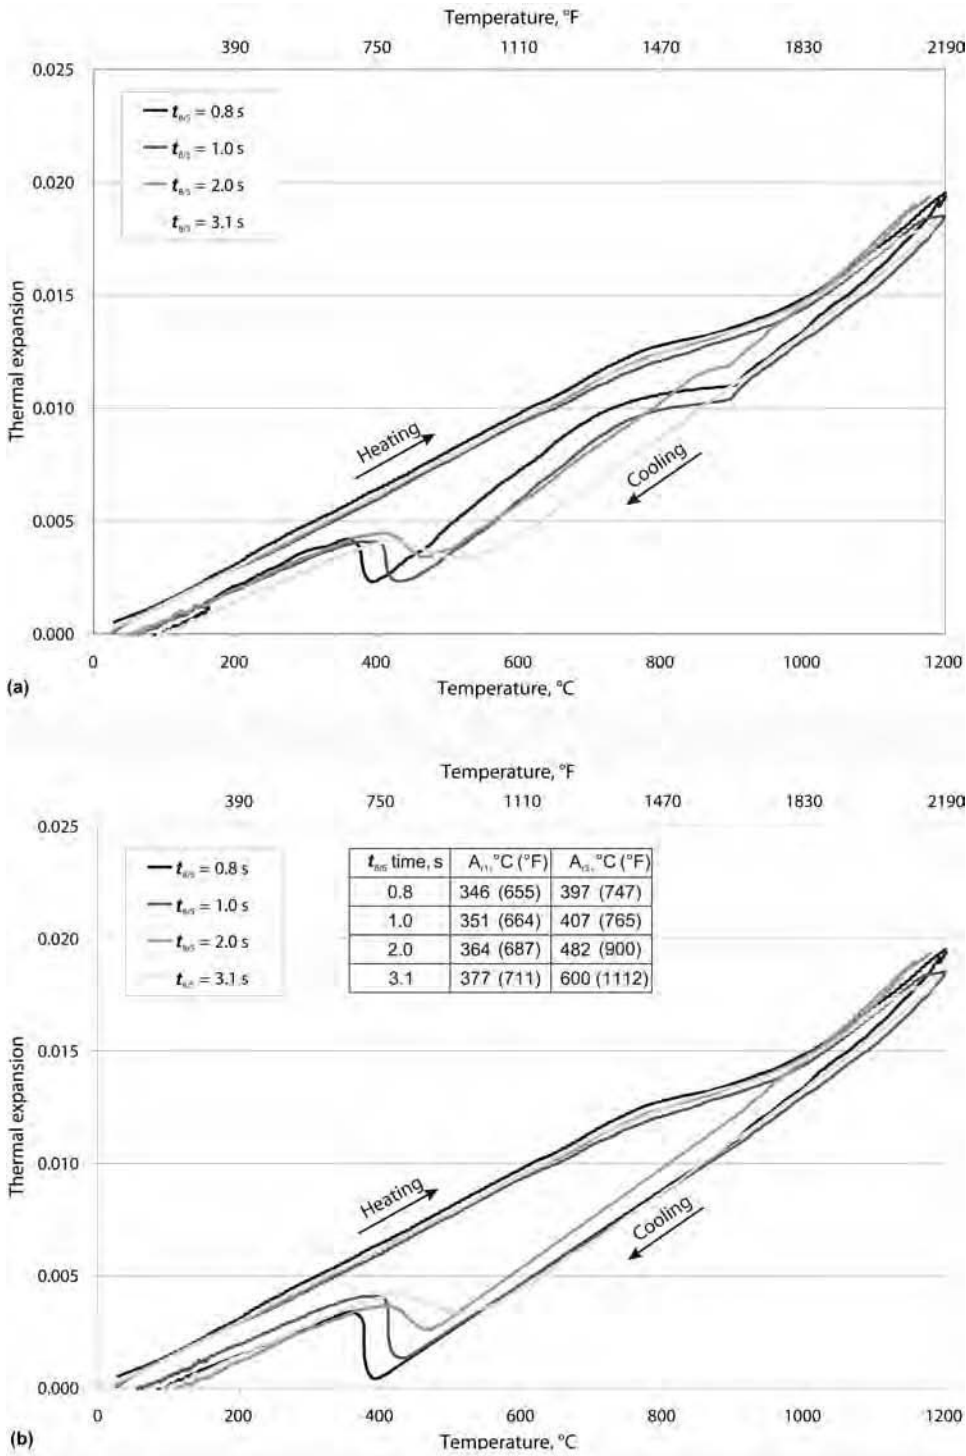

Fig. 4 Measured thermal expansion for DP-W 600 for various $t_{8/5}$ times. (a) Raw data. (b) Corrected curves for high cooling rates and transformation temperatures. Adapted from Ref 18

plausibility check of the data is needed to derive a high-quality material property dataset from the raw data of the measurements and is strongly recommended. The analysis methods help to identify possible systematic measurement errors. The temperature-dependent

thermophysical and thermomechanical material properties for three different alloys are given as a result of the preceding measurements and plausibility checks and are represented in a ready-to-use format for a numerical welding simulation in Ref 14.

Experimental Data for Validation of Thermal and Mechanical Results

Based on the current state-of-the-art in welding simulation, experimental validation of calculated results is imperative for the attainment of high-accuracy results (Ref 4, 5). This is also stated in a recently developed guideline about the execution and documentation of a numerical welding simulation (Ref 3). A missing validation and an unsuitable result display often make it impossible to judge the result quality and therefore transfer the conclusions to other tasks and make good use of the research results, or to compare them with similar analyses. Consequently, the presented workflow includes some general rules and specific aspects about how to validate a simulation and how to display the results. For the scope pointed out in the beginning, respective experimentally-determined data are required. Generally, it must be ensured that the experiments as well as the measurements are conducted based on the state-of-the-art and that the experimental result is not influenced more than a minimum degree by the measurements.

Temperature Field. For the experimental validation of the temperature field calculation, the basic required information is the 3-D weld pool geometry, that is, the cross section transverse to the welding direction and the weld pool length on the top and bottom sides of the specimen, respectively. For all cases, a quasi-stationary process regime is a prerequisite. Whereas the molten and heat-affected zone areas and shapes transverse to the welding direction can be determined directly from macrosections, the measurement of the weld pool length is more sophisticated. Possible direct measurement methods are digital images taken by a high-speed video camera or by thermal imaging techniques, but, in most cases, an indirect measurement is done with thermocouples by way of the temperature cycles. Here, a time-dependent measurement of the component temperatures in the direct weld vicinity for at least two points in linear arrangement transverse to the welding direction is adequate to allow mapping of the temperatures and temperature gradient. The data recording should start shortly before running the welding process and last until the specimen has completed cool-down to ambient temperature. This is normally done at the specimen top side and, if necessary, at the specimen bottom side, for example, when the thickness of the specimen leads to a temperature gradient in the thickness that is not negligible. During all thermocouple measurements, at least 50% of the solidus temperature in °C of the investigated material should be reached at the nearest measuring spot. Thermocouples with a wire diameter that is compatible with the welding process and a scanning frequency that permits reliable mapping of the peak and the achieved maximum temperature in the temperature-time history must be used.

Distortion. An experimental validation of the component distortions and residual stresses is needed to ensure the correct behavior of the thermomechanical part of the simulation model. The specimen support and the clamping conditions of the real part must be resembled in the simulation model as well. To have information for validating the general qualitative behavior of the welding simulation model, a time-dependent measurement of the welding distortions is needed for later comparison with the calculated results. It should run for the entire welding time and the following cooling time until reaching nearly ambient temperature, parallel to the temperature field measurements. A measurement of the longitudinal and transverse distortions is always necessary; it is strongly recommended for the angular distortions. Any rigid body displacements should be avoided beforehand or taken out of the calculation with the help of differential measurements, respectively. Examples of common measuring techniques are inductive displacement transducers or optical methods such as the 3-D gray-level correlation method. Additionally, coordinate-measuring machines can be used to monitor the status before and after welding; this is often done for special reference points or mounting dimensions of industrial parts.

Residual Stresses. The component residual stresses are the second aspect of the validation of thermomechanical simulation results. In comparison with the calculated distortions, they offer additional information about the simulation result quality. Whereas the calculated distortions of a welded specimen may be qualitatively and quantitatively satisfactory while neglecting the phase-transformation behavior of a material, the residual-stress state normally is strongly dependent on the transformation characteristics of an alloy. This is especially true for the local areas near the weld seam. Consequently, validation of the residual-stress state ensures a high-quality simulation result. The measurement of the residual stresses must be done after a complete cooling of the specimen to room temperature. To map the stress gradient in the weld seam and heat-affected zone, at least three points in linear arrangement transverse to the welding direction are recommended. Here, both the longitudinal and transverse directions should be considered. Possible measurement techniques are the hole-drilling method or diffraction methods such as x-ray, synchrotron, or neutron diffraction (Ref 19). An additional measurement using strain gages is also possible and can provide valuable transient information of the thermal strains. The information is also summarized in Table 1.

Workflow for Thermomechanical Welding Simulation

The major challenge in modeling of thermomechanical phenomena in fusion welding is to meet the industrial requirements for welding

simulation software (Ref 1). On one hand, in-house codes or multipurpose finite-element analysis products, such as ANSYS, Abaqus, or Marc, are very flexible and enable simulation, with various degrees of complexity, of most welding processes. Nevertheless, the prerequisite expert knowledge and the computational costs increase exponentially with the complexity of the simulation. On the other hand, special simulation software, such as Sysweld, has been designed with a particular focus on welding. In such programs, many tools are available, for example, a tool to consider solid-state transformations or a tool for the heat source, and so on. This software is very powerful and enables good results in a reasonable calculation time. However, it is mainly implemented in research institutions; a wide industrial application is not yet established. In most cases, the time to solution, that is, the preprocessing, calculation, and postprocessing times, hinder an industrial application. Even with a short calculation time, the pre- and postprocessing times can last up to several weeks for a single simulation task. A friendly and intuitive user interface could decrease the time significantly and make possible an industrial application of welding simulation (Ref 6). (For a summary of simulation programs for welding and other metals processing applications, see Appendix A, “Software for Computational Materials Modeling and Simulation,” in *Metals Process Simulation*, Vol 22B, of *ASM Handbook*, 2010.)

The general workflow for a welding simulation, according to the stated approach, is shown in Fig. 5. It consists of the experimental and material properties data, setup of the simulation, temperature field, calculation of the distortions and stresses, and finally, postprocessing in combination with cross-checking of the results. All single steps are explained in detail in the following sections.

A simplified phenomenological heat-source model is normally used to represent the heat

of the welding process. Because this model is not a process model but an abstract parameterized mathematical model, it must be calibrated in an iterative way so that the resulting temperature field and fusion zone fit well with the experimental data (Ref 21). Good agreement with the simulated and experimental thermal results is a prerequisite to achieving a high-quality mechanical simulation of distortions (Ref 5). The implementation of welding simulation in the automotive sector, a key industry for the application of various production simulation approaches, has been investigated in Ref 22. Some examples for automotive welded assemblies are a front axle carrier (Ref 23), rear axle carriers (Ref 24, 25), a gear wheel (Ref 26), and some fuel injector components (Ref 27, 28), which have been investigated with various techniques, software, and accuracy.

Setup of Simulation, Simplifications, and Assumptions

A complete, self-consistent welding simulation that includes all relevant physical aspects is not yet available, although various mathematical descriptions are available for different aspects of welding (Ref 5, 29, 30). However, many couplings are still unknown or not described mathematically, and incorporation of all aspects would result in a very complicated model that is not realistically solvable. Furthermore, the available computational capacities would be limiting for such a complex and demanding task. However, not all aspects must be known with absolute certainty for reliable calculation and clarification of individual effects (Ref 4, 31, 32). Welding simulations using finite elements have the ability to separate the influence of the various metallurgical parameters and their effect on the calculated results.

To assess the relevance and quality of the achieved simulation results, a detailed description of essential information about the entire

Table 1 Experimental data for validation

Information	Explanatory notes
Weld pool geometry	Information about the three-dimensional geometry of the weld pool—mainly cross section and length on top and bottom sides
Component temperatures in weld vicinity	Time-dependent measurement starting shortly before running the welding process and until completed cooling to room temperature Measurement at two or more points, in linear arrangement transverse to the welding direction, for mapping of the temperature gradient Measurement at the specimen top side; if needed, at the specimen bottom side as well At least 50% of the solidus temperature in °C of the investigated material should be reached.
Component distortions	Time-dependent measurement starting shortly before running the welding process and until completed cooling to room temperature Measurement of longitudinal and transverse distortion is always necessary; measurement of angular distortion is strongly recommended. Additional measurement of reference points or mounting dimensions is recommended. Rigid body displacements should be avoided or taken out of the calculation with the help of differential measurements.
Component residual stresses	Measurement after completed cooling of the component at three points (at least) in linear arrangement transverse to the welding direction to allow mapping of the stress gradient Additional transient measurement of the thermal strains using strain gages is also advisable. Longitudinal and transverse directions should be considered. Measurements should be carried out specifically in the weld vicinity and directly in the weld.

simulation is indispensable. The essential information concerns the exact designation of the welding process to be simulated, relevant simplifications and assumptions for the desired results, applied boundary conditions, material properties used, and heat sources, in addition to general information about the simulation project, such as the software package and version as well as solver settings that deviate from the standard, with a brief explanation.

Simplifications and Assumptions. The simplifications and assumptions that were made for the simulation task should be given in the order of their importance. In most cases, there are simplifications of the welded part geometry, for example, deviations between the ideal computer-aided design geometry and the real part because of production processes or the observed weld reinforcement after welding. This also includes the possible use of a partial model while taking advantage of mirror or rotational symmetry to save computation time. Finally, the relevant information about the meshed model should be given, namely, the number of nodes and elements applied, with the element base function or element type and the minimum element length in the areas where the maximum thermal and mechanical loads are applied. An overview picture plus zoomed pictures of important regions, such as a more dense mesh in the weld seam area, complete the data (Fig. 6). One important aspect is the possible influence of the mesh structure on the calculation results; here, the correct meshing strategy has a big influence on both the calculation time and result quality (Ref 33, 34).

Two other very important aspects are the consideration of previous process steps, such as primary forming or metal shaping, which have an influence on the residual-stress state, and assumptions made for the material properties, such as homogeneous and isotropic characteristics or neglect of segregations. The information about the consideration of the given real physical processes and their couplings, such as the neglect of weld pool fluid flow or the neglect of keyhole formation during laser beam welding, is also important. Further data referring to potential simplifications can be found in the literature (Ref 7, 32, 33, 35).

Boundary Conditions. Considering the boundary conditions used in the simulation, there are several important pieces of information to be stated. For the thermal aspects, the respective ambient temperature is needed. Furthermore, consideration of the conductive, convective, and radiative heat transfer between individual components and fixtures in the modeled system as well as across the system boundaries must be given to ensure a consistent heat transport and cooling behavior in the model. From the mechanical point of view, the boundary conditions include the support of the specimen and the applied clamping conditions with respect to the clamping position and area, clamping and unclamping time, and clamping force, which can be modeled in different ways,

for example, as a spring constant at individual nodes or with complex contact algorithms.

Material Properties. The thermophysical and thermomechanical material properties and the corresponding transformation behavior are a central aspect of a qualitatively-high welding simulation. The exact designation of the real alloy used in the experiments, for example, the alloy number and the actual chemical composition, as well as the material dataset used in the simulation must be mentioned. The simulation dataset is especially important because it is common to take an available dataset for a

comparable alloy and adapt the data to the special alloy in the experiment by using some additional measurements of the actual material. Information about the temperature dependence and, when applicable, the phase-transformation behavior is required, including the CCT diagram as well as the solidus temperature, which is necessary for validation of the transverse weld pool geometry. An indication of the reference source of the material characteristics or a graphical and tabular representation, respectively, of the material properties data is strongly recommended; see Ref 14 for an example.

Fig. 6 Example for the correct display of the meshed simulation model. Half model, sheet thickness = 1.5 mm (0.06 in.), approximately 15,000 nodes and 20,000 elements. Closeup of weld seam area is shown at left. Adapted from Ref 20

If the investigated alloy undergoes a phase transformation during heating and cooling, this effect can be integrated in welding simulations. In such a case, a thermal-metallurgical calculation is first completed using the thermal properties of the material, the calculated temperature field derived and validated from the welding experiments, and the CCT behavior formalized mathematically. The thermal-metallurgical calculation data are then used as an input to the mechanical calculation, which determines stresses and strains according to the transient and spatial distribution of the previously calculated temperatures in the model. It is noted that this one-way coupling, also referred to as weak coupling, does not account for the effect of stress on phase-transformation behavior. Furthermore, there is no interaction between the latent heat generated by solid-state phase transformations and the calculated temperature field. More detailed information about phase-transformation models and the influence of material property data on simulation results can be found in the literature (Ref 7–9, 36–45).

Heat Source. Finally, the applied heat source resembling the real heat input of the validation experiments must be given. There are different types of heat sources available that are sometimes combined to match the validation data; here, the most important fact is the statement of the approach that was chosen for the current task. A summary of the given aspects can be found in Table 2.

General Aspects

Based on the state-of-the art, the welding temperature field generation may be accomplished in various ways. A manual iterative approach may be adopted for heat-source parameter fitting. Alternatively, automated procedures may be drawn upon, as described in Ref 46 to 49. Both the numerical and analytical computational methods are basically equivalent with specific regard to the result. The correct spatial and transient representation of the real temperature field of welding is solely essential in any such approach. For validation of the simulation and representation of the calculated results, the following general aspects should be observed.

The values that are given and discussed should preferably be in SI units, and given rules of current standards regarding the graphical display must be respected (Ref 50). For every value that will be compared, the exact measuring point and time must be stated for a clear correlation of the position in the component as well as the simulation results, for example, the distance to the weld seam center for thermocouples. An interpolation between the nodes of the meshed model may be necessary. In the actual comparison, the positions for evaluation of the experiment and simulation must coincide in the range of experimental data scatter. Additionally, all scales and ranges of values that are important for the representation must be

indicated, especially the overall specimen dimensions, plate thickness for macrosections, and ranges of values for contour plots. In case of low absolute values, a scaling factor is often used for better visualization in the representation of the calculated results, for example, the overall distortion. This factor must be given if applicable.

For all comparisons of experimental and simulation data, the values must be displayed in a common chart. This is especially required for the weld pool geometry, temperature cycles, transient behavior of the distortions, and residual stresses. Details for each individual aspect are given in the following sections. Any time-

dependent data should be given with adequate resolution of both the time domain of actual welding and the time domain of subsequent cooling to at least 100 °C (212 °F) in order to display any deviations.

The differences between calculated results and measured data must be given in absolute numbers in an order of magnitude consistent with the value and may additionally be expressed as a percentage. When an experimentally determined scatter band is represented, the indication of the deviation may be omitted if the calculated results lie within the respective scatter band. See Table 3 for a summary.

Table 2 Setup of the simulation

Information	Explanatory notes
Welding process	Exact designation of the welding process to be simulated
Simplifications of geometry	Details on accomplished simplifications of geometry compared to the real component and their implementation in component mesh generation
Indication of applied symmetry boundary conditions	Use of a partial model to save computation time for mirror or rotational symmetry
Generation of the component mesh	Overview and detail meshes of the weld area and further relevant areas, where appropriate Indication of the number of nodes and elements as well as the applied element base function or element type Indication of the minimum element edge length in the area of maximum load, i.e., normally the weld area
Consideration of previous process steps	Details on the consideration of the component history and the associated influences on the component
Simplifications of the material	Details on simplifications and assumptions concerning the material characteristics for the simulation
Applied material characteristics	Exact alloy designation or material number, respectively, of the materials used for the simulation Indication of the temperature dependence and, where applicable, the phase dependence, including time-temperature transformation diagram as well as solidus temperature Indication of the reference source of the material characteristics or graphical and tabular representations, respectively, of data required for the simulation
Consideration and couplings of physical processes	Details on considered physical phenomena as well as applied couplings between them
Thermal boundary conditions	Indication of the ambient temperature Consideration of the conductive, convective, and radiative heat transfer between individual components and fixtures in the modeled system as well as across the system boundaries
Mechanical boundary conditions	Details on the support of the specimen and the applied clamping condition with respect to the position, area, clamping and unclamping time, and clamping force
Applied heat source	Statement about the chosen approach for the heat source
General information	Applied software and version number

Table 3 General aspects for validation and result display

Information	Explanatory notes
Indication of the position and time of the measured values	Exact measuring point and time must be stated for a clear correlation of the position in the component and the model
Position for evaluation of the experiment and simulation	Position for evaluation of the experiment and simulation must coincide in the range of scatter of the experimental data. Interpolation nodes of the meshed model may be necessary.
Indication of the scales and ranges of values	All scales and ranges of values that are important for the representation must be indicated.
Indication of any applied increase factor in the representation	In case of low absolute values, the applied scaling factor used for better visualization must be given.
Plotting of measured values and simulation results in a common chart	Plotting of simulation results and measured values in a common diagram for direct comparison
Representation of time dependencies	Time-dependent data must be given with adequate resolution for both the time of actual welding and the cooling time to at least 100 °C (212 °F).
Indication of differences between calculated results and measured data	Differences between calculated results and measured data must be given in absolute numbers in an order of magnitude consistent with the value and may additionally be expressed as a percentage. When an experimentally determined scatter band is represented, indication of the deviation can be abandoned, if the calculated results lie within the respective scatter band.

Temperature Field Simulation

In the given approach for modeling of thermomechanical phenomena in fusion welding, the temperature field simulation is the first step. For validation of the temperature field simulation and representation of the calculated results, the following factors should be observed.

Temperature Deviations. Two main aspects must meet the quality requirements: the temperature cycles, with the corresponding temperature gradient in the direct vicinity of the weld seam, and, at the same time, with identical heat-source parameters, the weld pool geometry. The first step is the check of the ambient temperature in the simulation, which must match the experiments. Any deviations must be justified. The correct calculation of the temperature increase from the moving heat source is, in most cases, not a challenge and normally shows very little deviation. For the maximum temperature, there are several aspects that must be considered. First, the maximum time step must be small enough to generate a well-developed peak; that is, the peak must be covered by several data points. Second, a comparison between the measured and calculated maximum temperatures should not exceed a deviation of 50 K (90 °F). Considering the cooling behavior, the difference between the relevant temperature gradients in the measurements and calculation, for example, $t_{8/5}$ or $t_{12/9}$ time, and so on, depending on the material and the application, should be less than 10%.

Weld Pool Geometry. Representation of the weld pool geometry is the second important aspect when validating the temperature field calculations. To have all the important information at hand, it is valuable to have a representation of the calculated weld pool geometry in the form of a contour plot, along with the solidus temperature. A comparative representation in one graph, showing the calculated weld pool geometry in the left half and the macrosection in the right half, combined with a marking of the weld pool contour, helps to judge the result quality. The scaling of both pictures should be identical to that of the macrosection from the experiment. The maximum deviation of the weld pool area or the characteristic weld seam shape, respectively, should generally not exceed 10%. An example picture for the temperature field validation is shown in Fig. 7. An alternative display method, in the case of asymmetric weld pool geometry, is a marking of the weld pool contour in the macrosection and a plot of the identical contour in the representation of the calculated weld pool geometry. Additionally, for both cases, an indication of the weld pool area in the cross section in mm^2 as well as the deviations between experiment and simulation (e.g., for penetration depth, weld width on the top and bottom sides, and so on) should be given in the accompanying descriptive text or in a table. Table 4 is a summary of the statements.

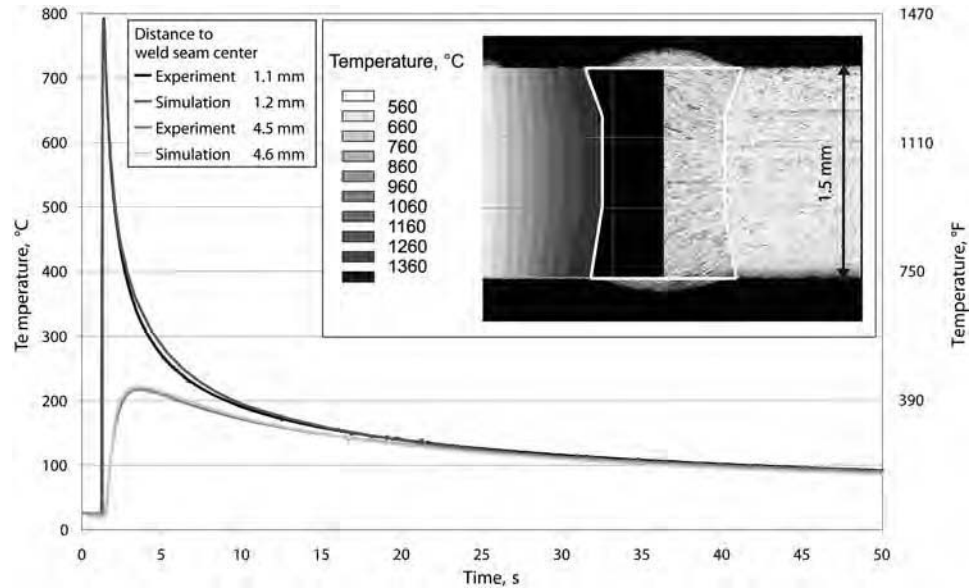

Fig. 7 Example for correct display of temperature field validation. H400 (EN 1.4376), 3 kW neodymium: yttrium-aluminum-garnet laser beam bead-on-plate weld, sheet thickness = 1.5 mm (0.06 in.), $v_{\text{weld}} = 6.5$ m/min (256 in./min). Adapted from Ref 20

Table 4 Validation and result display of the temperature field calculation

Information	Explanatory notes
Room temperature	Comparison between measured room temperature and room temperature entered into the simulation
Maximum temperature of the temperature-time histories	Comparison between measured and calculated maximum temperatures of the temperature-time histories Maximum deviation should not exceed 50 K (90 °F)
Temperature gradient during cooling to room temperature	Comparison between the relevant temperature gradients in the measurements and the calculation Maximum deviation should be less than 10%.
Representation of the weld pool geometry	Representation of calculated weld pool geometry in the form of a contour plot along with solidus temperature as an isotherm Comparative representation in one graph Scaling identical to macrosection from the experiment Maximum deviation of the weld pool area or characteristic weld formation parameters is 10%.

Fig. 8 Example for correct display of longitudinal distortion validation. H400 (EN 1.4376), 3 kW neodymium: yttrium-aluminum-garnet laser beam bead-on-plate weld, sheet thickness = 1.5 mm (0.06 in.), $v_{\text{weld}} = 6.5$ m/min (256 in./min). Adapted from Ref 20

Information	Explanatory notes
Quantitative value after completed cooling to room temperature	Comparison of calculated and measured distortion
Shape of the quality profile	Plotting of the time-dependent calculated and measured distortions in a common diagram

Mechanical Simulation

Distortion calculation is the second step in the approach for modeling of thermomechanical phenomena in fusion welding. Here, the qualitative and quantitative aspects of the results must be compared. Hence, the necessary information is the calculated quantitative value of the distortion in the longitudinal, transverse, and angular directions or the change of specific points in the model, such as distances between reference points. Additionally, the qualitative behavior of these distortions over time in an appropriate diagram, together with experimental data as stated in the general rules section, is important for the validation of the correct general distortion behavior of the simulation model. Figure 8 shows an example for the display of distortion results. The summary for the aspects is given in Table 5.

Residual Stress. The completion of a numerical welding simulation includes not only the temperature and distortion behavior but also the accompanying thermal and residual stresses. If these stresses are used for validation, the following aspects will be observed. A prerequisite for an analysis of the calculated residual stresses is an admissible position for evaluating the data. Because of possibly false calculated stresses in node areas with obstruction of individual or all degrees of freedom, any evaluation in the direct vicinity of modeled fixtures or clamping should be avoided.

The quantitative value of the residual stresses in the observed directions after completed cooling of the component to room temperature is best visualized in a diagram showing the distance to the weld seam or component edges; see Fig. 9 for an example. The determination of the values must be done analogously to the restraint conditions prevailing at the time of measurement during the experiment, that is, any clamping or unclamping of the specimen. In these diagrams, the weld seam area should be marked if appropriate in order to give information about the position and size of the weld seam and heat-affected zone area in combination with the stresses.

For both the measured values and the simulation, the local resolution attained in each case must be taken into account. This resolution is dependent on various factors, such as the measuring-dot diameter in x-ray residual-stress

Fig. 9 Example for correct display of residual-stress validation. H400 (EN 1.4376), 3 kW neodymium: yttrium-aluminum-garnet laser beam bead-on-plate weld, sheet thickness = 1.5 mm (0.06 in.), $v_{weld} = 6.5$ m/min (256 in./min). Adapted from Ref 20

Table 6 Validation and result display of the residual-stress calculation

Information	Explanatory notes
Position for evaluation of residual stresses in the simulation	Any evaluation of the calculated residual stresses in the vicinity of fixtures should be avoided. Weld area must be marked in the representation.
Quantitative value after completed cooling to room temperature	Residual stresses in longitudinal and transverse directions to the weld after completed cooling of the component to room temperature Determination of the values analogously to the restraint prevailing at the time of measurement during the experiment
Consideration of the local resolution	For both the measured values and the simulation, the local resolution (measuring point or element size) attained in each case must be taken into account.

analysis, the drill hole diameter and strain gage measuring surface in the application of the hole-drilling method, or the element edge length in the simulation. Table 6 shows a summary of the information.

Safe Welding Practices*

American Welding Society

HEALTH AND SAFETY CONSIDERATIONS are paramount in all welding, cutting, brazing, and related processes. No activity is satisfactorily completed if personal injury or property damage occurs. This article presents an overview of the rules, regulations, and techniques that are implemented to minimize the safety hazards associated with welding, cutting, and allied processes. It examines safety management, the protection of personnel and the work area, process-specific safety considerations, and robotic safety.

The limited scope of this discussion precludes an exhaustive examination of the health and safety considerations related to all welding processes, particularly those involving sophisticated technology. Additional safety and health information relating to the various welding processes is presented in the American National Standard “Safety in Welding, Cutting, and Allied Processes,” ANSI Z49.1 (Ref 1), and in *Safety and Health Fact Sheets* (Ref 2), the latter of which is available electronically at <http://www.aws.org>. (At the time of the preparation of this article, the referenced codes and other standards were valid. If a code or other standard is cited without a date of publication, it is understood that the latest edition of the document referred to applies. If a code or other standard is cited with the date of publication, the citation refers to that edition only, and it is understood that any future revisions or amendments to the code or standard are not included; however, as codes and standards undergo frequent revision, the reader is encouraged to consult the most recent edition.) Further process-specific information is published in *Welding Processes*, Volume 2 of the American Welding Society’s (AWS) *Welding Handbook*, 8th edition (Ref 3). The reader is encouraged to consult these sources and others listed in the References and Selected References at the end of this article.

Safety Management

According to estimates made by the U.S. Department of Labor, Occupational Safety and Health Administration (OSHA), over 30 million U.S. workers are potentially exposed to one or more chemical hazards from approximately 650,000 hazardous chemical products in the workplace. As these numbers increase with the growing workforce and the introduction of hundreds of new products annually, this situation poses a serious problem for exposed workers and their employers (Ref 4). Of these workers, an estimated 562,000 are at risk for exposure to chemical and physical hazards associated with welding, cutting, brazing, and related activities. Risks include injury from explosion, asphyxiation, electrocution, falling and crushing, and weld flash (burn to the eyes) as well as health hazards associated with over-exposure to fumes, gases, or radiation produced or released during welding and related activities. These include lung disease, heavy metal poisoning, and metal fume fever, among others (Ref 5).

The “Occupational Safety and Health Act” of 1970 (Ref 6) was promulgated to ensure safe and healthy working conditions for all workers by providing for the transmission of information, training, education, and research in the field of occupational health and safety. OSHA’s current standards for welding, cutting, and brazing in general industry and construction are based on the 1967 American National Standards Institute (ANSI) standard Z49.1 and the National Fire Protection Association’s (NFPA) “Standard for Fire Prevention in Use of Cutting and Welding Processes,” NFPA 51B-1962 (Ref 7). Although these standards have undergone several revisions, the OSHA rules presented in the latest edition of Subpart Q of Title 29 of *Code of Federal Regulations (CFR) 1910* (Ref 8) have not been updated.

Management Support

In compliance with the provisions of Title 29 CFR 1910, management must demonstrate its commitment to personnel safety and health by providing direction and support to an effective safety and health program. Management must clearly state safety guidelines and require that everyone—including management—follow safe practices consistently.

Moreover, in accordance with the provisions originally established in ANSI Z49.1:1967 and NFPA 51B:1962, management must designate approved areas where welding and cutting operations can be performed safely. When welding operations must be performed elsewhere, management must assure that proper safety procedures are established and followed to protect personnel and property. (The term *management* refers to “all persons who are responsible for welding operations such as owners, contractors, and others,” as defined in Ref 1.)

Management is also responsible for ensuring that only approved welding, cutting, and allied equipment is used in the workplace. This equipment includes torches, regulators, welding machines, electrode holders, and personal protective devices. Management must provide adequate supervision to ensure that all equipment is properly used and maintained (Ref 1).

Contractors hired by management to perform welding operations must employ trained, qualified personnel. Management must inform contractors about any hazardous conditions that may be present in the work area.

Hazard Communications

The “Hazard Communication Standard,” 29 CFR 1910.1200 (Ref 4), which is included in the “Occupational Safety and Health Act,” requires employers to inform personnel of potential hazards in the workplace and provide

* This article is reprinted by permission of the American Welding Society from *Welding Science & Technology*, Vol 1, *Welding Handbook*, 9th ed., American Welding Society, Miami, FL, 2001. It was prepared by the Welding Handbook Chapter Committee on Safe Practices, consisting of D.G. Scott, Consultant, Chair; K.L. Brown, The Lincoln Electric Company; M. Cooper, Premier Industries; R.C. DuCharme, Consultant; R.F. Gunow, Vacmet, Inc.; J.D. McKenzie, Emhart Automotive; C.F. Padden, Consultant; D.K. Roth, RoMan Manufacturing, Inc. (affiliations circa 2011).

training regarding the safe handling of hazardous materials. This standard addresses physical hazards, such as flammability and the potential for explosion, as well as acute and chronic health hazards. The "Hazard Communication Standard" requires that all chemicals produced, imported, or used in U.S. workplaces be evaluated and that hazard information be transmitted to affected employers and exposed employees by means of precautionary information on containers and material safety data sheets (MSDSs) and training (Ref 4).

The "Hazard Communication Standard" identifies many welding consumables as hazardous materials. When welders (in this article, the term *welder* is intended to include all welding and cutting personnel as well as brazers and solderers) and other equipment operators are properly taught safe practices, they work more safely and cause fewer accidents. Users must be trained to read and understand all safety documentation before work begins. This documentation includes precautionary information, such as that presented in Fig. 1, and the manufacturers' safety instructions for the use of materials and equipment, including MSDSs.

Material safety data sheets, which manufacturers, suppliers, and importers are required to provide customers under the "Hazard Communication Standard," 29 CFR 1910.1200 (Ref 4), identify products that could cause health hazards and provide information on each hazardous chemical, including its physical and chemical characteristics, potential effects, and recommendations for protective measures. Material safety data sheets also provide the permissible exposure

limit established by OSHA, another exposure limit such as the threshold limit value established by the American Conference of Governmental Industrial Hygienists (ACGIH), or any other limit recommended by the manufacturer.

All employers, including those who use welding consumables, must make applicable MSDSs readily available to their employees as well as train them to read and understand their contents. The MSDSs used in the welding industry contain important information about the ingredients in welding electrodes, rods, and fluxes; the composition of fumes that may be emitted during use; and means to protect the welder and others from potential hazards. A sample MSDS is presented in Fig. 2.

Training

As mandated by the provisions of the "Occupational Safety and Health Act," thorough and effective training is an essential aspect of a safety program. Therefore, in addition to providing access to all applicable government and industry standards, management must ensure that all personnel are properly trained in the safe operation and maintenance of all equipment. For example, personnel must be instructed to position themselves away from gases or fume plumes while performing welding or cutting operations. (The term *fume plume* refers to the smokelike cloud containing minute solid particles that arises directly from the area of melting metal. Unlike gases, fumes are metallic vapors that have condensed to a solid. They are often associated with a chemical reaction such as oxidation.)

Personnel must also be trained to recognize safety hazards in all situations and environments. If they are to work in an unfamiliar situation or environment, they must be thoroughly briefed on the potential hazards involved. For example, welders who work in confined areas that are poorly ventilated must be thoroughly trained in the proper ventilation practices and be cognizant of the adverse consequences of not using them (see the section "Welding in Confined Spaces" in this article). Moreover, employees should be trained to question their supervisors before initiating any type of welding or cutting operation if they believe that the safety precautions for a given task are inadequate or misunderstood.

In sum, training must be provided to ensure that all personnel have knowledge of the safety rules that apply for the practices of welding and circumstances they may encounter in the workplace and are familiar with the risks and consequences that may arise should these rules be ignored or violated.

Protection of the Work Area

Good housekeeping is essential in ensuring safe and healthy working conditions. Welders

and supervisors must keep work areas and locations such as passageways, ladders, and stairways clean and clear of obstructions. Because welders shield their vision with necessary eye protection, and those passing by a welding station must shield their eyes from the flame or arc radiation, vision is limited. Because eye protection interferes with their vision, welders and passersby can easily trip over objects on the floor. Therefore, management must lay out the production area so that gas hoses, cables, mechanical assemblies, and other pieces of equipment do not cross walkways or interfere with routine tasks.

Safety rails, harnesses, or lines must also be provided to keep workers away from restricted, potentially hazardous areas and prevent falls, whether work is being carried out at floor level or in an elevated location.

Hazard Notification and the Positioning of Equipment

In accordance with ANSI Z49.1:1999, notification signs should be posted to designate welding areas where eye protection must be worn. Because unexpected events such as fire and explosions can occur in industrial environments, all escape routes must be identified and kept clear to allow for an orderly, rapid, and safe evacuation (Ref 1).

Thus, materials and equipment must not be stored in evacuation routes. Equipment, machines, cables, hoses, and other apparatus should always be situated in such a manner so as not to present a hazard to personnel in passageways, on ladders, or on stairways. If an evacuation route must be blocked temporarily, the employees who normally use that route must be informed of the obstructions and trained to use another route to evacuate the premises.

Machinery Safeguarding

All personnel must be protected from injuries that may be caused by the machinery and equipment they operate as well as other machinery operating in the work area. Inasmuch as welding helmets and dark filter lenses restrict vision, welders may be more susceptible than other workers to injury from unseen, unguarded machinery. Therefore, moving components and drive belts must be equipped with guards to prevent physical contact. Rotating and automatic welding machines, fixtures, and welding robots must also be outfitted with appropriate guards or sensing devices to prevent operation when personnel are in the hazard area.

During the repair of machinery by means of welding or brazing, the power supply to the machine must be disconnected, locked out, and tagged out to prevent inadvertent operation and injury. (When a piece of machinery is locked out, a locking device that prevents the switch, valve, or other mechanism from being

<p>WARNING:</p> <p>PROTECT yourself and others. MATERIAL SAFETY DATA SHEET

(Welding Consumables and Related Products Conforms to the Requirements of OSHA's 29 CFR 1900.1200)

Section 1—IDENTIFICATION	
Manufacturer/Supplier Name	Telephone No.
Address	Date
Trade Name	
Product Type	

Section 2—HAZARDOUS* INGREDIENTS		
IMPORTANT! This section covers the materials from which this product is manufactured. The fumes and gases produced during welding with (normal use of)** this product are covered by Section 3.		
Ingredient***	Approximate Weight %**	Exposure Limit
		Source (1) OSHA (2) ACGIH TLV (3) Mfr. Recommendation
*The term "hazardous" should be interpreted as a term required and defined in the OSHA Hazard Communication Standard (29 CFR Part 1910.1200) and does not necessarily imply the existence of any hazard. **Optional ***Ingredient means the chemical name or common name, chemical abstract service (CAS) registry number (optional), or any other information that reveals precise chemical designation of the substance.		

Section 3—PHYSICAL AND CHEMICAL CHARACTERISTICS
Not applicable (<i>appearance information may be included</i>).

Section 4—FIRE AND EXPLOSION HAZARD DATA
Nonflammable. Welding arc and sparks, however, can ignite combustibles and flammable products. See guideline reference ANSI Z49.1.

Section 5—REACTIVITY DATA
Hazardous Decomposition Products Welding fumes and gases cannot be classified simply. The composition and quality of both are dependent upon the metal being welded and electrodes used. Other conditions which also influence the composition and quantity of the fumes and gases to which workers may be exposed include: coatings on the metal being welded (such as paint, plating, or galvanizing), the number of welders, the volume of the work area, the quality and amount of ventilation, the position of the welder's head with respect to the fume plume, the presence of contaminants in the atmosphere (such as chlorinated hydrocarbon vapors from cleaning and degreasing activities). When the electrode is consumed, the fume and gas decomposition products generated are different in percent and form from the ingredients listed in Section 2. Decomposition products of normal operation include those originating from the volatilization, reaction, or oxidation of the materials shown in Section 2, plus those from the base metal, coatings, etc., as noted above. Reasonably expected fume constituents of this product would include: (insert fume composition). Reasonably expected gaseous constituents of this product would include: (insert gas composition). Ozone and nitrogen oxides may be formed by the radiation from the arc. One recommended way to determine the composition and quantity of fumes and gases to which workers are exposed is to take an air sample inside the welder's helmet if worn or in the worker's breathing zone. See ANSI/AWS F.1.1 and ANSI/AWS F.1.2.

Section 6—HEALTH HAZARD DATA
Threshold Limit Value: The ACGIH recommended limit for Welding Fume NOC (Not Otherwise Classified) is 5 mg/m ³ . ACGIH-1995 (or latest date) preface states "These values are not fine lines between safe and dangerous concentrations and should not be used by anyone untrained in the discipline of industrial hygiene." See Section 5 for specific fume constituents.
Effects of Overexposure Welding may create one or more of the following health hazards: FUMES AND GASES can be dangerous to your health. Short-term (acute) overexposure to welding fumes may result in discomfort such as: metal fume fever, dizziness, nausea, or dryness or irritation of the nose, throat, or eyes and may aggravate pre-existing respiratory conditions, e.g., asthma or emphysema. Long-term (chronic) overexposure to welding fumes can lead to siderosis (iron deposits in the lungs) and may affect pulmonary function. Manganese overexposure can affect the central nervous system resulting in impaired speech and movement. The primary entry route for welding fumes and gases is by inhalation. ARC RAYS can injure eyes and burn skin. ELECTRIC SHOCK can kill. Before use, read and understand the manufacturer's instructions, Material Safety Data Sheets (MSDSs), and your employer's safety practices. Keep your head out of the fumes. Use enough ventilation, exhaust at the arc, or both, to keep fumes and gases from your breathing zone and the general area. Wear correct eye, ear, and body protection. Do no touch live electrical parts.
Emergency and First Aid Procedures Call for medical aid. Employ first aid techniques recommended by the American Red Cross.
Carcinogenicity: NTP? IARC Monographs? OSHA Regulated?

Section 7—PRECAUTIONS FOR SAFE HANDLING AND USE/APPLICABLE CONTROL MEASURES
Read and understand the manufacturer's instructions and the precautionary label on the product. See American National Standard Z49.1 (<i>Safety in Welding, Cutting, and Allied Processes</i>) and OSHA Publication (29 CFR 1910) for more detail on many of the following.
Ventilation Use enough ventilation, local exhaust at the arc, or both, to keep the fumes and gases from the worker's breathing zone and the general area. Train the welder to keep his head out of the fumes. Keep exposures as low as possible.
Respiratory Protection Use respirable fume respirator or air supplied respirator when welding in confined space or where local exhaust or ventilation does not keep exposure below the recommended exposure limit.
Eye Protection Wear helmet or use face shield with correct shade of filter lens. Provide protective screens and flash goggles, if necessary, to shield others. As a rule of thumb, start with a shade that is too dark to see the weld zone. Then go to the next lighter shade which gives sufficient view of the weld zone.
Protective Clothing Wear hand, head, and body protection which help to prevent injury from radiation, sparks, and electrical shock. See ANSI Z49.1. At a minimum this includes welder's gloves and a protective face shield, and may include arm protectors, aprons, hats, shoulder protection, as well as dark substantial clothing. Train the welder not to touch live electrical parts and to insulate himself from work and ground.
Procedure for Cleanup of Spills or Leaks Waste Disposal Method—Prevent waste from contaminating surrounding environment. Discard any product, residue, disposable container, or liner in an environmentally acceptable manner, in full compliance with federal, state, and local regulations. STEPS TO BE TAKEN IF MATERIAL IS RELEASED OR SPILLED: not applicable.

Fig. 2 Sample material safety data sheet. Adapted from Ref 9

opened has been installed. When a piece of machinery is tagged out, a tag reading "DANGER" or "WARNING" along with a short message has been attached to the locking device. The message includes the name and contact information of the person who is responsible for the lock out of the machinery.) Welders assigned to work on equipment whose safety devices are disengaged should fully understand

the hazards involved and the steps necessary to avoid accidental injury.

If the pinch points on resistance welding machines, robots, automatic arc welding machines, fixtures, and other mechanical equipment are not properly guarded, they can result in serious injury. To avoid injury with such equipment, a machine should be activated only when the workers' hands are at safe locations.

Otherwise, the pinch points must be suitably guarded mechanically. During equipment maintenance, pinch points should be blocked to prevent them from closing in case of equipment failure. In very hazardous situations, an observer should be stationed to prevent the power from being turned on during maintenance. The topic of the protection of personnel servicing automatic equipment is addressed in Ref 10 and 11.

Metalworking equipment should be carefully safeguarded so as to prevent welders from accidentally falling into or against it while working.

Protective Booths

According to the provisions of ANSI Z49.1:1999, workers and others in areas adjacent to welding and cutting areas must be protected from radiant energy and hot spatter by flame-resistant screens or shields or by suitable eye and face protection and protective clothing. Appropriate radiation-protective, semitransparent materials are permissible. Operations permitting, workstations should be separated by noncombustible screens or shields. Protective booths with semitransparent shielding are shown in Fig. 3. Booths and screens should permit air circulation at floor level as well as above the screen (Ref 1).

Wall Reflectivity

In areas where arc welding or cutting is routinely performed, the walls and nearby reflective surfaces must be painted with a finish having low reflectivity of ultraviolet (UV) radiation, such as those formulated with titanium dioxide or zinc oxide (Ref 12). Color pigments may be added, provided they do not increase reflectivity. The use of pigments that are based on powdered or flaked metals is not recommended, because these reflect a large amount of UV radiation. As an alternative, welding curtains can be used to minimize reflectivity (Ref 1).

Public Exhibitions and Demonstrations

Persons conducting exhibits and public demonstrations of arc or oxyfuel gas welding or cutting processes are responsible for the safety of demonstrators and the public. All welding and welding-related equipment used in trade shows and other public events must be installed by or under the supervision of a qualified individual at a site that is located and designed to ensure viewing safety. (The term *qualified person* denotes “a person who by reason of training, education, and experience is knowledgeable in the operation to be performed and is competent to judge the hazards involved,” according to Ref 1.) Electric cables and hoses must be routed away from the audience to avoid possible electric shock or tripping hazards. Exhibitors must also provide protection against fires from fuels, combustibles, and overheated apparatus and wiring. Fire extinguishers must be on hand, and combustible materials must be removed from the area or shielded from flames, sparks, and molten metal (Ref 1).

Appropriate protection for demonstrators, observers, and passersby is mandatory. Overexposure to welding fumes and gases must be controlled by the use appropriate ventilation. Individuals must also be shielded from flames, sparks, molten metal, and harmful radiation. A protective, moveable, transparent screen can be used to permit the audience to observe a welding operation under safe viewing conditions. After welding is completed, the screen can be moved to allow the audience to observe the completed weld (Ref 1).

Personal Protective Equipment

The use of personal protective equipment (PPE) is required by OSHA to reduce the risks of exposure to hazards when administrative measures are not feasible or effective in reducing these risks. Employers are required to identify all potential hazards in the workplace and determine whether PPE should be used to protect workers. Title 29 CFR 1910.132 stipulates that employers must establish general procedures, in the form of a PPE program, to provide employees protective equipment and training in how to use it (Ref 13).

Of particular importance in the welding industry are burns, a serious potential hazard during all welding, brazing, soldering, and cutting operations. Operators and others in the work area must always wear eye, face, hand, foot, and body protection to prevent burns from UV and infrared radiation, sparks, and spatter.

Eye, Face, and Head Protection

Protective equipment for the eyes, face, and head must be used by employees who perform tasks that may produce dust, flying particles, or molten metal; those who are exposed to extreme heat, physical or chemical irritants, or intense radiation and light, such as that created by welding arcs and lasers; and those who may be struck on the head by tools or falling objects.

The PPE for the eyes, face, and head includes welding helmets (Ref 14), face shields, welding goggles, and spectacles (Ref 15). In accordance with the specifications of ANSI Z49.1:1, the bodies of welding helmets and shields must be composed of material that is noncombustible, thermally and electrically insulating, and opaque to radiation. The lenses in helmets, shields, and goggles must have protective outer covers to protect the wearer from welding spatter. To protect against flying debris, lift-front helmets must incorporate inner impact-resistant safety lenses or plates (Ref 1).

Filter lenses must be selected in accordance with the ultraviolet, luminous, and infrared transmittance requirements specified in “Practice for Occupational and Educational Eye and Face Protection,” ANSI Z87.1 (Ref 15). The shade used must be in accordance with “Lens Shade Selector,” ANSI/AWS F2.2 (Ref 16). Table 1 presents suggested shade numbers of filter lenses for various welding, brazing, soldering, and thermal cutting processes.

Individuals who have special eye conditions should consult a health care provider for specific information about the use of protective equipment. Contact lens use is permitted, provided lenses are worn in combination with the appropriate safety eyewear, except when the industrial environment presents the probability of exposure to intense heat, significant chemical splash, an extremely particulate atmosphere, or where such use is prohibited by specific regulation (Ref 2).

Fig. 3 Protective screens between workstations

Table 1 Guide for shade numbers

Process	Electrode size		Arc current, A	Minimum protective shade	Suggested shade number (comfort)(a)
	mm	in.			
Shielded metal arc welding	2.5	Less than 3/32	Less than 60	7	...
	2.5-4	$\frac{3}{32}$ - $\frac{5}{32}$	60-160	8	10
	4-6.4	$\frac{5}{32}$ - $\frac{1}{4}$	160-250	10	12
	6.4	More than 1/4	250-550	11	14
Gas metal arc and flux cored arc welding	Less than 60	7	...
	60-160	10	11
	160-250	10	12
	250-500	10	14
Gas tungsten arc welding	Less than 50	8	10
	50-150	8	12
	150-500	10	14
Air carbon arc cutting	Less than 500	10	12
	500-1000	11	14
Plasma arc welding	Less than 20	6	6-8
	20-100	8	10
	100-400	10	12
	400-800	11	14
Plasma arc cutting	Less than 300	8	9
	300-400	9	12
	400-800	10	14
Torch brazing	3 or 4
Torch soldering	2
Carbon arc welding	14

	Plate thickness		Suggested shade number (comfort)(a)
	mm	in.			
Oxyfuel gas welding	Under 3.2	Under 1/2	4 or 5
	3.2 to 12.7	to 1/2	5 or 6
	Over 12.7	Over 1/2	6 or 8
Oxygen cutting	Under 25	Under 1	3 or 4
	25 to 150	1 to 6	4 or 5
	Over 150	Over 6	5 or 6

(a) As a rule of thumb, the user should start with a protective shade that is too dark to see the weld zone. Then, a lighter shade that provides sufficient visibility of the weld zone without going below the minimum number can be selected. In oxyfuel gas welding or cutting, in which a torch produces a high-yellow light, it is desirable to use a filter lens that absorbs the yellow or sodium line in the visible light of the (spectrum) operation. (b) These values apply where the arc is clearly seen. Experience has shown that lighter filters may be used when the arc is hidden by the workpiece. Adapted from Ref 1

Process-Specific Requirements. Specific PPE requirements for the common welding process are discussed as follows. These processes include arc welding and cutting, oxyfuel gas welding and cutting, submerged arc welding, torch brazing and soldering, and resistance welding, among others.

Arc Welding and Cutting. To protect against arc rays, sparks, and spatter, welding helmets or hand shields that have appropriate filter lenses and cover plates must be used by welders, welding operators, and nearby personnel when viewing a welding arc. Protective eyewear must also be used during all arc welding and cutting operations. Worn under the welding helmet during arc welding activities, this eyewear must have full, conforming side shields to protect against potentially hazardous rays or the flying particles generated by grinding or chipping operations. Protective eyewear with clear or colored lenses may be used, depending on the intensity of the radiation that personnel may be exposed to from adjacent welding or cutting operations while their welding helmets are raised or removed (Ref 1).

Oxyfuel Gas Welding and Cutting and Submerged Arc Welding. Safety goggles with filter lenses and full, conforming side shields

must be worn while performing operations using the oxyfuel gas welding and cutting processes.

During submerged arc welding operations, an arc welding helmet is not needed because the arc is covered by flux and is therefore not readily visible. However, because the arc occasionally flashes through the flux covering the arc zone, the operator should wear safety goggles at all times.

Resistance Welding and Other Processes. Personnel engaged in resistance, induction, salt bath, dip, and infrared processes must wear safety spectacles and a face shield to protect their eyes and face from spatter. Filter lenses are not necessary but may be used for comfort.

In resistance welding and other processes that may produce sparks and spatter, suitable protection against flying sparks must be provided. Protective devices include shields made of a suitable fire-resistant material or approved personal protective eyewear. However, because resistance welding operations vary, each operation must be evaluated individually with respect to the use of PPE.

Torch Brazing and Soldering. Safety spectacles with appropriate filter lenses and with or without side shields are recommended for use during the performance of torch brazing and soldering. As with oxyfuel gas welding and

Fig. 4 Typical protective clothing for arc welding

cutting, a bright yellow flame may be visible during torch brazing and soldering. Therefore, filters similar to those used for oxyfuel gas welding and cutting should be used for torch brazing and soldering operations.

Hand, Foot, and Body Protection

Protective gloves, sturdy shoes or boots, and heavy clothing like that shown in Fig. 4 should be worn to protect the whole body from

welding sparks, spatter, and radiation (Ref 1). Hand and arm injuries that may occur in the welding industry include burns, bruises, abrasions, cuts, and chemical exposure. To protect the hands, sturdy, flame-resistant gloves made of leather or other suitable material must always be worn during welding, cutting, and related processes. Dry leather gloves in good condition not only protect the hands from burns and abrasion but also provide insulation from welding current electrical shock. Gloves with special linings should be used to protect against high radiant energy.

The specifications for protective footwear are found in the American National Standard "Personal Protection—Protective Footwear," ANSI Z41 (Ref 17). This standard specifies requirements with respect to toe and metatarsal protection, impact and compression resistance, sole puncture resistance, conductivity, and static dissipation.

Body protection shields welding personnel from intense heat; splashes of molten metal; impacts from materials, machinery, and tools; hazardous chemicals; and radiation. Clothing treated with nondurable flame-retardant chemicals must be retreated as recommended by the manufacturer. Welding personnel should avoid wearing any clothing or shoes made of synthetic or plastic materials, which can melt and may cause severe burns. Outer clothing should be kept reasonably free of oil and grease, especially in an oxygen-rich atmosphere. Cuffless pants and covered pockets are recommended to avoid spatter or spark entrapment. Pockets should be emptied of flammable materials, and cuffless pant legs should be worn outside of shoes. A cap providing protection for the hair is recommended. In addition, flammable hair preparations such as hair spray should not be used (Ref 1).

Special protective clothing must be worn by personnel performing overhead welding or when special circumstances warrant additional protection. This clothing includes aprons, leggings, suits, capes, sleeves, and caps, all of which must be made of durable, flame-resistant materials (Ref 1).

Hearing Protection

Hearing loss is one of the leading occupational illnesses in the United States. Occupational exposure to excess noise is a recognized stressor that can affect both behavior and physical well being. Excessive noise, particularly continuous noise at high levels, can cause temporary or permanent full or partial hearing loss as well as hypertension. To protect workers from exposure to excessive noise, OSHA regulates allowable noise exposure levels in "General Industry Standards," Title 29 CFR 1910.95 (Ref 8).

In welding, cutting, and allied operations, noise may be generated by the process or the equipment, or both (Ref 18). Air carbon arc

and plasma arc cutting tend to have high noise levels. Engine-driven generators sometimes emit a high noise level, as do some high-frequency and induction welding power sources. Therefore, appropriate noise-limiting devices should be used to protect against possible hearing loss. Properly fitted, flame-resistant earplugs should also be worn when sparks or hot spatter could land in the ears.

Respiratory Protection

In areas where natural or mechanical ventilation is not adequate (see the section "Ventilation" in this article), respiratory protective equipment must be used (Ref 19). When the use of respiratory protective equipment is required by the job, a program must be established to identify and implement the appropriate equipment.

Either dust/mist/fume respirators or any of the new series of respirators approved by National Institute for Occupational Safety and Health (NIOSH) can be used for protection against metal fumes as long as the proper respirator type (e.g., half-mask, full-face, or powered air respiratory protection) is selected based on the calculated hazard ratio for the contaminant of concern. (According to Ref 20, NIOSH promulgated 42 CFR 84 in July 1995, which modified the requirements for particulate—dust/mist and dust/mist/fume—respirators. The dust/mist and dust/mist/fume classifications were replaced by nine new classes of respirators, categorized as the N-, R-, and P-series. The N-series respirators are not resistant to oils, which can degrade the filter media. The R-series respirators are more resistant to oils, while the P-series are significantly more resistant to oils. Production of the previous series of respirators ceased in July 1998, although distributors were allowed to sell either series until supplies were depleted, and OSHA and the Mine Safety and Health Administration, or MSHA, have allowed their use as long as they are available and properly maintained.) A powered air-purifying respirator is shown in Fig. 5.

Some welding materials (fluxes, welding rods, and residual cleaning and degreasing compounds, for example) may contain harmful materials or release gases and vapors for which filter respirators do not provide adequate protection. In these cases, a chemical cartridge/particulate, gas mask/particulate, or airline respirator should be used. As a general rule, a NIOSH-approved air-supplied respirator should be the only choice as adequate protection when the contaminants themselves or their concentrations have not been identified (Ref 20).

It is also important to note that according to the "Respiratory Protection Standard," OSHA 29 CFR 1910.134, respirators must not be passed from one worker to another without sanitizing the equipment (Ref 1). According to NIOSH, the service life of all filters is limited

Fig. 5 Powered air respiratory protection

by considerations of hygiene, damage, and breathing resistance. All filters should be replaced whenever they are damaged or soiled or they cause noticeably increased breathing resistance (Ref 21).

Considering that protection against fumes and gases is essential in the field of welding and its allied processes, this topic is discussed in greater length in the following section.

Protection Against Fumes and Gases

Many welding and welding-related processes generate gases and fumes that may be harmful. Fumes are composed of airborne particles of base metal, welding consumables, or coatings that may be present on the workpiece. Welders, welding operators, and all others in the work area must therefore be protected from overexposure to fumes and gases produced during welding, brazing, soldering, and cutting operations. The term *overexposure* is defined as exposure that may pose a health risk and exceeds the permissible limits specified by a government agency such as OSHA in Title 29 CFR 1910.1000 or other recognized authority, such as the ACGIH in its 1999 publication *TLVs and BEIs: Threshold Limit Values for Chemical Substances and Physical Agents, Biological Exposure Indices* (Ref 22).

The potential short- and long-term health effects of overexposure to welding fumes and gases can include nausea, headache, dizziness, dermatitis, chronic or acute systemic poisoning,

metal fume fever, pneumoconiosis, irritation of the respiratory tract, and possibly cancer.

Proper ventilation (see the section "Ventilation" in this article) usually provides protection against excess exposure. When exposure would exceed permissible limits with the available ventilation, respiratory protection must be used. Fume protection must be provided not only for the welding and cutting personnel but also for others in the area. It is important to note that individuals who have special health problems may have unusual sensitivity that requires even more stringent protection than that specified by a recognized authority.

Exposure Factors

Many factors contribute to the amount of fume exposure that may occur during arc welding. The most important factor is the position of the welder's head with respect to the fume plume. When the head is in such a position that the fume envelops the face or helmet, exposure levels can be very high. Thus, welders must be trained to keep their heads to one side of the fume plume. In some cases, the work can be positioned so the fume plume rises to one side.

Welding personnel can also reduce fume exposure by the kind of welding helmet they wear. The extent to which the helmet curves under the chin toward the chest affects the amount of fume exposure. However, it is important to note that the welding helmet alone is not considered an adequate respiratory protection device.

The amount of fume exposure also depends on the kind of ventilation used. Ventilation may be local, in which case the fumes and gases are extracted near the point of welding, or general, in which case the air from a portion of the shop is changed or filtered. The appropriate type of ventilation to use depends on the welding process, the material being welded, and other shop conditions. Adequate ventilation is necessary to maintain the personnel's exposure to fumes and gases within the recommended limits.

The size of the welding or cutting work area is also important. As a rule, fume exposure inside a tank, pressure vessel, or other confined area tends to be higher than that which occurs in a high-bay fabrication area. The size of the work area also affects the background fume level, which depends on the number and type of welding stations, type of ventilation, and the duty cycle for each station.

The type of base metal being welded influences both the constituents and the amount of fume generated. Surface contaminants or coatings may contribute significantly to the potential fume hazards. Paints containing lead and platings containing cadmium emit hazardous fumes during welding and cutting. Galvanized material emits zinc fume.

Sources of Fumes and Gases

Fumes and gases are usually a greater concern in arc welding than in oxyfuel gas welding, cutting, or brazing. Welding arcs may generate a larger volume of fume and gas, and a greater variety of materials are usually involved in arc welding. Special concerns related to arc welding and cutting, resistance welding, and oxyfuel gas welding and cutting are discussed in the following paragraphs.

Arc Welding and Cutting Fumes and Gases. The fumes and gases produced during arc welding and cutting operations are not simple to classify. Their composition and quantity depend on a number of factors. These include the welding process employed, the composition of the base metal, the consumables used, the coatings on the workpiece (e.g., paint, galvanizing, or plating), and the contaminants in the atmosphere (e.g., halogenated hydrocarbon vapors resulting from cleaning and degreasing activities), among others (Ref 1).

In welding and cutting, fume is a product of the vaporization, oxidation, and condensation of the components in the consumable and, to some degree, the base metal. The electrode, rather than the base metal, is usually the major source of fume. However, significant fume constituents can originate from the base metal if this contains alloying elements or is covered with a coating that is volatile at elevated temperatures. The composition of the fume usually differs from the composition of the electrode or consumable. The products of the volatilization, reaction, or oxidation of the consumables are reasonably expected fume constituents, as is material from base metals, coatings, and atmospheric contaminants.

Various gases are also generated during welding. Some are a product of the decomposition of fluxes and electrode coatings. Others are formed by the action of arc heat or UV radiation emitted by the arc on atmospheric constituents and contaminants. Still others may come from the external gas shielding that is an inherent part of some welding processes. Potentially hazardous gases include carbon monoxide, oxides of nitrogen, ozone, and phosgene, or other decomposition products of chlorinated hydrocarbons, as well as fluorides. Helium and argon, although chemically inert and nontoxic, can cause asphyxia and dilute the atmospheric oxygen concentration to harmfully low levels. Carbon dioxide and nitrogen can also cause asphyxiation.

Welding arcs, especially gas-shielded arcs using high levels of argon and helium, emit UV radiation. Ultraviolet radiation can produce ozone from the oxygen in the surrounding air, even at some distance from the UV source. Photochemical reactions between this UV radiation and chlorinated hydrocarbons can result in the production of phosgene and other decomposition products. Welding arcs can also produce carbon monoxide and nitrogen oxides. Arc heat is responsible for the formation of nitrogen

oxides from atmospheric nitrogen. Hence, nitrogen oxides may be produced by a welding arc or other high-temperature heat sources. Carbon monoxide forms when an arc decomposes carbon dioxide and inorganic carbonate compounds. Levels can be especially significant when carbon dioxide is used as the shielding gas.

The quantity and chemical composition of air contaminants vary substantially from process to process due to the wide range of variables inherent in each process. During arc welding, the arc energy and temperature depend on the process and the welding variables used in that process. Therefore, fumes and gases are generated in varying degrees in different welding operations.

Consequently, reliable estimates of fume and gas composition cannot be made without considering the nature of the welding process and chemical system being examined. For example, aluminum and titanium are normally arc welded in an atmosphere of argon or helium or a mixture of the two gases. The arc creates relatively little fume but may emit intense UV radiation that can produce ozone. The inert gas shielded arc welding of steels also creates a relatively low fume level.

However, the arc welding of steel in oxidizing environments generates considerable fume and can produce carbon monoxide and oxides of nitrogen. These fumes generally consist of discreet particles of complex oxides containing iron, manganese, silicon, and other metallic constituents, depending on the alloy system involved. Chromium and nickel compounds are found in fumes when stainless steels are arc welded. Some covered and flux cored electrodes are formulated with fluorides. The fumes associated with these electrodes can contain significantly more fluorides than oxides.

The generation rate of fumes and gases during the arc welding depends on numerous variables, including the following:

- Welding current
- Arc voltage and length
- Mode of metal transfer
- Shielding gas
- Welding process
- Consumables

These variables are interdependent and can have a substantial effect on total fume generation. They are examined in detail as follows.

Welding Current. Although fume-generation rates generally increase with welding current, the increase varies depending on the process and the type of electrode used. Certain covered, flux cored, and solid wire electrodes exhibit a disproportional increase in the fume-generation rate with increasing current. Several studies have shown that fume-generation rates with covered electrodes are proportional to the welding current raised to a power (Ref 23). For E6010 electrodes, the exponent is 2.24, whereas for E7018 electrodes, it is 1.54.

The relationship between flux cored and solid electrode fume-generation rates and the welding current is more complex. Welding current levels affect the type of metal droplet transfer. As a result, fume-generation rates can decrease with increasing current until a minimum is reached. At this point, fume generation increases in a somewhat proportional fashion.

An increase in current can also increase the emission of UV radiation from the arc. Therefore, the generation of gases formed photochemically by this radiation (e.g., ozone) can be expected to increase as the welding current is increased. Measurements of ozone concentration during gas metal arc and gas tungsten arc welding have shown such behavior.

Arc Voltage and Length. Arc voltage is directly related to arc length. For a given arc length, there is a corresponding arc voltage. The voltage is mostly dependent on the type of electrode, welding process, and power supply used. In general, increasing the arc voltage (arc length) increases the fume-generation rate for all open arc welding processes. The levels of generation differ somewhat for each process and electrode type.

Mode of Metal Transfer. When steel is joined by means of gas metal arc welding using a solid wire electrode, the resulting mode of metal transfer depends on the current and voltage used. At a low welding current and voltage, short-circuiting transfer takes place; that is, droplets are deposited during short circuits between the electrode and molten weld pool. As the current and voltage are increased, the mode of metal transfer changes to the globular type, in which large globules of metal are projected across the arc into the weld pool. At high currents and with argon-base shielding, the mode of transfer shifts to spray mode, in which fine metal droplets are serially propelled rapidly across the arc.

The fume-generation rate also appears to follow a transition. The fume rate is relatively high during short-circuiting transfer because of arc turbulence. As the transition current is approached in an argon-rich shielding gas, the fume rate decreases and then increases again as spray transfer is achieved. In the spray region, the rate of fume generation is proportional to the welding current.

It has been shown, moreover, that the use of pulsed arc transfer during gas metal arc welding results in the generation of significantly less welding fume as compared to conventional gas metal arc welding. This mode of transfer produces a controlled droplet size with a lower average welding current. Thus, the use of this mode can be an effective way of reducing and controlling exposure to welding fume emissions, particularly when implemented in conjunction with local exhaust ventilation that has been properly designed for the application (Ref 24).

For other welding processes, the type of metal transfer varies little with current and

voltage. In these cases, fume generation is approximately proportional to the changes in current.

Shielding gas must be used in gas metal arc welding. It is also required in flux cored arc welding when certain electrodes are used. The type of shielding gas used affects both the composition of the fume and its generation rate. It also affects the kind of gases found in the welding environment. For example, the fume-generation rate is higher with carbon dioxide shielding than with argon-rich shielding. The rate of fume formation with argon-oxygen or argon-carbon dioxide mixtures increases with the oxidizing potential of the mixture.

For welding processes in which inert gas shielding is used—gas tungsten arc or plasma arc welding, for example—the fume-generation rate varies with the type of gas or gas mixture. More fume can be generated with helium than with argon shielding.

By-product gases also vary with the composition of the shielding gas. The rate of formation of ozone depends on the wavelengths and intensity of the UV rays generated in the arc. Ozone is more commonly found with argon-rich gases than with carbon dioxide. Nitrogen oxides are present in the vicinity of any open arc process, and carbon monoxide is commonly found around carbon dioxide-shielded arcs.

Welding Process. Studies conducted on the relative fume-generation rates of the consumable electrode processes for welding on mild steel have shown definite trends. Considering the ratio of the weight of fumes generated per weight of metal deposited, covered electrodes and self-shielded flux cored electrodes produce the most fume. Gas shielded flux cored electrodes produce less fume, whereas solid wire electrodes produce an even lower amount. The submerged arc welding process consistently produces the lowest amount of fumes because the fume is captured in the flux and slag cover.

Consumables. Within a specific process, the fume rate depends on the composition of the consumables. Some components of covered and flux cored electrodes are designed to decompose and form protective gases during welding. Hence, they generate relatively high fume levels.

Many constituents of covered and flux cored electrodes are proprietary. Therefore, two electrodes with identical AWS classifications may have substantially different fume-generation rates because they are produced by two different manufacturers. One way that can be used to compare electrodes is to obtain the MSDS for the product composition to determine specific fume-emission characteristics.

Resistance Welding Fumes and Gases. In resistance welding, fumes and gases as well as airborne particulates can be generated by the materials being welded and the electrodes used. Adequate ventilation must be provided to maintain exposure levels below the allowable limits set by CFR Title 29, Chapter XVII, Part 1910.

For more information on resistance welding fumes and gases, the reader is encouraged to consult Section 10 of "Recommended Practices for Resistance Welding," AWS C1.1M/C1.1:2000 (Ref 25).

Oxyfuel Gas Welding and Cutting Fumes and Gases. The temperatures encountered in oxyfuel gas welding and cutting are lower than those found in electric arc processes. Consequently, the quantity of fumes emitted is normally lower. The gases formed are the reaction products of fuel-gas combustion and of the chemical reactions between the gases and other materials present. The fumes emitted are the reaction products of the base metals, coatings, filler metals, fluxes, and the gases being used. In the oxyfuel gas cutting of steel, the fumes produced are largely oxides of iron.

Fume constituents that present a greater hazard may be expected when coatings such as galvanizing, paint primers, or cadmium plating are present. The gases of greatest concern include oxides of nitrogen, carbon monoxide, and carbon dioxide. Oxides of nitrogen may be present in especially large amounts during the oxyfuel gas cutting of stainless steels using either the chemical flux or the iron powder process.

Ventilation

The bulk of fumes emitted during welding and cutting consists of small particles that remain suspended in the atmosphere for a considerable length of time. Thus, the concentration of fume in a closed area can build up over time, as can the concentration of any gas evolved or used in the process. Many particles eventually settle on the walls and floor. However, because fume is produced faster than it settles, fume concentration must be controlled by ventilation.

Adequate ventilation is the key to fume and gas control in the welding environment (Ref 1). Ventilation is adequate when fumes and gases are kept from breathing zones and the general area. Natural, mechanical, or respirator ventilation must be provided for all welding, cutting, brazing, and related operations. The ventilation must ensure that concentrations of hazardous airborne contaminants are maintained below recommended levels. These levels must be no higher than the allowable levels specified by OSHA or other recognized authority.

Welders must always take precautions to keep their breathing zone away from the fume plume, even when a sampling of the atmosphere indicates that the concentrations of contaminants do not exceed permissible limits. Air movement should always flow laterally from either side of the welder. Lateral airflow makes it easier for the welder to keep out of the plume and to keep fumes and gases out of the welding helmet. Air should not blow toward the face or back of the welder because it may force the fume into the breathing zone (Ref 1).

Many ventilation methods are available. They range from natural convection to localized devices, such as air-ventilated welding helmets. Additional ventilation methods include natural ventilation; general area mechanical ventilation; overhead exhaust hoods; portable local exhaust devices; downdraft, crossdraft, and water tables; and extractors built into the welding equipment.

General ventilation occurs naturally outdoors and indoors when the shop doors and windows are open. In most cases, general ventilation is more effective in safeguarding personnel in adjacent areas than in protecting the welders in the immediate area. According to CFR Title 29 CFR 1910 (Ref 26), when all of the following conditions are present, natural ventilation often keeps contaminant concentrations within permissible levels:

- A work area of more than 284 m³ (10,000 ft³) for each welder is provided.
- Ceiling height is above 5 m (16 ft).
- Welding is not performed in a confined area.
- The general welding area is free of partitions, balconies, or other structural barriers that significantly obstruct cross ventilation. (In this case, the term *general welding area* refers to a building or a room in a building, not a welding booth or screened area used to provide protection from welding radiation.)
- Toxic materials with low permissible exposure limits are not deliberately present as constituents (the employer should refer to the MSDS).

When natural ventilation is insufficient, fans may be used to force and direct the required amount of air through a building or work room.

The effectiveness of general ventilation, whether natural or forced, is dependent on the design of the system. Ventilation introducing fresh air and exhausting contaminated air must be arranged in work areas so that the welding fumes and gases are carried away, not concentrated in dead zones. In some cases, the fresh air supply may be located so that incoming fresh air provides the required protection for the welders and personnel in the general area. If this is not possible, general mechanical ventilation may need to supplement local ventilation to keep the background level of airborne contaminants at acceptable levels.

Local Ventilation. Although general ventilation can be used to control contamination levels in the work area, it does not usually provide sufficient local ventilation to protect personnel. Local exhaust ventilation is usually the most effective way of providing protection at workstations. Local ventilation, which provides efficient, economical fume control, can be accomplished with various methods, including the following:

- Fixed open or enclosing hood
- Moveable hood with a flexible duct

- Crossdraft or downdraft table
- Water table
- Gun-mounted fume-removal equipment

The fixed open or enclosing hood has at least a top and two sides. It must have sufficient airflow and velocity to keep contaminant levels at or below permissible limits (Ref 22). The movable hood, with a flexible duct, is positioned by the welder as close to the point of welding as practicable. This hood should allow sufficient airflow to produce a maximum velocity of 30 m/min (100 ft/min) in the zone of welding. An air velocity of 31 m/min (100 ft/min) will not disturb the torch gas shield during gas shielded arc welding if adequate shielding gas flow rates are used. Higher air velocities may disturb the gas shield and render it less effective. This method of providing local ventilation is shown in Fig. 6.

Air flow requirements range from 4 m³/min (150 ft³/min), when the hood is positioned 100 to 150 mm (4 to 6 in.) from the weld, to 17 m³/min (600 ft³/min) at 250 to 300 mm (10 to 12 in.) from the weld. These requirements are particularly applicable for bench work but may be used for any location, provided the hood is moved as required.

Another method of achieving local ventilation is the crossdraft or downdraft table. A crossdraft table is a welding bench with the exhaust hood placed to draw air laterally across the table. A downdraft table has a grill as a work surface and an exhaust hood below that draws the air downward and away from the welder's head.

Fig. 6 Movable hoods positioned near the welding arcs

The water table is another technique used to provide local ventilation of the work area. Used for oxyfuel gas and plasma arc cutting operations, this cutting table fills with water to near to the bottom or in contact with the bottom surface of the workpiece. A great deal of the fume that emerges from the cut is captured in the water.

Gun-mounted fume-removal equipment, often used with self-shielded flux cored arc welding, extracts the fumes at the point of welding, creating an almost smokeless environment. The exhaust rate must be set so that it does not interfere with the shielding gas pattern provided by the welding process. Virtually all the fume produced by the flux cored arc welding process can be collected using a gun-mounted fume-removal device. A fume-extracting torch for gas metal arc welding is shown in Fig. 7.

Where permissible, air cleaners that can efficiently collect submicron particles may be used to recirculate a portion of ventilated air that would otherwise be exhausted. However, it is important to note that some air cleaners do not remove gases. Therefore, the filtered room air must be monitored to prevent the accumulation of harmful gas concentrations.

Special Ventilation Situations

Some situations are potentially more hazardous than routine welding circumstances. Situations requiring special ventilation include welding in a confined space or welding with certain materials. These are discussed in the following sections.

Welding in Confined Spaces. The terms *confined spaces* and *permit-required confined space* are employed by OSHA to refer to those workspaces that hinder employees' activities while entering, performing operations, or exiting, and those spaces that both hinder employees' activities and pose health or safety hazards, respectively (Ref 27). The American National Standard "Safety in Welding, Cutting, and Allied Processes," ANSI Z49.1:1999, defines the term as a small or restricted space in which poor ventilation may exist due to the

Fig. 7 Fume-extracting gas metal arc welding torch. Courtesy of Abicor Binzel

size or shape of the space (Ref 1). Welding personnel who work in confined spaces are apt to be exposed to serious health and safety hazards, such as asphyxiating or flammable atmospheres. Examples of confined spaces are small rooms, furnaces, ship compartments, reactor vessels, and storage tanks.

Ventilation in confined spaces must ensure sufficient oxygen for life support. In addition, it must keep airborne contaminants at or below the recommended limits in breathing atmospheres and prevent the accumulation of flammable mixtures (Ref 28). Inasmuch as ventilation must also prevent the occurrence of oxygen-enriched atmospheres, oxygen levels should remain between 19.5 and 23.5% per volume (natural air contains approximately 21% oxygen by volume). Only clean, respirable air must be used for ventilation; the use of pure oxygen, other gases, or mixtures of gases for ventilation purposes is prohibited (Ref 1).

Without an adequate supply of the proper concentration of oxygen, welders may asphyxiate, become unconscious, and possibly die without apparent warning symptoms. It should be noted that in confined areas, oxygen-enriched atmospheres—especially those with more than 25% oxygen—also pose other hazards. Materials that burn normally in air may flare up violently in such atmospheres. Therefore, clothing may burn fiercely; oil- or grease-soaked clothing or rags may catch fire spontaneously; and paper may flare into flame, all of which may cause severe or even fatal burns.

Confined areas must be tested for toxic or flammable gases and vapors and adequate oxygen supply prior to entry and during occupancy. The tests should be conducted with instruments approved by the U.S. Mine Safety and Health Administration (MSHA). It is also advisable that a continuous monitoring system with audible alarms be used. It is important to note that these same safety precautions apply to other areas as well. Gases that are heavier than air—argon, methylacetylene-propadiene, propane, and carbon dioxide, for example—may accumulate in pits, tank bottoms, low areas, and near floors. Gases that are lighter than air—helium and hydrogen, for example—may accumulate in tank tops, high areas, and near ceilings (Ref 1).

If proper ventilation cannot be ensured, personnel lacking the proper training and PPE must never enter the confined work area. The welders, cutters, and other personnel who do work in such areas must wear an approved positive-pressure air-supplied breathing apparatus that is self-contained. (Air-supplied respirators and hose masks must be approved by MSHA or other recognized agency.) They must also have an emergency air supply lasting at least 5 min in the event that the main air source fails. Another person wearing similar safety equipment should also be present. When work is carried out in confined areas in atmospheres that are immediately hazardous to life and health, attendants knowledgeable in rescue procedures

must be stationed outside of the area. Each attendant must have his or her own self-contained breathing device (Ref 1).

Besides testing atmospheric conditions, workers in confined space must take additional precautions. Because compressed gas cylinders could leak gases or volatiles, they must be located outside confined areas. Welding power sources must also be placed outside of any confined space to reduce the hazard of electric shock and asphyxiation from engine exhaust. Personnel must be able to exit quickly in the event of an emergency. Those using safety belts and lifelines must ensure that this equipment is worn properly so that it does not become entangled or jammed while they are attempting to exit (Ref 1).

The operation of brazing furnaces also poses potential hazards. These furnaces, which are a type of confined space, use a variety of atmospheres (vacuum, inert gas, flammable gas, or flammable gas combustion products, for example) to exclude oxygen. Thus, among the hazards presented are the accumulation of hazardous fumes or gases in the work area, the development of explosive mixtures of flammable gas and air, and the asphyxiation of personnel (Ref 1).

Welding of Containers and Piping. The welding or cutting of containers and vessels also presents special risks. (In accordance with Ref 29, the following types of containers require specialized safety considerations: containers that can be entered by personnel; containers that have held radioactive substances; containers that have held compressed gases; containers that have held explosive substances; ship tanks, bunkers, or compartments; gasometers or gas holders for natural and manufactured gases; outside, above-ground vertical petroleum storage tanks; and containers holding flammable substances that must be repaired while in service. For safe practices specific to these container types, the reader is advised to consult the latest edition of this standard and any other applicable regulatory and industry-specific codes and guidelines.) Fires, explosions, and health hazards can result if the objects contain combustible, reactive, or toxic materials. Thus, the precautions for confined spaces must be observed. All containers should be considered unsafe for welding and cutting unless they are judged clean or rendered safe by a qualified person. Additionally, the immediate area outside and inside the container should be cleared of all obstacles and hazardous

materials (Ref 26, 29). When repairing a container in place, the welder must never allow hazardous substances released from the floor or the soil beneath the container to enter. The required personal and fire protection equipment must also be available, serviceable, and in position for immediate use.

One method used to weld containers safely involves filling the container with an inert medium such as water, gas, or sand. When using water, the level should be kept to within a few inches from the welding point. The space above the water should be vented to allow the heated air to escape. When employing inert gas, the responsible individual must know how to produce and maintain a safe atmosphere during welding, including the percentage of inert gas required in the tank to prevent fire or explosion.

Gases generated during welding must be discharged safely and in an environmentally friendly manner in accordance with government rules and regulations. This is especially important when welding inside containers, where workers must prevent pressure buildup. When needed, testing for gases, fume, and vapors should be conducted periodically to ensure that recommended limits are maintained during welding.

Low-Allowable-Limit Materials. Certain materials sometimes present in consumables, base metals, coatings, or atmospheres for welding, cutting, or brazing operations have permissible exposure limits at or below those specified by the authority having jurisdiction. These constituents include antimony, arsenic, barium, beryllium, cadmium, chromium, cobalt, copper, lead, manganese, mercury, nickel, selenium, silver, and vanadium (Ref 1). Table 2 presents the base and filler metals that may release some of these materials in fume during welding, cutting, and allied operations.

The manufacturer's MSDSs, which should be supplied, can be consulted to determine if any of these materials are present in the welding filler metals and fluxes being used. It is best to remember, however, that hazardous materials may also be present in base metals, coatings, or other sources in the work area. Radioactive materials under the jurisdiction of the Nuclear Regulatory Commission require special consideration.

When any of these materials is encountered as a designated constituent in welding, brazing, or cutting operations, special precautions must be taken to ensure that atmospheric

Table 2 Possible hazardous materials emitted during welding or thermal cutting

Base or filler metal	Emitted metals or their compounds
Carbon and low-alloy steels	Chromium, manganese, vanadium
Stainless steels	Chromium, manganese, nickel
Manganese steels and hardfacing materials	Chromium, cobalt, manganese, nickel, vanadium
High-copper alloys	Beryllium, chromium, copper, lead, nickel
Coated or plated steel or copper	Cadmium(a), chromium, copper, lead, nickel, silver

(a) When cadmium is a constituent in a filler metal, a precautionary label must be affixed to the container or coil. Source: Ref 1

contaminants remain at or below permissible levels for human exposure. Unless atmospheric tests under the most adverse conditions establish that exposure is within acceptable concentrations, certain precautions are necessary—both indoors and outdoors. Whenever any materials with a low allowable limit are encountered in indoor operations, local exhaust mechanical ventilation must be used. When beryllium is encountered indoors, respiratory protection in addition to local exhaust ventilation is essential. In confined spaces, local exhaust ventilation and respiratory protection must be used, and all personnel in adjacent areas must be similarly protected (Ref 1).

Additionally, personnel must refrain from consuming food in areas where fumes contain materials with very low allowable exposure limits. To prevent the ingestion of these contaminants, welding personnel should also practice good personal hygiene, such as washing their hands before touching food.

Fluorine and Zinc Compounds. The inhalation of the fumes and gases from fluorine compounds can be hazardous. These compounds can also burn the eyes and skin on contact. Thus, local mechanical ventilation or respiratory protection must be provided when welding, brazing, cutting, or soldering operations in confined areas involve fluxes, coatings, or other material containing fluorine compounds.

In open spaces, the need for local exhaust ventilation or respiratory protection against fluorine compounds depends on the circumstances. Local exhaust ventilation is not necessary when air samples taken in breathing zones indicate that all fluorides are within allowable limits. However, local exhaust ventilation is always desirable when fluorine compounds are used in fixed-location or stainless steel production welding.

Zinc compounds, which may be present in consumables, base metals, or coatings, can produce nausea, dizziness, or metal fume fever (sometimes referred to as Galo fever). Therefore, the same safety procedures for fumes containing fluorine compounds also apply to fumes containing zinc compounds.

Cleaning Compounds. Inasmuch as cleaning compounds may be hazardous or flammable, they often require special ventilation precautions. The manufacturer's instructions should be carefully followed before welding or cutting on cleaned materials (Ref 1).

Chlorinated Hydrocarbons. Degreasing or cleaning involving chlorinated hydrocarbons must be carried out in an area where the vapors from these operations are prevented from entering the atmosphere in the vicinity of the molten weld metal or the welding arc. When these vapors enter the atmospheres of arc welding operations, a reaction produces highly toxic phosgene gas, which has an irritating, objectionable odor. Low levels of exposure can cause nausea, dizziness, and weakness, whereas high exposure levels can cause serious health impairment or even death (Ref 1).

Cutting of Stainless Steel. Because stainless steel contains chromium and nickel compounds, the fume emitted during cutting operations may be hazardous. Symptoms of overexposure to fumes containing these compounds may include headaches, nausea, and dizziness. Therefore, when cutting stainless steel using oxyfuel gas, gas shielded arc, or plasma arc cutting, local mechanical ventilation should be implemented to remove the fumes emitted. In underwater plasma arc cutting, the water captures most of the fume.

Air Sampling and Measurement of Exposure

When ventilation is questionable, the only manner in which to ensure that airborne contaminant levels are within the allowable limits is to take air samples of the breathing zone. When an operator's actual on-the-job exposure to welding fume and gases is to be sampled, the guidelines provided in "Methods for Sampling Airborne Particulates Generated by Welding and Allied Processes," ANSI/AWS F1.1 (Ref 19), must be adhered to. This document describes the techniques used to obtain an accurate breathing zone sample of welding fume for a particular welding operation. Both the amount and composition of the fume can be determined in a single test using the method described. Multiple samples are recommended for increased accuracy, one of which must be collected inside the welder's helmet, if one is worn.

The ACGIH and OSHA have established allowable limits of airborne contaminants, referred to as threshold limit values (TLVs) or permissible exposure limits, respectively. The TLV is the concentration of an airborne substance to which most workers may be repeatedly exposed, day after day, without adverse effect. The threshold limit value-time weighted average (TLV-TWA) is used to adapt TLVs to normal workplace conditions. The TLV-TWA is the time-weighted average airborne substance concentration to which nearly all personnel may be repeatedly exposed without adverse effect during a normal 8 h workday or 40 h workweek. TLV-TWA values should be used as a general guide for controlling health hazards, not as a sharp, clear division between safe and hazardous concentrations of airborne substances. Revised annually, the TLVs may or may not correspond to OSHA's permissible exposure limits for the same materials. In many cases, current ACGIH values for welding materials are more stringent than OSHA levels.

Safe Handling of Compressed Gases

The gases used in welding and cutting operations are packaged in containers that are referred to as cylinders (Ref 30). The gas cylinders used in welding operations contain gas that

is pressurized at approximately 17,237 kPa (2500 psig) or higher. Gases at these pressures must be handled properly to prevent damage to the cylinders. Mishandling may result in leaks or explosions, causing damage, injury, or death (Ref 1).

Only cylinders constructed and maintained in accordance with U.S. Department of Transportation (DOT) specifications can be used in the United States. The use of other cylinders is illegal and may be extremely hazardous. Cylinders requiring periodic retest under DOT regulations may not be filled unless the retest is current (Ref 31).

Filling Cylinders and Mixing Gases

According to the provisions of ANSI Z49.1:1999 (Ref 1) and "Safe Handling of Gas in Containers," CGA P-1-1999 (Ref 31), cylinders may be filled only by the owner or individual authorized by the owner. Mixing gases and filling one cylinder from another are hazardous; therefore, the mixing and transfilling should not be attempted by anyone who is not qualified and authorized to perform this activity. Combustible or incompatible combinations of gases must never be mixed in cylinders (Ref 1).

Labeling

Before using gas from a cylinder, welding personnel must carefully read the label, which provides the chemical or trade name of the contents in accordance with regulations. The label is the only proper notice of the cylinder's contents. Other means of marking—including cylinder color, banding, or shape—must not be used because they may vary among manufacturers, geographical areas, or product lines and could be misleading. If the label is illegible or no label is affixed to the cylinder, the contents must not be used and the cylinder must be returned to the supplier (Ref 1).

Storage and Usage

Gas cylinders and other containers must be stored in accordance with all state and local regulations and the appropriate standards issued by OSHA and the Compressed Gas Association (CGA). Safe handling and storage procedures are discussed in detail in the CGA's *Handbook of Compressed Gases* (Ref 30) and "Safe Handling of Gas in Containers," CGA P-1 (Ref 31).

Numerous precautions must be taken in the use and storage of gas cylinders. Cylinders must be stored in areas where they are protected against tampering and exposure to extreme temperatures. Storage temperatures must not fall below $-30\text{ }^{\circ}\text{C}$ ($-20\text{ }^{\circ}\text{F}$) or exceed $52\text{ }^{\circ}\text{C}$ ($125\text{ }^{\circ}\text{F}$). They must also be stored at an adequate distance from welding activities to prevent exposure to slag, sparks, or flames;

alternatively, fire-resistant shields must be used. The rough handling of gas cylinders should be avoided; therefore, cylinders must be protected from bumps, falls, falling objects, and weather and must never be dropped. In addition, cylinders must be stored away from passageways, elevators, or stairs where they may be struck, knocked over, or damaged by vehicles.

Cylinders containing acetylene and liquefied gas must always be stored and used in the upright position. Other cylinders are preferably stored and used in the upright position. Moreover, cylinders must always be secured to prevent them from falling during storage and use. During transport by motor vehicle, they must be secured according to U.S. DOT regulations. During lifting, they must be hoisted using the proper cradle or platform, not electromagnets or slings. Any of these exposures, misuses, or abuses could cause damage to cylinders and severe consequences (Ref 1, 31).

Due to the inherent risks of fire and explosion, gas cylinders must never be welded. Cylinders must never be used as work rests or rollers. Moreover, they must not be allowed to become part of an electrical circuit, because arcing may result. Cylinders containing the shielding gases used in conjunction with arc welding must not be placed where they may become part of an electrical circuit. To prevent arcing or interference with valve operation, items such as electrode holders, welding torches, cables, hoses, or tools must not be stored on gas cylinders. Arc-damaged gas cylinders may leak or rupture, thereby injuring and possibly killing anyone nearby (Ref 1).

Many cylinders have a valve protection cap to protect the cylinder valve. This cap should always be in place except when the cylinder is in use. The cylinder should never be lifted by the valve protection cap, because the threads that secure these protection caps may not be capable of supporting the full weight of the cylinder. The caps should always be threaded completely onto the cylinder and hand-tightened.

Gas Withdrawal. Many gases in high-pressure cylinders are filled to pressures of 13,790 kPa (2000 psig) or more. Unless the equipment to be used with a gas is designed to operate at full-cylinder pressure, an approved regulator must be used to reduce pressure by withdrawing gas from a cylinder or manifold. Simple needle valves should never be used. A pressure-relief or safety valve that is rated to function at less than the maximum allowable pressure of the welding equipment should also be employed as a backup in case the regulator fails. The valve is designed to prevent equipment failure at pressures in excess of working limits. The equipment involved in the withdrawal of gas from cylinders is discussed in more detail as follows.

Cylinder Valves. Valves on cylinders containing high-pressure gas, particularly oxygen, must always be opened slowly. If the valves are opened too rapidly, the high temperature associated with adiabatic recompression can

occur. In the case of oxygen, the heat can ignite the valve seat, which, in turn, may cause the metal to melt or burn. To avoid injury, welding personnel must open the cylinder valve outlet while standing to one side of the outlet, not in front of it.

Before a gas cylinder can be connected to a pressure regulator or a manifold, the valve outlet must be cleaned of dirt, moisture, and other foreign matter by wiping it with a clean, oil-free cloth. Then, to prevent dirt or dust from entering the regulator, the valve is opened for an instant and closed immediately—a procedure known as cracking the cylinder valve. Fuel gas cylinders must never be cracked near sources of ignition (i.e., sparks and flames), in confined spaces, or while operators are smoking. In addition, before a regulator is connected to a gas cylinder, the regulator must be drained of gas pressure. After shutting down the operation, the cylinder valve must be closed (Ref 1).

The outlet threads on cylinder valves are standardized for specific gases so that only regulators or manifolds with similar threads can be attached (Ref 32). Preferably, the valves on low-pressure fuel gas cylinders should be opened using no more than one turn. This usually provides adequate flow and allows the valve to be closed quickly in the event of an emergency. In contrast, high-pressure cylinder valves must usually be opened fully to backseat the packing and prevent packing leaks during use.

The cylinder valve should be closed after each cylinder use and when returning an empty cylinder to the supplier. This prevents hazardous gas leaks that may develop and remain undetected while the cylinder is unattended. It also prevents the back flow of contaminants into the cylinder. It is advisable to return cylinders to the supplier with approximately 172 kPa (25 psi) of contents remaining. This practice prevents possible contamination of the cylinder by the atmosphere during shipment.

Pressure-relief devices are intended to protect cylinders that are subjected to a hostile environment, such as fire or other source of heat that may raise the pressure within the cylinders. These safety mechanisms are designed to relieve the pressure in gas cylinders to within safe limits. Only trained personnel are allowed to adjust cylinder pressure-relief devices. The available types of pressure-relief devices, their maintenance, and application are addressed in “Pressure-Relief Device Standards—Part I: Cylinders for Compressed Gases,” CGA S-1.1 (Ref 33).

Regulators. A pressure-reducing regulator must always be used when withdrawing gas from cylinders for use in welding or cutting operations. All gas regulators must meet the requirements specified in “Standard for Gas Pressure Regulators,” CGA E-4 (Ref 34), and other code regulations.

Pressure-reducing regulators must be used only for the gas and pressure specified on the label affixed to the cylinder, although the

cylinder valve outlet threads may be the same as those on other gas cylinders. Threaded connections should never be forced onto the regulator. An improper fit between the gas cylinder and the regulator or between the regulator and hose constitutes an improper—and unsafe—combination of devices. Before a cylinder is used, all threads and the regulator connection glands must be inspected for dirt or damage. If a hose or cylinder connection leaks, the connection must not be forced with excessive torque. Damaged regulators and components must be repaired by properly trained mechanics or returned to the manufacturer for repair.

A suitable valve or flowmeter should be used to control gas flow from a regulator. The regulator internal pressure must be drained before the regulator is connected or removed from a gas cylinder or manifold. An adapter must not be used to change the cylinder connection, because this increases the risk of using an inappropriate or contaminated regulator. For instance, gases that are contaminated with oil can deposit an oily film on the internal parts of the regulator. This film can contaminate oil-free gas or, in the case of oxygen, can cause fire or explosion. Further details are specified in CGA’s “Standard Connections for Regulator Outlets, Torches, and Fitted Hose for Welding and Cutting Equipment,” CGA E-1 (Ref 35).

Manifold Piping Systems. A manifold is used when gas is needed without interruption or at a higher delivery rate than can be supplied from a single cylinder. A manifold and its components must be leaktight and designed for a specific gas and operating pressure. The components of the manifold must be used for the gas and pressure for which they are approved only. Oxygen and fuel gas manifolds must meet additional specific design and safety requirements (Ref 36).

Manifold piping systems must incorporate an appropriate overpressure relief valve unless the system is specifically designed and constructed to withstand full cylinder or tank pressure. A pressure-relief device should be sufficient to prevent the overpressurization of the weakest element of the system. To be effective, a pressure-relief device such as a relief valve or bursting disc must be isolated from other protective devices (such as another relief valve) and located in every section of the system that may be exposed to the full force of the supply pressure. However, welding personnel should beware of relying solely on pressure-reducing regulators. Some pressure regulators have integral safety-relief valves designed for the protection of the regulator only. These alone should not be relied on to protect the downstream system, however.

In cryogenic piping systems, relief devices must be located in every section of the system that could trap liquefied gas. Upon warming, such liquids vaporize to gas, and in a confined area, gas pressure can increase dramatically. Pressure-relief devices protecting fuel-gas piping systems or other hazardous gas systems

must vent gas in safe locations. Piping and fittings for manifolds carrying acetylene or methylacetylene-propadiene (MPS) must not consist of any unalloyed copper or alloys containing 70% or more copper. Acetylene and MPS react with copper under certain conditions to form unstable copper acetylide, a compound that may detonate under shock or heat.

In addition, each fuel gas cylinder lead should incorporate a back flow check valve and a flash arrester. Back flow check valves should also be installed in each line at each station outlet where both fuel gas and oxygen are provided for a welding, cutting, or preheating torch. Back flow check valves must be examined periodically for tightness in accordance with the manufacturer's instructions (Ref 37).

Oxygen

Although oxygen is nonflammable, it vigorously accelerates combustion in flammable materials. Therefore, oxygen cylinders and liquid-oxygen containers must be stored away from combustibles and fuel-gas cylinders. Oil, grease, and combustible dusts may spontaneously ignite on contact with pure oxygen. Hence, all manifold systems and apparatus manufactured expressly for oxygen service must be kept free of any combustibles. Oxygen valves, regulators, and apparatus must never be lubricated with oil. If lubrication is required, the type of lubricant and the method of applying the lubricant should be specified in the manufacturer's literature. If these indications are not specified, the device should be returned to the manufacturer or authorized representative for service. Valves, piping, or system components not expressly manufactured for oxygen service must be cleaned and approved for oxygen service before use in an operation (Ref 38).

It is also important to note the difference between pure oxygen and air. Pure oxygen supports combustion much more vigorously than air, which contains only 21% oxygen. Thus, pure oxygen should never be used as a substitute for compressed air; otherwise, raging fires and explosions may occur. For example, pure oxygen must never be used to power compressed air tools, which are typically lubricated with oil. Similarly, pure oxygen must never be used to blow dirt from workpieces and clothing, which are also often contaminated with oil, grease, or combustible dust. Only clean clothing should be worn when working with oxygen systems. In addition, pure oxygen must never be used to ventilate confined areas. This would create an oxygen-rich atmosphere that could be ignited by a chemical reaction or separate ignition energy in conjunction with a fuel.

Information regarding special procedures for oxygen cylinders is provided in Section 10 of ANSI Z49.1:1999 (Ref 1). Additional information is available in "Oxygen," CGA G-4 (Ref 39), and "Torch Standard for Welding and Cutting," CGA E-5 (Ref 40).

Fuel Gas

Fuel gases commonly used in oxyfuel gas welding and cutting are acetylene, MPS, natural gas, propane, and propylene. Hydrogen is also used in a few applications. Gasoline, which vaporizes in the torch, is sometimes used as a fuel for oxygen cutting. These gases should always be referred to by name, not by the generic term *gas*. The rate of withdrawal of fuel gases from cylinders must never surpass that recommended by the manufacturer (Ref 1).

Acetylene and MPS require special precautions. Acetylene possesses the lowest explosive limit of all the fuel gases. When acetylene is stored in cylinders, it is dissolved in a solvent so that it can be safely maintained under pressure. In the free state, acetylene must never be used at pressures higher than 103 kPa (15 psig) because it can decompose with explosive violence. Moreover, neither acetylene nor MPS should be used in contact with silver, mercury, or alloys containing 70% or more copper. These gases react with these metals to form unstable compounds that may detonate under shock or heat. For this reason, the valves on fuel gas cylinders must never be opened to clean the valve outlet near possible sources of flame ignition or in confined areas (Ref 41).

Hydrogen also requires special attention. Hydrogen flames may be difficult to see or invisible. Because of this lack of visibility, the torch and flame should be handled with extreme care because the body, clothes, or combustibles may easily be exposed to hydrogen flames.

Fuel gases used for brazing furnace atmospheres must be burned or vented to a safe location. Before filling a furnace or retort with fuel gas, the equipment must first be purged with a nonflammable gas, such as nitrogen or argon, to prevent the formation of an air-fuel mixture that could explode.

Preventing Fuel-Gas Fires. Fuel-gas systems can cause fire hazards. Most fuel gases in cylinders are in liquid form or dissolved in liquids. Therefore, gas cylinders should always be used in the upright position to prevent liquid surges into the system.

One source of fire in welding and cutting is the ignition of leaking fuel by sparks or spatter. The best procedure for avoiding fire from a fuel gas or liquid is to prevent leaks in the manifold system. All fuel systems should be checked carefully for leaks upon assembly and at frequent intervals thereafter. Fuel-gas cylinders should frequently be examined for leaks, especially at fuse plugs, safety devices, and valve packing.

If a leak is discovered around the valve of a fuel gas cylinder, the packing nut must be tightened or the valve must be closed (Ref 1). If the fuel leak cannot be stopped, the cylinder should be removed by trained fire personnel to a safe location outdoors. The supplier should also be notified. A warning sign should be posted, and no smoking or other sources of ignition should be permitted in the area. In case of fire, the fire

alarm should be activated, and trained fire personnel should be summoned immediately.

One of the most effective means of controlling a fuel fire is to shut off the fuel valve, if accessible. A fuel gas valve should never be opened beyond the point necessary to provide adequate flow, which is usually no more than one turn of the handle. This practice makes it possible for the valve to be shut off quickly in an emergency. If the immediate valve controlling the burning gas is inaccessible, another upstream valve may cut off the flow of gas.

A small fire near a cylinder safety device or valve can be controlled using water, wet cloths, or fire extinguishers. If a large fire at a fuel-gas cylinder occurs, the fire alarm should be sounded, and all personnel should be evacuated from the area. The cylinder should be kept wet and cool by fire personnel with a heavy stream of water. It is usually better to allow the fire to continue to burn and consume all issuing gas rather than attempt to extinguish the flame. Otherwise, although the flames have been extinguished, the escaping gas may reignite, with explosive violence (Ref 1).

Shielding Gas

Argon, helium, nitrogen, and carbon dioxide and their mixtures in cylinders and manifold systems are used for shielding with some welding processes. All of these, except carbon dioxide, are used as brazing atmospheres. These gases are odorless and colorless, and they can displace the air needed for breathing. For this reason, confined areas filled with these gases must be well ventilated before personnel are permitted to enter.

Should there be any question regarding the presence of these gases in a work area, the area must be monitored for adequate oxygen concentration with an oxygen analyzer. If an analyzer is not available, air-supplied respirators must be worn by personnel entering the area. In addition, containers filled with these gases must not be placed in confined spaces, as pointed out previously (see the section "Welding of Containers and Piping" in this article).

Cryogenic Liquids

Cryogenic cylinders and tanks are used to store at very low temperatures those liquids that evaporate at room temperature. The cryogenic liquids used for commercial purposes include oxygen, nitrogen, and argon, although other gases may also be handled similar to cryogenic liquids. The cylinders and tanks used for storing cryogenic liquids are usually double-walled. They are evacuated and insulated between the walls. Designed to keep temperatures low and minimize heat increase, these liquid-gas containers hold a greater amount of gas for a given volume than high-pressure gas cylinders.

For safety, these containers must be handled carefully. They must always be maintained in an upright position and transported only in cylinder-handling trucks specifically designed for the transport of these containers. In addition, they must not be rolled on a bottom edge, as is often done with high-pressure cylinders. Overpressurization could cause an explosion.

If these cylinders are handled improperly, the inner or outer cylinder wall can rupture, causing a loss of vacuum and a rapid rise of internal pressure. When this occurs, the cylinder protective devices are designed to activate, allowing the contents to escape. These cylinder protection devices must never be tampered with.

A visible frosting on the container exterior is a sign of damage to the internal walls or fittings. Whenever this frosting appears, the gas supplier must be notified, and personnel should keep clear until the frost disappears. Generally, when the frost disappears, the contents have evaporated and any internal pressure has been relieved.

Cryogenic liquid, which is a gas at room temperature, evaporates before exiting the cylinder by passing through a vaporizer system, warming the gas to atmospheric temperature. In some cases, however, the user may want to withdraw the contents in liquid form. Should this extremely cold liquid contact the skin, it may cause burns similar to those caused by hot substances. Contact with the liquid can also result in severe frostbite. Therefore, to prevent bodily contact from these cold liquids, users must wear protective clothing. An adequate face shield and loose-fitting insulated gloves that can be quickly removed in case of an exposure emergency are essential.

The properties of many materials at room temperature change drastically at cryogenic liquid temperatures. Many metals, including carbon steel, and most elastomers, such as rubber, become extremely brittle. When cryogenic liquids are to be withdrawn from cylinders, the transfer line must be made of materials that maintain satisfactory properties at these low temperatures.

It is also important to note that liquid oxygen may react with explosive violence on contact with asphalt or similar bituminous materials. Thus, liquid oxygen must not be allowed to come into contact with these materials. Liquid-oxygen tanks must always be installed on concrete pads—never on asphalt or similar bituminous materials.

Further information on this topic is provided in "Safe Handling of Cryogenic Liquids," P-12 (Ref 42), "Safe Handling of Liquefied Nitrogen and Argon," CGA AV-5 (Ref 43), and "Standard for Cryogenic Liquid Transfer Connections," CGA V-6 (Ref 44).

Protection Against Electromagnetic Radiation

Electromagnetic fields, UV radiation, and infrared radiation are produced by most arc

welding and cutting processes as well as by electron beam welding; laser beam welding; and torch welding, cutting, brazing, or soldering. Although radiation is invisible, it can inflict injury. The most common injuries resulting from exposure to radiation are skin burns and eye damage.

Two types of radiation—ionizing and non-ionizing—can be produced during welding operations. Ionizing radiation, produced by electron beam welding, can be maintained within acceptable levels with shielding around the welding area. During the grinding of thoriated tungsten electrodes for gas tungsten arc welding, a local exhaust system must be used to prevent the inhalation of the dust, which is radioactive. Respiratory protection should also be used, if necessary. Otherwise, users should follow the instructions on the manufacturer's MSDS for the thoriated tungsten electrode. Protection against nonionizing radiation includes the use of safety glasses with UV protective side shields in addition to a welding helmet with the correct filter plate. In addition, the skin must be protected with adequate hand and body PPE, as specified by ANSI Z49.1:1999 (Ref 1, 2).

Electrical Safety

Most welding and cutting operations employ some type of electrical equipment. For example, even oxyfuel gas cutting machines use motor drives, controls, and various other electrical systems. In the absence of precautionary measures, personnel may be injured or even killed by electric shock in welding and cutting operations. Some electrical accidents, such as those caused by lightning, are unavoidable; however, the majority can be avoided with the proper training and safety precautions.

A good safety training program in electrical safety is essential. Before working with any electrical application, employees must be fully instructed in electrical safety by a competent professional. As a minimum, this training should include the points covered in part II of ANSI Z49.1:1999 (Ref 1).

Electric shock occurs when an electric current of sufficient magnitude passes through the body. The severity of the shock depends primarily on the amount of current, the duration and path of flow, and the individual's state of health. The amount of current depends upon the applied voltage, which causes the current to flow, and the resistance of the body path. The frequency of the current may also be a factor when alternating current (ac) is involved.

Currents greater than approximately 5 mA are considered primary shock currents because they are capable of causing direct physiological harm. Steady-state currents less than 5 mA are considered secondary shock currents, which are capable of causing involuntary muscular reactions without normally causing direct physiological harm. Most people begin to feel a

tingle from the current at 0.5 mA; therefore, this point is referred to as the perception threshold.

Sources of Electric Shock

Electric shock can originate from natural sources or from equipment. Shock from natural sources is exemplified by that caused by lightning-induced voltage surges in power distribution systems. Even earth grounds can attain high potential relative to true ground during severe transient phenomena due to power line faults or lightning strikes, although such circumstances are rare. Most electrical equipment can present a hazard of shock if improperly installed, used, or maintained. Thus, for purposes of safety, all equipment must be installed, operated, maintained, and repaired by qualified personnel. Worn, damaged, or inappropriate cables must not be used.

In welding and cutting activities, most electrical equipment is powered from ac sources of 115 to 575 V or by engine-driven generators. Most welding operations require less than 100 V. Some arc cutting methods use power sources that operate at more than 400 V, while electron beam welding machines operate at up to approximately 150 kV. These levels warrant precautions because fatalities can result even with equipment that operates at less than 80 V.

In the welding industry, most instances of electric shock occur because of accidental contact with bare or poorly insulated conductors. Therefore, welders must take precautions against contacting bare elements in the welding circuit and primary circuits.

When performing welding operations in electrically hazardous conditions, personnel must take special care to prevent electric shock. Examples of electrically hazardous conditions are wet or damp areas; restricted work areas that force personnel to work in an uncomfortable position, making contact with conductive parts; and areas in which contact with conductive elements is likely (Ref 1).

Water or moisture typically reduces electrical resistance, often creating more severe electrical hazards. When arc welding or cutting in damp or wet conditions—including conditions creating heavy perspiration—welding personnel must wear dry, nonconductive gloves and clothing in good condition to prevent electrical shock. Welders should also be protected from electrically conductive surfaces, including the earth, by means of rubber-soled shoes or an insulating layer such as a rubber mat or dry wooden board, which is preferred. Under such hazardous conditions, welders can also employ a semiautomatic direct current (dc) power source, a dc manual shielded metal arc power source, or an arc welding power source with reduced voltage control. The use of these power sources can reduce the possibility of electric shock.

When welders are required to work in a cramped kneeling, sitting, or lying position,

they should implement the same precautions discussed previously. The hazards posed by making contact with conductive elements can be minimized by insulating the parts in the operator's vicinity (Ref 1).

As a general safety precaution, rings and other jewelry should be removed before welding, to decrease the possibility of electric shock.

Equipment Selection

In addition to the use of proper clothing and body protection, operators can reduce the possibility of electric shock by selecting and using the proper equipment. Operators should use the correct equipment designed for each job and situation. All equipment must meet the applicable standards, such as "Transformer-Type Arc Welding Machines," UL 551 (Ref 45), and other standards issued by the National Electrical Manufacturers Association, such as "Electric Arc Welding Power Sources," ANSI/NEMA EW 1 (Ref 46).

As previously mentioned, if a significant amount of welding and cutting work is performed under electrically hazardous conditions, the use of automatic machine controls that reduce the no-load (open-circuit) voltage to a safe level is recommended. When special welding and cutting processes require open-circuit voltages higher than those specified in ANSI/NEMA EW 1 (Ref 46), adequate insulation and operating procedures must be provided to protect personnel from these higher voltages.

Installation

Personnel installing electrical equipment must follow the requirements of the National Fire Protection Association's (NFPA) "National Electric Code (NEC)," ANSI/NFPA 70 (Ref 47), and other local codes. These codes describe necessary disconnects, fusing, and the different types of incoming power lines, among other topics. All electrical equipment should be installed in an area that is clean and dry. If installation in a clean, dry area is not possible, the equipment should be adequately safeguarded from dirt and moisture.

Terminals for welding leads and power cables must be shielded from accidental contact with personnel or metal objects, such as vehicles and cranes. Connections between welding leads and power supplies may be guarded utilizing dead-front construction using receptacles for plug connections, terminals located in a recessed opening or under a nonremovable hinged cover, insulating sleeves, or other equivalent mechanical means (Ref 1).

Grounding

The workpiece and the frame or chassis of all electrically powered machines must be placed or connected to a good electrical ground, such as a grounded metal floor or platen. They can

also be connected to a properly grounded building frame or other satisfactory ground. Special radio-frequency grounding may also be necessary for arc welding machines equipped with high-frequency arc-initiating devices and arc stabilizers (Ref 46). Chains, wire ropes, cranes, hoists, and elevators must never be used as grounding connectors or as carriers of welding current (Ref 1).

It is important to note that the work lead is not the grounding lead. The work lead connects the work terminal on the power source to the workpiece. A separate lead is required to ground the workpiece or power source work terminal. Thus, great care must be taken when connecting the grounding circuit to avoid double-grounding. Otherwise, the welding current may flow through a connection intended only for grounding, and the welding current may be of higher magnitude than the grounding conductor can safely carry.

Portable control devices such as push buttons must not be connected to circuits having operating voltages above approximately 120 V. Exposed metal parts on portable control devices operating on circuits above 50 V must be grounded by a grounding conductor in the control cable. Controls using intrinsically safe voltages below 30 V are recommended.

Connections and Cables

Electrical connections must be tight and clean to prevent local heating; therefore, they must be checked periodically. Magnetic work clamps must be free of an accumulation of metal particles and spatter on contact surfaces. Coiled welding leads should be spread out before use to avoid overheating and damage to the insulation. When jobs alternately require long and short leads, insulated cable connectors should be used so that the idle lengths can be disconnected when they are not needed (Ref 1).

Equipment, cables, fuses, plugs, and receptacles must be used within their current-carrying and duty-cycle capacities. The operation of apparatuses above the current rating or the duty cycle causes overheating and the rapid deterioration of insulation and other parts. When welding with short leads or low voltages, or both, the actual welding current may be higher than that shown by the indicators on the welding machine. General-purpose welding machines are likely to render high currents when they are used with processes that use low arc voltage, such as gas tungsten arc welding.

Welding lead cable should be flexible and designed especially for the rigors of welding service. The insulation on cables used with high voltages or high-frequency oscillators must provide adequate protection. The cable manufacturer's recommendations and precautions must be followed. Cable insulation must be maintained in good condition, and cables must be repaired or replaced promptly when necessary.

Operation

To ensure overall safe operation, welding personnel must be knowledgeable of the codes and standards related to their responsibilities. Personnel must have access to written rules governing the safe operation of equipment. These rules must be strictly followed (Ref 1).

Welders must not allow the energized metal parts of electrodes, electrode holders, or torches to touch their bare skin or any wet apparel. Electrode holders must not be cooled by immersion in water, and electrode-holder insulation must be kept in good condition. Before using water-cooled welding guns or holders, welders must inspect them for any water leaks and condensation, which would compromise safety. In addition, welders must not drape or coil the welding leads around their bodies (Ref 1).

During operation and work interruptions, welding circuits must be de-energized to avoid electric shock while the electrode, torch, or gun is being changed or adjusted. The only exception is shielded metal arc welding, during which the welding circuit need not be de-energized while electrodes are changed. However, when the circuit is energized in shielded metal arc welding, covered electrodes must be changed with dry welding gloves, never with bare hands. De-energizing a circuit is always desirable for optimum safety, even with covered electrodes (Ref 1).

At the end of an operation or when leaving the workstation for an appreciable time, operators must turn a welding machine off. Similarly, when the machine is to be moved, the input power supply must be disconnected at the source. When equipment is not in use, exposed electrodes must be removed from the holder to eliminate the hazard of accidental electrical contact with workers or conducting objects. Semiautomatic welding guns must be placed so that the gun switch cannot be operated accidentally (Ref 1).

Modification and Maintenance

Defective electrical equipment or safety hazards must be reported to the supervisor as soon as these are identified. Faulty equipment must not be used until it has been serviced by authorized personnel and its safety has been assured. Only qualified personnel are permitted to modify and maintain electrical equipment. Welding machines require numerous modification and maintenance procedures. Typical procedures are listed below (Ref 1):

- Commutators on rotating welding machines must be kept clean to prevent excessive arcing.
- Rectifier welding machines must be inspected frequently for accumulations of dust or lint that may interfere with ventilation.
- Louvers and internal electrical coil ventilating ducts require inspection for the accumulation of dust and lint.

- Welding machines may be blown out occasionally with clean, dry, compressed air at low pressure unless prohibited by the manufacturer. Adequate safety precautions, such as the proper eye protection, must be observed.
- The use of air filters in the ventilating systems of electrical components is not recommended unless these are provided by the welding machine manufacturer. If used, filters should be inspected as recommended by the manufacturer, because the reduction of air flow from dust accumulating on the air filter can cause internal components to overheat and fail altogether.
- Machines that have become wet must be thoroughly dried and properly retested before being operated.
- All input connections must be checked.
- All grounding connections must be verified.

Multiple-Arc Welding Operations

Increased hazard of electrical shock exists when several welders are working on a large metal structure, such as a building frame or ship, that is part of the return welding circuits. Proper electrical contact must exist at all joints in the structure. Sparking or heating at any point in the structure renders it unsuitable as a return circuit.

When two or more welders working on the same structure are likely to touch the exposed parts of more than one electrode holder simultaneously, the welding machines must be connected to minimize the hazard of shock. Ideally, all dc welding machines should be connected with the same polarity. A test lamp or voltmeter can be used to determine whether the polarities are matched. It is also preferable to connect all single-phase ac welding machines to the same phase of the supply circuit with the same instantaneous polarity. These precautions minimize the potential difference in polarity between electrode holders.

In some cases, the preferable connections may not be available. Welding may require both dc polarities, or supply circuit limitations may necessitate the distribution of ac welding machines among the phases of the supply circuit. In these cases, the no-load voltage between electrode holders or welding guns may be twice the normal voltage. Because of the increased voltage, the welders and other personnel in the area must be instructed to avoid simultaneous contact with more than one electrode holder, welding gun, or installed electrode (Ref 1).

Special Precautions for Pacemaker Wearers

Inasmuch as pacemakers are electrical in operation, their functioning may be compromised by the presence of the strong electromagnetic fields

produced by electric arc welding and cutting. Therefore, the wearers of pacemakers or other electronic equipment vital to life must consult a physician and the manufacturer regarding possible hazards before performing these operations.

Pacemaker wearers who have been cleared to perform welding and cutting activities must observe special precautions. Welding current settings higher than necessary should not be used by pacemaker wearers. Welding cables should be kept close together and positioned to one side of the welder. Repeated, short spurts of welding should be avoided; 10 s should be allowed to transpire between welds. Pacemaker wearers should not work alone and must stop welding and seek immediate medical attention if they feel ill (Ref 2).

Fire Prevention and Protection

Most precautions against electrical shock are also applicable to the prevention of electrical equipment fires, which may be caused by overheating electrical components, sparks, or spatter from welding or cutting operations, or the mishandling of fuel in overheated engine-driven equipment. For engine-driven equipment, fuel systems must be in good condition. Otherwise, the ignition system, electrical controls, spark-producing components, or engine heat may start a fire. Leaks must be repaired promptly. Engine-driven machines must be turned off before refueling, and any fuel spills should be wiped up and fumes allowed to dissipate before the engine is restarted.

In most welding, cutting, and allied processes, a high-temperature heat source is present. Open flames, electric arcs, molten metal, sparks, and spatter are ready sources of ignition. Sparks and spatter can pass through or lodge in cracks, holes, and other small openings in floors and walls, often causing fires. Because sparks can travel up to 10.7 m (35 ft) from their source and fall much greater distances, floors must always be free of combustible materials for a radius of at least 10.7 m (35 ft) around the work area (Ref 2).

Without the proper protective shields, welding or cutting too close to combustibles increases the risk of fire. The materials most commonly ignited are combustible floors, roofs, partitions, and building contents including trash, wood, paper, textiles, plastics, chemicals, and flammable liquids and gases. Outdoors, the most common combustibles are dry grass and brush.

The best protection against fire is to perform welding and cutting away from combustibles in specially designated areas or noncombustible enclosures. Combustibles should always be removed from the work area. Combustibles that cannot be removed from the area, including combustible walls, ceilings, doorways, windows, cracks, and other openings, should be covered with tight-fitting flame-resistant material. Alternatively, the work area itself can be

enclosed with portable flame-resistant screens. Combustible floors must be protected with damp sand, sheet metal, or water. If water is used, measures must be taken to protect personnel from experiencing electric shock. Appropriate fire-extinguishing equipment must be available for immediate use in the work area (Ref 1).

Personnel should refrain from welding or cutting in atmospheres that contain hazardously reactive or flammable gases, liquids, vapor, or dust. Moreover, heat should not be applied to a container that has held an unidentified substance or combustible material or to a work-piece covered with an unidentified substance or flammable coating (Ref 2).

The fuel for engine-driven equipment must be carefully stored and handled. The equipment manufacturer's instructions should be followed because the fuels and vapors commonly found in welding and cutting areas are combustible and can be explosive under some conditions. Examples of such fuel gases are acetylene and propane. All fuel-gas cylinders, hoses, and apparatus must be carefully inspected for leaks. Welders must also be alert for the traveling vapors of flammable liquids. Vapors are often heavier than air and can travel along floors and in depressions for a considerable distance from the location where the flammable liquid is stored. In addition, light vapors can travel along ceilings to adjacent rooms.

When welding or cutting material on or adjacent to a metal wall, ceiling, or partition, heat that is conducted through the metal can ignite combustibles on the opposite side. Therefore, combustibles on the other side of the barrier must be moved to a safe location. If this cannot be accomplished, a fire watcher (see the section "Fire Watchers" in this article) must be stationed to monitor the combustibles.

Welding, brazing, or cutting must not be performed on any material having a combustible coating or internal structure. This is the case with certain walls, ceilings, floors, and platforms. Moreover, hot scrap or slag must not be placed in containers holding combustible materials. After the operation has been completed, the work area should be inspected for fires for at least 30 min. Personnel should be alert for conditions that may warrant an extension of this period. Supervisory personnel should also inspect the area before leaving.

Fire Watchers

According to the provisions of ANSI Z49.1:1999 (Ref 1) and "Fire Prevention during Welding, Cutting, and Other Hot Work," NFPA 51B (Ref 48), fire watchers—qualified personnel who are trained in fire detection, the fire-reporting process, and emergency rescue procedures—must be situated in areas where welding or cutting operations are being performed and where a fire may start. Fire watchers must also be posted when any of the following are present:

- Combustibles within 10.7 m (35 ft) of welding or cutting operations
- Wall or floor openings that expose combustible materials within a radius of 10.7 m (35 ft)
- Metal walls, ceilings, roofs, or pipes adjacent to which materials that are likely to ignite by means of radiation or conduction are located
- Ship work that poses a fire hazard to an adjacent compartment

Fire watchers are allowed to perform additional duties, provided these do not distract them from detecting fires.

Hot-Work Authorization

When welding, cutting, or similar hot-work operations are to be performed in an area not designated for these activities, the hot-work authorization system is used to alert area supervisors to the extraordinary hazard of fire. (The term *hot work* is defined in Ref 1 as “any work involving burning, welding, or similar operations capable of initiating fires or explosions.”) The authorization, which is usually written, should incorporate a checklist of safety precautions, including an inspection of fire extinguishers; the establishment of fire watches, if necessary; a search for flammable materials; and safety instructions for area personnel who are not involved in the hot work (Ref 1).

Explosion Prevention

When certain gases, vapors, and dusts are mixed with oxygen or other elements in certain proportions, they can cause explosions and fires. The heat, sparks, and spatter produced during welding and related activities may cause otherwise low-volatile materials to produce flammable vapors. All of these materials must be kept in leaktight containers or be well removed from the work area.

Welding, brazing, soldering, or cutting activities should never be carried out in an atmosphere containing flammable material. Personnel must also refrain from placing any operating equipment that can produce heat or sparks near these flammables. Inasmuch as some welding operations involve the risk of explosion, personnel must always wear proper PPE.

Containers must be vented before applying heat. Heat must not be applied to a container that has held an unknown material, a combustible substance, or a substance that may form flammable vapors upon the application of heat (Ref 29). The container must first be thoroughly cleaned or filled with an inert gas. In addition, heat should never be applied to a workpiece covered by an unknown substance or to a substance that may form flammable or toxic vapors when heated.

Process-Specific Safety Considerations

Broad safety guidelines for most welding, cutting, brazing, or soldering processes have been addressed earlier. The precautions and procedures unique to particular processes are discussed in this section. All applicable precautions and guidelines discussed subsequently must be considered as part of a safety program in the workplace.

Oxyfuel Gas Welding and Cutting

Acetylene, MPS, natural gas, propane, propylene, and hydrogen are commonly used in oxyfuel gas welding and cutting. In addition, gasoline is sometimes used as a fuel for oxygen cutting. As mentioned previously, these fuels should always be referred to by name, not by the generic term *gas*.

Oxygen equipment—including cylinders and pipelines—must not be used interchangeably with any other gas. Failure to comply with this measure may result in spontaneous combustion or explosion as a result of the contamination of the oxygen apparatus with combustible substances (Ref 1).

Torches. Only welding and cutting torches that have been approved by the authority with jurisdiction must be used in oxyfuel gas welding and cutting operations. Oxyfuel gas torches must meet appropriate government regulations and the requirements stipulated in “Torch Standard for Welding and Cutting,” CGA E-5 (Ref 40). Torches should be kept in good working order and serviced at regular intervals by the manufacturer or qualified technicians. A torch must be used only with the fuel gas for which it was designed. The fuel-gas and oxygen pressures should be those recommended by the torch manufacturer. Torches must be inspected for leaking before lighting, and frequent leak testing should be performed when the equipment has been employed in such a way as to induce leaks (Ref 1).

To minimize the hazard of burns on the hands and fingers, the manufacturer’s recommendations must be followed when lighting and extinguishing the torch. The torch should be lighted only with a friction lighter, pilot light, or similar ignition source. Matches, cigarette lighters, or welding arcs must never be used as a source of ignition. The manufacturer’s specifications must also be followed regarding the sequencing of operations while lighting, adjusting, and putting out torch flames (Ref 1).

Hoses. Only those hoses that have been specified for use in oxyfuel gas welding and cutting systems may be used. Hoses used in oxyfuel gas service must be manufactured in accordance with the standard “Specifications for Rubber Welding Hose,” ANSI/RMA IP-7 (Ref 49). Hoses must be in good condition and free of oil and grease. Worn, leaking, defective hoses must be repaired or replaced.

In the United States, red hose with left-hand threaded fittings is typically used for fuel gas, while green hose with right-hand threaded fittings is used for oxygen. (Hose connections must comply with requirements stipulated in Ref 35.) To permit color recognition and ensure adequate ventilation, when parallel lengths of hose are strapped together, no more than 100 mm (4 in.) of any 300 mm (12 in.) section of hose should be taped. The hose colors used internationally are specified in “Welding—Rubber Hoses for Welding, Cutting, and Allied Processes,” ISO 3821 (Ref 1, 50).

Only the proper ferrules and clamps should be used to secure hose to fittings. Long runs of hose should be avoided. Excess hose should be coiled to prevent kinks and tangles, but it should not be wrapped around cylinders or cylinder carts while in use.

Backfire and Flashback. The term *backfire* refers to the momentary retrogression of the flame back into the torch tip, causing the tip flame to disappear and then reappear. This is accompanied by a pop or bang, depending on the size of the tip. In severe cases, the hot combustion products within the tip may be forced back into the torch and even the hoses. Backfires occasionally ignite the inner liner of the hose and result in burnthrough of the hose wall, especially when using oxygen. Such backfires can result in injury. In addition, when the hose ruptures, the gases flow out of the tube into the atmosphere until the valve at the tank is closed.

The term *flashback* describes a phenomenon that is usually characterized by a whistling or squealing sound. Flashback is initiated by a backfire in which the flame continues to burn inside the equipment instead of being re-established at the tip. This causes a very rapid internal heating that can easily destroy the equipment. This rapid heating may also cause sparks to issue from the tip. Flashback should be extinguished by turning off the torch valves as quickly as possible. Different manufacturers recommend shutting off either the fuel or oxygen first, but the most important concern is to shut both valves quickly.

Backfires and flashbacks are not ordinarily a concern when the manufacturer’s instructions have been followed. When they do occur, the operator allowed the tip to become overheated by flame backwash, forcing the tip into the work, or providing insufficient gas flow for the size of the tip. If frequent backfires or flashbacks occur, the work should be stopped, and the equipment or operation should be investigated.

To prevent backfires and flashbacks, hose lines should always be purged before oxyfuel gas equipment is lighted. Purging flushes out any combustible oxygen-fuel or air-fuel gas mixtures in the hoses. Hoses are purged by opening either the fuel or the oxygen valve on the torch and allowing the gas to flow for several seconds to clear the hose of any possible gas mixtures. That valve is then closed, and

the other valve is opened to allow the other gas to flow for a similar period. The purge stream must not be directed toward any flame or other source of ignition. Torches must not be purged in confined areas because accumulated, highly concentrated gas may explode.

Hose-Line Safety Devices. When they are installed and operating properly on hose lines, reverse-flow check valves and flashback arrestors can prevent the reverse flow of gases and flashbacks into hoses. These safety devices must be used, inspected, and maintained strictly in accordance with the manufacturer's instructions and recommendations (Ref 1).

Regulators. Pressure-reducing regulators must be approved according to the specifications of "Standard for Gas Pressure Regulators," CGA E-4 (Ref 34). These regulators must be used for the gases and pressures specified on their labels only. Inlet connections must be made in accordance with *Compressed Gas Cylinder Valve Outlet and Inlet Connections*, ANSI/CGA V-1 (Ref 32), and all connections must be inspected for leaktight performance before use. Regulators must not be used interchangeably among designated gas applications. To minimize the possibility of fire, oxygen regulators must be drained of gas before they are connected to a manifold or a cylinder, and valves must always be opened slowly (Ref 1).

Shutdown Procedures. When oxyfuel gas operations are finished, the equipment must always be completely shut down, with the gas pressures drained from the system and all cylinder supply valves closed. The equipment must not be left unattended until the shutdown has been completed.

Ventilated Storage. Oxyfuel gas cylinders or equipment connected to cylinders must always be stored in well-ventilated areas, rather than in confined areas, such as unventilated cabinets. Even small gas leaks in confined areas can create mixtures that may cause disastrous explosions. For the same reason, gas cylinders should never be transported in enclosed vehicles, particularly in closed vans or the trunks of automobiles.

Arc Welding and Cutting

The potential hazards of arc welding and cutting, discussed in detail earlier, necessitate precautions that must be followed. Potential hazards encountered in arc welding and cutting include electric shock, asphyxiation, fumes and gas, infrared and UV radiation, burns, fire, explosion, and noise. Noise levels during arc cutting operations can be very high, and prolonged exposure can cause hearing impairment. A certified safety specialist or industrial hygienist can be consulted to measure occupational exposure levels in the work area and make recommendations. Whenever necessary, approved ear protection, such as ear plugs or muffs, must be provided for operators and others in the area.

Plasma arc cutting is a particularly noisy process and one that also emits a great deal of fume. Two common accessories can be used in the mechanized plasma arc cutting of plate to aid in fume and noise control. One method is the water table, discussed earlier in the section "Local Ventilation." This is a cutting table filled with water to the bottom surface of the plate or above the plate. In the latter case, cutting is done under water using a special torch to minimize noise and reduce radiation. The high-speed gases emerging from the plasma jet produce turbulence in the water, consequently trapping most fume particles in the water.

Another accessory designed to reduce noise is the water muffler, a nozzle attached to a special torch body that produces a curtain of water around the front of the torch. The water muffler is always used in conjunction with a water table. The combination of a water curtain at the top of the plate and a water table contacting the bottom of the plate encloses the arc and creates a noise-reducing shield, attenuating noise by roughly 20 dB. These accessories should not be confused with cutting variations using water injection or water shielding, however.

Resistance Welding

When selecting resistance welding equipment, personnel safety must be a consideration. All equipment must be installed by qualified personnel under the direction of a technical supervisor in accordance with the "Electrical Standard for Industrial Machinery," NFPA 79 (Ref 51) and the "National Electric Code," NFPA 70 (Ref 47) or its equivalent. Operators must be properly trained to operate all resistance welding equipment safely.

Machinery Safeguarding. Devices that initiate a resistance welding operation—push buttons, foot switches, retraction, and dual-schedule switches on portable guns, for example—must be arranged or guarded to prevent inadvertent activation (Ref 1). One or more emergency stop buttons must be provided on all welding machines that require three or more seconds to complete a sequence and have mechanical movements that can be hazardous to personnel if the guards are removed. It should be verified that the installation and use of these emergency stop buttons do not in themselves create additional hazards (Ref 1).

Stationary Equipment. All gears, chains, operating linkages, and belts used with welding equipment must be guarded in accordance with ANSI safety standards for mechanical power transmission devices. It is crucial that the operator's hands be kept away from the point of operation. On stationary single-ram welding machines, an appropriate device must be used to prevent the hands from making contact with the point of operation during the machine cycle unless the size of the workpiece, its configuration, or fixture keeps both of the operator's

hands away from the point of operation. Appropriate safety apparatus includes latches, two-handed controls, machine guards, or fixtures to prevent the hands from passing under the point of operation, and presence-sensing equipment. Similar precautions must be taken if the operator's hands must pass under the point of operation during a multigun welding machine operation (Ref 1).

Portable Equipment. All suspended portable welding gun equipment, except the gun assembly, must be fail-safe. It must incorporate a support system that is capable of withstanding the total impact load in case any component of the supporting system should fail. Cables, chains, and clamps are satisfactory support system components (Ref 1).

Moving holder mechanisms on portable welding equipment require additional precautions. A moving holder mechanism that enters the gun frame must be designed to ensure that no sharp shear points could cause injury to fingers. If shear points are present, appropriate guarding must be provided. If adequate guarding from shear cannot be accomplished, the use of two handles—one for each hand—is permitted, provided each handle has one or two operating switches at appropriate holding points. These handles and operating switches must be positioned a safe distance away from any shear or pinch point to prevent contact when the hands are on the controls (Ref 1).

Electrical Considerations. All external weld-initiating control circuits must operate at or below 120 V ac for stationary equipment. Portable equipment must operate at or below 36 V ac root mean square. In addition, resistance welding equipment and control panels containing capacitors used for stored-energy resistance welding involving high voltages (above 550 V ac) must be suitably insulated and protected by complete enclosures. All doors on this equipment must have suitable interlocks and contacts wired into the control circuit. These interlocks or contacts must be designed to interrupt power and short circuit all capacitors when the panel is open. As an added safety measure ensuring absolute discharge of all capacitors, a manual switch or suitable positive device must be installed in addition to the mechanical interlocks or contacts. It is important to note that because the panel box itself is considered an enclosure, the capacitors inside it require no additional protection when all other safety requirements have been met (Ref 1).

To prevent unauthorized access to live portions of equipment, all electrical resistance welding equipment must be locked or interlocked, including all doors and access panels on resistance welding machines and remote control panels that are accessible at floor level. A door or access panel is considered locked when a key, wrench, or other instrument is required to open it. Control panels that are located on overhead platforms or in separate rooms must be locked, interlocked, or guarded

by a physical barrier or a sign, except when the equipment is undergoing service. In addition, panel doors must always be closed (Ref 1).

On large welding machines that have a platen, electrically interlocked safety apparatus such as pins, blocks, or latches must be provided when the platen or the head can move. When activated, this safety device must break the energizing circuit. The device itself must prevent movement of the platen or head under static load. Although more than one device may be required, depending on the machine size or accessibility, each device alone must be capable of sustaining the full static load involved (Ref 1).

To ensure the safety of personnel in the area, protection from flying sparks and molten metal must be provided by a guard of suitable fire-resistant material or approved protective eye-wear. For flash welding equipment, flash guards of suitable fire-restraint material must be provided to control flying sparks and molten metal. In addition, for proper electrical safety, resistance welding equipment must have appropriate grounding. The welding transformer secondary may be grounded by either permanent grounding of the welding secondary circuit or by connecting a grounding reactor across the secondary winding with reactor tap(s) to ground. As an alternative on stationary machines, an isolation contactor can be arranged to open both sides of the line to the primary of the welding transformer (Ref 1).

It is important to remember that because resistance welding operations vary, each operation must be evaluated individually to provide proper protection.

High-Frequency Welding

Injuries from high-frequency welding power, especially at the upper range of welding frequencies, tend to produce severe localized surface tissue damage. These injuries are not likely to be fatal, however, because the current flow is shallow and does not penetrate deeply into the body.

On the other hand, high-frequency welding generators, which emit lethal voltages ranging from 400 to 20,000 V in either low or high frequency, can cause fatal injuries. Thus, proper care and safety precautions must be taken while working on high-frequency welding generators and their control systems. Units must be equipped with safety interlocks on access doors and with automatic safety grounding devices to prevent equipment operation when access doors are open. The equipment must not be operated with the panels or high-voltage covers removed or with the interlocks and grounding devices blocked. (This equipment should not be confused with high-frequency arc stabilization equipment, which is used in gas tungsten arc welding.)

The output high-frequency primary leads must be encased in metal ducting and should

not be operated in the open. Induction coils and contact systems must always be properly grounded for operator protection. High-frequency currents are more difficult to ground than low-frequency currents, and grounding lines must be kept short and direct to minimize inductive impedance. The magnetic field from the output system must not induce heat in adjacent metallic sections, which could cause burns or fires.

High-frequency welding stations often emit a loud, steady whine that can cause permanent hearing loss. Ear protection is essential under these circumstances.

Electron Beam Welding

The standards "Recommended Practices for Electron Beam Welding," ANSI/AWS C7.1 (Ref 52), and "Safety in Welding, Cutting, and Allied Processes," ANSI Z49.1 (Ref 1), stipulate general safety requirements that must be followed strictly at all times while performing electron beam welding. The primary hazards associated with electron beam welding equipment are electric shock, x-radiation, fumes and gases, and damaging visible radiation. Thus, precautionary measures must be taken at all times. These hazards are discussed as follows.

Electric Shock. Electron beam welding machines operate at voltages that are much higher than those employed in other welding processes. Electron beam equipment is typically operated at voltages above 20 kV. These voltages can cause fatal injury regardless of whether the machine is labeled as being a low-voltage or a high-voltage device. Even though the manufacturers of electron beam welding equipment produce machines that are well insulated against high voltage, precautions must be taken with all systems when high voltage is present. The manufacturer's instructions should be followed for proper equipment operation and maintenance.

The x-radiation generated by electron beam welding machines is produced when electrons traveling at high velocity collide with matter. The majority of x-rays are produced when the electron beam impinges upon the workpiece. Substantial amounts are also produced when the beam strikes gas molecules or metal vapor in the gun column and work chamber. Producers and users must follow procedures that adhere to regulations established by Underwriters Laboratories and OSHA, providing firm rules for permissible x-ray exposure levels.

Electron beam welding and cutting equipment must be properly shielded to block out x-radiation or reduce it to acceptable levels (Ref 1). The steel walls of the chamber are generally adequate protection in systems up to 60 kV, assuming proper design. High-voltage machines use lead lining to block x-ray emission beyond the chamber walls. Lead glass windows are employed in both high- and low-voltage electron beam systems. The shielded

vacuum chamber walls normally provide adequate protection for the operator.

If a system does not have a vacuum, a radiation enclosure must be provided to assure the safety of the operator and others in the work area. Instead of lead, thick walls of high-density concrete or other similar material may be used, especially for large radiation enclosures on non-vacuum installations. Special safety precautions should also be implemented to prevent personnel from accidentally entering or becoming trapped inside the enclosure during equipment operation.

A complete x-ray radiation survey of the electron beam equipment should always be made at the time of installation and at regular intervals thereafter. This survey must be conducted by qualified technicians to ensure initial and continued compliance with all radiation regulations and standards applicable to the site where the equipment is installed. The results should be documented and posted (Ref 1).

Fumes and Gases. Nonvacuum and medium-vacuum electron beam systems can produce ozone and oxides of nitrogen in harmful concentrations as well as other types of airborne contaminants in concentrations above acceptable levels. Therefore, adequate area ventilation must reduce the concentrations of airborne contaminants around the equipment to within permissible exposure limits. Proper exhausting techniques should also be employed to maintain permissible residual concentrations in the area.

High-vacuum electron beam chambers are unlikely to produce ozone and oxides in harmful concentrations because of the small amount of air in the chamber.

Personnel must consult the pertinent MSDSs before welding unfamiliar material or using unfamiliar cleaning products (Ref 1).

Visible Radiation. Because the electron beam welding process produces visible, UV, and infrared (IR) radiation, direct viewing of the process can be hazardous to the eyesight. Therefore, adequate optical protection must be provided against UV and IR radiation by the installation of leaded glass in the viewing ports. In addition, visible light must be reduced to a comfortable level by means of the appropriate filters (Ref 1).

Laser Beam Welding and Cutting

The basic hazards associated with laser operation are eye damage, including burns of the cornea or retina, or both; skin burns; electrical shock; respiratory system damage from hazardous materials emitted during operation; and chemical hazards, including contact with cryogenic coolants.

Laser manufacturers are required to qualify their equipment with the U.S. Bureau of Radiological Health. Electrical components must comply with the standards issued by the National Electrical Manufacturers Association.

The use of lasers is governed by OSHA requirements. In all cases, the “American National Standard for Safe Use of Lasers,” ANSI Z136.1, should be adhered to (Ref 53). In addition, a laser safety officer (LSO)—responsible for the protection of personnel and the enforcement of laser safety regulations—must be present at all installations performing laser welding and cutting (Ref 2).

Eye and Skin Hazards. Laser beams can readily inflict eye injury. With laser beams operating at visible or near-infrared wavelengths, even a 5 mW beam can inflict retinal damage. Thus, the use of safety glasses is essential. Glasses appropriate to the specific laser system must be used. Safety glasses substantially transparent to visible light but opaque to specific laser beam outputs are available. Selective filters for ruby, neodymium: yttrium-aluminum-garnet (Nd:YAG), and other laser systems are also available. Ordinarily, transparent materials such as glass are opaque to longer infrared wavelengths, such as those produced by carbon dioxide lasers, so clear safety glasses with side shields may be used with these systems. In this case, the only light reaching the eye is from the incandescence of the workpiece. Nevertheless, plasma generation at high powers can cause extreme brilliance, so filter lenses should be used for viewing the operation.

According to the specifications of ANSI Z136.1 (352), laser protective eyewear—whether plain or prescription—must be labeled with the optical density and the wavelengths for which protection is provided. This standard also requires that protection be afforded against secondary radiation. Protection against UV light, which may leak into the work area, should also be provided by the eyewear (Ref 2).

To prevent skin burns, welding personnel must always avoid all contact with laser beams. The burns these produce can be deep and very slow to heal. All laser beams used for welding and cutting are visible only when they impinge on a solid, so workers must take special precautions to avoid accidental exposure. As a preventive measure, the laser beams can be enclosed, or a safety device can be used to prevent operation of the beam unless its path is unobstructed.

Electrical Hazards. Because lasers have high voltages and large capacitor storage devices, the possibility of lethal electric shock is always present during laser beam welding. Hazards range from those inherent in any conventional electrical power source to those common to lasers in general and those unique to the particular laser beam welding and cutting process. As a general precaution, electrical system enclosures should have appropriate interlocks on all access doors and provisions for discharging capacitor banks before entry. All laser equipment should also be appropriately grounded. The manufacturer’s recommended safety procedures must be followed at all times.

Respiratory Hazards. Although the fumes and gases produced during laser beam welding

and cutting are often not visible, they pose potentially serious respiratory hazards. Hazardous products may be generated from the interaction of the beam and the workpiece, making adequate ventilation and exhaust provisions for laser work areas necessary. For example, the plastic materials used for “burn patterns” to identify beam shape and distribution in high-power carbon dioxide laser systems can generate highly toxic vapors if irradiated in an oxygen-lean atmosphere. In deep-penetration welding, fine metal fume can arise from the joint. In addition, intense plasma generation can produce ozone.

The LSO must ensure that all laser-generated air contaminants are characterized in accordance with applicable regulations. When exposure exceeds acceptable levels as established by Title 29 CFR 1910, Subpart Z and the applicable ACGIH standards, the LSO may require the implementation of control measures such as exhaust ventilation systems, respiratory protection, or process isolation (Ref 53).

Chemical Hazards. Many hazardous chemicals and gases are used in laser welding and cutting operations. These include toxic or corrosive gases such as chlorine, fluorine, hydrogen chloride, and hydrogen fluoride. Cryogenic gases can cause injuries due to freezing because of their extremely low temperatures. Safety hazards are also associated with the use of laser dye compounds. Manufacturers’ MSDSs should always be consulted, and appropriate measures must be taken to ensure personnel safety in all cases.

Friction Welding

The risks posed by friction welding include mechanical hazards, heat, and spatter. To minimize the risk of injury, friction welding machines should be equipped with appropriate mechanical guards and shields. They should also have two-hand operating switches and electrical interlocks to prevent machine operation when the operator or others have access to the work area, rotating drive, or force system.

Friction welding machines are similar to machine tool lathes in that one workpiece is rotated by a drive system, and to hydraulic presses in that one workpiece is forced against the other. Thus, operating personnel should wear the eye protection and safety apparel that is commonly used for machine tool operations. Also, the applicable OSHA standards should be strictly observed.

Explosion Welding

Explosives and explosion devices are an integral part of explosion welding. If these devices are misused, they can cause injury, death, property damage, and destruction. Although these materials are inherently hazardous, safe practices can minimize the risks associated with

their handling. For this reason, explosive materials must be used only by trained personnel who are experienced in their safe handling.

Handling and safety procedures must comply with all applicable federal, state, and local regulations. The U.S. Bureau of Alcohol, Tobacco, and Firearms; the Hazardous Materials Regulation Board of the U.S. Department of Transportation; OSHA; and the Environmental Protection Agency have federal jurisdiction on the sale, transport, storage, and use of explosives. Many state and local governments require a blasting license or permit, and some cities have special requirements for explosives.

Other organizations also provide safety education for the handling of explosives. The Institute of Makers of Explosives distributes educational publications to promote the safe handling, storage, and use of explosives. The NFPA also provides recommendations for the safe manufacture, storage, handling, and use of explosives (Ref 54).

Ultrasonic Welding

Ultrasonic welding may pose the risk of mechanical hazards, electric shock, heat, and burns. In high-power ultrasonic equipment, high voltages are present in the frequency converter, the welding head, and the coaxial cable connecting these components. Thus, the equipment should not be operated when its panel doors are open or its housing covers are removed. Door interlocks are normally installed to prevent the introduction of power to the equipment when its high-voltage circuitry is exposed. Because the cables are fully shielded, they should present no hazard if properly connected and maintained.

Because of the hazards associated with clamping force, operators must not place hands or arms in the vicinity of the welding tip when the equipment is energized. In accordance with OSHA regulations, the equipment must have two palm buttons for manual operation. These must be pressed simultaneously to initiate a weld cycle, and both must be released before the next cycle can begin. For automated systems in which the weld cycle is sequenced with other operations, protective guards should be installed to protect operators. As a further precaution, the welding stroke can be set to the minimum that is compatible with workpiece clearance.

Thermite Welding

Thermite welding is a process that uses the thermochemical reaction between metal oxide and aluminum to produce the heat to form a weld. Moisture in the thermite mix, whether in storage, in the crucible, or on the workpieces, can rapidly emit steam during the chemical reaction for thermite welding. This may cause the ejection of molten metal from the crucible. To minimize the risk of steam formation, the

thermite mix should be stored in a dry place, the crucible should be dry, and moisture should not be permitted to enter the system prior to or during welding.

The preheating required for the thermite process should be carried out using the safety precautions applicable to oxyfuel gas equipment and operations. The work area should be free of materials that may be ignited by sparks or small particles of molten metal. The area should also be well ventilated to prevent the buildup of fumes and gases from the thermite reaction. Starting powders and rods should be protected against accidental ignition.

Personnel should use appropriate PPE to shield against hot particles or sparks. Full-face shields with filter lenses for eye protection, headgear, gloves, and safety boots should be used. Clothing should not have pockets or cuffs that may catch hot particles.

Brazing and Soldering

The hazards encountered in brazing and soldering operations are similar to those associated with the welding and cutting processes (Ref 55). Personnel and property must be protected against gases, fumes, hot materials, electrical shock, radiation, and chemicals (Ref 56, 57). Because hazardous materials may be present in the fluxes, filler metals, coatings, and atmospheres used in brazing, the MSDSs should be consulted as a prerequisite to any job.

Hazardous and Explosive Gases and Fumes. Brazing and soldering operations may be performed at temperatures that induce some elements in the filler metal to vaporize into fumes and gases. Some of these elements are hazardous. These include cadmium, beryllium, zinc, mercury, and lead. Thus, it is essential that adequate ventilation be provided to protect personnel from inhaling the gases and fumes emitted during brazing or soldering. Brazing fluxes may also contain chemical compounds of fluorine, chlorine, and boron. These compounds are harmful if they are inhaled or come into contact with the eyes or skin. Ventilation methods used to avoid these hazards were described earlier (see the section "Ventilation" in this article).

Flammable gases, such as combusted fuel gas, hydrogen, and disassociated ammonia, are sometimes used as atmospheres for furnace brazing operations. Before introducing such atmospheres, the furnace or retort must be purged of air by safe procedures recommended by the furnace manufacturer. These gases may emanate from furnace purging and brazing operations. Thus, adequate area ventilation must exhaust and discharge explosive or hazardous gases to a safe location. Local environmental regulations should be consulted when designing the exhaust system.

In dip brazing and soldering, the parts to be immersed in the bath must be completely dry. Any moisture on the parts instantly creates

steam. The expanding steam may then cause an explosion, expelling the contents of the dip pot and creating a serious burn hazard. If supplementary flux is necessary, it must be adequately dried to remove all moisture and water of hydration to prevent the hazard of explosion.

Solder Flux. Some fluxes, such as rosin, petrolatum, and reaction types, emit considerable smoke, the amount depending on the soldering temperature and the duration of heating. Other fluxes emit fumes that are hazardous if inhaled in large quantities. The prolonged inhalation of halides and some of the newer organic fluxes must be avoided. Aniline fluxes and some of the other amines also emit harmful fumes that can cause dermatitis. The fluorine in flux is also hazardous to health. It causes skin burns and can be fatal if ingested.

The ACGIH has established the safe TLV for the decomposition products of rosin-core solder at 0.1 mg/m³ aliphatic aldehydes, measured as formaldehyde. Suitable ventilation must be provided to meet this requirement. When ventilation is insufficient to reduce contaminants or the implementation of ventilation is not feasible, personnel must use the appropriate approved respiratory protective equipment.

Thermal Spraying

All thermal spraying processes involve the deposition of molten metallic or nonmetallic materials to coat an object. These processes use modifications of oxyfuel, arc, and plasma energy sources to create the high temperatures and projectile velocities required to perform spray operations. These operations present safety hazards to all individuals in the work area. Thus, the safe practices described previously for these processes should be implemented when conducting thermal spraying activities with similar equipment. However, thermal spraying generates dust and fumes to a greater degree. Additional information may be found in Ref 58.

Those involved with and in the proximity of thermal spraying operations must take precautions against dust, fire, electrical shock, arc radiation, fumes and gases, and noise. Thermal spray operators must be protected with the proper eye, respiratory, and bodily protection. Appropriate protective clothing required for a thermal spraying operation will vary with the

size, nature, and location of the work performed.

Dust. Finely divided airborne solids, especially metal dusts, must be treated as an explosive and inhalation hazard. Therefore, the dust produced during thermal spraying must be adequately vented out of spray booths. Instead of bag and filter collectors, a water-wash wet collector is recommended to collect spray dust. Good housekeeping in the work area prevents the accumulation of metal dusts, particularly on rafters, the tops of booths, and in floor cracks. Paper, wood, oily rags, and other combustibles that could cause a fire in the spraying area should be removed before the equipment is operated. Clothing should be fastened tightly around the wrists and ankles to keep dusts from contacting the skin. When personnel work in confined areas, they should wear flame-resistant clothing and gloves.

Electrical Shock. The high voltages used in the thermal spraying processes increase the hazard of electrical shock. Thus, general safety precautions for the avoidance of electric shock must be implemented to protect personnel.

Radiation. Because thermal spraying processes generate both UV and infrared radiation, helmets, hand shields, face shields, or eye protection must be used to protect the eyes, face, and neck at all times. Safety goggles must be worn to avoid eye damage and burns. Table 3 presents a guide for the selection of the proper filter shade number for viewing specific spraying operations.

The intense UV radiation of plasma and electric arc spraying can cause skin burns through normal clothing. Thus, the protection against radiation that is used during arc spraying is practically the same as that employed for arc welding at equivalent current levels.

Fumes and Gases. Most thermal spraying operations require operators to wear adequate respiratory protection. The nature, type, and magnitude of the fume and gas exposure determine which respiratory protective device should be used. All devices used must be approved by MSHA, NIOSH, or other recognized authority.

Noise. Thermal spraying operations generate noise in high decibel ranges. Consequently, noise control programs must be implemented in accordance with Title 29 CFR 1910.95. In addition, operators and others in the area should

Table 3 Recommended eye filter plates for thermal spraying operations

Operation	Filter shade numbers
Wire flame spraying (except molybdenum)	5
Wire flame spraying of molybdenum	5-6
Flame spraying of metal powder	5-6
Flame spraying of exothermics or ceramics	5-8
Plasma and arc spraying	9-12
Fusing operations	5-6

Note: When cadmium is a constituent in a filler metal, a precautionary label must be affixed to the container or coil. Refer to Section 9 of Ref 1.

wear earmuffs or properly fitted soft rubber earplugs.

Adhesive Bonding

Because corrosive materials, flammable liquids, and hazardous substances are commonly used in adhesive bonding, adequate safety precautions must be observed in compliance with all federal, state, and local regulations, including "Air Contaminants," Title 29 CRF 1900.1000.

Safety Facilities. Management must properly supervise manufacturing operations to ensure that proper safety procedures, protective devices, and protective clothing are employed. Areas in which adhesives are handled should be separated from those in which other operations are performed. In addition to being equipped with the proper fire protection equipment, these areas should have ventilating facilities, a first-aid kit, a sink with running water, and an eye shower or rinse fountain. To ensure proper ventilation, ovens, presses, and other curing equipment should be individually vented to remove fumes. Vent hoods should be provided at mixing and application stations.

All personnel should also practice good personal hygiene. They should be instructed in the proper procedures to prevent skin contact with solvents, curing agents, and uncured base adhesives. Showers, wash bowls, mild soaps, clean towels, refatting creams, and protective equipment should be available. Curing agents on hands should be cleaned off with soap and water. Resins should be removed with soap and water, alcohol, or a suitable solvent. Solvents should be used sparingly; following use, they should be washed off with abundant soap and water. If an allergic reaction or burning occurs, prompt medical attention should be sought.

Personal Protective Equipment. While working with potentially hazardous adhesives, personnel must wear plastic or rubber gloves at all times. Contaminated gloves should never touch objects that others may touch with their bare hands. Instead, these gloves should be discarded or cleaned using procedures that remove the particular adhesive. Cleaning may require solvents, soap and water, or both. The hands, arms, face, and neck should be coated with a commercial barrier ointment or cream, which provides short-term protection and makes adhesives easier to wash off the skin.

Full-face shields should be worn for eye protection whenever the possibility of splashing exists. Otherwise, glasses or goggles should be worn. In case of irritation, the eyes should be flushed immediately with water and then promptly treated by a physician.

Protective clothing should be worn at all times by those who work with adhesives. Shop coats, aprons, or coveralls may be suitable, and they should be cleaned before reuse.

Flammable and Hazardous Materials. To prevent fires during the storage and use of flammable materials such as solvents, these hazardous materials must be stored in tightly sealed drums and issued in suitably labeled safety cans. Solvents and flammable liquids must not be used in poorly ventilated confined areas. When solvents are used in trays, safety lids should be provided. Flames, sparks, or spark-producing equipment must not be permitted in the area where flammable materials are being handled. In addition, fire extinguishers should be readily available.

Factors to be considered in identifying the types of precautionary measures that should be implemented while working with hazardous materials include the frequency and duration of exposure, the degree of hazard associated with a specific adhesive, the solvent or curing agent used, the temperature at which the operations are performed, and the potential evaporation surface area exposed at the workstation.

For most personnel, preventing skin contact with an adhesive should be an adequate safety measure. It is mandatory that protective equipment, barrier creams, or both be used to avoid skin contact with certain types of formulations. However, others may suffer severe allergic reactions produced by direct contact with or the inhalation or ingestion of phenolics, epoxies, and most catalysts and accelerators. The eyes or skin may become sensitized over a long period of time even though no signs of irritation are visible. Once personnel become sensitized to a particular adhesive, they may no longer be able to work in its vicinity because of allergic reactions.

Proper safety rules must be observed to prevent the careless handling of adhesives and thereby prevent exposure to hazardous materials. For example, personnel performing adhesive bonding with potentially hazardous materials should avoid contact tools, door-knobs, light switches, or other objects that may become contaminated.

Safety in Robotic Operations

The hazards associated with robotic welding, cutting, and allied process are those generally related to equipment (e.g., faulty power sources, protective devices, control circuits, and so on), installations (human errors during setup, ergonomics, maintenance, mounting, positioning, loose objects, and so forth), and the robot system itself or its interaction with other equipment and persons (e.g., moving components that cause trapping or crushing, hazardous atmospheres, inadvertent operation, and so forth) (Ref 59).

Personnel must be safeguarded against hazards during all stages of robotic system implementation—design and development, installation and integration, verification, operation, and maintenance. Safeguarding is the

responsibility of those involved in all of these stages. In addition, the user must ensure that all personnel are trained in robotic system operation and that the appropriate safeguarding devices are installed and functioning. Awareness signals (signs, lights, floor markers, horns, and beepers, for example) and barriers should be used in conjunction with safeguarding devices (Ref 59).

The welding process equipment may have specific additional safety requirements regarding barriers, guarding, and precautionary labels. The safety requirements of the welding process that is performed by the robotic system must be implemented. In addition, the testing and startup of robots and robotic systems must be performed according to the specifications of "American National Standard for Industrial Robots and Robot Systems—Safety Requirements," ANSI/RIA R15.06-1999 (Ref 59).

Inasmuch as robotic installations vary significantly from application to application, they must be scrutinized individually for specific safety hazards. During the design stage and again upon completing the final configuration and setup of an installation, the user or integrator must perform a risk assessment of the installation. This assessment involves a task and hazard identification as well as a risk estimation. The selection of the appropriate safeguards is based on the information collected and documented as part of the risk assessment (Ref 59).

Among the safeguarding devices that may be used to protect personnel are barriers; two-hand controls; and presence-sensing devices, including area scanning systems, single and multiple safety beams, safety mats, and safety light curtains or screens (Ref 59). Figure 8 shows several typical robotic installations.

With respect to personnel training, the user must ensure that individuals who program, teach, operate, or maintain robots are properly trained in the tasks performed by the robot, the hazards presented by the system, health and safety procedures, and the purpose and function of safeguarding devices. Training must include general and emergency workplace safety procedures, industry codes and standards, vendor safety information, and lockout and tag-out procedures. Maintenance personnel must be trained in emergency operations as well as in the hazards related to process variables and materials, preventive maintenance, troubleshooting, faulty safety devices, and communication systems. Retraining is required to ensure safe operation following personnel or system changes or an accident (Ref 59).

For detailed information regarding the safety regulations governing robotic operations, the reader is encouraged to consult the "American National Standard for Industrial Robots and Robot Systems—Safety Requirements," ANSI/RIA R15.06-1999, the primary industry standard (Ref 59).

Table 2 Summary of shielding gases and mixtures and their use

Shielding gas	Gas reaction	GMAW and FCAW(a)	GTAW and PAW(b)
Pure gases			
Argon (Ar)	Inert	Nonferrous	All metals
Helium (He)	Inert	Nonferrous	Al, Mg, Cu, and alloys
Carbon dioxide (CO ₂)	Oxidizing	Mild and low-alloy steels, some stainless steels	Not used
Two-component mixtures			
Argon mixtures			
Ar + 20–50% He	Inert	Al, Mg, Cu, and alloys	Al, Mg, Cu, and alloys
Ar + 1–2% CO ₂	Oxidizing	Stainless and low-alloy steels	Not used
Ar + 3–5% CO ₂	Oxidizing	Mild, low-alloy, and stainless steels	Not used
Ar + 20–30% CO ₂	Slightly oxidized	Mild and low-alloy steels, some stainless steels	Not used
Ar + 2–4% He	Reducing	Not used	Nickel and alloy and austenitic stainless steels
Helium mixtures			
He + 25% Ar	Inert	Al and alloys, Cu and alloys	Al and alloys, Cu and alloys
CO ₂ mixtures			
CO ₂ + up to 20% O ₂	Oxidizing	Mild and low-alloy steels	Not used
CO ₂ + 3–10% O ₂	Oxidizing	Mild and low-alloy steels	Not used
Three-component mixtures			
Helium mixtures			
He + 75% Ar + 25% CO ₂	Inert	Stainless steel and low-alloy steels	Not used
Argon mixtures			
CO ₂ + 3–10% O ₂ + 15% CO ₂	Oxidizing	Mild steels	Not used

Summary of Fusion Welding Processes

Table 1 Fusion welding and cutting processes

Process	Heat source	Power source and polarity	Mechanics	Shielding or cutting agent	Typical applications		Industrial use
					Metals	Thickness range	
Electroslag welding	Resistance heating of liquid slag	Alternating or direct current	Automatic; joint set up vertically; weld pool and slag contained by water-cooled shoes; filler wire fed into slag pool and melted by resistance heating; no arc	Slag	Carbon, low-alloy and high-alloy steel	50 mm (2.0 in.) and upward	Welding thick sections for press frames, pressure vessels, shafts, etc.; foundry and steelworks applications; general engineering
Submerged arc welding	Arc	Alternating or direct current	Automatic or semi-automatic; arc maintained in cavity of molten flux formed from granular material	Slag and self-generated gas	Carbon, low-alloy, and high-alloy steels; copper alloys	1 mm (0.04 in.) and upward (but generally over 10 mm, or 0.4 in.)	Downhand or horizontal vertical joints suitable for automatic welding; boilers, pressure vessels, structural steel; horizontal joints in storage tanks
Manual metal arc welding (coated electrodes)	Arc	Alternating or direct current; electrode positive or negative	Short lengths of wire coated with flux; manual operation	Slag and self-generated gas	All engineering metals and alloys except pure Cu, precious metals, low-melting and reactive metals	1 mm (0.04 in.) and upward	All fields of engineering
Gas metal arc welding (flux cored wire)	Arc	Direct current; electrode positive	Flux is enclosed in tubular electrode of small diameter; automatic or semi-automatic; wire fed continuously through a gun with or without a gas shield	Slag and gas, either self-generated or from external source (normally CO ₂)	Carbon steel	1 mm (0.04 in.) and upward	Sheet metal welding; general engineering
Gas metal arc welding (solid wire)	Arc	Direct current; electrode positive	As above but using solid wire; free-flight metal transfer	Argon or helium, argon-O ₂ or argon-CO ₂	Nonferrous metal; carbon, low-alloy or high-alloy steel	2 mm (0.08 in.) and upward	Welding of high-alloy and nonferrous metals; pipe welding; general engineering
	Arc	Direct current; electrode positive	As above but in short-circuiting metal-transfer mode	Argon-O ₂ , argon-CO ₂ , or CO ₂	Carbon and low-alloy steel	1 mm (0.04 in.) and upward	Sheet metal; root pass in pipe welding; positional welding
	Pulsed arc	Direct current; electrode positive; 50–100 Hz pulse superposed on low background current	Pulse detaches drop at electrode tip and permits free-flight transfer at low current	Argon, argon-O ₂ , or argon-CO ₂	Nonferrous metals; carbon, low-alloy, and high-alloy steels	1 mm (0.04 in.) and upward	Positional welding of relatively thin carbon or alloy steel
Gas welding	Oxyacetylene flame	...	Manual; metal melted by flame and filler wire fed in separately	Gas (CO, H ₂ , CO ₂ , H ₂ O)	Carbon steel, copper, aluminum, zinc, and lead; bronze welding	Sheet metal and pipe up to approx. 6 mm (0.24 in.)	Sheet metal welding, small-diameter pipe
Gas cutting	Oxyacetylene/oxygen flame	...	Oxygen jet injected through flame oxidizes and ejects metal along the cutting line	Oxygen	Carbon and low-alloy steel	...	Cutting and bevelling plate for welding; general engineering applications
Gas tungsten arc welding	Arc	Alternating current with stabilization for aluminum, magnesium, and alloys; direct current; electrode negative for other metals	Manual or automatic arc maintained between nonconsumable tungsten electrode and work; filler wire fed in separately	Argon, helium, or argon-helium mixtures	All engineering metals except Zn and Be and their alloys	1 to approx. 6 mm (0.04 to 0.24 in.)	Nonferrous and alloy steel welding in all engineering fields; root pass in pipe welds
Pulsed gas tungsten arc welding	Arc	Direct current; electrode negative with low-frequency	Low-frequency pulse allows better control over weld pool behavior; high-frequency pulse improves arc stiffness	Argon	As above	1 to approx. 6 mm (0.04 to 0.24 in.)	Automatic gas temperature welding of tubes or tubes to tubesheets to improve consistency of penetration or

(continued)

Table 1 (continued)

Process	Heat source	Power source and polarity	Mechanics	Shielding or cutting agent	Typical applications		Industrial use
					Metals	Thickness range	
		(1 Hz) or high-frequency (1 kHz) current modulation					(high frequency) prevent arc wander
Plasma welding	Arc	Direct current; electrode negative	As for gas tungsten arc, except that arc forms in a chamber from which plasma is ejected through a nozzle; improved stiffness and less power variation than gas tungsten arc welding	Argon, helium, or argon-hydrogen mixtures	As above	Usually up to approx. 1.5 mm (0.6 in.)	Normally low-current application where gas tungsten arc lacks stiffness; also used at higher currents in keyholing mode for root runs
Plasma cutting	Arc	Direct current; electrode negative	As for welding but higher current and gas flow rates	Argon-H ₂	All engineering metals	1 mm (0.04 in.) and upward	Used particularly for stainless and nonferrous metal but also carbon and low-alloy steel
Stud welding	Arc	Direct current; electrode negative for steel, positive for nonferrous	Semiautomatic or automatic; arc drawn between tip of stud and work until melting occurs and stud then pressed onto surface; weld cycle controlled by timer	Self-generated gas plus ceramic ferrule around weld zone	Carbon, low-alloy, and high-alloy steel; aluminum; nickel and copper alloys require individual study	Stud diameters up to approx. 25 mm (1.0 in.)	Shipbuilding, railway, and automotive industries; pressure vessels (for attaching insulation); furnace tubes and general engineering
Spot, seam, and projection welding	Resistance heating at interface of lapped joint	Alternating current; transformer with low-voltage, high-current output	Lapped sheet clamped between two copper electrodes and welded by means of high-current pulses; weld may be continuous (seam) or intermittent (spot and projection)	Self-shielded plus water for resistance welding Mo, Ta, and W	All engineering metals except Cu and Ag; Al requires special treatment	Sheet metal up to approx. 6 mm (0.24 in.)	Automobile and aircraft industries; sheet metal fabrication in general engineering
Electron beam welding	Electron beam	Direct current; 10–200 kV; power generally in range 0.5–10 kW; workpiece positive	Automatic welding carried out in vacuum; beam of electrons emitted by cathode focused on joint; no metal transfer	Vacuum (~10 ⁻⁴ mm Hg)	All metals except where excessive gas evolution and/or vaporization occurs	Up to approx. 25 mm (1.0 in.) normally but may go to 100 mm (4.0 in.)	Nuclear and aerospace industries; welding and repair of machinery components such as gears
Laser welding	Light beam	None	As for electron beam except different energy source	Helium	As for electron beam	Up to 10 mm (0.4 in.)	Potentially as for electron beam; cutting nonmetallic materials
Thermit welding	Chemical reaction	None	A mixture of metal oxide and aluminum is ignited, forming a pool of superheated liquid metal, which then flows into and fuses with the joint faces.	None	Steel, austenitic CrNi steel, copper, copper alloys, steel-copper joints	Normally up to 100 mm (4.0 in.)	Welding rails and copper conductors to each other and to steel

Table 3 Process selection guide for arc welding carbon steels

Usability	Cost factors	Weld-metal quality	Effect on base metal	General comments
Shielded metal arc welding (SMAW):				
Very adaptable, all-position process. Can be used outdoors. Gives excellent joint accessibility. Very portable. Can be used on carbon steels down to 18 gage. Joint preparation is required on thicknesses over 3.2 mm (1/8 in.). Unlimited upper thickness, but other processes (GMAW, FCAW, or SAW) are usually more economical.	A low-deposition-rate process (up to 9 kg/h, or 20 lb/h) with low deposit efficiency (typically 65%). Low operator factor. Equipment cost is low and spare parts are minimal. Welding speeds are generally low. Housekeeping is required to deslag and dispose of flux and electrode stubs.	Strongly dependent on the skill of the welder. Lack of fusion or slag inclusions are potential problems. The relatively small beads usually result in a high percentage of refining in multipass welds, and very good toughness is achievable with some electrodes.	Low heat inputs can cause rapid heat-affected zone (HAZ) cooling. Flux coatings are a potential source of hydrogen.	Very versatile, low-cost process. Especially strong on nonroutine or repair jobs. Usually not economical on standard thick welds or on repetitive jobs that can be mechanized
Gas metal arc welding (GMAW):				
An all-position process in the short-arc or pulsed mode. Moderately adaptable, but use limited outside where loss of shielding is possible. Usable on steel down to <0.25 mm (0.010 in.) thick. Above 4.8 mm (3/16 in.), requires joint preparation. No upper limit of plate thickness	Deposition rates (to 16 kg/h, or 35 lb/h) are higher than SMAW. Deposition efficiency (90–95%) and operator factor (typical 50%) are also higher. Equipment and spare parts cost are moderate to high (pulsed-arc power supplies are higher cost). Welding speeds are moderate to high (buried-arc CO ₂ can weld at over 2540 mm/min, or (100 in./min). Cleanup is minimal.	Very good quality. Porosity or lack of fusion can be a problem. Less tolerant of rust and millscale than flux-using processes. Very good toughness is achievable.	Generally a low-hydrogen process	Relatively versatile. Equipment more costly, complex, and less portable than SMAW. Easily mechanized. A clean process with higher deposition rates and efficiencies than SMAW
Flux cored arc welding (FCAW):				
All-position process. Equipment similar to GMAW, but self-shielded version has better portability and is usable outdoors. Minimum plate thickness is 18 gage. Self-shielded material above 6.4 mm (1/4 in.) requires joint preparation. With CO ₂ shielding, materials above 13 mm (1/2 in.) require joint preparation. There is no upper limit on plate thickness.	Deposition rates (up to 18 kg/h, or 40 lb/h) are higher than GMAW. Deposition efficiencies (80–90%) are lower, but operator factors (50%) are similar to GMAW. Equipment cost is moderate. Good out-of-position deposition rates can be achieved with conventional power sources. Welding speeds are moderate to high. Slag and spatter removal and disposal is required.	Good quality. Weld metal toughness is fair to good (best with basic electrodes). Slag inclusions are a potential problem.	Flux core can contribute hydrogen.	Relatively versatile (self-shielded version can be used outside). Higher deposition rates than GMAW (higher fumes also). Welds easily out-of-position. Readily mechanized
Gas tungsten arc welding (GTAW)/plasma arc welding (PAW):				
An all-position process with fair joint accessibility. Limited outdoor use. Can weld very thin material in all positions; GTAW—<0.13 mm (0.005 in.) min thickness, joint prep. over 3.2 mm (1/8 in.), PAW—<0.13 mm (0.005 in.) min thickness, joint prep. over 6.4 mm (1/4 in.). No upper limit on thickness but other processes are more efficient	Low deposition rates (up to 5.4 kg/h, or 12 lb/h) but high deposition efficiency (99%). If automated, the operator factor is high. Equipment and spare parts cost is moderate to high, depending on complexity (PAW is slightly more expensive). Cleanup is generally unnecessary due to no flux or spatter.	High quality but requires clean plate. Excellent toughness possible due to small bead size (high refined weld metal, finer grain size)	A low-hydrogen process. Low heat inputs can cause rapid HAZ cooling.	Extremely good welds in all positions. Requires more preparation. Low deposition rates limit process to thinner plates.
Submerged-arc welding (SAW):				
Limited to flat and horizontal position. Semiautomatic version has some adaptability, but process is most often mechanized and has limited portability. Minimum material thickness is 1.6 mm (1/16 in.) (mechanized). Joint preparation is required on material above 13 mm (1/2 in.) thick. The process lends itself to welding thick materials.	Deposition rates are very high (over 45 kg/h, or 100 lb/h, with multiwire systems). Deposition efficiency is 99%, but that does not include the flux (a 1:1 flux-to-wire ratio is common). Because the process is usually mechanized, operator factors are high. Cost is moderate for single-wire systems. High welding speeds are achievable. Higher housekeeping costs result from the need to handle the slag and unfused flux.	Very good. Good weld-metal toughness is possible. Handles rust and millscale well with proper flux selection. High-dilution process	Higher heat inputs can result in large HAZ and possible deterioration of baseplate properties (especially quenched and tempered plate). Flux is a source of hydrogen.	A high-deposition, high-penetration process, but thin material can be welded at high speeds. Easily mechanized. Natural for welding thicker plates. Housekeeping and position limitation can be a problem.

(continued)

Table 3 (continued)

Usability	Cost factors	Weld-metal quality	Effect on base metal	General comments
Electrogas welding (EGW)/electroslag welding (ESW):				
Limited to vertical or near-vertical. O.K. outside. Fair portability. Used on plate 9.5 to 102 mm (¾ to 4 in. thick).	High joint-completion rate. High deposition efficiency (solid wires 99%, cored wires lower). High operator factor. High equipment and set-up costs	Large columnar grain structure results in only fair toughness. High dilution of baseplate (up to 35% for EGW, up to 50% for ESW)	High heat input results in large HAZ and grain growth. Not recommended for quenched and tempered steels unless reheat treatment is to be done. Slow weld cooling allows hydrogen to escape weld area.	High joint-completion rate but limited to vertical. Used mainly on long, vertical welds. High heat input can limit baseplates.
Stud arc welding:				
All-position. O.K. outside. Fair portability. Used on plate 1.0 mm (0.04 in.) and above. No joint preparation required	Equipment cost is moderate.	Minimal weld size. Usually fine-grained due to fast cooling. Weld structure is as-cast.	Causes rapid cooling of HAZ	Specialized process for attaching studs to steel plate. Usually more economical than drilling and tapping

Weldability of Ferrous and Nonferrous Alloys

WELDABILITY refers to the ease of welding a material under the imposed fabrication conditions to perform satisfactorily during service. All metals can be welded to themselves by at least one of the fusion welding processes.

A fusion weld cannot be made between dissimilar metals unless they have metallurgical solubility; otherwise, brittle compounds may form. Solid-state welding processes, which do not involve melting and solidification, are suited

to welding dissimilar metals or joining heat-sensitive alloys such as precipitation-hardening aluminum alloys. Tables 1 to 4 summarize the general weldability of ferrous and nonferrous alloys by common fusion welding processes.

Table 1 General weldability of specific metals and alloys by arc welding processes

Base metals welded	Welding processes

Metal or process rating: A, recommended or easily weldable; B, acceptable but not best selection or weldable with precautions; C, possibly usable but not popular or restricted use or difficult to weld; No, not recommended or not weldable. Source: Ref 1

Table 2 Weldability of cast irons

Weld processes(a)		Procedure	Remarks
Gray cast iron	MMA, MIG, TIG, oxyacetylene. Filler rods 3.5C-3Si-0.6P	Ferritic gray irons are readily welded, but complex irons are difficult to weld. Increasing silicon above 2% also decreases weld-ability. Preheat to 400–600 °C (750–1110 °F) or to 1000 °C (1830 °F) with 60/40 brass filler (bronze welding). Preheat to avoid hard, brittle deposit. Difficult to machine unless preheated. Prone to cracking—cool slowly and/or stress relieve at 600 °C (1110 °F) when hot. Can alsopeen when red hot	Complications in weld-metal and heat-affected zones. Massive free carbide and martensite in weld deposit. Welding used in repair of castings and production of welded assemblies. Filler materials are cast iron, low-carbon steel, nickel-base alloys, copper-base alloys
Ductile irons	Most fusion processes	Welding should be done on fully annealed material. Composition affects weld quality. For MIG, a 60Ni-4Fe filler is best. Preheat to 250 °C (480 °F). Interpass 80–100 °C (175–212 °F).	(b)
Malleable cast iron (ferritic and pearlitic)	Use low-hydrogen rods. Can be successfully brazed or soldered	Preheat or other procedures to minimize heat buildup. Heat concentration should be held to a minimum. Very important to clean before welding to avoid porosity and low joint strength	(b) Welding not recommended
Chilled and white cast irons			
Corrosion-resistant cast irons (high Si, high Cr, high Ni) and heat-resistant cast irons		Welding confined to minor repair of castings subject to availability of filler materials. For more extensive welding, properties of material should be determined.	(b)
Iron-nickel-chromium heat-resisting alloys (e.g., PH Incoloy, 800, 802, 901)	TIG most widely used, especially in thin sections. Also manual arc (<12 mm, or 0.5 in., thickness) is used. MIG is employed where TIG is not practical. Submerged arc is employed for thick sections, provided a suitable flux is available. Fillers are employed to produce weld metal of similar composition to the base metal.	Heat input kept low. Rapidly cool to maintain weld ductility. Precipitation-hardenable alloys containing Al, Ti, Ni are very difficult to weld. Can obtain high joint efficiency up to 2.5 mm (0.10 in.) thickness. Sensitive to cracking and require preweld and postweld heat treatment and selection of most suitable filler material. Solid-solution-strengthened alloys are more easily welded.	Usual range of temperature, 1200–1400 °C (2190–2550 °F). Limits the selection of filler materials and possible pre- and postweld treatment

(a) MMA, manual metal arc; MIG, metal inert gas; TIG, tungsten inert gas. (b) Cast irons are less weldable than carbon steel owing to higher carbon and silicon content leading to lower ductility. More metallurgical complications occur in weld metal and heat-affected zones. Massive free carbide and martensite occur in weld deposit. Filler materials are cast iron, low-carbon steel, nickel-base alloys, copper-base alloys. With MIG, base wire electrodes of low-carbon steel and nickel-base alloys are also used. Adapted from Ref 2

Table 3 Weldability of steels

Steel type	Preheat, °C (°F)	Interpass, °C (°F)	Hold cool, °C (°F)	Postweld, °C (°F)	Remarks
Mild steel	Excellent weldability—no precautions necessary with rutile and basic electrodes
Vanadium steel	Low-carbon-grade electrodes. Minimum heat input 30 kJ/mm (760 kJ/in.) for 30 mm (1.2 in.) thickness, unless preheating or low-hydrogen electrodes are employed
C-Mn steel (0.15–0.025 C)	100–200 (212–390)	For thick sections, low-hydrogen electrode, high heat input, and preheat. For thin sections, no preheat required
C-Mn steel (<0.2 C, <1.4 Mn)	100–250 (212–480)	For thick sections, low-hydrogen electrode, high heat input, preheat. For thin sections, no preheat required
Medium-carbon steel	250–350 (480–660)	High heat input. Low-hydrogen electrodes
High strength, low alloy, low carbon (HSLA)	250–300 (480–570)	High heat input. Low-hydrogen electrodes
Carbon-molybdenum	150–300 (300–570)	650–700 (1200–1290)	Filler as parent metal
Medium carbon and low alloy	200–350 (390–660)	200–350	...	550–600 (1020–1110)	Filler rod lower carbon than parent metal. Make test welds with highly hardenable low-alloy steels
Chromium-molybdenum steels	250–300 (420–570)	Normalize 870–980 (1600–1800) Temper 680–770 (1260–1420) Anneal 840–900 (1545–1650) Stress relieve 700–730 (1290–1350)	Filler as parent metal, but lower Cr. Postweld treatment depends on properties.
Cryogenic steels (9Ni, 5Ni)	Electrodes 50Ni-16Cr/Fe, electrodes 25Cr-20Ni Fe-25Cr-12Ni Fe. Preheat/postweld not required up to 50 mm (2.0 in.) thickness
Martensitic stainless steels (AISI 410, AISI 420)	250 (480) 250 (480)	250–350 (480–660) 250–350 (480–660)	80–100 (175–212) 150–180 (300–355)	700–750 (1290–1380) 700–750 (1290–1380)	No special precautions if C <0.1%. Austenitic fillers or fillers for matching strength. Require preheat to avoid H ₂ cracking. Tendency to harden when cooled from high temperatures
Martensitic stainless 440	Welding not recommended
Ferritic stainless steels	200 (390)	Anneal after welding 700–850 (1290–1560)	Limited transformation to martensite via austenite can occur. Grain growth. Two factors reduce

876 / Reference Information

Table 3 (continued)

Steel type	Preheat, °C (°F)	Interpass, °C (°F)	Hold cool, °C (°F)	Postweld, °C (°F)	Remarks
Precipitation-hardened stainless steel alloy W	ductility. Most weldable grades contain Al, Nb to retain ferrite Good weldability. If joint strength not required equal to parent metal, use 18Cr-8Ni-type filler. For precipitation-hardened joint, use similar composition and precipitate harden after welding.
Precipitation stainless steel types: 17-4 PH, 15-5 PH, 17-7 PH, 15-7 Mo	650–870 (1200–1600) then refrigerate or cold work	Good weldability. Weld in annealed condition. Filler depends on mechanical properties required. Can be precipitation-hardened stainless steel. Postweld treatment precipitates carbides and martensite.
Austenitic stainless steels (301, 302)	Arc welding not recommended. Flash welding possible
Austenitic stainless steel types: 303, 304 L, 304, 305, 309, 310, 314, 316, 321, 347	Not recommended	950–1150 (1740–2100) If undertaken—or stress relieve below 650 °C (1200 °F) (to avoid weld decay)	Excellent weldability. Filler materials of similar composition but higher alloy content. Weld cracking is avoided by ensuring that the weld contains 5–10% ferrite. Weld decay (chromium carbide precipitation) leads to loss of corrosion resistance. Minimized by C <0.03% or add Nb, Ti (stabilized steel) and pay regard to postweld heat treatment. Heat-affected zone liquation cracking: Low energy input. Fine grain size. Ferrite ≥5%
Maraging steels	Age after welding at 500 °C (930 °F)	Soft martensite matrix. No risk of decarburization, distortion, or cracking. Very poor weldability

Adapted from Ref 2

Table 4 Weldability of nonferrous metals

Material	Welding processes(a)	Preheat, °C (°F)	Postweld, °C (°F)	Remarks
Aluminum alloys				
Series 1000, pure Al	MIG, TIG, gas resistance, laser	Thick sections only	Most welds left in as-welded condition	Readily weldable, sheets and pressings
Series 2000, Al-Cu	Resistance	Thick sections only	As welded or(b)	Not normally fusion welded
Series 3000, Al-Mn	MIG, TIG, gas resistance, laser	Thick sections only	As welded	Readily weldable, building and transport applications
Series 4000, Al-Si	MIG, TIG, resistance, gas, laser	Thick sections only	As welded	Not normally welded
Series 5000, Al-Mg	MIG, TIG, resistance, gas, laser	Thick sections only	As welded	Readily weldable, high-strength welded applications
Series 6000, Al-Mg-Si	Resistance, MIG, TIG	Thick sections	As welded or reheated(b)	Widely welded but welds have low strength and care must be taken to avoid cracks
Series 7000, Al-Zn-Mg	Resistance, MIG, TIG	Thick sections	As welded or reheated(b)	Can be welded, structures with high mechanical strength through age hardening
Series 8000, Al-Li	MIG, TIG, laser, electron beam	Thick sections	As welded or reheated(b)	Can be welded, careful choice of filler wire to avoid cracking
Copper and copper alloys				
Tough pitch copper, deoxidized copper	MIG, TIG, electron beam, resistance, MIG, MMA	For arc welding, preheat thick sections up to 700 °C (1290 °F) and conserve heat with insulating blanket	...	Difficult to weld—high-temperature weakness, porosity, low weld ductility(c)
High-conductivity copper	MIG, TIG, electron beam, resistance, MIG, MMA	Same as tough pitch Cu	...	More suitable for welding, especially with copper fillers(c)
Brass (<20% Zn)	MIG, TIG	250–400 (480–750)	Stress relief	Good weldability
Brass (20% <Zn <40%)	Resistance	250–400 (480–750)	...	Excessive zinc or 2% Pb gives hot shortness (weld-metal cracking). Zinc causes porosity. Use oxidizing conditions
High-tensile brass (additions Pb-Fe + Al)	...	250–400 (480–750)	...	Susceptible to lead and sulfur embrittlement. Aluminum impedes coalescence of liquid metal
Phosphor bronze (Cu5–8%Sn)	TIG, resistance, MIG, electron beam	Heavy sections 175–290 °C (350–555 °F)	Peen at 480–500°C (895–930 °F) then rapid cool for maximum ductility	Relatively good weldability
Gunmetal (5–10%Sn,2–5%Zn)	TIG, resistance, MIG, electron beam	Same as phosphor bronze	Same as phosphor bronze	Hot cracks and porosity (avoid overheating or joint stressing). Greater than 2% Pb gives hot shortness
9% Sn	Resistance good, arc welding fair	Welding not recommended at or above 9% Sn
Silicon bronzes (Cu3%Si1%Mn)	TIG, MIG, resistance	Preheat 20–65 °C (70–150 °F)	...	Can be welded by arc, resistance methods. Avoid stressing joints. Filler as parent metal

(continued)

(a) MIG, metal inert gas; TIG, tungsten inert gas; MMA, manual metal arc (b) Heat treatable aluminum alloys may be re-heat treated after welding. (c) If metal of identical composition is not required, use fillers of silicon or phosphor bronze or brazing. (d) Strong reactivity of refractory metals requires thorough protection. Weld pool is prone to recrystallization and low ductility.

Table 4 (continued)

Material	Welding processes(a)	Preheat, °C (°F)	Postweld, °C (°F)	Remarks
Aluminum bronzes (Cu-5%Al, Cu-10% Al, 5%Fe, 5%Ni)	TIG, resistance, MIG, electron beam	20–150 (70–300)	...	Good weldability
Nickel silver (10–18%Ni, 25%Zn)	TIG, resistance	20–110 (70–230)	Not required	Good weldability
Cupronickel (Cu-10NiFe, Cu-30NiFe)	TIG, MIG, MMA	Not normally required	Not required	Readily weldable, argon gas
Copper beryllium (1.0–2.75% Be, 2.5–0.2% Ni)	Electron beam	Increasing beryllium decreases weldability. Poor heat conductors. Toxic fumes
Nickel alloys				
Commercial-purity nickel, nickel-copper (Monels), nickel-molybdenum-chromium (Hastelloys), nickel-chromium (Inconel 600, 625)	TIG, MIG, manual arc, electron beam	Not normally required	Necessary to avoid intergranular corrosion	Solution-hardened nickel alloys: low-ductility temperature range; avoid stressing welds. Particularly susceptible to hot shortness with Pb, S. Danger of oxide formation. Generally good weldability. Generally more viscous than steel except Hastelloys. This should be allowed for in joint designs.
Nickel-chromium-cobalt-aluminum-titanium (Nimonic)	TIG, MIG	Anneal in inert atmosphere before welding	Resolution treat and age after welding (some alloys can be solution treated before and aged after welding)	Precipitation-hardened alloys. Susceptible to heat-affected zone cracking
Titanium alloys				
Commercially pure grades and alpha alloys	TIG, MIG, electron beam, resistance pressure, flash butt	Weld in annealed condition	Stress relieve 400–650 °C (750–1200 °F)	Highly reactive, requires good shielding. No filler is used below 2.5 mm (0.10 in.) thickness. Otherwise parent metal or commercial-purity titanium is used.
Ti-6Al-4V	TIG, electron beam, resistance pressure, flash butt		2 h at 538 °C (1000 °F) Complete aging during stress relief	
Air-hardenable alloys (Ti-4Al-4Mo-0.5Si-2.4Sn, Ti-2.25Al-1.1Sn-Si, Ti-2.25Al-1.1Sn-5Zr-Si, Ti-6Al-5Zn-Mo-Si, Ti-6Al-6V-2Sn)				Air-hardenable alloys. Welding not recommended
Ti-13V-11Cr-3Al beta alloy	Electron beam, resistance pressure, flash butt		Cold work and fully reheat treat	Low-strength welds, ductile as welded
Other alloys				
Lead and zinc-lead alloys	Gas resistance, TIG			Equal to base metal in corrosion resistance and strength. Lead easy, Pb-Sb more difficult. Zinc difficult. Fillers of parent metal
Molybdenum and tungsten alloys	Electron beam, TIG	150 (300) for TIG-welded tungsten alloy		Brittle—avoid restraint on joints. 0.05% oxygen in argon arc. Grain growth occurs(d)
Niobium, tantalum, tantalum alloys with up to 15% Hf, Mo, W, Re	TIG, electron beam		Stress relieve 1 h at 816 °C (1500 °F)	Broadly similar to titanium. Can weld tantalum alloys to give very high room-temperature bend strength(d)
Zirconium	TIG	Weld in annealed condition	Stress relieve 400–650 °C (750–1200 °F)	Zirconium requires even better protection (chamber) than titanium(d)
Beryllium	Electron beam pressure welding, TIG			Brittle—avoid restraint on joints. 0.05% oxygen TIG. Grain growth occurs. Satisfactory joints obtainable
Magnesium	TIG, resistance	Heat thin sections to prevent cracking 260–380 °C (500–715 °F) depending on alloy recommendations	Stress relieve anneal wherever possible, particularly when likely to be exposed to wet or corrosive environments	Weldable but prone to stress corrosion in alloys containing aluminum. Ce, Th are used in MgZnZr alloy to improve weldability. Welding of alloys containing zinc only satisfactory with thorium or rare earth additions

(a) MIG, metal inert gas; TIG, tungsten inert gas; MMA, manual metal arc (b) Heat treatable aluminum alloys may be re-heat treated after welding. (c) If metal of identical composition is not required, use fillers of silicon or phosphor bronze or brazing. (d) Strong reactivity of refractory metals requires thorough protection. Weld pool is prone to recrystallization and low ductility.

AOD	argon-oxygen decarburization	<i>e</i>	natural log base, 2.71828; charge of an electron
API	American Petroleum Institute	EB	electron beam
Ar _{cm}	temperature at which cementite begins to precipitate from austenite on cooling	EBC	electron beam cutting
Ar ₁	temperature at which transformation to ferrite or to ferrite plus cementite is completed on cooling	EBW	electron beam welding
Ar ₃	temperature at which transformation of austenite to ferrite begins on cooling	EDM	electrical discharge machining
ASME	American Society of Mechanical Engineers	EDXA	energy-dispersive x-ray analysis
ASTM	American Society for Testing and Materials	EGW	electrode gas welding
at.%	atomic percent	ELI	extra-low interstitial
atm	atmospheres (pressure)	emf	electromotive force
AWS	American Welding Society	EPA	Environmental Protection Agency
bal	balance	EPFM	elastic-plastic fracture mechanics
bcc	body-centered cubic	EPRI	Electric Power Research Institute
bct	body-centered tetragonal	Eq	equation
C	cementite; coulomb	ESW	electroslag welding
<i>C</i>	heat capacity	et al.	and others
CAC	carbon arc cutting	ETP	electrolytic tough pitch
CAC-A	air carbon arc cutting	eV	electron volt
CAD/CAM	computer-aided design/computer-aided manufacturing	EXB	exothermic brazing
CAW	carbon arc welding	exp	base of the natural logarithm
CAW-G	gas carbon arc welding	EXW	explosion welding
CAW-S	shielded carbon arc welding	<i>f</i>	frequency
CBN	cubic boron nitride	FCAW	flux cored arc welding
CCD	charge-coupled device	fcc	face-centered cubic
CCT	continuous cooling transformation	fct	face-centered tetragonal
CE	carbon equivalent	FEA	finite-element analysis
cgs	centimeter-gram-second (system of units)	FEM	finite-element method
cm	centimeter	Fig.	figure
cP	centipoise	FRW	friction welding
CP	commercially pure	FS	furnace soldering
cSt	centiStokes	ft	foot
CTE	coefficient of thermal expansion	FW	flash welding
CTOD	crack tip opening displacement	g	gram
CVD	chemical vapor deposition	<i>g</i>	acceleration due to gravity
CVN	Charpy V-notch (impact test or specimen)	gf	gram force
<i>D</i>	diameter	GMA	gas metal arc
<i>da/dN</i>	fatigue crack growth rate	GMAC	gas metal arc cutting
dB	decibel	GMAW	gas metal arc welding
DB	diffusion bonding; dip brazing	GPa	gigapascal
DBTT	ductile-to-brittle transition temperature	GTA	gas tungsten arc
dc	direct current	GTAC	gas tungsten arc cutting
		GTAW	gas tungsten arc welding
		h	hour
		<i>h</i>	Planck's constant (6.626×10^{-27} erg · s)
		H	Henry
		<i>H</i>	enthalpy; hardness; magnetic field
		HAZ	heat-affected zone

HB	Brinell hardness	MO	multiple operator
hcp	hexagonal close-packed	MPa	megapascal
HHC	hot-hollow cathode	mpg	miles per gallon
HIC	hydrogen-induced cracking	mph	miles per hour
HIP	hot isostatic pressing	MRR	material removal rate
HK	Knoop hardness	ms	millisecond
hp	horsepower	M _s	temperature at which martensite starts to form from austenite on cooling
HR	Rockwell hardness (requires scale designation, such as HRC for Rockwell C hardness)	mV	millivolt
HREM	high-resolution electron microscopy	MV	megavolt
HSLA	high-strength, low-alloy (steel)	N	Newton
HSS	high-speed steel(s)	N	number of cycles; normal solution; normal force
HTLA	heat-treatable low-alloy (steel)	NACE	National Association of Corrosion Engineers
HV	Vickers hardness	NASA	National Aeronautics and Space Administration
Hz	hertz	NDE	nondestructive evaluation
<i>I</i>	intensity; electrical current	NEC	National Electric Code
IGA	intergranular attack	NEMA	National Electrical Manufacturers Association
IGSCC	intergranular stress-corrosion cracking	NIST	National Institute of Standards and Technology
IIW	International Institute of Welding	nm	nanometer
IMO	International Maritime Organization	No.	number
in.	inch	OAW	oxyacetylene welding
IPTS	International Practical Temperature Scale	OCV	open-circuit voltage
IR	infrared	Oe	oersted
IRS	infrared soldering	OFG	oxyfuel gas
IS	induction soldering	OFW	oxyfuel gas welding
ISCC	intergranular stress-corrosion cracking	ORNL	Oak Ridge National Laboratory
ISO	International Organization for Standardization	OSHA	Occupational Safety and Health Administration
J	joule	oz	ounce
k	equilibrium distribution coefficient	p	page
<i>k</i>	thermal conductivity; Boltzmann constant	P	pearlite
K	Kelvin	Pa	pascal
kg	kilogram	PAW	plasma arc welding
kgf	kilogram force	PEEM	photoemission electron microscopy
<i>K_{1c}</i>	plane-strain fracture toughness	pH	negative logarithm of hydrogen-ion activity
<i>K_{ISCC}</i>	threshold stress intensity to produce stress-corrosion cracking	PH	precipitation hardenable; precipitation hardening
km	kilometer	PID	proportional-integral-differential
kN	kilonewton	PM	planar magnetron
kPa	kilopascal	ppb	parts per billion
ksi	kips (1000 lbf) per square inch	ppm	parts per million
kV	kilovolt	ppt	parts per trillion
kW	kilowatt	PRE	pitting resistance equivalent
L	longitudinal, liter	psi	pounds per square inch
lb	pound	psia	pounds per square inch absolute
lbf	pound force	psig	gage pressure (pressure relative to ambient pressure) in pounds per square inch
LBW	laser beam welding	PSTM	photon scanning tunneling microscopy
LCL	lower control limit	PW	projection welding
LEED	low-energy electron diffraction	PWAA	postweld artificial aging
LEFM	linear elastic fracture mechanics	PWHT	postweld heat treatment
LME	liquid metal embrittlement	PWM	pulse width modulation
LMP	Larson-Miller parameter	Q&T	quenched and tempered
ln	natural logarithm (base <i>e</i>)	R	roentgen
LNG	liquefied natural gas	<i>R_a</i>	surface roughness in terms of arithmetic average
log	common logarithm (base 10)	RA	rosin fully activated; roughness average; reduction in area
m	meter	RE	rare earth
mA	milliampere	Ref	reference
MC	metal carbide	REF	relative erosion factor
MeV	megaelectronvolt	rf	radio frequency
<i>M_f</i>	temperature at which martensite formation finishes during cooling	RH	relative humidity
mg	milligram	RMA	rosin mildly activated
Mg	megagram (metric tonne, or kg × 10 ³)	rms	root mean square
MIC	microbiologically influenced corrosion	RPF	relative potency factor
min	minute; minimum	rpm	revolutions per minute
mL	milliliter	<i>R_q</i>	rms (root mean square) roughness
mm	millimeter	RS	resistance soldering

894 / Reference Information

RSA	rosin superactivated	T	tesla
RSEW	seam welding	<i>T</i>	temperature
RSW	resistance spot welding	TB	torch brazing
RT	room temperature	tcp	topologically close-packed
RW	resistance welding	TEM	transmission electron microscope/microscopy
RWMA	Resistance Welder Manufacturers Association	TGA	thermogravimetric analysis
s	second	TGSCC	transgranular stress-corrosion cracking
S	siemens	TIG	tungsten inert gas (welding)
SAE	Society of Automotive Engineers	TMCP	thermomechanically controlled process
SAM	scanning acoustic microscope/microscopy	TS	torch soldering
SAW	submerged arc welding	TTT	time-temperature transformation
SCC	stress-corrosion cracking	TW	thermit welding; thermite welding
SEM	scanning electron microscope/microscopy	UNS	Unified Numbering System
SHE	standard hydrogen electrode	USW	ultrasonic welding
SI	Système International d'Unités	UTS	ultimate tensile strength
SIR	surface insulation resistance	UW	upset welding
SLAM	scanning laser acoustic microscope/microscopy	<i>v</i>	velocity
SLEEM	scanning low-energy electron microscopy	V	volt
SMA	shielded metal arc	VIM-VAR	vacuum induction melted-vacuum arc remelted
SMAW	shielded metal arc welding	vol	volume
SPA-LEED	spot profile analysis-low-energy electron diffraction	vol%	volume percent
SPC	statistical process control	VPPA	variable polarity plasma arc
SQC	statistical quality control	W	watt
SRA	stress-relief annealing	WI	wettability index
SSW	solid-state welding	WRC	Welding Research Council
STA	solution treated and aged	WS	wave soldering
STEM	scanning transmission electron microscope/microscopy	WSN	weld set number
STM/S	scanning tunneling microscopy/spectroscopy	wt%	weight percent
SUS	Saybolt universal seconds (viscosity)	XPS	x-ray photoelectron spectroscopy
Sv	sievert	yr	year
SW	stud arc welding	Z	atomic number
<i>t</i>	thickness; time		

Officers and Trustees of ASM International (2010–2011)

Mark F. Smith

President and Trustee
National Laboratories

Christopher C. Berndt

Vice-President and Trustee Swinburne University
of Technology

Frederick J. Lisy

Immediate Past President and Trustee
Orbital Research Incorporated

Stanley C. Theobald

Managing Director & Secretary
ASM International

Robert J. Fulton

Treasurer and Trustee
Hoeganaes Corporation (retired)

Riad I. Asfahani

United States Steel Corporation

Mufit Akinc

Iowa State University

Sunniva R. Collins

Swagelok

Diana Essock

Metamark Inc.

David U. Furrer

Pratt & Whitney

Robert Hill, Jr.

President Solar Atmospheres, Inc.

Richard Knight

Drexel University

John J. Letcavits

AEP

Vilupanur A. Ravi

California State Polytechnic University
Student Board Members

Kathryn (Katie) S. Czaja

University of Connecticut

Emily J. Kuster

Iowa State University

Indranil Lahiri

Florida International University

Members of the ASM Handbook Committee (2010–2011)

Craig D. Clauser

Chair 2010–
Member 2005–
Craig Clauser Engineering Consulting Incorporated

Joseph W. Newkirk

Vice Chair 2010–
Member 2005–
Missouri University of Science and Technology

Kent L. Johnson

Immediate Past Chair 2010–
Member 1999–
Materials Consulting and Engineering, Ltd.

Viola L. Acoff (2005–)

University of Alabama

Scott W. Beckwith (2010–)

BTG Composites Inc

Rodney R. Boyer (2010–)

Boeing Company

Lichun Leigh Chen (2002–)

Umicore Technical Materials North America

Sarup K. Chopra (2007–)

Consultant

Craig V. Darragh (1989–)

The Timken Company (ret.)

Jon L. Dossett (2006–)

Consultant

Alan P. Druschitz (2009–)

University of Alabama-Birmingham

Gerald S. Frankel (2010–)

The Ohio State University

David U. Furrer (2006–)

Pratt & Whitney

Larry D. Hanke (1994–)

Materials Evaluation and Engineering Inc

Jeffrey A. Hawk (1997–)

National Energy Technology Laboratory

Kang N. Lee (2010–)

Rolls Royce Corporation

Dale E. Newbury (2010–)

National Inst. of Standards

Robert P. O'Shea, Jr. (2008–)

Baker Engineering and Risk Consultants

Toby V. Padfield (2004–)

ZF Sachs Automotive of America

Cynthia A. Powell (2009–)

National Energy Technology Laboratory

Thomas E. Prucha (2010–)

American Foundry Society

Prasan K. Samal (2010–)

North American Höganäs

Jeffrey S. Smith (2009–)

Material Processing Technology LLC

George Vander Voort (1997–)

Consultant, Struers

Michael K. West (2008–)

South Dakota School of Mines and Technology

Chairs of the ASM Handbook Committee

J.F. Harper

(1923–1926) (Member 1923–1926)

W.J. Merten

(1927–1930) (Member 1923–1933)

L.B. Case

(1931–1933) (Member 1927–1933)

C.H. Herty, Jr.

(1934–1936) (Member 1930–1936)

J.P. Gill

(1937) (Member 1934–1937)

R.L. Dowdell

(1938–1939) (Member 1935–1939)

G.V. Luerssen

(1943–1947) (Member 1942–1947)

J.B. Johnson

(1948–1951) (Member 1944–1951)

E.O. Dixon

(1952–1954) (Member 1947–1955)

N.E. Promisel

(1955–1961) (Member 1954–1963)

R.W.E. Leiter

(1962–1963) (Member 1955–1958, 1960–1964)

D.J. Wright

(1964–1965) (Member 1959–1967)

J.D. Graham

(1966–1968) (Member 1961–1970)

W.A. Stadler

(1969–1972) (Member 1962–1972)

G.J. Shubat

(1973–1975) (Member 1966–1975)

R. Ward

(1976–1978) (Member 1972–1978)

G.N. Maniar

(1979–1980) (Member 1974–1980)

M.G.H. Wells

(1981) (Member 1976–1981)

J.L. McCall

(1982) (Member 1977–1982)

L.J. Korb

(1983) (Member 1978–1983)

T.D. Cooper

(1984–1986) (Member 1981–1986)

D.D. Huffman

(1986–1990) (Member 1982–2005)

D.L. Olson

(1990–1992) (Member 1982–1988, 1989–1992)

R.J. Austin

Metric Conversion Guide

This Section is intended as a guide for expressing weights and measures in the Système International d'Unités (SI). The purpose of SI units, developed and maintained by the General Conference of Weights and Measures, is to provide a basis for worldwide standardization of units and measure. For more information on metric conversions, the reader should consult the following references:

- *The International System of Units*, SP 330, 1991, National Institute of Standards and Technology. Order from Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402-9325
- *Metric Editorial Guide*, 5th ed. (revised), 1993, American National Metric Council, 4340 East West Highway, Suite 401, Bethesda, MD 20814-4411
- "Standard for Use of the International System of Units (SI): The Modern Metric System," IEEE/ASTM SI 10-1997 Institute of Electrical and Electronics Engineers, 345 East 47th Street, New York, NY 10017, USA
- *Guide for the Use of the International System of Units (SI)*, SP811, 1995, National Institute of Standards and Technology, U.S. Government Printing Office, Washington, DC 20402

Base, supplementary, and derived SI units

Measure	Unit	Symbol	Measure	Unit	Symbol
Base units			Base units		
Amount of substance	mole	mole	Force	newton	N
Electric current	ampere	A	Frequency	hertz	Hz
Length	meter	m	Heat capacity	joule per kelvin	J/K
Luminous intensity	candela	cd	Heat flux density	watt per square meter	W/m ²
Mass	kilogram	kg	Illuminance	lux	lx
Thermodynamic temperature	kelvin	K	Inductance	henry	H
Time	second	s	Irradiance	watt per square meter	W/m ²
			Luminance	candela per square meter	cd/m ²
			Luminous flux	lumen	lm
Supplementary units			Supplementary units		
Plane angle	radian	rad	Magnetic field strength	ampere per meter	A/m
Solid angle	steradian	sr	Magnetic flux	weber	Wb
			Magnetic flux density	tesla	T
Derived units			Derived units		
Absorbed does	gray	Gy	Molar energy	joule per mole	J/mol
Acceleration	meter per second squared	m/s ²	Molar entropy	joule per mole kelvin	J/mol · K
Activity (of radionuclides)	becquerel	Bq	Molar heat capacity	joule per mole kelvin	J/m · K
Angular acceleration	radian per second squared	rad/s ²	Moment of force	newton meter	N · m
Angular velocity	radian per second	rad/s	Permeability	henry per meter	H/m
Area	square meter	m ²	Permittivity	farad per meter	F/m
Capacitance	farad	F	Power, radiant flux	watt	W
Concentration (of amount of substance)	mole per cubic meter	mol/m ³	Pressure, stress	pascal	Pa
Current density	ampere per square meter	A/m ²	Quantity of electricity, electric charge	coulomb	C
Density, mass	kilogram per cubic meter	kg/m ³	Radiance	watt per square meter steradian	W/m ² · sr
Does equivalent, does equivalent index	sievert	Sv	Radiant intensity	watt per steradian	W/sr
Electric charge density	coulomb per cubic meter	C/m ³	Specific heat capacity	joule per kilogram kelvin	J/kg · K
Electric conductance	siemens	S	Specific energy	joule per kilogram	J/kg
Electric field strength	volt per cubic meter	V/m	Specific entropy	joule per kilogram kelvin	J/kg · K
Electric flux density	coulomb per square meter	C/m ²	Specific volume	cubic meter per kilogram	m ³ /kg
Electric potential, potential difference, electromotive force	volt	V	Specific volume	cubic meter per kilogram	m ³ /kg
Electric resistance	ohm	Ω	Surface tension	newton per meter	N/m
Energy, work, quantity of heat	joule	J	Thermal conductivity	watt per meter kelvin	W/m · K
Energy density	joule per cubic meter	J/m ³	Velocity	meter per second	m/s
Entropy	joule per kelvin	J/K	Viscosity, dynamic	pascal second	Pa · s
			Viscosity, kinematic	square meter per second	m ² /s
			Volume	cubic meter	m ³
			Wavenumber	1 per meter	1/m

(a) kg × 10³ = 1 metric ton or 1 megagram (Mg). (b) Preferred expression is 10⁻⁶/F as length units are unnecessary.

Policy on Units of Measure

By a resolution of its Board of Trustees, ASM International has adopted the practice of publishing data in both metric and customary U.S. units of measure. In preparing this Handbook, the editors have attempted to present data in metric units based primarily on *Système International d'Unités* (SI), with secondary mention of the corresponding values in customary U.S. units. The decision to use SI as the primary system of units was based on the aforementioned resolution of the Board of Trustees and the widespread use of metric units throughout the world.

For the most part, numerical engineering data in the text and in tables are presented in SI-based units with the customary U.S. equivalents in parentheses (text) or adjoining columns (tables). For example, pressure, stress, and strength are shown both in SI units, which are pascals (Pa) with a suitable prefix, and in customary U.S. units, which are pounds per square inch (psi). To save space, large values of psi have been converted to kips per square inch (ksi), where 1 ksi = 1000 psi. The metric tonne ($\text{kg} \times 10^3$) has sometimes been shown in megagrams (Mg). Some strictly scientific data are presented in SI units only.

To clarify some illustrations, only one set of units is presented on artwork. References in the accompanying text to data in the illustrations are presented in both SI-based and customary U.S. units. On graphs and charts, grids corresponding to SI-based units usually appear along the left and bottom edges. Where appropriate, corresponding customary U.S. units appear along the top and right edges.

Data pertaining to a specification published by a specification-writing group may be given in only the units used in that specification or in dual units, depending on the nature of the data. For example, the typical yield strength of steel sheet made to a specification written in customary U.S.

units would be presented in dual units, but the sheet thickness specified in that specification might be presented only in inches.

Data obtained according to standardized test methods for which the standard recommends a particular system of units are presented in the units of that system. Wherever feasible, equivalent units are also presented. Some statistical data may also be presented in only the original units used in the analysis.

Conversions and rounding have been done in accordance with IEEE/ASTM SI-10, with attention given to the number of significant digits in the original data. For example, an annealing temperature of 1570 °F contains three significant digits. In this case, the equivalent temperature would be given as 855 °C; the exact conversion to 854.44 °C would not be appropriate. For an invariant physical phenomenon that occurs at a precise temperature (such as the melting of pure silver), it would be appropriate to report the temperature as 961.93 °C or 1763.5 °F. In some instances (especially in tables and data compilations), temperature values in °C and °F are alternatives rather than conversions.

The policy of units of measure in this Handbook contains several exceptions to strict conformance to IEEE/ASTM SI-10; in each instance, the exception has been made in an effort to improve the clarity of the Handbook. The most notable exception is the use of g/cm^3 rather than kg/m^3 as the unit of measure for density (mass per unit volume).

SI practice requires that only one virgule (diagonal) appear in units formed by combination of several basic units. Therefore, all of the units preceding the virgule are in the numerator and all units following the virgule are in the denominator of the expression; no parentheses are required to prevent ambiguity.

Glossary of Terms*

A

activated rosin flux A rosin-base flux containing an additive that increases wetting by the solder.

actual throat The shortest distance between the weld root and the face of a fillet weld.

adhesive bonding A materials joining process in which an adhesive is placed between the faying surfaces. The adhesive solidifies to produce an adhesive bond.

air carbon arc cutting (AC-A) An arc cutting process that melts base metals by the heat of a carbon arc and removes the molten metal by a blast of air.

arc blow The deflection of an electric arc from its normal path because of magnetic forces.

arc brazing (AB) A brazing process that uses an arc to provide the heat. See *carbon arc brazing*.

arc cutting (AC) A group of cutting processes that melt the base metal with the heat of an arc between an electrode and the base metal.

air cutting gun (gas metal arc cutting) A device used in semiautomatic, machine, and automatic arc cutting to transfer current, guide the consumable electrode, and direct the shielding gas.

arc force The axial force developed by an arc plasma.

arc gouging An arc cutting process variation used to form a bevel or groove.

arc oxygen cutting A nonstandard term for *oxygen arc cutting*.

arc seam weld A seam weld made by an arc welding process.

arc spot weld A spot weld made by an arc welding process.

arc spraying (ASP) A thermal spraying process using an arc between two consumable electrodes of surfacing materials as a heat source and a compressed gas to atomize and propel the surfacing material to the substrate.

arc strike A discontinuity consisting of any localized remelted metal, heat-affected metal, or change in the surface profile of any part of a weld or base metal resulting from an arc.

arc welding (AW) A group of welding processes that produces coalescence of metals by heating them with an arc, with or without

the application of pressure, and with or without the use of filler metal.

arc welding electrode A component of the welding circuit through which current is conducted and which terminates at the arc.

arc welding gun A device used in semiautomatic, machine, and automatic arc welding to transfer current, guide the consumable electrode, and direct the shielding gas.

as-welded The condition of weld metal, welded joints, and weldments after welding, but prior to any subsequent thermal, mechanical, or chemical treatments.

autogenous weld A fusion weld made without the addition of filler metal.

automatic welding Welding with equipment that performs the welding operation without adjustment of the controls by a welding operator. The equipment may or may not load and unload the workpieces. See also *machine welding*.

B

back bead A weld bead resulting from a back weld pass.

backfire The momentary recession of the flame into the welding tip or cutting tip followed by immediate reappearance or complete extinction of the flame.

back gouging The removal of weld metal and base metal from the other side of a partially welded joint to facilitate complete fusion and complete joint penetration upon subsequent welding from that side.

backhand welding A welding technique in which the welding torch or gun is directed opposite to the progress of welding.

backing A material or device placed against the back side of the joint, or at both sides of a weld in electroslag and electrogas welding, to support and retain molten weld metal. The material may be partially fused or remain unfused during welding and may be either metal or nonmetal.

backing bead A weld bead resulting from a backing pass.

backing filler metal A nonstandard term for *consumable insert*.

backing pass A weld pass made for a backing weld.

backing ring Backing in the form of a ring, generally used in the welding of pipe.

backing shoe A nonconsumable backing device used in electroslag and electrogas welding.

backing weld Backing in the form of a weld.

backstep sequence A longitudinal sequence in which weld passes are made in the direction opposite to the progress of welding.

back weld A weld made at the back of a single-groove weld.

balling up The formation of globules of molten brazing filler metal or flux due to lack of wetting of the base metal.

base material The material to be welded, brazed, soldered, or cut. See also *base metal* and *substrate*.

base metal The metal to be welded, brazed, soldered, or cut. See also *base material* and *substrate*.

bead weld A nonstandard term for *surfacing weld*.

bevel An angular edge preparation.

bevel angle The angle formed between the prepared edge of a member and a plane perpendicular to the surface of the member.

bevel groove weld A type of groove weld.

bit That part of the soldering iron, usually made of copper, that actually transfers heat (and sometimes solder) to the joint.

blacksmith welding A nonstandard term for *forge welding*.

block sequence A combined longitudinal and cross-sectional sequence for a continuous multiple-pass weld in which separated increments are completely or partially welded before intervening increments are welded.

blowhole A nonstandard term for *porosity*.

bond See *bonding force*, *covalent bond*, *mechanical bond*, and *metallic bond*.

bond coat (thermal spraying) A preliminary (or prime) coat of material that improves adherence of the subsequent spray deposit.

bonding force The force that holds two atoms together. It results from a decrease in energy as two atoms are brought closer to one another.

bond line The cross section of the interface between thermal spray deposits and substrate, or between adhesive and adherend in an adhesive bonded joint.

bottle A nonstandard term for *gas cylinder*.

boxing The continuation of a fillet weld around a corner of a member as an extension of the principal weld.

braze A weld produced by heating an assembly to the brazing temperature using a filler metal having a liquidus above 450 °C (840 °F) and below the solidus of the base metal. The filler metal is distributed between the closely fitted faying surfaces of the joint by capillary action.

braze interface The interface between filler metal and base metal in a brazed joint.

brazement An assembly whose component parts are joined by brazing.

brazier One who performs a manual or semiautomatic brazing operation.

braze welding A welding process variation in which a filler metal, having a liquidus above 450 °C (840 °F) and below the solidus of the base metal, is used. Unlike brazing, in braze welding the filler metal is not distributed in the joint by capillary action.

brazing (B) A group of welding processes that produce coalescence of materials by heating them to the brazing temperature in the presence of a filler metal having a liquidus above 450 °C (840 °F) and below the solidus of the base metal. The filler metal is distributed between the closely fitted faying surfaces of the joint by capillary action.

brazing alloy A nonstandard term for *brazing filler metal*.

brazing filler metal The metal that fills the capillary joint clearance and has a liquidus above 450 °C (840 °F) but below the solidus of the base metals.

brazing operator One who operates machine or automatic brazing equipment.

brittle nugget A nonstandard term used to describe a faying plane failure in a resistance weld peel test.

bronze welding A nonstandard term for *braze welding*.

buildup A surfacing variation in which surfacing metal is deposited to achieve the required dimensions. See also *buttering*.

burner A nonstandard term for *oxygen cutter*.

burning A nonstandard term for *oxygen cutting*.

burn through A nonstandard term for excessive melt through or a hole.

burn through weld A nonstandard term for a *seam weld* or *spot weld*.

buttering A surfacing variation that deposits surfacing metal on one or more surfaces to provide metallurgically compatible weld metal for the subsequent completion of the weld. See also *buildup*.

butt joint A joint between two members aligned approximately in the same plane.

button That part of a weld, including all or part of the nugget, that tears out in the destructive testing of spot, seam, or projection welded specimens.

butt weld A nonstandard term for a weld in a butt joint.

C

carbon arc brazing (CAB) A brazing process that produces coalescence of metals by heating them with an electric arc between two carbon electrodes. The filler metal is distributed in the joint by capillary action.

carbon arc cutting (CAC) An arc cutting process that severs base metals by melting them with the heat of an arc between a carbon electrode and the base metal.

carbon arc welding (CAW) An arc welding process that produces coalescence of metals by heating them with an arc between a carbon electrode and the base metal. No shielding is used. Pressure and filler metal may or may not be used.

carbonizing flame A nonstandard term for *reducing flame*.

caulk weld A nonstandard term for *seal weld*.

chain intermittent weld An intermittent weld on both sides of a joint in which the weld increments on one side are approximately opposite those on the other side.

chamfer A nonstandard term for *bevel*.

chemical flux cutting (FOC) An oxygen cutting process that severs base metals using a chemical flux to facilitate cutting.

chill ring A nonstandard term for *backing ring*.

clad brazing sheet A metal sheet on which one or both sides are clad with brazing filler metal.

coalescence The growing together or growth into one body of the materials being welded.

coated electrode A nonstandard term for *covered electrode*.

coating density A nonstandard term for *spray deposit density ratio*.

coextrusion welding (CEW) A solid-state welding process that produces coalescence of the faying surfaces by heating and forcing base metals through an extrusion die.

cold crack A crack that develops after solidification is complete.

cold soldered joint A joint with incomplete coalescence caused by insufficient application of heat to the base metal during soldering.

cold welding (CW) A solid-state welding process in which pressure is used at room temperature to produce coalescence of metals with substantial deformation at the weld. See also *diffusion welding*, *forge welding*, and *hot pressure welding*.

complete fusion Fusion which has occurred over the entire base metal surface intended for welding and between all adjoining weld beads.

complete joint penetration A penetration by weld metal for the full thickness of the base metal in a joint with a groove weld.

complete penetration A nonstandard term for *complete joint penetration*.

concavity The maximum distance from the face of a concave fillet weld perpendicular to a line joining the weld toes.

cone The conical part of an oxyfuel gas flame next to the orifice of the tip.

constricted arc (plasma arc welding and cutting) A plasma arc column that is shaped by a constricting nozzle orifice.

consumable insert Preplaced filler metal that is completely fused into the joint root and becomes part of the weld.

contact resistance (resistance welding) Resistance to the flow of electric current between two workpieces or an electrode and a workpiece.

contact tube A device that transfers current to a continuous electrode.

convexity The maximum distance from the face of a convex fillet weld perpendicular to a line joining the weld toes.

copper brazing A nonstandard term for brazing with a copper filler metal.

cored solder A solder wire or bar containing flux as a core.

corner-flange weld A flange weld with only one member flanged at the joint.

corner joint A joint between two members located approximately at right angles to each other.

corona (resistance welding) The area sometimes surrounding the nugget of a spot weld at the faying surface which provides a degree of solid-state welding.

CO₂ welding A nonstandard term for *gas metal arc welding*.

covalent bond A primary bond arising from the reduction in energy associated with overlapping half-filled orbitals of two atoms.

covered electrode A composite filler metal electrode consisting of a core of a bare electrode or metal-cored electrode to which a covering sufficient to provide a slag layer on the weld metal has been applied. The covering may contain materials providing such functions as shielding from the atmosphere, deoxidation, and arc stabilization and can serve as a source of metallic additions to the weld.

crack A fracture type discontinuity characterized by a sharp tip and high ratio of length and width to opening displacement.

crater A depression at the termination of a weld bead.

cutting attachment A device for converting an oxyfuel gas welding torch into an oxygen cutting torch.

cutting blowpipe A nonstandard term for cutting torch.

cutting nozzle A nonstandard term for *cutting tip*.

cutting tip The part of an oxygen cutting torch from which the gases issue.

cutting torch (arc) A device used in air carbon arc cutting, gas tungsten arc cutting, and plasma arc cutting to control the position of the electrode, to transfer current, and to control the flow of gases.

cutting torch (oxyfuel gas) A device used for directing the preheating flame produced by the controlled combustion of fuel gases and to direct and control the cutting oxygen.

cylinder manifold A multiple header for interconnection of gas or fluid sources with distribution points.

D

defect A discontinuity or discontinuities that by nature or accumulated effect (for example, total crack length) render a part or product unable to meet minimum applicable acceptance standards or specifications. This term designates rejectability. See also *discontinuity* and *flaw*.

deposit (thermal spraying) A nonstandard term for *spray deposit*.

deposited metal Filler metal that has been added during welding.

deposition efficiency (arc welding) The ratio of the weight of deposited metal to the net weight of filler metal consumed, exclusive of stubs.

deposition efficiency (thermal spraying) The ratio of the weight of spray deposit to the weight of the surfacing material sprayed, usually expressed in percent.

deposition sequence A nonstandard term for *weld pass sequence*.

depth of fusion The distance that fusion extends into the base metal or previous pass from the surface melted during welding.

diffusion bonding A nonstandard term for *diffusion brazing* and *diffusion welding*.

diffusion brazing (DFB) A brazing process that produces coalescence of metals by heating them to brazing temperature and by using a filler metal or an *in situ* liquid phase. The filler metal may be distributed by capillary action or may be placed or formed at the faying surfaces. The filler metal is diffused with the base metal to the extent that the joint properties have been changed to approach those of the base metal. Pressure may or may not be applied.

diffusion welding (DFW) A solid-state welding process that produces coalescence of the faying surfaces by the application of pressure at elevated temperature. The process does not involve macroscopic deformation, melting, or relative motion of the workpieces. A solid filler metal may or may not be inserted between the faying surfaces. See also *cold welding*, *forge welding*, and *hot pressure welding*.

dilution The change in chemical composition of a welding filler metal caused by the admixture of the base metal or previous weld metal in the weld bead. It is measured by the percentage of base metal or previous weld metal in the weld bead.

diode laser A semiconductor laser. A p-n junction semiconductor with a resonator cavity that is capable of emitting electromagnetic radiation in the wavelength range of 0.180 μm to 1 mm, by radiative recombination in the semiconductor.

diode pumped solid state (DPSS) laser: also known as DPSSL, employs diodes to pump/excite the solid state lasing gain medium

such as a ruby crystal, a Neodymium doped Yttrium Aluminum Garnet (Nd:YAG) crystal, a Ytterbium doped silica core fiber (Yb: fiber) or a Ytterbium doped Yttrium Aluminum Garnet crystal (Yb:YAG) thin disk laser

dip brazing (DB) A brazing process using the heat furnished by a molten chemical or metal bath. When a molten chemical bath is used, the bath may act as a flux. When a molten metal bath is used, the bath provides the filler metal.

dip soldering (DS) A soldering process using the heat furnished by a molten metal bath which provides the solder filler metal.

direct current electrode negative (DCEN) The arrangement of direct current arc welding leads in which the workpiece is the positive pole and the electrode is the negative pole of the welding arc.

direct current electrode positive (DCEP) The arrangement of direct current arc welding leads in which the workpiece is the negative pole and the electrode is the positive pole of the welding arc.

direct current reverse polarity A nonstandard term for *direct current electrode positive*.

direct current straight polarity A nonstandard term for *direct current electrode negative*.

discontinuity An interruption of the typical structure of a weldment, such as a lack of homogeneity in the mechanical, metallurgical, or physical characteristics of the material or weldment. A discontinuity is not necessarily a defect. See also *defect* and *flaw*.

double-bevel-groove weld A type of groove weld.

double-flare-bevel-groove weld A weld in grooves formed by a member with a curved surface in contact with a planar member.

double-flare-V-groove weld A weld in grooves formed by two members with curved surfaces.

double-J-groove weld A type of groove weld.

double-square-groove weld A type of groove weld.

double-U-groove weld A type of groove weld.

double-V-groove weld A type of groove weld.

double-welded joint A fusion-welded joint that is welded from both sides.

downhand A nonstandard term for *flat position*.

drag (thermal cutting) The offset distance between the actual and straight line exit points of the gas stream or cutting beam measured on the exit surface of the material.

E

edge-flange weld A flange weld with two members flanged at the location of welding.

edge joint A joint between the edges of two or more parallel or nearly parallel members.

edge weld A weld in an edge joint.

edge weld size The weld metal thickness measured at the weld root.

effective throat The minimum distance minus any convexity between the weld root and the face of a fillet weld.

electric arc spraying A nonstandard term for *arc spraying*.

electric bonding A nonstandard term for surfacing by thermal spraying.

electric brazing A nonstandard term for *arc brazing* and *resistance brazing*.

electrode See *welding electrode*.

electrode extension For gas metal arc welding, flux cored arc welding, and submerged arc welding, the length of unmelted electrode extending beyond the end of the contact tube.

electrode force The force between the electrodes in making spot, seam, or projection welds by resistance welding.

electrode holder A device used for mechanically holding the electrode while conducting current to it.

electrode indentation (resistance welding) The depression formed on the surface of workpieces by electrodes.

electrode lead The electrical conductor between the source of arc welding current and the electrode holder.

electrogas welding (EGW) An arc welding process that produces coalescence of metals by heating them with an arc between a continuous filler metal electrode and the work. Molding shoes are used to confine the molten weld metal for vertical position welding. The electrodes may be either flux cored or solid. Shielding may or may not be obtained from an externally supplied gas or mixture.

electron beam cutting (EBC) A cutting process that uses the heat obtained from a concentrated beam composed primarily of high-velocity electrons which impinge upon the workpieces; it may or may not use an externally supplied gas.

electron beam gun A device for producing and accelerating electrons. Typical components include the emitter (also called the filament or cathode), which is heated to produce electrons via thermionic emission; a cup (also called the grid or grid cup); and the anode.

electron beam welding (EBW) A welding process that produces coalescence of metals with the heat obtained from a concentrated beam composed primarily of high-velocity electrons impinging on the joint.

electroslag welding (ESW) A welding process that produces coalescence of metals with molten slag that melts the filler metal and the surfaces of the workpieces. The weld pool is shielded by this slag, which moves along the full cross section of the joint as welding progresses. The process is initiated by an arc that heats the slag. The arc is then extinguished by the conductive slag, which is kept molten by its resistance to electric current passing between the electrode and the workpieces.

end return A nonstandard term for *boxing*.

erosion (brazing) A condition caused by dissolution of the base metal by molten filler metal resulting in a reduction in the thickness of the base metal.

explosion welding (EXW) A solid-state welding process that affects coalescence by high-velocity movement together with the workpieces produced by a controlled detonation.

F

face reinforcement Weld reinforcement at the side of the joint from which welding was done. See also *root reinforcement*.

faying surface That mating surface of a member that is in contact with or in close proximity to another member to which it is to be joined.

ferrite number An arbitrary, standardized value designating the ferrite content of an austenitic stainless steel weld metal. It should be used in place of percent ferrite or volume percent ferrite on a direct replacement basis.

fiber laser: a solid state laser in which the active (lasing) medium is a doped optical fiber. See also **diode pumped solid state laser**

filler metal The metal to be added in making a welded, brazed, or soldered joint. See also *brazing filler metal, consumable insert, solder, welding electrode, welding rod, and welding wire*.

filler wire A nonstandard term for *welding wire*.

fillet weld A weld of approximately triangular cross section joining two surfaces approximately at right angles to each other in a lap joint, T-joint, or corner joint.

fillet weld break test A test in which the specimen is loaded so that the weld root is in tension.

fillet weld leg The distance from the joint root to the toe of the fillet weld.

fillet weld size For equal leg fillet welds, the leg lengths of the largest isosceles right triangle that can be inscribed within the fillet weld cross section. For unequal leg fillets, the leg lengths of the largest right triangle that can be inscribed within the fillet weld cross section.

fillet weld throat See *actual throat, effective throat, and theoretical throat*.

firecracker welding A variation of the shielded metal arc welding process in which a length of covered electrode is placed along the joint in contact with the workpieces. During the welding operation, the stationary electrode is consumed as the arc travels the length of the electrode.

fish-eye A discontinuity found on the fracture surface of a weld in steel that consists of a small pore or inclusion surrounded by an approximately round, bright area.

flame cutting A nonstandard term for *oxygen cutting*.

flame propagation rate The speed at which a flame travels through a mixture of gases.

flame spraying (FLSP) A thermal spraying process in which an oxyfuel gas flame is the source of heat for melting the surfacing material. Compressed gas may or may not

be used for atomizing and propelling the surfacing material to the substrate.

flange weld A weld made on the edges of two or more members to be joined, usually light gage metal, at least one of the members being flanged.

flange weld size The weld metal thickness measured at the weld root.

flare-bevel-groove weld A weld in a groove formed by a member with a curved surface in contact with a planar member.

flare-V-groove weld A weld in a groove formed by two members with curved surfaces.

flash Material that is expelled from a flash weld prior to the upset portion of the welding cycle.

flash butt welding A nonstandard term for *flash welding*.

flash coat A thin coating usually less than 0.05 mm (0.002 in.) in thickness.

flash welding (FW) A resistance welding process that produces coalescence at the faying surfaces of a butt joint by a flashing action and by the application of pressure after heating is substantially completed. The flashing action, caused by the very high current densities at small contacts between the parts, forcibly expels the material from the joint as the parts are slowly moved together. The weld is completed by a rapid upsetting of the workpieces.

flat position The welding position used to weld from the upper side of the joint; the face of the weld is approximately horizontal.

flaw A near synonym for discontinuity but with an undesirable connotation. See also *defect and discontinuity*.

flux brightening (soldering) Fusion of a metallic coating on a base metal.

flux Material used to prevent, dissolve, or facilitate removal of oxides and other undesirable surface substances.

flux cored arc welding (FCAW) An arc welding process that produces coalescence of metals by heating them with an arc between a continuous filler metal electrode and the work. Shielding is provided by a flux contained within the tubular electrode. Additional shielding may or may not be obtained from an externally supplied gas or gas mixture. See also *flux cored electrode*.

flux cored electrode A composite filler metal electrode consisting of a metal tube or other hollow configuration containing ingredients to provide such functions as shielding atmosphere, deoxidation, arc stabilization, and slag formation. Minor amounts of alloying materials may be included in the core. External shielding may or may not be used.

flux cover (metal bath dip brazing and dip soldering) A layer of molten flux over the molten filler metal bath.

flux oxygen cutting A nonstandard term for *chemical flux cutting*.

forehand welding A welding technique in which the welding torch or gun is directed toward the progress of welding.

forge welding (FOW) A solid-state welding process that produces coalescence of metals by heating them in air in a forge and by applying pressure or blows sufficient to cause permanent deformation at the interface. See also *cold welding, diffusion welding, hot pressure welding, and roll welding*.

friction welding (FRW) A solid-state welding process that produces coalescence of materials under compressive force contact of workpieces rotating or moving relative to one another to produce heat and plastically displace material from the faying surfaces.

furnace brazing (FB) A brazing process in which the workpieces are placed in a furnace and heated to the brazing temperature.

furnace soldering (FS) A soldering process in which the workpieces are placed in a furnace and heated to the soldering temperature.

fused spray deposit (thermal spraying) A self-fluxing spray deposit that is subsequently heated to coalescence within itself and with the substrate.

fusion The melting together of filler metal and base metal (substrate), or of base metal only, which results in coalescence. See also *depth of fusion*.

fusion face A surface of the base metal that will be melted during welding.

fusion welding Any welding process that uses fusion of the base metal to make the weld.

fusion zone The area of base metal melted as determined on the cross section of a weld.

G

gap A nonstandard term for *joint clearance and root opening*.

gas brazing A nonstandard term for *torch brazing*.

gas cutter A nonstandard term for *oxygen cutter*.

gas cutting A nonstandard term for *oxygen cutting*.

gas cylinder A portable container used for transportation and storage of a compressed gas.

gas gouging A nonstandard term for *oxygen gouging*.

gas laser A laser in which the lasing medium is a gas.

gas metal arc cutting (GMAC) An arc cutting process in which metals are severed by melting them with the heat of an arc between a continuous filler metal electrode and the workpiece. Shielding is obtained entirely from an externally supplied gas.

gas metal arc welding (GMAW) An arc welding process that produces coalescence of metals by heating them with an arc between a continuous filler metal electrode and the workpieces. Shielding is obtained entirely from an externally supplied gas.

gas pocket A nonstandard term for *porosity*.

gas regulator A device for controlling the delivery of gas at some substantially constant pressure.

gas shielded arc welding A general term used to describe *flux cored arc welding* (when gas shielding is employed), *gas metal arc welding*, and *gas tungsten arc welding*.

gas torch A nonstandard term for cutting torch and welding torch.

gas tungsten arc cutting (GTAC) An arc cutting process in which metals are severed by melting them with an arc between a single tungsten electrode and the workpiece. Shielding is obtained from a gas.

gas tungsten arc welding (GTAW) An arc welding process that produces coalescence of metals by heating them with an arc between a tungsten electrode (nonconsumable) and the workpieces. Shielding is obtained from a gas. Pressure may or may not be used, and filler metal may or may not be used.

gas welding A nonstandard term for *oxyfuel gas welding*.

globular transfer (arc welding) The transfer of molten metal in large drops from a consumable electrode across the arc. See also *short circuiting transfer* and *spray transfer*.

gouging The forming of a bevel or groove by material removal. See also *arc gouging*, *back gouging*, and *oxygen gouging*.

groove angle The total included angle of the groove between the workpieces.

groove face That surface of a joint member included in the groove.

groove radius The radius used to form the shape of a J- or U-groove weld.

groove weld A weld made in a groove between the workpieces.

groove weld size The joint penetration of a groove weld.

groove weld throat A nonstandard term for *groove weld size*.

ground connection An electrical connection of the welding machine frame to the earth for safety. See also *workpiece connection* and *workpiece lead*.

ground lead A nonstandard term for *workpiece lead*.

gun See *air cutting gun*, *arc welding gun*, *electron beam gun*, *resistance welding gun*, *soldering gun*, and *thermal spraying gun*.

H

hammer welding A nonstandard term for *cold welding* and *forge welding*.

hard solder A nonstandard term for silver-base brazing filler metals.

heat affected zone That portion of the base metal that has not been melted, but whose mechanical properties or microstructure have been altered by the heat of welding, brazing, soldering, or cutting.

high frequency resistance welding A group of resistance welding process variations that uses high frequency welding current to

concentrate the welding heat at the desired location.

horizontal fixed position (pipe welding) The position of a pipe joint in which the axis of the pipe is approximately horizontal, and the pipe is not rotated during welding.

horizontal position (fillet weld) The position in which welding is performed on the upper side of an approximately horizontal surface and against an approximately vertical surface.

horizontal position (groove weld) The position of welding in which the weld axis lies in an approximately horizontal plane and the weld face lies in an approximately vertical plane.

horizontal rolled position (pipe welding) The position of a pipe joint in which the axis of the pipe is approximately horizontal, and welding is performed in the flat position by rotating the pipe.

hot crack A crack that develops during solidification.

hot pressure welding (HPW) A solid-state welding process that produces coalescence of metals with heat and application of pressure sufficient to produce macrodeformation of the base metal. Vacuum or other shielding media may be used. See also *diffusion welding* and *forge welding*.

hydrogen brazing A nonstandard term for any brazing process that takes place in a hydrogen atmosphere.

I

impulse (resistance welding) A group of pulses occurring on a regular frequency separated only by an interpulse time.

inclined position The position of a pipe joint in which the axis of the pipe is at an angle of approximately 45° to the horizontal, and the pipe is not rotated during welding.

inclined position (with restriction ring) The position of a pipe joint in which the axis of the pipe is at an angle of approximately 45° to the horizontal, and a restriction ring is located near the joint. The pipe is not rotated during welding.

included angle A nonstandard term for *groove angle*.

induction brazing (IB) A brazing process in which the heat required is obtained from the resistance of the workpieces to induced electric current.

induction soldering (IS) A soldering process in which the heat required is obtained from the resistance of the workpieces to induced electric current.

induction welding (IW) A welding process that produces coalescence of metals by the heat obtained from the resistance of the workpieces to the flow of induced high frequency welding current with or without the application of pressure. The effect of the high frequency welding current is to concentrate the welding heat at the desired location.

inert gas A gas that normally does not combine chemically with the base metal or filler metal. See also *protective atmosphere*.

inert gas metal arc welding A nonstandard term for *gas metal arc welding*.

inert gas tungsten arc welding A nonstandard term for *gas tungsten arc welding*.

infrared brazing (IRB) A brazing process in which the heat required is furnished by infrared radiation.

infrared soldering (IRS) A soldering process in which the heat required is furnished by infrared radiation.

intergranular penetration The penetration of a filler metal along the grain boundaries of a base metal.

interpass temperature In a multipass weld, the temperature of the weld metal before the next pass is started.

iron soldering (INS) A soldering process in which the heat required is obtained from a soldering iron.

J

J-groove weld A type of groove weld.

joint The junction of members or the edges of members which are to be joined or have been joined.

joint clearance The distance between the facing surfaces of a joint. In brazing, this distance is referred to as that which is present before brazing, at the brazing temperature, or after brazing is completed.

joint efficiency The ratio of the strength of a joint to the strength of the base metal, expressed in percent.

joint penetration The depth a weld extends from its face into a joint, exclusive of reinforcement.

joint root That portion of a joint to be welded where the members approach closest to each other. In cross section, the joint root may be either a point, a line, or an area.

joint type A weld joint classification based on the five basic arrangements of the component parts such as butt joint, corner joint, edge joint, lap joint, and T-joint.

K

kerf The width of the cut produced during a cutting process.

L

lamellar tear A terracelike fracture in the base metal with a basic orientation parallel to the wrought surface. It is caused by the high stress in the thickness direction that results from welding.

land A nonstandard term for *root face*.

lap joint A joint between two overlapping members in parallel planes.

laser A device that produces a concentrated coherent light beam by stimulating electronic or molecular transitions to lower energy levels. Laser is an acronym for light amplification by stimulated emission of radiation.

laser beam cutting (LBC) A thermal cutting process that severs materials by melting or vaporizing them with the heat obtained from a laser beam, with or without the application of gas jets to augment the removal of material.

laser beam welding (LBW) A welding process that produces coalescence of materials with the heat obtained from the application of a concentrated coherent light beam impinging upon the joint.

lead burning A nonstandard term for the welding of lead.

liquation The separation of a low melting constituent of an alloy from the remaining constituents, usually apparent in alloys having a wide melting range.

locked-up stress A nonstandard term for *residual stress*.

longitudinal crack A crack with its major axis orientation approximately parallel to the weld axis.

M

machine welding Welding with equipment that performs the welding operation under the constant observation and control of a welding operator. The equipment may or may not load and unload the workpieces. See also *automatic welding*.

macroetch test A test in which the specimen is prepared with a fine finish and etched to give a clear definition of the weld.

manual welding A welding operation performed and controlled completely by hand. See also *automatic welding*, *machine welding*, and *semiautomatic welding*.

mask (thermal spraying) A device for protecting a substrate surface from the effects of blasting or adherence of a spray deposit.

mechanical bond (thermal spraying) The adherence of a spray deposit to a roughened surface by the mechanism of particle interlocking.

melt-through Visible root reinforcement produced in a joint welded from one side.

metal arc cutting (MAC) Any of a group of arc cutting processes that serves metals by melting them with the heat of an arc between a metal electrode and the base metal. See also *gas metal arc cutting* and *shielded metal arc cutting*.

metal cored electrode A composite filler metal electrode consisting of a metal tube or other hollow configuration containing alloying materials. Minor amounts of ingredients and fluxing of oxides may be included. External shielding gas may or may not be used.

metal electrode A filler or nonfiller metal electrode used in arc welding or cutting that consists of a metal wire or rod that has been manufactured by any method and that is either bare or covered.

metallic bond The principal bond that holds metals together and is formed between base metals and filler metals in all welding processes. This is a primary bond arising from

the increased spatial extension of the valence electron wave functions when an aggregate of metal atoms is brought close together. See also *bonding force* and *covalent bond*.

metallizing A nonstandard term for *thermal spraying*.

metallurgical bond A nonstandard term for *metallic bond*.

metal powder cutting (POC) An oxygen cutting process that severs metals through the use of powder, such as iron, to facilitate cutting.

MIG welding A nonstandard term for *flux cored arc welding* and *gas metal arc welding*.

mixing chamber That part of a welding or cutting torch in which a fuel gas and oxygen are mixed.

molten weld pool A nonstandard term for *weld pool*.

multiport nozzle (plasma arc welding and cutting) A constricting nozzle containing two or more orifices located in a configuration to achieve a degree of control over the arc shape.

N

neutral flame An oxyfuel gas flame in which the portion used is neither oxidizing nor reducing. See also *oxidizing flame* and *reducing flame*.

nontransferred arc (plasma arc welding and cutting, and plasma spraying) An arc established between the electrode and the constricting nozzle. The workpiece is not in the electrical circuit. See also *transferred arc*.

nozzle A device that directs shielding media.

nugget The weld metal joining the workpieces in spot, roll spot, seam, or projection welds.

nugget size (resistance welding) The diameter of a spot or projection weld or width of a seam weld measured in the plane of the faying surfaces.

O

orifice gas (plasma arc welding and cutting) The gas that is directed into the torch to surround the electrode. It becomes ionized in the arc to form the plasma and issues from the orifice in the torch nozzle as the plasma jet.

oven soldering A nonstandard term for *furnace soldering*.

overhead position The position in which welding is performed from the underside of the joint.

overlap The protrusion of weld metal beyond the weld toes or weld root.

overlap (resistance seam welding) The portion of the preceding weld nugget remelted by the succeeding weld.

overlaying A nonstandard term for *surfacing*

oxidizing flame An oxyfuel gas flame having an oxidizing effect due to excess oxygen. See also *neutral flame* and *reducing flame*.

oxyacetylene welding (OAW) An oxyfuel gas welding process that produces coalescence

of metals by heating them with a gas flame or flames obtained from the combustion of acetylene with oxygen. The process may be used with or without the application of pressure and with or without the use of filler metal.

oxyfuel gas cutting (OFC) A group of cutting processes used to sever metals by means of the chemical reaction of oxygen with the base metal at elevated temperatures. The necessary temperature is maintained by means of gas flames obtained from the combustion of a specified fuel gas and oxygen. See also *oxygen cutting*.

oxyfuel gas spraying A nonstandard term for *flame spraying*.

oxyfuel gas welding (OFW) A group of welding processes that produces coalescence by heating materials with an oxyfuel gas flame or flames, with or without the application of pressure, and with or without the use of filler metal.

oxygas cutting A nonstandard term for *oxygen cutting*.

oxygen arc cutting (AOC) An oxygen cutting process used to sever metals by means of the chemical reaction of oxygen with the base metal at elevated temperatures. The necessary temperature is maintained by an arc between a consumable tubular electrode and the base metal.

oxygen cutter One who performs a manual oxygen cutting operation.

oxygen cutting (OC) A group of cutting processes used to sever or remove metals by means of the chemical reaction between oxygen and the base metal at elevated temperatures. In the case of oxidation-resistant metals, the reaction is facilitated by the use of a chemical flux or metal powder. See also *chemical flux cutting*, *metal powder cutting*, *oxyfuel gas cutting*, *oxygen arc cutting* and *oxygen lance cutting*.

oxygen cutting operator One who operates machine or automatic oxygen cutting equipment.

oxygen gouging An application of oxygen cutting in which a bevel or groove is formed.

oxygen grooving A nonstandard term for *oxygen gouging*.

oxygen lance A length of pipe used to convey oxygen to the point of cutting in oxygen lance cutting.

oxygen lance cutting (LOC) An oxygen cutting process used to sever metals with oxygen supplied through a consumable lance. The preheat to start the cutting is obtained by other means.

oxygen lancing A nonstandard term for *oxygen lance cutting*.

oxyhydrogen welding (OHW) An oxyfuel gas welding process that produces coalescence of materials by heating them with a gas flame or flames obtained from the combustion of hydrogen with oxygen, without the application of pressure and with or without the use of filler metal.

P

parallel welding A resistance welding secondary circuit variation in which the secondary current is divided and conducted through the workpieces and electrodes in parallel electrical paths to simultaneously form multiple resistance spot, seam, or projection welds.

parent metal A nonstandard term for *base metal*.

partial joint penetration Joint penetration that is intentionally less than complete.

penetration A nonstandard term for *joint penetration* and *root penetration*.

percussion welding (PEW) A welding process that produces coalescence at the faying surface using the heat from an arc produced by a rapid discharge of electrical energy. Pressure is applied percussively during or immediately following the electrical discharge.

pilot arc (plasma arc welding) A low current continuous arc between the electrode and the constricting nozzle to ionize the gas and facilitate the start of the welding arc.

plasma arc cutting (PAC) An arc cutting process that severs metal by melting a localized area with a constricted arc and removing the molten material with a high velocity jet of hot, ionized gas issuing from the constricting orifice.

plasma arc welding (PAW) An arc welding process that produces coalescence of metals by heating them with a constricted arc between an electrode and the workpiece (transferred arc) or the electrode and the constricting nozzle (nontransferred arc). Shielding is obtained from the hot, ionized gas issuing from the torch which may be supplemented by an auxiliary source of shielding gas. Shielding gas may be an inert gas or a mixture of gases. Pressure may or may not be used, and filler metal may or may not be supplied.

plasma metallizing A nonstandard term for *plasma spraying*.

plasma spraying (PSP) A thermal spraying process in which a nontransferred arc of a plasma torch is utilized to create a gas plasma that acts as the source of heat for melting and propelling the surfacing material to the substrate.

plenum chamber (plasma arc welding and cutting, and plasma spraying) The space between the inside wall of the constricting nozzle and the electrode.

plug weld A weld made in a circular hole in one member of a joint, fusing that member to another member. A fillet-welded hole is not to be construed as conforming to this definition.

polarity See *direct current electrode negative* and *direct current electrode positive*.

porosity Cavity type discontinuities formed by gas entrapment during solidification.

postheating The application of heat to an assembly after welding, brazing, soldering, thermal spraying, or thermal cutting. See also *postweld heat treatment*.

postweld heat treatment Any heat treatment after welding.

powder cutting A nonstandard term for *chemical flux cutting* and *metal powder cutting*.

precoating Coating the base metal in the joint by dipping, electroplating, or other applicable means prior to soldering or brazing.

preform Brazing or soldering filler metal fabricated in a shape or form for a specific application.

preheat A nonstandard term for *preheat temperature*.

preheat current (resistance welding) An impulse or series of impulses that occur prior to and are separated from the welding current.

preheat temperature A specified temperature that the base metal must attain in the welding, brazing, soldering, thermal spraying, or cutting area immediately before these operations are performed.

pressure-controlled welding A resistance welding process variation in which a number of spot or projection welds are made with several electrodes functioning progressively under the control of a pressure-sequencing device.

pressure gas welding (PGW) An oxyfuel gas-welding process that produces coalescence simultaneously over the entire area of faying surfaces by heating them with gas flames obtained from the combustion of a fuel gas and oxygen and by the application of pressure, without the use of filler metal.

pretinning A nonstandard term for *precoating*.

procedure qualification The demonstration that welds made by a specific procedure can meet prescribed standards.

procedure qualification record (PQR) A document providing the actual welding variables used to produce an acceptable test weld and the results of tests conducted on the weld to qualify a welding procedure specification.

process A grouping of basic operational elements used in welding, cutting, adhesive bonding, or thermal spraying.

projection welding (PW) A resistance welding process that produces coalescence by the heat obtained from the resistance to the flow of the welding current. The resulting welds are localized at predetermined points by projections, embossments, or intersections.

protective atmosphere A gas or vacuum envelope surrounding the workpieces used to prevent or facilitate removal of oxides and other detrimental surface substances.

puddle A nonstandard term for *weld pool*.

pull gun technique A nonstandard term for *backhand welding*.

pulse (resistance welding) A current of controlled duration of either polarity through the welding circuit.

R

random intermittent welds Intermittent welds on one or both sides of a joint in which the weld increments are made without regard to spacing.

reaction flux (soldering) A flux composition in which one or more of the ingredients reacts with a base metal upon heating to deposit one or more metals.

reaction stress A stress that cannot exist in a member if the member is isolated as a free body without connection to other parts of the structure.

reducing atmosphere A chemically active protective atmosphere which at elevated temperature will reduce metal oxides to their metallic state.

reducing flame A gas flame having a reducing effect due to excess fuel gas. See also *neutral flame* and *oxidizing flame*.

reflowing A nonstandard term for *flow brightening*.

reflow soldering A nonstandard term for a soldering process variation in which preplaced solder is melted to produce a soldered joint or coated surface.

residual stress Stress present in a member that is free of external forces or thermal gradients.

resistance brazing (RB) A brazing process in which the heat required is obtained from the resistance to electric current flow in a circuit of which the workpiece is a part.

resistance butt welding A nonstandard term for *flash welding* and *upset welding*.

resistance seam welding (RSW) A resistance welding process that produces coalescence at the faying surfaces of overlapped parts progressively along a length of a joint. The weld may be made with overlapping weld nuggets, a continuous weld nugget, or by forging the joint as it is heated to the welding temperature by resistance to the flow of the welding current.

resistance soldering (RS) A soldering process in which the heat required is obtained from the resistance to electric current flow in a circuit of which the workpiece is a part.

resistance spot welding (RSW) A resistance welding process that produces coalescence at the faying surfaces of a joint by the heat obtained from resistance to the flow of welding current through the workpieces from electrodes that serve to concentrate the welding current and pressure at the weld area.

resistance welding (RW) A group of welding processes that produces coalescence of the faying surfaces with the heat obtained from resistance of the work to the flow of the welding current in a circuit of which the work is a part, and by the application of pressure.

resistance welding electrode The part(s) of a resistance welding machine through which the welding current and, in most cases, force are applied directly to the work. The

electrode may be in the form of a rotating wheel, rotating bar, cylinder, plate, clamp, chuck, or modification thereof.

resistance welding gun A manipulatable device to transfer current and provide electrode force to the weld area (usually in reference to a portable gun).

reverse polarity A nonstandard term for *direct current electrode positive*.

roll welding (ROW) A solid-state welding process that produces coalescence of metals by heating and by applying sufficient pressure with rolls to cause deformation at the faying surfaces. See also *forge welding*.

root A nonstandard term for *joint root* and *weld root*.

root bead A weld that extends into or includes part or all of the joint root.

root edge A root face of zero width. See also *root face*.

root face That portion of the groove face adjacent to the joint root.

root gap A nonstandard term for *root opening*.

root opening The separation at the joint root between the workpieces.

root penetration The depth that a weld extends into the joint root.

root radius A nonstandard term for *groove radius*.

root reinforcement Weld reinforcement opposite the side from which welding was done.

root surface The exposed surface of a weld opposite the side from which welding was done.

S

scarf joint A form of butt joint.

seal coat Material applied to infiltrate the pores of a thermal spray deposit.

seal weld Any weld designed primarily to provide a specific degree of tightness against leakage.

seam weld A continuous weld made between or upon overlapping members, in which coalescence may start and occur on the faying surfaces, or may have proceeded from the outer surface of one member. The continuous weld may consist of a single weld bead or a series of overlapping spot welds. See also *arc seam weld* and *resistance seam welding*.

secondary circuit That portion of a welding machine that conducts the secondary current between the secondary terminals of the welding transformer and the electrodes, or electrode and workpiece.

self-fluxing alloys (thermal spraying) Surfacing materials that wet the substrate and coalesce when heated to their melting point, without the addition of a flux.

semiautomatic arc welding Arc welding with equipment that controls only the filler metal feed. The advance of the welding is manually controlled.

series welding A resistance welding secondary circuit variation in which the secondary current is conducted through the workpieces and electrodes or wheels in a series electrical

path to simultaneously form multiple resistance spot, seam, or projection welds.

set down A nonstandard term for *upset*.

shadow mask A thermal spraying process variation in which an area is partially shielded during thermal spraying, thus permitting some overspray to produce a feathering at the coating edge.

sheet separation (resistance welding) The gap surrounding the weld between faying surfaces, after the joint has been welded in spot, seam, or projection welding.

shielded metal arc cutting (SMAC) A metal arc cutting process in which metals are severed by melting them with the heat of an arc between a covered metal electrode and the base metal.

shielded metal arc welding (SMAW) An arc welding process that produces coalescence of metals by heating them with an arc between a covered metal electrode and the workpieces. Shielding is obtained from decomposition of the electrode covering. Pressure is not used, and filler metal is obtained from the electrode.

shielding gas Protective gas used to prevent atmospheric contamination.

short circuiting transfer (arc welding) Metal transfer in which molten metal from a consumable electrode is deposited during repeated short circuits. See also *globular transfer* and *spray transfer*.

shoulder A nonstandard term for *root face*.

shrinkage stress A nonstandard term for *residual stress*.

shrinkage void A cavity type discontinuity normally formed by shrinkage during solidification.

silver alloy brazing A nonstandard term for brazing with a silver-base filler metal.

silver soldering A nonstandard term for brazing with a silver-base filler metal.

single-bevel-groove weld A type of groove weld.

single-flare-bevel-groove weld A weld in a groove formed by a member with a curved surface in contact with a planar member.

single-flare-V-groove weld A weld in a groove formed by two members with curved surfaces.

single impulse welding A resistance welding process variation in which spot, projection, or upset welds are made with a single impulse.

single-J-groove weld A type of groove weld.

single-port nozzle A constricting nozzle containing one orifice, located below and concentric with the electrode.

single-square-groove weld A type of groove weld.

single-U-groove weld A type of groove weld.

single-V-groove weld A type of groove weld.

single-welded joint A fusion welded joint that is welded from one side only.

skull The unmelted residue from a liquated filler metal.

slag inclusion Nonmetallic solid material entrapped in weld metal or between weld metal and base metal.

slot weld A weld made in an elongated hole in one member of a joint fusing that member to another member. The hole may be open at one end. A fillet weld slot is not to be construed as conforming to this definition.

slugging The act of adding a separate piece or pieces of material in a joint before or during welding that results in a welded joint not complying with design, drawing, or specification requirements.

soft solder A nonstandard term for *solder*.

solder A filler metal used in soldering that has a liquidus not exceeding 450 °C (840 °F).

soldering (S) A group of welding processes that produces coalescence of materials by heating them to the soldering temperature and by using a filler metal having a liquidus not exceeding 450 °C (840 °F) and below the solidus of the base metals. The filler metal is distributed between the closely fitted faying surfaces of the joint by capillary action.

soldering gun An electrical soldering iron with a pistol grip and a quick heating, relatively small bit.

soldering iron A soldering tool having an internally or externally heated metal bit usually made of copper.

solder interface The interface between filler metal and base metal in a soldered joint.

solid-state welding (SSW) A group of welding processes that produces coalescence at temperatures essentially below the melting point of the base metal without the addition of a brazing filler metal. Pressure may or may not be used.

spacer strip A metal strip or bar prepared for a groove weld and inserted in the joint root to serve as a backing and to maintain the root opening during welding. It can also bridge an exceptionally wide root opening due to poor fit.

spit A nonstandard term for *flash*.

split pipe backing Backing in the form of a pipe segment used for welding round bars.

spool A filler metal package consisting of a continuous length of welding wire in coil form wound on a cylinder (called a barrel) which is flanged at both ends. The flange contains a spindle hole of smaller diameter than the inside diameter of the barrel.

spot weld A weld made between or upon overlapping members in which coalescence may start and occur on the faying surfaces or may proceed from the outer surface of one member. The weld cross section (plan view) is approximately circular. See also *arc spot weld* and *resistance spot welding*.

spray deposit The coating or layer of surfacing material applied by a thermal spraying process.

spray deposit density ratio (thermal spraying) The ratio of the density of the spray deposit to the theoretical density of a surfacing material, usually expressed as a percent of theoretical density.

spray transfer (arc welding) Metal transfer in which molten metal from a consumable electrode is propelled axially across the arc in small droplets. See also *globular transfer* and *short circuiting transfer*.

square-groove weld A type of groove weld.

stack cutting Thermal cutting of stacked metal plates arranged so that all the plates are severed by a single cut.

staggered intermittent weld An intermittent weld on both sides of a joint in which the weld increments on one side are alternated with respect to those on the other side.

standoff distance The distance between a nozzle and the workpiece.

stick electrode A nonstandard term for *covered electrode*.

stick electrode welding A nonstandard term for *shielded metal arc welding*.

stickout A nonstandard term for *electrode extension*.

stopoff A material used on the surfaces adjacent to the joint to limit the spread of soldering or brazing filler metal.

straight polarity A nonstandard term for *direct current electrode negative*.

stranded electrode A composite filler metal electrode consisting of stranded wires that may mechanically enclose materials to improve properties, stabilize the arc, or provide shielding.

stress relief cracking Intergranular cracking in the heat affected zone or weld metal that occurs during the exposure of weldments to elevated temperatures during postweld heat treatment or high temperature service.

stress relief heat treatment Uniform heating of a structure or a portion thereof to a sufficient temperature to relieve the major portion of the residual stresses, followed by uniform cooling.

stringer bead A type of weld bead made without appreciable weaving motion. See also *weave bead*.

stub The short length of welding rod or consumable electrode that remains after its use for welding.

stud arc welding (SW) An arc welding process that produces coalescence of metals by heating them with an arc between a metal stud, or similar part, and the other workpiece. When the surfaces to be joined are properly heated, they are brought together under pressure. Partial shielding may be obtained by the use of a ceramic ferrule surrounding the stud. Shielding gas or flux may or may not be used.

stud welding A general term for joining a metal stud or similar part to a workpiece. Welding may be accommodated by arc, resistance, friction, or other processes with or without external gas shielding.

submerged arc welding (SAW) An arc welding process that produces coalescence of metals by heating them with an arc or arcs between a bare metal electrode or electrodes and the workpieces. The arc and molten

metal are shielded by a blanket of granular, fusible material on the workpieces. Pressure is not used, and filler metal is obtained from the electrode and sometimes from a supplemental source (welding rod, flux, or metal granules).

substrate Any material to which a thermal spray deposit is applied.

surface expulsion Expulsion occurring at an electrode-to-workpiece contact rather than at the faying surface.

surfacing The application by welding, brazing, or thermal spraying of a layer or layers of material to a surface to obtain desired properties or dimensions, as opposed to making a joint.

surfacing material The material that is applied to a base metal or substrate during surfacing.

surfacing metal The metal that is applied to a base metal or substrate during surfacing. See also *surfacing material*.

surfacing weld A weld applied to a surface, as opposed to making a joint, to obtain desired properties or dimensions.

sweat soldering A soldering process variation in which two or more parts that have been precoated with solder are reheated and assembled into a joint without the use of additional solder.

synchronous timing (resistance welding) The initiation of each half cycle of welding transformer primary current on an accurately timed delay with respect to the polarity reversal of the power supply.

T

tacker A nonstandard term for a tack welder.

tack weld A weld made to hold parts of a weldment in proper alignment until the final welds are made.

theoretical throat The distance from the beginning of the joint root perpendicular to the hypotenuse of the largest right triangle that can be inscribed within the cross section of a fillet weld. This dimension is based on the assumption that the root opening is equal to zero.

thermal cutting (TC) A group of cutting processes that melts the base metal. See also *arc cutting*, *electron beam cutting*, *laser beam cutting*, and *oxygen cutting*.

thermal spraying (THSP) A group of processes in which finely divided metallic or non-metallic surfacing materials are deposited in a molten or semimolten condition on a substrate to form a spray deposit. The surfacing material may be in the form of powder, rod, or wire. See also *arc spraying*, *flame spraying*, and *plasma spraying*.

thermal spraying gun A device for heating, feeding, and directing the flow of a surfacing material.

thermal stress Stress resulting from nonuniform temperature distribution.

thermit crucible The vessel in which the thermit reaction takes place.

thermit mixture A mixture of metal oxide and finely divided aluminum with the addition of alloying metals as required.

thermit mold A mold formed around the workpieces to receive the molten metal.

thermit reaction The chemical reaction between metal oxide and aluminum that produces superheated molten metal and a slag containing aluminum oxide.

thermit welding (TW) A welding process that produces coalescence of metals by heating them with superheated liquid metal from a chemical reaction between a metal oxide and aluminum, with or without the application of pressure. Filler metal is obtained from the liquid metal. (*Note:* The *ASM Handbook* uses the spelling "thermite welding.")

thermocompression bonding A nonstandard term for *hot pressure welding*.

throat of a fillet weld See *actual throat*, *effective throat*, and *theoretical throat*.

throat of a groove weld A nonstandard term for *groove weld size*.

TIG welding A nonstandard term for *gas tungsten arc welding*.

finning A nonstandard term for *precoating*.

T-joint A joint between two members located approximately at right angles to each other in the form of a T.

toe crack A crack in the base metal at the toe of a weld.

torch brazing (TB) A brazing process in which the heat required is furnished by a fuel gas flame.

torch soldering (TS) A soldering process in which the heat required is furnished by a fuel gas flame.

torch tip See *cutting tip* and *welding tip*.

transferred arc (plasma arc welding) A plasma arc established between the electrode and the workpiece.

transverse crack A crack with its major axis oriented approximately perpendicular to the weld axis.

twin carbon arc brazing A nonstandard term for *carbon arc brazing*.

U

U-groove weld A type of groove weld.

ultrasonic coupler (ultrasonic soldering and ultrasonic welding) Elements through which ultrasonic vibration is transmitted from the transducer to the tip.

ultrasonic soldering A soldering process variation in which high frequency vibratory energy is transmitted through molten solder to remove undesirable surface films and thereby promote wetting of the base metal. This operation is usually accomplished without a flux.

ultrasonic welding (USW) A solid-state welding process that produces coalescence of materials by the local application of high frequency vibratory energy as the workpieces are held together under pressure.

underbead crack A crack in the heat affected zone generally not extending to the surface of the base metal.

undercut A groove melted into the base metal adjacent to the weld toe or weld root and left unfilled by weld metal.

underfill A depression on the weld face or root surface extending below the adjacent surface of the base metal.

upset Bulk deformation resulting from the application of pressure in welding. The upset may be measured as a percent increase in interface area, a reduction in length, a percent reduction in lap joint thickness, or a reduction in cross wire weld stack height.

upset butt welding A nonstandard term for *upset welding*.

upset distance The total loss of axial length of the workpieces from the initial contact to the completion of the weld. In flash welding, the upset distance is equal to the platen movement from the end of flash time to the end of upset.

upset welding (UW) A resistance welding process that produces coalescence over the entire area of faying surfaces or progressively along a butt joint by the heat obtained from the resistance to the flow of welding current through the area where those surfaces are in contact. Pressure is used to complete the weld.

V

vacuum brazing A nonstandard term for various brazing processes that take place in a chamber or retort below atmospheric pressure.

vertical position The position of welding in which the weld axis is approximately vertical.

vertical position (pipe welding) The position of a pipe joint in which welding is performed in the horizontal position and the pipe may or may not be rotated.

V-groove weld A type of groove weld.

W

wave soldering (WS) An automatic soldering process where workpieces are passed through a wave of molten solder. See also *dip soldering*.

wax pattern (thermit welding) Wax molded around the workpieces to the form desired for the completed weld.

weave bead A type of weld bead made with transverse oscillation.

weld A localized coalescence of metals or nonmetals produced either by heating the materials to the welding temperature, with or without the application of pressure, or by the application of pressure alone, with or without the use of filler metal.

weldability The capacity of a material to be welded under the imposed fabrication conditions into a specific, suitably designed structure and to perform satisfactorily in the intended service.

weld axis A line through the length of the weld, perpendicular to and at the geometric center of its cross section.

weld bead A weld resulting from a pass. See also *stringer bead* and *weave bead*.

weld bonding A resistance spot welding process variation in which the spot weld strength is augmented by adhesive at the faying surfaces.

weld brazing A joining method that combines resistance welding with brazing.

weld crack A crack located in the weld metal or heat affected zone.

welder One who performs manual or semiautomatic welding operation.

welder performance qualification The demonstration of a welder's ability to produce welds meeting prescribed standards.

weld face The exposed surface of a weld on the side from which welding was done.

welding A materials joining process used in making welds.

welding blowpipe A nonstandard term for welding torch.

welding current The current in the welding circuit during the making of a weld.

welding cycle The complete series of events involved in the making of a weld.

welding electrode A component of the welding circuit through which current is conducted and that terminates at the arc, molten conductive slag, or base metal. See also *arc welding electrode*, *flux cored electrode*, *metal cored electrode*, *metal electrode*, *resistance welding electrode*, and *stranded electrode*.

welding ground A nonstandard term for *workpiece connection*.

welding leads The workpiece lead and electrode lead of an arc welding circuit.

welding machine Equipment used to perform the welding operation; for example, spot welding machine, arc welding machine, and seam welding machine.

welding operator One who operates machine or automatic welding equipment.

welding position See *flat position*, *horizontal fixed position*, *horizontal position*, *horizontal rolled position*, *inclined position*, *overhead position*, and *vertical position*.

welding procedure The detailed methods and practices involved in the production of a weldment. See also *welding procedure specification*.

welding procedure specification (WPS) A document providing in detail the required variables for a specific application to ensure repeatability by properly trained welders and welding operators.

welding rod A form of welding filler metal, normally packaged in straight lengths, that does not conduct electrical current.

welding sequence The order of making the welds in a weldment.

welding tip That part of an oxyfuel gas welding torch from which the gases issue.

welding torch (arc) A device used in the gas tungsten and plasma arc welding processes to control the position of the electrode, to transfer current to the arc, and to direct the flow of shielding and plasma gas.

welding torch (oxyfuel gas) A device used in oxyfuel gas welding, torch brazing, and torch soldering for directing the heating flame

produced by the controlled combustion of fuel gases.

welding wheel A nonstandard term for *resistance welding electrode*.

welding wire A form of welding filler metal, normally packaged as coils or spools, that may or may not conduct electrical current depending upon the welding process with which it is used. See also *welding electrode* and *welding rod*.

weld interface The interface between weld metal and base metal in a fusion weld, between base metals in a solid-state weld without filler metal or between filler metal and base metal in a solid-state weld with filler metal, and in a braze.

weld line A nonstandard term for *weld interface*.

weldment An assembly whose component parts are joined by welding.

weld metal That portion of a weld that has been melted during welding.

welder A nonstandard term for *welder*.

weld pass A single progression of welding or surfacing along a joint or substrate. The result of a pass is a weld bead, layer, or spray deposit.

weld pass sequence The order in which the weld passes are made.

weld penetration A nonstandard term for *joint penetration* and *root penetration*.

weld pool The localized volume of molten metal in a weld prior to its solidification as weld metal.

weld puddle A nonstandard term for *weld pool*.

weld reinforcement Weld metal in excess of the quantity required to fill a joint. See also *face reinforcement* and *root reinforcement*.

weld root The points, as shown in cross section, at which the back of the weld intersects the base metal surfaces.

weld size See *edge weld size*, *fillet weld size*, *flange weld size*, and *groove weld size*.

weld tab Additional material on which the weld may be initiated or terminated.

weld throat See *actual throat*, *effective throat*, and *theoretical throat*.

weld toe The junction of the weld face and the base metal.

wetting The phenomenon whereby a liquid filler metal or flux spreads and adheres in a thin continuous layer on a solid base metal.

wiped joint A joint made with solder having a wide melting range and with the heat supplied by the molten solder poured onto the joint. The solder is manipulated with a hand-held cloth or paddle so as to obtain the required size and contour.

work connection A nonstandard term for *workpiece connection*.

work lead A nonstandard term for *workpiece lead*.

workpiece The part being welded, brazed, soldered, or cut.

workpiece connection The connection of the workpiece lead to the workpiece.

workpiece lead The electrical conductor between the arc welding current source and the workpiece connection.
